Marie Boltz, PhD, RN, GNP-BC, FGSA, FAAN, is the Elouise Ross Eberly and Robert Eberly Endowed Chair Professor, Penn State College of Nursing, where she teaches both gerontological nursing and PhD courses. She is a gerontological nurse consultant at the Hospital of the University of Pennsylvania, the Office of Inspector General, and the Department of Justice, and a senior nurse scientist at the Munn Center for Nursing Research, Massachusetts General Hospital. She served as director of practice at the Hartford Institute for Geriatric Nursing from 2003 to 2013. Her areas of research include interventions to promote functional health and cognition in older adults, approaches to support family and formal caregiving efficacy and coping with dementia and delirium, organizational models to address complex aging-related care issues, and translational dementia research. She has authored and coauthored over 150 journal publications, organizational tools, and book chapters and coedited five books. Dr. Boltz is a former John A. Hartford Foundation Claire Fagin fellow, recipient of the American Nurses Credentialing Center (ANCC) Margretta Madden Styles Credentialing Scholar Award, and Eastern Nursing Research Society John A. Hartford Geriatric Nursing Research Award. She is a fellow in the American Academy of Nursing and the Gerontological Society of America. Dr. Boltz received her bachelor's degree in nursing from LaSalle University, her master's degree as a geriatric advanced practice nurse from the University of Pennsylvania, and her doctoral degree from New York University. She participated in postdoctoral study at the University of Maryland.

Elizabeth A. Capezuti, PhD, RN, FAAN, is the William Randolph Hearst Foundation Chair in gerontology at the Hunter-Bellevue School of Nursing of the City University of New York (CUNY). Dr. Capezuti teaches in the graduate doctor of nursing practice (DNP) program and is a professor in the PhD program in nursing science and social welfare at the Graduate Center, CUNY. She is known for her work in improving the care of older adults by interventions and models that positively influence healthcare providers' knowledge and work environment. Dr. Capezuti's research interests include nonpharmacological approaches to improve sleep, palliative care, the geriatric nursing work environment, and the design of the "built environment" to facilitate older persons' health outcomes. Dr. Capezuti has disseminated the findings of 40 funded projects in five coedited books and more than 150 peer-reviewed articles and book chapters. She is the recipient of the Otsuka/American Geriatrics Society Outstanding Scientific Achievement for Clinical Investigation Award in 2001 and received the American Academy of Nursing Nurse Leader in Aging Award in 2013. Dr. Capezuti received her bachelor's degree in nursing from Lehman College (CUNY), her master's degree as a geriatric advanced practice nurse from Hunter College, and her doctoral degree in nursing from the University of Pennsylvania.

DeAnne Zwicker, DrNP, AGNP-BC, is an American Nurses Credentialing Center (ANCC)-certified adult nurse practitioner and geriatric nurse practitioner. She is currently working as an independent geriatric consultant. She completed her doctor of nursing practice degree in 2010 with a primary focus as a clinical scientist and secondary focus in nursing education at Drexel University in Philadelphia. Her dissertation was a mixed-method study titled "Preparedness, Appraisal of Behaviors, and Role Strain in Dementia Family Caregivers and the Caregiver Perspective of Preparedness." She has been a coeditor and chapter author for many versions of the *Evidence-Based Geriatric Nursing Protocols for Best Practice* book, as well as a content editor for ConsultGeriRN.org since its inception. She has been a registered nurse for 32 years with clinical practice experience as a geriatric nurse practitioner since 1992 in primary care; subacute, long-term care; and, recently, palliative care, and a clinical expert consultant in many domains in geriatrics. She has also taught nursing at the graduate level at New York University, Drexel University, and George Mason University. Her areas of interest in geriatrics include proactive intervention in older adults to prevent adverse drug events, pain control to aid in maintaining function and quality of life, and preventing hospital iatrogenesis, particularly in persons with dementia.

Terry Fulmer, PhD, RN, FAAN, is the president of The John A. Hartford Foundation in New York City (NYC), a foundation dedicated to improving the care of older adults. Established in 1929, the Foundation has a current endowment of more than half a billion dollars. She serves as the chief strategist for the Foundation and was recently recognized for her leadership as one of the top 50 Influencers in Aging by PBS's Next Avenue, the premier digital publication dedicated to covering issues for older Americans. Dr. Fulmer is an elected member of the National Academy of Medicine. She previously served as distinguished professor and dean of Bouvé College of Health Sciences at Northeastern University. Before that, she served as the Erline Perkins McGriff Professor and dean of New York University (NYU) College of

Nursing. She received her bachelor's degree from Skidmore College, her master's and doctoral degrees from Boston College, and her geriatric nurse practitioner post-master's certificate from NYU. She completed a Brookdale National Fellowship and was the first nurse to serve on the board of the American Geriatrics Society. She was the first nurse to serve as president of the Gerontological Society of America. Dr. Fulmer is nationally and internationally recognized as a leading expert in geriatrics and is best known for conceptualization and development of the national Nurses Improving Care for Healthsystem Elders (NICHE) program and research on the topic of elder abuse and neglect, work that has been funded by the National Institute on Aging and the National Institute of Nursing Research. She is a trustee for the Josiah Macy Jr. Foundation, Springer Publishing Company, and the Bassett Healthcare System and is cochair of the National Academy of Medicine's Forum on Aging, Disability, and Independence. She previously served as the chair of the National Advisory Committee for the Robert Wood Johnson Foundation Executive Nurse Fellows Program and held board positions at Skidmore College, the Institute for Healthcare Improvement, the Geriatrics and Gerontology Advisory Committee for the U.S. Department of Veterans Affairs, and the Advisory Board for Hong Kong Polytechnic University School of Nursing. She is the recipient of prestigious awards, including the 2017 American Society on Aging Rosalie S. Wolf Award for her body of work on elder abuse. In 2016, she received the Award for Exceptional Service to The New York Academy of Medicine for her distinguished service on the Academy's Board of Trustees, including as vice-chair and for her active engagement in the policy work of the Academy, especially its age-friendly NYC initiative. She has been honored with invitations for named lectureships from noted universities. She has held faculty appointments at Columbia University, where she was the Anna C. Maxwell Chair in Nursing, and she has also held appointments at Boston College, Yale University, and the Harvard Division on Aging at Harvard Medical School. She has served as a visiting professor of nursing at the University of Pennsylvania and Case Western Reserve University. She is a distinguished practitioner of the National Academies of Practice and currently is an attending nurse and senior nurse in the Yvonne L. Munn Center for Nursing Research at the Massachusetts General Hospital and an attending nurse at Mount Sinai Medical Center in NYC. Dr. Fulmer's clinical appointments have included the Beth Israel Hospital in Boston, the Massachusetts General Hospital, and the NYU Langone Medical Center. She is a fellow of the American Academy of Nursing, the Gerontological Society of America, and the New York Academy of Medicine where she served as vice-chair. She has authored over 150 peer-reviewed papers and edited 10 books.

Contents

Contributors *xi*
Foreword Ann Kolanowski, PhD, RN, FGSA, FAAN *xvii*
Preface *xix*
Acknowledgments *xxi*

I. INCORPORATING EVIDENCE INTO PRACTICE

1. **Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach** ***3***
   Kathleen Phillips

2. **Measuring Performance and Improving Quality** ***13***
   Lenard L. Parisi

3. **Informational Technology: Embedding Geriatric Clinical Practice Guidelines** ***21***
   Rebecca L. Trotta and Terese Kornet

4. **Organizational Approaches to Promote Person-Centered Care** ***27***
   Andrea Yevchak Sillner and Liza Behrens

5. **Environmental Approaches to Support Aging-Friendly Care** ***43***
   Rana Sagha Zadeh

II. ASSESSMENT AND MANAGEMENT PRINCIPLES

6. **Age-Related Changes in Health** ***59***
   Marianne Logan Fingerhood

7. **Healthcare Decision-Making** ***81***
   Joanne Roman Jones and Marie Boltz

8. **Sensory Changes in the Older Adult** ***95***
   Pamela Z. Cacchione

9. **Assessing Cognitive Function in the Older Adult** ***119***
   Donna M. Fick, Pieter Heeren, and Koen Milisen

10. **Assessment of Physical Function in the Older Adult** ***133***
    Denise M. Kresevic

11. **Oral Healthcare in the Older Adult** ***149***
    Linda J. O'Connor

12. **Managing Oral Hydration in the Older Adult** ***157***
    Phyllis M. Gaspar and Janet C. Mentes

13. **Nutrition in the Older Adult** ***179***
    Rose Ann DiMaria-Ghalili

14. **Family Caregiving** ***191***
    Deborah C. Messecar

15. **Issues Regarding Sexuality in Older Adults** ***223***
    Elaine E. Steinke

16. **Elder Mistreatment Detection** ***241***
    Billy A. Caceres, Neelima Kurup, and Terry Fulmer

17. **Advance Care Planning** ***259***
    Joanne Roman Jones and Marie Boltz

III. CLINICAL INTERVENTIONS

18. Preventing Functional Decline in the Acute Care Setting *281*
Marie Boltz, Barbara Resnick, and Elizabeth Galik

19. Late-Life Depression *295*
Glenise McKenzie and Kathryn Sexson

20. Delirium: Prevention, Early Recognition, and Treatment *317*
Cheri Blevins

21. Dementia: Assessment and Care Strategies *331*
Marie Boltz

22. Pain Management in the Older Adult *353*
Ann L. Horgas, Joanne Laframboise-Otto, Karen Aul, and Saunjoo L. Yoon

23. Assessing, Managing, and Preventing Falls in Acute Care *375*
Deanna Gray-Miceli and Patricia A. Quigley

24. Reducing Adverse Drug Events in the Older Adult *409*
DeAnne Zwicker, Carolina Carvajal, and Terry Fulmer

25. Urinary Incontinence in the Older Adult *439*
Annemarie Dowling-Castronovo, Joanna Long, and Christine Bradway

26. Prevention of Catheter-Associated Urinary Tract Infection *467*
Michelle Kidd and Mary Beth Flynn Makic

27. Physical Restraints and Side Rails in Acute and Critical Care Settings *485*
Cheryl M. Bradas, Satinderpal K. Sandhu, and Lorraine C. Mion

28. Preventing Pressure Injuries and Skin Tears *501*
Reneeka Persaud-Jaimangal, Elizabeth A. Ayello, and R. Gary Sibbald

29. Optimizing Mealtimes for Persons Living With Dementia *527*
Melissa Batchelor

30. Disorders of Sleep in the Older Adult *545*
Jonna L. Morris, Lynn Baniak, Michelle L. Klimpt, Eileen R. Chasens, and Grace E. Dean

31. The Frail Hospitalized Older Adult *563*
Stewart M. Bond

32. HIV Prevention and Care for the Older Adult *577*
Rosanna F. DeMarco and Simon Manga

33. LGBTQ Perspectives for Older Adult Care *595*
Janejira J. Chaiyasit and Anthony R. Lutz

IV. INTERVENTIONS IN SPECIALTY PRACTICE

34. Substance Misuse and Alcohol Use Disorder in the Older Adult 609
Donna E. McCabe, Michelle M. Knapp, and Madeline A. Naegle

35. Comprehensive Assessment and Management of the Critically Ill Older Adult 633
Michele C. Balas, Lee Cordell, Paige Donahue, and Mary Beth Happ

36. Fluid Overload: Identifying and Managing Heart Failure Patients at Risk for Hospital Readmission 659
Ameera Chakravarthy and Joan Davenport

37. Cancer Assessment and Intervention Strategies in the Older Adult 683
Janine Overcash

38. Perioperative Care of the Older Adult 697
Fidelindo Lim and Larry Z. Slater

39. General Surgical Care of the Older Adult 755
Fidelindo Lim and Larry Z. Slater

40. Care of the Older Adult With Fragility Hip Fracture 757
Anita J. Meehan, Ann Butler Maher, Valerie MacDonald, Karen Hertz, and Ami Hommel

V. MODELS OF CARE

41. Acute Care Models 789
Elizabeth Capezuti, Marie Boltz, Michael L. Malone, and Robert M. Palmer

42. Transitional Care 807
Fidelindo Lim and Janice B. Foust

43. Palliative Care Models 825
Constance Dahlin

44. Care of the Older Adult in the Emergency Department 847
Rachel Arendacs and Marie Boltz

Index 871

Foreword

Older adults are the largest consumers of healthcare in the United States. Their health needs are often complex, with a trend toward declining function and a higher likelihood of having one or more chronic diseases. Most practitioners are unprepared to adequately care for older adults who present with health issues that are compounded by age changes, chronicity, and contributing social determinants. The current healthcare system tends to manage these complex health issues in a fragmented way without coordination across care providers, settings, and time. What we have learned after years of ineffective approaches to the health needs of older adults is this: Poor care is costly care and costly care is not sustainable. For more than half a century, visionary leaders have made healthcare improvement for older adults their rallying cry. Geriatric nurses, including the editors and contributing authors of *Evidence-Based Geriatric Nursing Protocols for Best Practice*, have been among those leaders and at the forefront of needed change.

Just like healthcare providers, geriatric nurses are uniquely and strategically positioned to make an enduring impact on the quality of direct care and on the effectiveness of systems where that care is delivered. Geriatric nurses have a duty of care to adhere to a set of standards that guide practice for the purpose of improving the lives of others. These standards of care are not invariant, but change over time as new knowledge is gained through research and as new public health issues emerge in society. The trust and respect given to the profession will be determined by the competency and compassion demonstrated at the point of care.

Trust and respect are fragile commodities, however, and must be earned. There is no better way to ensure competency than by keeping informed of what constitutes best practice at any point in time. *Evidence-Based Geriatric Nursing Protocols for Best Practice* was written for this purpose. A wide audience—students, faculty, and clinicians—will find this text engaging, instructive, and indispensable.

The sixth edition of *Evidence-Based Geriatric Nursing Protocols for Best Practice* completely updates and expands the award-winning fifth edition. What impresses me about this new edition is the depth of information provided and the carefully crafted structure of the text. Each of the 44 chapters is written by experts in the field, scientists, educators, and clinicians, who bring years of experience working with older adults who live with common and complex clinical problems. These experts not only share the latest research, guidelines, and protocols for practice but also bring the content to life using actual case studies that skillfully illustrate best practice.

I was especially excited to see new chapters that address emerging clinical and social issues that impact health outcomes for older adults. The chapters on person-centered care, technology, HIV in older adults, and dementia assessment and intervention are cutting edge and essential reading. The chapters that take on some of the social determinants of health, the effect of the physical environment on function and the needs of the LGBTQ community, will help nurses contribute to older adults' ability to live healthy and full lives.

I like to think of *Evidence-Based Geriatric Nursing Protocols for Best Practice* as a compendium of critical competencies written by some of the most successful experts in the field. Every geriatric nurse who wants to improve the lives of older adults will keep this resource in their library and, like a trusted mentor, turn to it often.

Ann Kolanowski, PhD, RN, FGSA, FAAN
Professor Emerita
Penn State University College of Nursing
University Park, Pennsylvania

Preface

Across healthcare settings, older adults represent the majority of consumers served. They present with the most clinically and socially complex situations and thus require nurses to possess highly developed assessment competencies, critical thinking abilities, and relationship-based skills. Nurses have an enormous responsibility when providing care to older adults in this rapidly changing healthcare environment with its increasing regulatory requirements, variable staffing levels, and unpredictable reimbursement. Nurses also have an amazing opportunity to positively change the daily experiences and health of older adults. The nurse who is armed with an understanding of the unique clinical presentations and response to treatment in older adults and who has knowledge about evidence-based assessment and interventions is situated to not only prevent and manage health problems but also to promote function and quality of life.

As in the previous editions of *Evidence-Based Geriatric Nursing Protocols for Best Practice*, we present up-to-date information on assessment and interventions for common health problems and geriatric syndromes. We have expanded our robust clinical content to include evidence-based approaches to support LGBTQ elders, persons living with dementia and their families, and older adults living with HIV. We are pleased to also include three new chapters that comprise operational strategies in the following areas: embedding clinical practice guidelines into the electronic health record, person-centered care approaches, and age-friendly environmental considerations.

In this sixth edition, we provide guidelines that are developed by experts on the topics of each chapter and are based on the best available evidence. A systematic method, the AGREE (Appraisal of Guidelines for Research and Evaluation) appraisal process (AGREE Next Steps Consortium, 2013), was used to evaluate the protocols and identify a process to help us improve the validity of the book's content. Thus, a systematic process, described in Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach, was developed for authors to retrieve and evaluate the level of evidence of key references related to specific assessment and management strategies in each chapter. This first chapter details the process of how the clinical practice guidelines were developed and how they complied with the AGREE items for rigor of development (AGREE Next Steps Consortium, 2013). Chapter 1 is an important chapter reference for understanding the rating of the levels of evidence throughout the book.

HOW TO BEST USE THIS BOOK

Chapters provide overview and background information on the topic, evidence-based assessment and intervention strategies, and, when appropriate, a topic-specific case study with discussion. The text of the chapter provides the context and detailed evidence for the protocol; the tabular protocol is not intended to be used in isolation of the text. We recommend that the reader take the following approach when reviewing the chapters:

1. Review the *objectives* to ascertain what is to be achieved by reviewing the chapter.
2. Review the *text*, noting the level of evidence presented in the reference section: Level I being the highest (e.g., systematic reviews/meta-analyses) and Level VI the lowest (e.g., expert opinions). Refer back to Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach, Figure 1.1, for the definitions of the levels of evidence to understand the quantitative evidence that supports each of the recommendations. Keep in mind that it is virtually impossible to have evidence for all assessments and interventions,

which does not mean they are not going to be used as an intervention. Many interventions that have been successfully used for years have not been quantitatively researched but are well known to be effective to experts in the field of geriatrics.

3. Review the *protocols* and remember that they reflect assessment and intervention strategies for acute care recommended by experts who have reviewed the evidence. This evidence is from all levels of care (e.g., community, primary care, long-term care) and should be applied to the unique needs of the individual patient.
4. Review the *case study* on each topic, which provides a more real-life, practical manner in which the protocol may be applied in clinical practice.

The *resources* in the chapters provide easy access to tools discussed in the chapter and link readers with organizations that provide ongoing, up-to-date information on the topic.

Although this book is titled *Evidence-Based Geriatric Nursing Protocols for Best Practice*, the text may be used by educators for geriatric nursing courses and advanced practice nurses, and by many other disciplines, including interprofessional team members, long-term care and other staff educators, social workers, dietitians, and physicians. It is our hope that this book provides a resource to help nurses and interprofessional colleagues collaborate effectively to provide effective and person-centered care.

Acknowledgments

The editors would like to thank the following for their involvement, support, and leadership during the production of this book:

- All the authors of this sixth edition
- Those nursing experts who participated in the Nurse Competence in Aging project, who contributed the first protocols to GeroNurseOnline, and led the way for the ongoing dissemination of evidence-based protocols
- Authors who provided a valuable contribution in previous editions and their ongoing gerontological scholarship
- The institutions that supported faculty and clinicians who were contributors to this book
- The older adults and families who teach and inspire us to continually seek new and effective ways to improve care delivery
- Springer Publishing Company for its ongoing support of quality geriatric nursing publications

Evidence-Based Geriatric Nursing Protocols for Best Practice

Incorporating Evidence Into Practice

EDUCATIONAL OBJECTIVES

After completion of this chapter, the reader should be able to:

1. Describe how to level the evidence used to develop and substantiate a practice protocol.
2. Differentiate among recommendations, guidelines, and practice protocols.
3. Evaluate clinical practice guidelines using Appraisal of Guidelines for Research and Evaluation (AGREE) II.
4. Identify the five steps of the process for discovery of best evidence and integration into practice.
5. Describe the best sources of evidence available to answer background/overview questions to support protocol development.
6. Describe the specialized evidence sources most appropriate to support protocol development for specific patients and/or problems.

OVERVIEW

Clinical decision-making that is grounded in the best available evidence is essential to promote patient safety and quality healthcare outcomes. With the knowledge base for geriatric nursing rapidly expanding, assessing geriatric clinical practice guidelines (CPGs) for their validity and incorporation of the best available evidence is critical to the safety and outcomes of care. In the second edition of this book, Lucas and Fulmer (2003) challenged geriatric nurses to take the lead in the assessment of CPGs, recognizing that, in the absence of best evidence, guidelines and protocols have little value for clinical decision-making. In the third edition of this book, Levin, Singleton, and Jacobs (2008) proposed a method for ensuring that the protocols included here were based on meta-analysis (if data are available), systematic review of the literature, and synthesis of best evidence.

The purpose of this chapter is to describe the process that was used to create the fourth, fifth, and the current sixth edition of *Evidence-Based Geriatric Nursing Protocols for Best Practice*. Before the third edition of this book, there was no standard process or specific criteria for protocol development, nor was there any indication of the "level of evidence" of each source cited in a chapter (i.e., the evidence base for the protocol). In the third and fourth editions of this book, the process previously used to develop the geriatric nursing protocols was enhanced and described in detail. That process differed from the procedures followed in the current edition. This chapter is a guide to

understanding how the protocols contained in this book were developed and it details how to use a systematic, efficient, and evidence-based approach to discovering and evaluating evidence, which is the process needed to guide the assessment, development, and updating of practice protocols in any area of nursing practice.

DEFINITION OF TERMS

Evidence-based practice (EBP) is a framework for clinical decision-making that uses (a) the best available evidence, (b) the clinician's expertise, and (c) a patient's values and circumstances to guide judgments about a patient's personal health condition (Keefer & Levin, 2013; Melnyk & Fineout-Overholt, 2015; Straus, Glasziou, Richardson, & Haynes, 2010). Healthcare professionals often use the terms *recommendations, guidelines*, and *protocols* interchangeably, but they are not synonymous.

A recommendation is a suggestion for practice, not necessarily sanctioned by a formal, expert group. A CPG is an "official recommendation" or suggested approach to diagnose and manage a broad health condition or problem (e.g., heart failure, smoking cessation, or pain management). A protocol is a more detailed guide for approaching a clinical problem or health condition and is tailored to a specific practice situation. For example, guidelines for falls prevention recommend developing a protocol for toileting older, sedated, or confused patients (Gray-Miceli & Quigley, 2013). The specific practices or protocols that each healthcare organization implements, however, are agency specific. The validity of any of these practice guides can vary depending on the type and the level of evidence on which they are based. Using standard criteria to develop or refine CPGs or protocols assures reliability of their content. Standardization gives both nurses, who use the guideline/protocol, and patients, who receive care based on the guideline/protocol, assurance that the geriatric content and practice recommendations are based on the best evidence.

In contrast to these practice guides, "standards of practice" are not specific or necessarily evidence based; rather, they are a generally accepted, formal, and published framework for practice. As an example, the American Nurses Association document, *Nursing: Scope and Standards of Practice,* Third Edition, contains a standard regarding nurses' accountability for making an assessment of a patient's health status (American Nurses Association, 2015). The standard is a general statement, whereas a protocol may specify the measurement tool(s) to use in that assessment—for example, STRATIFY, an instrument used to measure the risk of falls (Smith, Forster, & Young, 2006).

The AGREE (Appraisal of Guidelines for Research and Evaluation) and AGREE II Instruments

The AGREE instrument (www.agreetrust.org/resource-centre/the-original-agree-instrument), originally created and evaluated by a team of international guideline developers and researchers for use by the National Health Service, has been revised and updated and remains a generic tool designed primarily to help guideline developers and users assess the methodological quality of guidelines (Brouwers et al., 2010). This appraisal includes evaluation of the methods used to develop the CPG, assessment of the validity of the recommendations made in the guideline, and consideration of factors related to the use of the CPG in practice. Although the AGREE instrument was created to critically appraise CPGs, the process and criteria can also be applied to the development of clinical practice protocols. Thus, the AGREE instrument has been expanded for that purpose to standardize the creation and revision of the geriatric nursing practice protocols in this book.

The initial AGREE instrument and the one used for clinical guideline/protocol development in the third edition of this book has six quality domains: *scope and purpose*, *stakeholder involvement, rigor of development, clarity and presentation, application,* and *editorial independence*. A total of 23 items divided among the domains were rated on a 4-point Likert-type scale from "strongly disagree" to "strongly agree." Appraisers evaluate how well the guideline they are assessing meets the criteria (i.e., items) of the six quality domains. For example, when evaluating the *rigor of development,* appraisers rated seven items. The reliability of the AGREE instrument is increased when each guideline is appraised by more than one appraiser. Each of the six domains receives an individual domain score and, based on these scores, the appraiser subjectively assesses the overall quality of a guideline.

Important to note, however, is that the original AGREE instrument was revised in 2009 (AGREE Next Steps Consortium, 2013) and is now called AGREE II, which is the version that we used for the fourth, fifth, and sixth editions of this book. The revision added one new item to the *rigor of development* domain. This is the current item 9, which underscores the importance of evaluating the evidence that is applied to practice. Item 9 reads: "The strengths and limitations of the body of evidence are clearly described" (Exhibit 1.1). The remainder of the changes included a revision of the Likert-type scale used to evaluate each item in the AGREE II, a reordering of the number assigned to each item based on the addition of the new item 9, and minor editing of items for clarity. No other substantive changes were made. Exhibit 1.1 includes the items that are in the

EXHIBIT 1.1

Sample Domain and Items From the AGREE II Instrument for Critical Appraisal of Clinical Practice Guidelines

Domain 3: Rigor of Development
7. Systematic methods were used to search for evidence.
8. The criteria for selecting the evidence are clearly described.
9. The strengths and limitations of the body of evidence are clearly described.
10. The methods for formulating the recommendations are clearly described.
11. The health benefits, side effects, and risks have been considered in formulating the recommendations.
12. There is an explicit link between the recommendations and the supporting evidence.
13. The guideline has been externally reviewed by experts prior to its publication.
14. A procedure for updating the guideline is provided.

AGREE, Appraisal of Guidelines for Research and Evaluation.

rigor of development domain and were used for evaluation of evidence in the current edition of this book. A 2013 update of the AGREE II instrument (www.agreetrust.org/resource-centre/agree-ii-training-tools) includes a history of the project, information about language translations, and enhanced online training tools freely available to support guideline developers (AGREE Enterprise, 2014).

The *rigor of development* section of the AGREE instrument provides standards for literature searching and documenting the databases and terms searched. Adhering to these criteria to find and use the best available evidence on a clinical question is critical to the validity of geriatric nursing protocols and ultimately to patient safety and outcomes of care.

Published guidelines can be appraised using the AGREE II instrument. In the process of guideline development, however, the clinician is faced with the added responsibility of appraising all available evidence for its quality and relevance. In other words, how well does the available evidence support recommended clinical practices? The clinician needs to be able to support or defend the inclusion of each recommendation in the protocol based on its level and quality of evidence. To do so, the guideline must reflect a systematic, structured approach to find and assess the available evidence.

Searching for the Best Evidence

Models of EBP describe the evidence-based process in five steps (Melnyk & Fineout-Overholt, 2015; Titler, 2010):

1. Develop an answerable question.
2. Locate the best evidence.
3. Critically appraise the evidence.
4. Integrate the evidence into practice using clinical expertise with attention to patient's values and perspectives.
5. Evaluate the outcome(s).

Although the evidence-based process encompasses these five steps, for the purposes of this volume of protocols and their development, this chapter focuses on the first three steps in more detail.

Step 1: Develop an Answerable Question

Developing an answerable question is critical before one can choose relevant sources to search. The information needed may be in the form of a specific "foreground" question (one that is focused on a particular clinical issue) or it may be a broad question (one that asks for overview information about a disease, condition, or aspect of healthcare; Melnyk & Fineout-Overholt, 2015; Straus et al., 2010) to gain some background of the practice problem and interventions, and gain insight into its significance. Background information includes both internal data from a specific agency and external data to place the health condition or problem in a broader societal context. Internal data usually include quality metrics from the healthcare agency in conjunction with healthcare providers' observations. External data might require a search for local and/or national benchmarking data and prevalence statistics as well as general literature describing the local problem as one that goes beyond a specific healthcare setting, population, or intervention.

An example of a background query might be one that seeks data: *What is the prevalence of falls in older residents in a long-term care facility?* Should these data demonstrate an unacceptable fall rate compared with national benchmark and safety target statistics, then the local problem can be shown to have significance beyond the specific clinical agency. A broad research query (an example of an overarching background question) related to a larger category of disease or health problem and encompassing multiple interventions

might be: *What is the best evidence for fall prevention in hospitalized older adults?* The first place to search for evidence would be the ECRI Institute's Guidelines Trust™ (http://guidelines.ecri.org), as described in Table 1.1.

A related question—*What is the best evidence for falls prevention for the elderly in hospitals and long-term care facilities?*—is addressed in a systematic review (Cameron et al., 2012) from the Cochrane Library, as cited in Table 1.1. The *Cochrane Library of Systematic Reviews* contains rigorous and comprehensive narrative and statistical (meta-analyses) reviews that synthesize multiple studies of interventions. The information contained in this review synthesizes multifactorial interventions and may help to further focus the inquiry into a question about the effectiveness of a specific intervention.

A similar example (Slade, 2013) in Table 1.1 cites a Joanna Briggs Institute's evidence summary, which answers a general background or overview question: *What is the evidence regarding specific interventions to prevent falls in older adults?*

Once the overall evidence regarding a background question is uncovered, the question can be narrowed into a specific "PICO" format to specify the intervention or assessment tool being examined (Straus et al., 2010, p. 15). PICO stands for:

- P = Population or patient problem
- I = Intervention
- C = Comparison group or standard practice
- O = Outcomes
- T = Time

The focused clinical or PICO question now specifies a patient problem or population and focuses on a specific intervention—for example, *Does the introduction of a video-based educational module for staff decrease the rate of falls for hospitalized patients?*

A case study (Cangany et al., 2015), located in the Cumulative Index to Nursing and Allied Health Literature (CINAHL) article database, provides an example of evidence in a specialized hospital setting. Foreground questions are best answered by individual primary studies or syntheses of multiple studies, such as systematic reviews or meta-analyses. PICO templates work best to gather the evidence for focused clinical questions. In the question mentioned earlier, the *problem* was identified as a hospital progressive care unit with a fall rate higher than the National Database of Nursing Quality Indicators (NDNQI) benchmark, for a population of patients with heart disease. The *intervention* was the implementation of an educational video for staff, along with improved signage, improved documentation of bed alarm usage, a fall risk assessment, and a "patient/family fall teaching contract." The *comparison* implied was the usual care, and the *outcome* measures were both a reduction in the fall rate and the costs associated with the intervention versus the change in fall rate.

Step 2: Locate the Best Evidence

Step 2, locate the evidence, requires an evidence search based on the elements identified in the clinical question. Gathering the evidence for the protocols in this book presented the challenge of conducting literature reviews encompassing *both* the breadth of overview information as well as the depth of specificity represented in high-level systematic reviews and clinical trials to answer specific clinical questions.

Not every nurse, whether he or she is a staff nurse, advanced practice nurse, educator, or administrator, has developed proficient database search skills to conduct a literature review to locate evidence. Beyond a basic knowledge of Boolean logic, truncation, and applying categorical limits to filter results, competency in "information literacy" requires experience with the idiosyncrasies of databases, selection of terms, and ease with controlled vocabularies and database functionality (Association of College & Research Libraries, 2013). Many nurses report that limited access to resources, gaps in information literacy skills, and, most of all, a lack of time are barriers to "readiness" for EBP (Pravikoff, Tanner, & Pierce, 2005).

The digital age presents both consumers of research evidence and researchers with an array of tools for searching, managing, and citing both the published literature and the unpublished literature. The ever-changing electronic environment provides an array of search engines, "apps," and specialized discovery tools. Such an environment can be daunting and often overwhelming to novice and experienced users alike. Research portals promoting "one-box" search tools purport comprehensiveness, yet search results are often vast and unfiltered. The apparent ease of keyword searching invites cherry picking from the first few pages of results and can unwittingly introduce "search bias" (Wentz, 2002) into the quest for evidence, thus negating the sophisticated methodologies that were employed in primary searches to decrease experimenter bias and increase quality of evidence.

Health sciences librarians as intermediaries have been called "an essential part of the health care team by allowing knowledge consumers to focus on the wise interpretation and use of knowledge for critical decision making, rather than spending unproductive time on its access and retrieval" (Homan, 2010, p. 51). The *Cochrane Handbook* points out the complexity of conducting a systematic literature review

TABLE 1.1

Selected Databases, Examples of Types of Questions, Sample Citations, and Level of Evidence of Citation

Database/Description/Access	Overview Question	PICO or Focused Clinical Question	Sample Citation	Level of Evidence
PubMed/MEDLINE Premier biomedical database produced by the U.S. National Library of Medicine containing more than 25 million citations for biomedical literature from MEDLINE, life science journals, and online books. http://pubmed.gov		In hospitalized elders, does the STRATIFY falls risk assessment tool predict falls in hospital and after discharge?	Smith et al. (2006)	Level IV

and highly recommends enlisting the help of a healthcare librarian when searching for evidence (Lefebvre, Manheimer, & Glanville, 2011).

Search Strategies

General or overview/background questions may be answered in textbooks, review articles, and "point of care" tools that aggregate overviews of best evidence, for example, clinical reference tools, systematic reviews, and synthesis tools. Locating systematic or narrative review articles or clinical guidelines based on systematic reviews may be helpful in the initial steps of gathering external evidence to support the significance of a problem before developing a narrower PICO question and investing a great deal of time in a question for which there might be limited evidence.

A search for individual studies in the published literature begins with database selection and translation of search terms into the controlled vocabulary of the database, if possible. In addition to the published literature, unpublished "grey" literature should also be considered. Grey literature, defined during the Fourth International Conference on Grey Literature, is the information "which is produced on all levels of government, academics, business and industry in print and electronic formats, but which is not controlled by commercial publishers" (National Information Center on Health Services Research and Health Care Technology, n.d., para 2). It includes resources such as theses, dissertations, conference proceedings, standards, technical documentation, newsletters, corporate organizations, and government documents. Although grey literature may not be peer-reviewed or evaluated, it is nonetheless a part of a comprehensive gathering of evidence as a source for CPGs and protocols. One example in Table 1.1, clinicaltrials.gov, lists a study that proposes an exercise program for patients who have Parkinson's disease, with the status "recruiting participants" as of 2014 (ClinicalTrials.gov, 2014). Trial registries and open-access repositories of clinical trials provide study criteria, outcome measures, and historical revisions to studies. They may be specialized for a particular kind of publication; for example, the Cochrane Library (www.cochranelibrary.com) and the PROSPERO database (www.crd.york.ac.uk/prospero), are both examples of systematic review protocol repositories. The major article databases for finding the best primary evidence for most clinical nursing questions are the *CINAHL* database (https://www.ebscohost.com/nursing/products/cinahl-databases), the *MEDLINE,* and the U.S. National Library of Medicine's premier biomedical article database (www.ncbi.nlm.nih.gov/pubmed). The PubMed interface to MEDLINE includes newly added citations to provide access to the most recently published literature. Another of the many sources of ongoing trials for nursing research is the Virginia Henderson Global Nursing e-Repository (www.sigmarepository.org). The Cochrane Library (which includes the Database of Systematic Reviews) and the Joanna Briggs publications (a paid subscription service including evidence summaries, practice sheets, and systematic reviews; http://connect.jbiconnectplus.org) are examples of synthesized, appraised sources of evidence for broad topic areas.

The AGREE II instrument was used as a standard against which we could evaluate the process for evidence searching and use in chapter and protocol development (AGREE Next Steps Consortium, 2013). Domain 3, *rigor of development*, Item 7, states: "Systematic methods were used to search for evidence" (AGREE Next Steps Consortium, 2013, p. 4). And the user's manual directs: "The search strategy should be as comprehensive as possible and executed in a manner free from potential biases and sufficiently detailed to be replicated" (p. 23). Taking a tip from the *Cochrane Handbook*, a literature search should capture both the subject terms and the methodological aspects of studies when gathering relevant records (Higgins & Green, 2011). The following guidelines reflect the process used to gather evidence for this book's protocols and are recommended guidelines for conducting a literature search.

- To facilitate replication and update of searches, save a search strategy listing the keywords/descriptors and search string used in each database searched (e.g., MEDLINE, PsycINFO, CINAHL, trial registries).
- Specify the time period searched (e.g., 2014–2019).
- Specify the categorical limits or methodological filters used (e.g., the article type: "meta-analysis" or the "systematic review subset" in PubMed; the "methodology" limit in PsycINFO for meta-analysis *or* clinical trial; the "research" limit in CINAHL).

Aggregate and organize evidence in a bibliographic management tool (e.g., Endnote [www.endnote.com], Mendeley [www.mendeley.com], RefWorks [https://www.refworks.com/refworks2], or Zotero [www.zotero.org]). Gathering evidence to support broader topics, such as the protocols in this book, presents the searcher with a greater challenge. Limiting searches by methodology can unwittingly eliminate the best evidence for study designs that do not lend themselves to these methods. For example, a cross-sectional retrospective design may provide the highest level of evidence for a study that examines "nurses' perception" of the practice environment (Boltz et al., 2008).

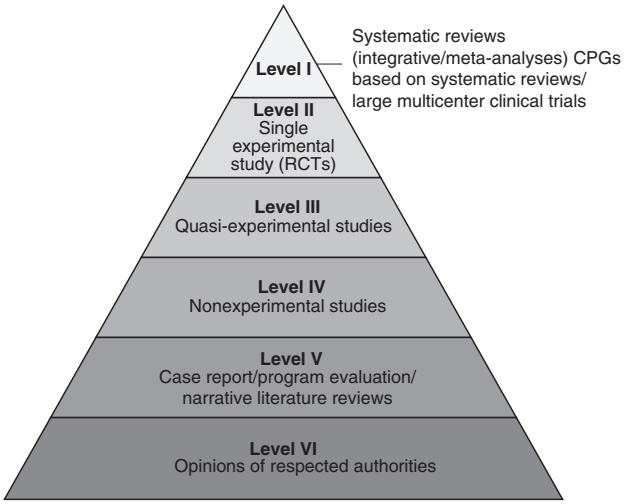
A challenge to a searcher is the need to balance the comprehensiveness of recall (or "sensitivity") with precision ("specificity") to retrieve a manageable number of references. The *Cochrane Handbook* states: "Searches should seek high

sensitivity, which may result in relatively low precision" (Lefebvre et al., 2011, Section 6.1). Thus, retrieving a large set of articles may include many irrelevant hits. Conversely, putting too many restrictions on a database search may exclude relevant studies. The goal of retrieving the relevant studies for broad topic areas requires "sacrificing precision" and manually filtering false or irrelevant hits. Pitfalls of computerized retrieval are justification for the review by the searcher to hand weed false hits from the retrieved list of articles.

The iterative nature of any literature search means that an initial set of relevant references for both broad or specific questions serves to *point* protocol authors toward best evidence as an adjunct to their own knowledge and their own pursuit of "chains of citation" (McLellan, 2001), related records, and their clinical expertise. For example, a core list of references on the topic of physical restraints might lead to exploring citations related to wandering, psychogeriatric care, or elder abuse.

Step 3: Critically Appraise the Evidence

Step 3, critically appraise the evidence, begins with identifying the methodology used in a study (often evident from reviewing the article abstract) followed by a critical reading and evaluation of the research methodology and results. The coding scheme described subsequently provides the first step in filtering retrieved studies based on research methods.



Levels of evidence (LOE) offer a schema that, once known, helps the reader to follow an efficient path for evidence searching as well as understand the relative value of the information presented to the clinical topic or question under review. There are many extant schemas used to identify the LOE of sources. Although multiple schemas exist, there are commonalities in their hierarchical structure, often represented by a pyramid or "publishing wedge" (DiCenso, Bayley, & Haynes, 2009). The highest level of evidence is seen at the top of a pyramid, usually systematic reviews (meta-analyses) and CPGs based on high-level evidence. The LOE for the current edition can be seen in Figure 1.1 (Levin, 2011). A major difference exists between the former and current pyramids that are recommended for guiding your evidence search. Quantitative and qualitative research ask very different questions and thus cannot be included in the same hierarchy-of-evidence scheme. A hierarchy of qualitative evidence, developed by Daly et al. (2007), further aids researchers in the process of guiding the evidence search.

A Level I evidence rating is given to evidence from synthesized sources: systematic reviews, which can either be meta-analyses or structured integrative reviews of evidence, and CPGs based on Level I evidence as well as multicenter clinical trials. Evidence that is judged to be at Level II comes from a single randomized controlled trial. A quasi-experimental study, such as a nonrandomized controlled single group pretest/posttest, time series, or matched case-controlled study, is considered Level III evidence. Level IV evidence comes from a nonexperimental study, such as correlational descriptive research or case-control studies. A narrative literature review, a case report systematically obtained and of verifiable quality, or program evaluation data are rated as Level V. Level VI evidence is identified as the opinion of respected authorities (e.g., internationally or nationally known) based on their clinical experience or the opinions of an expert committee, including their interpretation of nonresearch-based information. This level also includes regulatory or legal opinions. Level I evidence is considered the strongest.

The critical appraisal of extant CPGs and research studies uses specialized tools designed to evaluate the quality of each type of evidence. Examples are the AGREE II instrument (which this volume of protocols conforms to), the Critical Appraisal Skills Programme (www.casp-uk.net), and the PRISMA checklist (a 27-item list of criteria for evaluation; www.prisma-statement.org) for reporting systematic reviews and meta-analyses, among others.

Source: Originally published in Levin, R. F. (2011). Edifices of evidence: The proliferation of pyramids. *Research and Theory for Nursing Practice*, *25*(1), 8–10. doi:10.1891/1541-6577.25.1.8. Reprinted with permission.

This book provides the inclusion of the level and type of evidence for references in chapter citations, which leads to a recommendation for practice. Using this type of standard approach ensures that this book contains protocols and recommendations for use with geriatric patients and their families that are based on the best available evidence and a similar standard of evaluation.

SUMMARY

The protocols contained in this edition, therefore, have been refined, revised, and developed by the authors using the best available research evidence as a foundation, with the ultimate goal of improving patient safety and outcomes. The systematic process used for finding, retrieving, and disseminating the best evidence for this edition of *Evidence-Based Geriatric Nursing Protocols for Best Practice* provides a model for the use of research evidence in nursing education and in clinical practice. Translating nursing research into practice requires competency in information literacy, knowledge of the evidence-based process, and the ability to discern the context of a research study as ranked hierarchically. The following chapters and protocols present both overview (background) and foreground information in readiness for taking the next steps in the EBP process: Step 4: Integrate the evidence into practice using clinical expertise with attention to patient's values and perspectives, and Step 5: Evaluate the outcome(s).

ACKNOWLEDGEMENTS

The author expresses appreciation for the work of previous authors of this chapter: Rona F. Levin and Susan Kaplan Jacobs.

Measuring Performance and Improving Quality

Lenard L. Parisi

2

EDUCATIONAL OBJECTIVES

After completion of this chapter, the reader should be able to:

1. Discuss key components of the definition of quality as outlined by the Institute of Medicine.
2. Describe three challenges of measuring quality of care.
3. Delineate three strategies for addressing the challenges of measuring quality.
4. List three characteristics of a good performance measure.

OVERVIEW

Nadzam and Abraham (2003) state that "The main objective of implementing best practice protocols for geriatric nursing is to stimulate nurses to practice with greater knowledge and skill, and thus improve the quality of care to older adults" (p. 11). Although improved patient care and safety are certainly necessary goals, providers also need to be focused on the implementation of evidence-based practice and improvement of outcomes of care. The implementation of evidence-based nursing practice as a means of providing safe, quality patient care and positive outcomes is well supported in the literature. However, in order to ensure that protocols are implemented correctly, as is true with the delivery of all nursing care, it is essential to evaluate the care provided. Clinical outcomes are a focus of many payment-related initiatives such as value-based payments, bundled payment arrangements with payer and providers, and other quality incentive programs (Struth, 2017).

The improvement of care and clinical outcomes, commonly known as performance improvement, requires a defined, organized approach. Improvement efforts are typically guided by the organization's quality-assessment (measurement) and performance-improvement (process improvement) model. There are many resources available online, such as the Institute for Healthcare Improvement (IHI) website (IHI.org), where there is information about their model for improvement. Some other well-known models or approaches for improving care and processes include Plan–Do–Study–Act (PDSA), IHI website, and Lean Six Sigma (www.ihi.org/resources/Pages/Tools/Quality-Improvement-Essentials-Toolkit.aspx). These methodologies are simply an organized approach to defining improvement priorities, collecting data, analyzing the data, making sound recommendations for process improvement, implementing identified changes, and then reevaluating the measures. Through performance improvement, standards of care (Nurses Improving Care for Healthsystem Elders [NICHE] protocols, in this case) are identified, evaluated, and analyzed for variances in practice and then improved. The goal is to standardize and improve patient care and outcomes. Improvements in quality of patient care occur through restructuring, redesigning, and innovating processes. For these changes to occur, nursing professionals need to be supported by a structure that provides a vision

for continuous improvement, empowers them to make changes, and delivers ongoing and reliable outcome information (Johnson, Hallsey, Meredith, & Warden, 2006).

From the very beginning of the NICHE project in the early 1990s (Capezuti et al., 2013), the NICHE team has struggled with the following questions: How can we measure whether the combination of models of care, staff education and development, and organizational change leads to improvements in patient care? How can we provide hospitals and health systems that are committed to improving their nursing care to older adults with guidance and frameworks, let alone tools for measuring the quality of geriatric care? In turn, these questions generated many other questions: Is it possible to measure quality? Can we identify direct indicators of quality? Or do we have to rely on indirect indicators (e.g., if 30-day readmissions of patients older than 65 years drop, can we reasonably state that this reflects an improvement in the quality of care)? What factors may influence our desired quality outcomes, whether these are unrelated factors (e.g., the pressure to reduce length of stay) or related factors (e.g., the severity of illness)? How can we design evaluation programs that enable us to measure quality without adding more burden (of data collection, of taking time away from direct nursing care)? No doubt, the results from evaluation programs should be useful at the "local" level. Would it be helpful, though, to have results that are comparable across clinical settings (within the same hospital or health system) and across institutions (e.g., as quality benchmarking tools)? Many of these questions remain unanswered today, although the focus on defining practice through an evidence-based approach is becoming the standard, for it is against a standard of care that we monitor and evaluate expected care. Defining outcomes for internal and external reporting is expected, as is the improvement of processes required to deliver safe, affordable quality patient care.

This chapter provides guidance in the selection, development, and use of performance measures to monitor quality of care as a springboard to performance-improvement initiatives. Following a definition of quality of care, the chapter identifies several challenges in the measurement of quality. The concept of performance measures as the evaluation link between care delivery and quality improvement is introduced. Next, the chapter offers practical advice on what and how to measure (Capezuti et al., 2013). It also describes external comparative databases sponsored by the Centers for Medicare & Medicaid Services (CMS) and other quality-improvement organizations. It concludes with a description of the challenges inherent in selecting performance measures.

It is important to reaffirm two key principles for the purposes of evaluating nursing care in this context. First, at the management level, it is indispensable to measure the quality of geriatric nursing care; however, doing so must help those who actually provide care (nurses) and must impact those who receive care (older adult patients). Second, measuring quality of care is not the end goal; rather, it is done to enable the continuous use of quality-of-care information to improve patient care.

QUALITY HEALTHCARE DEFINED

It is not uncommon to begin a discussion of quality-related topics without reflecting on one's own values and beliefs surrounding quality healthcare. Many have tried to define the concept, but like the old cliché "beauty is in the eye of the beholder" so is our own perception of quality. Healthcare consumers and providers alike are often asked: What does quality mean to you? The response typically varies and includes statements such as a safe healthcare experience, receiving correct medications and receiving them in a timely manner, a pain-free procedure or postoperative experience, compliance with regulation, accessibility to services, effectiveness of treatments and medications, efficiency of services, good communication among providers (information sharing), and a caring environment. These are important attributes to remember when discussing the provision of care with clients and patients.

The National Academy of Medicine (NAM; known originally as the Institute of Medicine or IOM) defines quality of care as "the degree to which health services for individuals and populations increase[s] the likelihood of desired health outcomes and are consistent with current professional knowledge" (Kohn, Corrigan, & Donaldson, 2000, p. 211). Note that this definition does not tell us what quality is, but what quality should achieve. This definition also does not say that quality exists if certain conditions are met (e.g., a ratio of *x* falls to *y* in older orthopedic surgery patients, a 30-day readmission rate of *z*, etc.). Instead, it emphasizes that the likelihood of achieving desired levels of care is what matters. In other words, quality is not a matter of reaching something but, rather, the challenge, over and over, of improving the odds of reaching the desired level of outcomes. Thus, the definition implies the cyclical and longitudinal nature of quality: What we achieve today must guide us as to what to do tomorrow—better and better, over and over—the focus being on improving processes while demonstrating sustained improvement.

The NAM definition stresses the framework within which to conceptualize quality: knowledge. The best knowledge to have is research evidence—preferably from randomized clinical trials (experimental studies)—yet without ignoring the relevance of less rigorous studies

(nonrandomized studies, epidemiological investigations, descriptive studies, even case studies). To be realistic, in nursing we have limited evidence to guide the care of older adults. Therefore, professional consensus among clinical and research experts is a critical factor in determining quality. Furthermore, knowledge is needed at three levels: To achieve quality, we need to know what to do (knowledge about best practice), we need to know how to do it (knowledge about behavioral skills), and we need to know what outcomes to achieve (knowledge about best outcomes).

The NAM definition of quality of care contains several other important elements. "Health services" focuses the definition on the care itself. Granted, the quality of care provided is determined by factors such as knowledgeable professionals, good technology, and efficient organizations; yet, these are not typically the focus of quality measurement. Rather, the definition implies a challenge to healthcare organizations: The system should be organized in such a way that knowledge-based care is provided and that its effects can be measured. This brings us to the "desired health outcomes" element of the definition. Quality is not an attribute (as in "My hospital is in the top 100 hospitals in the United States as ranked by *U.S. News & World Report*") but an ability (as in "Only *x*% of our older adult surgical patients develop acute confusion; of those who do, *y*% return to normal cognitive function within *z* hours after onset").

In the NAM definition, *degree* implies that quality occurs on a continuum from unacceptable to excellent. The clinical consequences are on a continuum as well. If the care is of unacceptable quality, the likelihood that we will achieve the desired outcomes is nil. In fact, we probably will achieve outcomes that are the opposite of what are desired. As the care moves up the scale toward excellent, the more likely the desired outcomes will be achieved. "Degree" also implies quantification. Although it helps to be able to talk to colleagues about, say, unacceptable, poor, average, good, or excellent care, these terms should be anchored by a measurement system. Such systems enable us to interpret what, for instance, poor care is by providing us with a range of numbers that correspond to "poor." In turn, these numbers can provide us with a reference point for improving care to the level of average: We measure care again, looking at whether the numbers have improved, then checking whether these numbers fall in the range defined as "average." Likewise, if we see a worsening of scores, we will be able to conclude whether we have gone from, say, good to average. "Individuals and populations" underscores that quality of care is reflected in the outcomes of one patient and in the outcomes of a set of patients. It focuses our attention on providing quality care to individuals while aiming to raise the level of care provided to populations of patients.

In summary, the NAM definition of quality of care forces us to think about quality in relative and dynamic terms rather than in absolute and static terms. Quality of care is not a state of being but rather a process of becoming. Quality is and should be measurable, using performance measures: "a quantitative tool that provides an indication of an organization's performance in relation to a specified process or outcome" (Schyve & Nadzam, 1998, p. 222).

Quality improvement is a process of attaining ever better levels of care in parallel with advances in knowledge and technology. It strives toward increasing the likelihood that certain outcomes will be achieved. This is the professional responsibility of those who are charged with providing care (i.e., clinicians, managers, and their organizations). On the other hand, consumers of healthcare (i.e., patients, but also purchasers, payers, regulators, and accreditors) are much less concerned with the processes in place as with the results of those processes.

CLINICAL OUTCOMES AND PUBLICLY REPORTED QUALITY MEASURES

Although it is important to evaluate clinical practices and processes, it is equally important to evaluate and improve outcomes of care. Clinical outcome indicators are receiving unprecedented attention within the healthcare industry from providers, payers, and consumers alike. Regulatory and accrediting bodies review outcome indicators to evaluate the care provided by the organization before and during regulatory and accrediting surveys and to evaluate clinical and related processes. Organizations are expected to use outcome data to identify and prioritize the processes that support clinical care and demonstrate an attempt to improve performance. Providers may use outcome data to support best practices by benchmarking their results with similar organizations. The benchmarking process is supported through publicly reported outcome data at the national and state levels. National reporting occurs on the CMS website, where consumers and providers alike may access information and compare hospitals, home care agencies, nursing homes, and managed care plans. For example, the websites www.medicare.gov/hospitalcompare/about/what-is-hos.html, www.medicare.gov/NHCompare, and www.medicare.gov/HHCompare list outcome indicators relative to the specific service or delivery model. Consumers may use these websites to select organizations and compare outcomes, one against another, to aid in their selection of a facility or service. These websites also serve as a resource for providers to benchmark their outcomes

against those of another organization. Outcome data also become increasingly important to providers as the industry continues the shift toward payment models. With these models, practitioners are reimbursed for achieving quality-of-care outcomes.

One important nationwide quality initiative, which is sure to have a positive impact on the care for older adults, is the focus on readmissions (www.cms.gov/Medicare/Medicare-Fee-for-Service-Payment/AcuteInpatientPPS/Readmissions-Reduction-Program.html). This is an important outcome measure that is sure to foster improved evaluation of clinical processes across the healthcare continuum.

Measuring Quality of Care

Schyve and Nadzam (1998) identified several challenges to measuring quality. First, the suggestion that quality of care is in the eye of the beholder points to the different interests of multiple users. This issue encompasses both measurement and communication challenges. Measurement and analysis methods must generate information about the quality of care that meets the needs of different stakeholders. In addition, the results must be communicated in ways that meet these different needs. Second, we must have good and generally accepted tools for measuring quality. Thus, user groups must come together in their conceptualization of quality care so that relevant healthcare measures can be identified and standardized. A common language of measurement must be developed, grounded in a shared perspective on quality that is cohesive across the continuum, yet meets the needs of various user groups. Third, once the measurement systems are in place, data must be collected. This translates into resource demands and logistic issues as to who is to report, record, collect, and manage data. Fourth, data must be analyzed in statistically appropriate ways. This is not just a matter of using the right statistical methods; it is more important that user groups must agree on a framework for analyzing quality data to interpret the results. Fifth, healthcare environments are complex and dynamic in nature. There are differences across healthcare environments, between types of provider organizations, and within organizations. Furthermore, changes in healthcare occur frequently, such as the movement of care from one setting to another and the introduction of new technology. Finding common denominators is a major challenge.

ADDRESSING THE CHALLENGES

These challenges to measuring quality are not insurmountable. However, making a commitment to quality care entails a commitment to putting the processes and systems in place to measure quality through performance measures and to report quality-of-care results. This commitment applies as much to a quality-improvement initiative on a nursing unit as it does to a corporate commitment by a large healthcare system. In other words, once an organization decides to pursue excellence (i.e., quality), it must accept the need to overcome the various challenges to measurement and reporting. Let us examine how this could be done in a clinical setting.

McGlynn and Asch (1998) offer several strategies for addressing the challenges of measuring quality. First, the various user groups must identify and balance competing perspectives. This is a process of giving and taking: not only proposing highly clinical measures (e.g., prevalence of pressure ulcers) but also providing more general data (e.g., use of restraints). It is a process of asking and responding: not only asking management for monthly statistics on medication errors but also agreeing to provide management with the necessary documentation of the reasons stated for restraint use. Second, there must be an accountability framework. Committing to quality care implies that nurses assume several responsibilities and are willing to be held accountable for each of them: (a) providing the best possible care to older patients, (b) examining their own geriatric nursing knowledge and practice, (c) seeking ways to improve it, (d) agreeing to evaluation of their practice, and (e) responding to needs for improvement. Third, there must be objectivity in the evaluation of quality. This requires setting and adopting explicit criteria for judging performance, then building the evaluation process on these criteria. Nurses, their colleagues, and their managers need to reach consensus on how performance will be measured and what will be considered excellent (and good, average, etc.) performance. Fourth, once these indicators have been identified, nurses need to select a subset of indicators for routine reporting. Indicators should give a reliable snapshot of the team's care to older patients. Fifth, it is critical to separate as much as possible the use of indicators for evaluating patient care and the use of these indicators for financial or nonfinancial incentives. Should the team be cost-conscious? Yes, but cost should not influence any clinical judgment as to what is best for patients. Finally, nurses in the clinical setting must plan how to collect the data. At the institutional level, this may be facilitated by information systems that allow performance measurement and reporting. Ideally, point-of-care documentation will also provide the data necessary for a systematic and goal-directed quality-improvement program, thus eliminating separate data abstraction and collection activities.

The success of a quality-improvement program in geriatric nursing care (and the ability to overcome many of

the challenges) hinges on the decision as to what to measure. We know that good performance measures must be objective, that data collection must be easy and as burdenless as possible, that statistical analysis must be guided by principles and placed within a framework, and that communication of results must be targeted toward different user groups. Conceivably, we could try to measure every possible aspect of care; realistically, however, the planning for this will never reach the implementation stage. Instead, nurses need to establish priorities by asking these questions: Based on our clinical expertise, what is critical for us to know? What aspects of our care to older patients are of high risk or high volume? What parts of our elder care are problem-prone, either because we have experienced difficulties in the past or because we can anticipate problems as a result of the lack of knowledge or resources? What clinical indicators would be of interest to other user groups: patients, the general public, management, payers, accreditors, and practitioners? Throughout this prioritization process, nurses should keep asking themselves: What questions are we trying to answer, and for whom?

Measuring Performance-Selecting Quality Indicators

The correct selection of performance measures or quality indicators is a crucial step in evaluating nursing care and is based on two important factors: frequency and volume. Clearly, high-volume practices or frequent processes require focused attention—to ensure that the care is being delivered according to protocol or processes are functioning as designed. Problem-prone or high-risk processes would also warrant a review as these are processes with inherent risk to patients or potential variances in implementing the process. The selection of indicators must also be consistent with organizational goals for improvement. In today's healthcare environment, selection of indicators may be based on external requirements such as value-based payment measures or reporting of publicly reported measures. This provides buy-in from practitioners as well as administration when reporting and identifying opportunities for improvement. Performance measures (i.e., indicators) must be based on a standard of care, policy, procedure, or protocol. These documents, or standards of care, define practice and expectations in the clinical setting and, therefore, determine the criteria for the monitoring tool. The measurement of these standards simply reflects adherence to or implementation of these standards. Once it is decided what to measure, nurses in the clinical geriatric practice setting face the task of deciding how to measure performance. There are two possibilities: either the appropriate measure (indicator) already exists or a new performance measure must be developed. Either way, there are a number of requirements of a good performance measure that will need to be applied.

Although indicators used to monitor patient care and performance do not need to be subject to the rigors of research, it is imperative that they reflect some of the attributes necessary to make relevant statements about the care. The measure and its output need to focus on improvement, not merely the description of something. It is not helpful to have a very accurate measure that just tells the status of a given dimension of practice. Instead, the measure needs to inform us about current quality levels and relate them to previous and future quality levels. It needs to be able to compute improvements or declines in quality over time so that we can plan for the future. For example, to have a measure that only tells the number of medication errors in the past month would not be helpful. Instead, a measure that tells what types of medication errors were made, perhaps even with a severity rating indicated, compares this to medication errors made during the previous months and shows in numbers and graphs the changes over time that will enable us to do the necessary root cause analysis to prevent more medication errors in the future.

Performance measures need to be clearly defined, including the terms used, the data elements collected, and the calculation steps employed. Establishing the definition before implementing the monitoring activity allows for precise data collection. It also facilitates benchmarking with other organizations, when the data elements are similarly defined and the data-collection methodologies are consistent. Imagine that we want to monitor falls on the unit. The initial questions would be: What is considered a fall? Does the patient have to be on the floor? Does a patient slumping against the wall or onto a table while trying to prevent himself or herself from falling to the floor constitute a fall? Is a fall caused by physical weakness or orthostatic hypotension treated the same way as a fall caused by tripping over an obstacle? The next question would be: Over what time period are falls measured: a week, a fortnight, a month, a quarter, or a year? The time frame is not a matter of convenience, but of accuracy. To be able to monitor falls accurately, we need to identify a time frame that will capture enough events to be meaningful and interpretable from a quality improvement point of view. External indicator definitions, such as those defined for use in the National Database of Nursing Quality Indicators, provide guidance for both the indicator definition and the data-collection methodology for "nursing-sensitive indicators." The nursing-sensitive indicators reflect the structure, process, and outcomes of nursing care. The *structure* of nursing care

is indicated by the supply of nursing staff, the skill level of the nursing staff, and the education/certification of nursing staff. *Process* indicators measure aspects of nursing care such as assessment, intervention, and RN job satisfaction. Patient *outcomes* that are determined to be nursing sensitive are those that improve if there is a greater quantity or quality of nursing care (e.g., pressure ulcers, falls, intravenous [IV] infiltrations). However, frequency of primary Cesarean sections and cardiac failure is not considered "nursing sensitive" (for details, see https://www.pressganey.com/docs/default-source/default-document-library/clinical excellence_ndnqi_solution-summary.pdf?sfvrsn=0). Several nursing organizations across the country participate in data collection and submission, which allows for a robust database and excellent benchmarking opportunities.

Additional indicator attributes include validity, sensitivity, and specificity. *Validity* refers to whether the measure actually measures what it says it measures. *Sensitivity* and *specificity* refer to the ability of the measure to capture all true cases of the event being measured, and only true cases. We want to make sure that a performance measure identifies true cases as true and false cases as false and does not identify a true case as false or a false case as true. Sensitivity of a performance measure determines the likelihood of a positive test when a condition is present. Lack of sensitivity is expressed as false positives, that is, the indicator calculates a condition as present when in fact it is not. *Specificity* refers to the likelihood of a negative test when a condition is not present. False negatives reflect lack of specificity, that is, the indicator calculates a condition as not present when in fact it is. Consider the case of depression and the recommendation in Chapter 19 to use the Geriatric Depression Scale, in which a score of 11 or greater is indicative of depression. How robust is this cutoff score of 11? What is the likelihood that someone with a score of 9 or 10 (i.e., negative for depression) might actually be depressed (i.e., false negative)? Similarly, what is the likelihood that a patient with a score of 13 would not be depressed (i.e., false positive)?

Reliability means that results are reproducible, that is, the indicator measures the same attribute consistently across the same patients and across time. Reliability begins with a precise definition and specification, as described earlier. A measure is reliable if different people calculate the same rate for the same patient sample. The core issue of reliability is measurement error, or the difference between the actual phenomenon and its measurement: The greater the difference, the less reliable the performance measure. For example, suppose that we want to focus on pain management in older adults with end-stage cancer. One way of measuring pain would be to ask patients to rate their pain as none, a little, some, quite a bit, or a lot. An alternative approach would be to administer a visual analog scale, a 10-point line on which patients indicate their pain levels. Yet another approach would be to ask the pharmacy to produce monthly reports of analgesic use by type and dose. Generally speaking, the more subjective the scoring or measurement, the less reliable it will be. If all these measures were of equal reliability, they would yield the same result. The concept of reliability, particularly inter-rater reliability, becomes increasingly important to consider in those situations in which data collection is assigned to several staff members (Albanese et al., 2010). It is important to review the data-collection methodology, and the instrument in detail, to avoid different approaches and interpretation by the various people collecting the data.

Several of the examples given earlier imply the criterion of interpretability. A performance measure must be interpretable, that is, it must convey a result that can be linked to the quality of clinical care. First, the quantitative output of a performance measure must be scaled in such a way that users can interpret it. For example, a scale that starts with 0 as the lowest possible level and ends with 100 is much easier to interpret than a scale that starts with 13.325 and has no upper boundary except infinity. Second, we should be able to place the number within a context. Suppose we are working in a hemodialysis center that serves quite a large proportion of end-stage renal disease (ESRD) patients older than 60 years—the group least likely to be fit for a kidney transplant yet with several years of life expectancy remaining. We know that virtually all ESRD patients develop anemia (i.e., hemoglobin [Hb] <11 g/dL), which in turn impacts their activities of daily living (ADL) and instrumental activities of daily living (IADL) performance. In collaboration with the nephrologists, we initiate a systematic program of anemia monitoring and management, relying in part on published best practice guidelines. We want to achieve the best practice guideline of 85% of all patients having Hb levels equal to or greater than 11 g/dL. We should be able to succeed because the central laboratory provides us with Hb levels, which allows us to calculate the percentage of patients having Hb levels of 11 g/dL or greater.

The concept of risk-adjusted performance measures or outcome indicators is an important one. Some patients are sicker than others, some have more comorbidities, and some are older and frailer. No doubt, we could come up with many more risk variables that influence how patients respond to nursing care. Good performance measures take this differential risk into consideration. They create a "level playing field" by adjusting quality indicators on the basis of the risk for severity of illness of the patients. It would

not be fair to the healthcare team if the patients on the unit are a lot sicker than those on the unit a floor above. The team is at greater risk of having lower quality outcomes not because the patients are provided inferior care but because the patients are a lot sicker and are at greater risk of a compromised response to the care provided. The sicker patients have greater needs in terms of care and ultimately are less likely to achieve the same outcomes as less-ill patients. Performance measures must be easy to collect. The many examples cited earlier also refer to the importance of using performance measures for which data are readily available, can be retrieved from existing sources, or can be collected with little burden. The goal is to gather good data quickly without running the risk of having "quick and dirty" data.

We begin the process of deciding how to measure by reviewing existing measures. There is no need to reinvent the wheel, especially if good measures are out there. Nurses should review the literature, check with national organizations, and consult with colleagues. Yet, we should not adopt existing measures blindly; instead, we need to subject them to a thorough review using the characteristics identified earlier. Also, healthcare organizations that have adopted these measures can offer their experience.

Recently, an initiative of the John A. Hartford Foundation and the IHI in partnership with the American Hospital Association and the Catholic Health Association of America (CHA) defined the four elements of a friendly health system. These elements, the **4Ms**, are:

- **What Matters:** alignment of patient goals with preferences
- **Medication:** use of medication that does not interfere with mentation, mobility, and what matters
- **Mentation:** prevention, identification, and management of delirium dementia and depression across care settings
- **Mobility:** ensuring older adults can move safely in order to maintain function and do what matters

This framework for age-friendly care can be integrated into quality initiatives to guide program goals and measures (Fulmer, Mate, & Berman, 2018).

Implementing the Quality-Assessment and Performance-Improvement Program

Successful performance-improvement programs require an organizational commitment toward implementation of the performance-improvement processes and principles outlined in this chapter (Kliger, Lacey, Olney, Cox, & O'Neil, 2010). Consequently, this commitment requires a defined, organized approach that most organizations embrace and define in the form of a written plan. The plan outlines the approach that the organization uses to improve care and safety for its patients. There are several important elements that must be addressed to implement the performance-improvement program effectively. The scope of service, which addresses the types of patients and care that is rendered, provides direction on the selection of performance measures. An authority and responsibility statement in the document defines who is able to implement the quality program and make decisions that will affect its implementation. Finally, it is important to define the committee structure used to effectively analyze and communicate improvement efforts to the organization.

The success of the performance-improvement program is highly dependent on a well-defined structure and appropriate selection of performance measures. The following is a list of issues that, if not addressed, may negatively impact the success of the quality program:

1. Lack of focus: a measure that tries to track too many criteria at the same time or is too complicated to administer, interpret, or use for quality monitoring and improvement
2. Wrong type of measure: a measure that calculates indicators the wrong way (e.g., uses rates when ratios are more appropriate, uses a continuous scale rather than a discrete scale, measures a process when the outcome is measurable and of greater interest)
3. Unclear definitions: a measure that is too broad or too vague in its scope and definitions (e.g., population is too heterogeneous, no risk adjustment, unclear data elements, poorly defined values)
4. Too much work: a measure that requires too much clinician time to generate the data or too much manual chart abstraction
5. Reinventing the wheel: a measure that is a reinvention rather than an improvement of a performance measure
6. Events not under control: a measure focusing on a process or outcome that is out of the organization's (or the unit's) control to improve
7. Trying to do research rather than quality improvement: data collection and analysis are done for the sake of research rather than for improvement of nursing care and the health and well-being of the patients
8. Poor communication of results: the format of communication does not target and enable change
9. Uninterpretable and underused: uninterpretable results are of little relevance to improving geriatric nursing care

SUMMARY

In summary, the success of the quality-assessment and performance-improvement program's ability to measure, evaluate, and improve the quality of nursing care to healthsystem elders is in the planning. First, it is important to define the scope of services provided and those to be monitored and improved. Second, performance measures that are reflective of the care provided need to be identified. Indicators may be developed internally or obtained from external sources of outcomes and data-collection methodologies. Third, it is important to analyze the data, pulling together the right people to evaluate processes, make recommendations, and improve care. Finally, it is important to communicate the findings across the organization and celebrate success.

Terese Kornet

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Define computerized provider order entry and identify its contribution to geriatric care.
2. Describe how clinical decision support systems can promote positive geriatric care.
3. Discuss a case example that illustrates the development of a comprehensive geriatric nutrition dashboard.

OVERVIEW

Electronic health records (EHRs) are the mainstay of nearly all hospitals. The impetus for transition from a paper to an electronic health record was driven largely by payers (Medicare/Medicaid and Health Maintenance Organizations), quality improvement organizations, and Institute of Medicine panels (Gillum, 2013). They were conceived of as a solution to the myriad of limitations inherent in a paper recording system, mainly inconsistency in content and quality, illegibility, and safety concerns (Berner, Detmer, & Simborg, 2005). In addition to the portability of EHRs, two additional features have been particularly successful in improving safety and care quality for older adult patients: computerized provider order entry (CPOE) and clinical decision support systems (CDSS).

CPOE is a central tenet of the EHRs and is a required component as part of meaningful use. It is defined by the Centers for Medicare and Medicaid Services as "the provider's use of computer assistance to directly enter medication orders from a computer or mobile device. The order is also documented or captured in a digital, structured, and computable format for use in improving safety and organization" (Centers for Medicare and Medicaid Services, 2014, p. 1). The intent of CPOE is to improve patient safety via several features. CPOE ensures prescribing providers have access to patients' allergy information at the time of prescribing. It also ensures patients receive appropriate dosages for medications based on weight, renal function, or other clinical situations. For older adult patients, CPOE systems can support providers in avoidance or judicious use of medications that may be potentially inappropriate in older adults. Potentially inappropriate medications are outlined in the Beers Criteria, a comprehensive evidence-based list of medications identified as potentially inappropriate for use in older adults for a variety of reasons (American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015). EHRs that contain alerts for prescriptions of Beers Criteria medications have been successful in decreasing or eliminating the use of these medications (Clyne, Bradley, Hughes, Fahey, & Lapane, 2012; Mattison, Afonso, Ngo, & Mukamal, 2010; Zillich et al., 2008).

Another valuable aspect of the EHR is the opportunity to embed CDSS. These systems can support geriatric care in several ways. First, they can provide direction to clinicians regarding what needs to be assessed and what evidence-based care should be implemented. For example,

Dowding, Turley, and Garrido (2012) found that when risk assessments for hospital-acquired pressure ulcers and falls were embedded in the nursing assessment portion of the EHR, the percentage of patients with completed assessments increased significantly, leading to improved outcomes. Another type of CDSS involves embedding algorithms into the EHR to synthesize information entered by providers to determine a patient's level of risk for a particular outcome or to support culmination of an evidence-based assessment. Lekan and colleagues (2017) created an algorithm for identifying a frailty risk score by synthesizing various data points from the EHR, such as history of falls, vision impairment, poor appetite, and low albumin. The frailty risk score was statistically significantly correlated with in-hospital mortality. Rather than clinicians evaluating discrete pieces of data, the frailty risk score allows for an integrated assessment that can be leveraged to implement an individualized multicomponent intervention strategy (Lekan et al., 2017).

Despite the fact that the EHR contains a vast amount of information that can be accessed from nearly any electronic device at any time, some drawbacks have been identified. One of the biggest limitations of EHRs is their inability to "show" a summary of pertinent information in one view to tell the patient's story. Traditional inpatient paper medical records have progress notes that track the patient's story on a day-to-day timeline. It is easy for the reviewer to see what happened on a progressive timeline as he or she reads and turns the pages on what has happened from one day to the next. For example, the patient was admitted on a Monday morning; surgery was performed as evidenced by the surgeon's postoperative note; ambulation and activity were tracked in the next day's physical therapy note. The patient's story is told in a sequential fashion.

Electronic records disrupt this book-like storytelling by constantly forcing the user to reorient information and data and where it sits on a timeline. Since a user flips from one section of the EHR to another, and may be looking at a graph, a flowsheet of data, or a text-written note, understanding the sequence of events and how the information fits together can be challenging. This makes it much more difficult for clinicians to synthesize data on which to base care interventions. For geriatric patients, this concern is even more prominent. With regard to identifying the burden of "geriatric syndromes" on a patient, for example malnutrition, vision impairment, or walking difficulty, Kharrazi and colleagues (2018) found that structured EHR data provide an incomplete picture. Their study showed that information recorded in unstructured text fields in the EHR contained the most relevant information for identification of geriatric syndromes. Another limitation is the EHR's ability to support care coordination, especially across acute and community-based care settings (O'Malley, Grossman, Cohen, Kemper, & Pham, 2010).

Relevant components of a particular assessment often reside in various aspects of the medical record. To alleviate this, some organizations have customized their EHRs to create dashboards that summarize information relevant to the clinical situation (Mlaver et al., 2017; Schleyer et al., 2019; Swartz, Cimino, Fred, Green, & Vawdrey, 2014). For example, Schleyer and colleagues (2019) created a chest pain dashboard that displays five data points relevant to the management of chest pain on one screen. Swartz and colleagues (2014) created a dashboard to summarize patient history, labs, test results, and medications all in one view.

The fragmented nature of clinical information in the EHR is an important limitation to comprehensive interdisciplinary care of geriatric patients. A functional assessment performed by a physical therapist, a social assessment by a social worker, and a medication management assessment performed by a pharmacist all reside in completely separate areas of the EHR. Therefore, to get a comprehensive view of a patient's needs, a provider would need to know where all the various assessments reside and be able to synthesize and refer to the information when determining a course of treatment. This chapter will provide a case example of a comprehensive geriatric nutrition dashboard and a protocol for clinicians to follow, outlining the critical steps involved in EHR dashboard development and implementation.

CASE EXAMPLE 3.1: CREATING A COMPREHENSIVE GERIATRIC NUTRITION DASHBOARD

In one large academic medical center, geriatric nurse consultants (GNCs) conduct a comprehensive geriatric assessment (CGA) for adults over age 70 admitted to the hospital medicine service and support the interprofessional care team in implementing geriatric evidence-based practices to prevent excess disability and other avoidable negative outcomes over the course of a hospital stay (Trotta, Rao, Hermann, & Boltz, 2018). On discharge, GNCs write transition notes to facilitate continuation of geriatric evidence-based care in the home setting. Recommendations for ongoing nutrition support are a fundamental component of the transition.

As part of the CGA, GNCs conduct a screening for malnutrition, and if the screen is positive, they refer the patient to the nutritionist for a full assessment, including the Mini Nutritional Assessment (Vellas et al., 1999). The GNCs also assess for functional ability using validated instruments. However, the GNCs recognized that in order to

provide recommendations for nutritional support as older adult patients transitioned home after hospitalization, they needed more information. For example, they needed to know the patient's current diet order and chewing and swallowing ability level. They also needed to know whether or not the patient screened positive for food insecurity, as this finding would impact the way in which the GNC and case manager intervened. The patient's functional status would impact the ability to shop for food, prepare food, and clean up. Given the complexity of a truly comprehensive assessment of an older adult's current nutritional status, it was challenging to locate and organize the findings of these various aspects of nutrition in the EHR. They also recognized that to access more information within the EHR about these various assessments that impact nutrition, the GNC would have to search several areas of the EHR (see Table 3.1).

In order to get a comprehensive view of a patient's nutritional needs, at least five locations in the EHR needed to be accessed. Not only is this time consuming, but most practitioners would likely not remember to check all these areas. In addition, the results of these various pieces of a comprehensive nutritional assessment could not be viewed together in one place. To address this issue, we created a customized comprehensive geriatric nutrition dashboard. This dashboard pulls from the various areas within the EHR where these assessments and recommendations are

TABLE 3.1

Nutrition-Related Data and Location in the EHR

Data Point(s)	Location of Data in the EHR
Results of nutrition assessment	Nutrition navigator
Results of screen for food insecurity	Nursing admission navigator
Current diet order (cardiac, renal, diabetic, etc.)	Medical orders
Speech therapist recommendations for diet consistency (regular, chopped, pureed, etc.)	Speech pathologist note
Current diet consistency order	Medical orders
Patient's food likes and dislikes	Nutrition navigator
Cultural considerations	Nursing admission navigator
Food preparation and shopping ability	Functional assessment within the geriatric nurse consultant assessment navigator

EHR, electronic health record.

TABLE 3.2

Example of information contained in the EHR geriatric nutrition dashboard for a fictitious patient.

Geriatric Nutritional Concerns	
Malnutrition Assessment Findings	**Patient meets established criteria for: Severe protein-calorie malnutrition in the context of acute illness or injury.** Documented 10/08/2018 1143
Within the past 12 months, you worried that your food would run out before you got money to buy more.	**Sometimes true** Documented 10/22/2018 0900
Within the past 12 months, the food you bought just didn't last and you didn't have money to get more.	**Sometimes true** Documented 10/22/2018 0900
SLP Recommended Diet	**Chopped, thin** [strict 1:1 feed, encourage chin tuck position. NO straws, small sips] Documented 10/19/2018 1555
SLP Medication Administration Recommendations	**Whole, in puree** Documented 10/19/2018 1555
SLP General Recommendations	**Aspiration precautions, small bites/small sips, slow rate of intake, feed only when alert, 1:1 feed, reflux precautions, if signs/symptoms of aspiration--> initiate NPO, upright posture, 90 degrees w/all PO intake, alternate between food and liquid** Documented 10/19/2018 1555
Other SLP General Recommendations	**Pharyngeal strengthening exercises** Documented 10/16/2018 1401
Likes	**Scrambled eggs for breakfast, rice** Documented 10/22/2018 0917
Dislikes	**Noodles** Documented 10/22/2018 0917
Cultural Considerations	**No pork, lactose intolerant** Documented 10/22/2018 0917
Food Preparation	**Heats and serves prepared meals or prepares meals but does not maintain adequate diet** Documented 10/22/2018 0900
Shopping	**Needs to be accompanied on any shopping trip** Documented 10/22/2018 0900

NPO, nothing by mouth; PO, by mouth; SLP, speech-language pathologist.

documented so that they can be viewed in one location (see Figure 3.1). Table 3.2 provides an example of the information contained in the EHR geriatric nutrition dashboard for a fictitious patient. The left column lists the discrete field or assessment from the EHR. The right column represents the corresponding documentation, along with the date and time that information was entered in the EHR. This table shows that the information in the geriatric nutrition dashboard presents a comprehensive picture of information that is otherwise available in various locations in the EHR and was documented on various dates and times over the course of the patient's hospital stay.

Once the geriatric nutritional concerns dashboard became available in the EHR, GNCs were able to use it to efficiently evaluate a patient's current comprehensive nutrition status and make recommendations to the home-based care team for ongoing nutritional support. Depending on the patient's individualized needs, recommendations could include social work services to secure nutritional support to address food insecurity, specific involvement of caregivers to support food preparation and shopping, ongoing speech therapy services in the home, or any combination of these interventions.

PROTOCOL FOR CREATING A DASHBOARD

1. Identify the problem/limitation in the EHR. What problem are you trying to solve? Do not start by proposing a solution. Rather, begin with the problem at hand.
2. Gather key stakeholders. These are people who conduct these assessments, people who would use the solution, and potentially someone who has knowledge of the EHR functionality.
3. Identify the governing body for making changes within the EHR. These groups have different names in different organizations, but they are usually comprised of clinical informaticists, IT applications analysts, and end users. This is usually a clinical informatics group along with IT application analysts.
4. Identify the process for requesting modifications to the EHR to enhance usability. This is frequently done by placing a ticket containing the request.
5. Key stakeholder group should identify the specific components they want to have in their customized dashboard and the specific locations in the EHR where they currently reside.
6. Identification of the scope of the project. The governing body will respond to the ticket and ask additional questions to determine the scope and timeline of the project.
7. Identify the approvals that will be necessary to carry out the request. This process may be in parallel to or embedded within the process for making the initial modification request. Ensuring you have the appropriate approvals is critical.
8. Discuss how the data should be displayed, with particular attention to what units of measure to display, for example, pounds versus kilograms. If dates are included, determine the direction: chronological or reverse chronological.
9. Work with an EHR analyst to create an initial version in an EHR test environment. Several iterations will likely be needed before the dashboard becomes "live."
10. Identify the timeline for steps to unfold and follow up regularly, as EHR analysists are dealing with many requests.
11. Conduct the appropriate testing to ensure that data you want are being pulled from the correct sources. This is critical to avoid the pulling of rogue data into the dashboard, meaning, data points might have various names in various locations in the EHR. Working closely with your analyst will help ensure this step unfolds as planned.
12. Once your dashboard is functioning accurately and the build is complete, publicize your dashboard to any interprofessional team member who may want to use it.
13. Continue to monitor the functionality of your dashboard. Missing data can limit functionality. For example, if a daily weight is needed to measure patient progress on a nutrition regimen, absence of consistent documentation of weights will limit functionality. This presents an opportunity to work with clinical staff to ensure consistent documentation of the specific data elements required for your dashboard.

SUMMARY

This chapter provides an example of how a dashboard to address comprehensive management of geriatric nutrition can be created within an EHR. Further iterations of this dashboard are in progress and will include additional aspects of the assessment, such as depression and cognitive status. The GNCs recognized that patients experiencing depression may need additional nutritional support, because they may have low intake and lack the motivation to eat. The GNCs also recognized that the patient's cognitive status could impact aspects of nutrition such as remembering to eat and having the necessary executive function to plan for, prepare, and cook meals. This case example also provides a prototype for other geriatric clinical issues that require multiple considerations; for example, functional maintenance.

Organizational Approaches to Promote Person-Centered Care

4

Andrea Yevchak Sillner
and Liza Behrens

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe person-centered care (PCC).
2. Discuss national initiatives to support PCC.
3. List PCC nursing strategies.
4. Identify approaches to evaluate PCC.

OVERVIEW

Person-centered care (PCC) is considered the gold standard for healthcare delivery in the United States and globally. The National Academies of Sciences, Engineering, and Medicine published *Crossing the Quality Chasm: A New Health System for the 21st Century* in 2001 and *Crossing the Global Quality Chasm: Improving Health Care Worldwide* in 2018; both reports identified the individual as a codesigner and decision maker within the healthcare system (Committee on Improving the Quality of Health Care Globally, 2018; Committee on Quality Health Care in American, 2001). The Institute for Healthcare Improvement has also put forth person-centered values and initiatives to improve care for all (Fulmer, Mate, & Berman, 2018).

The purpose of this chapter is to define PCC; provide an overview of its origin and history; summarize federal and state initiatives supporting PCC; outline nursing strategies for PCC; explore organizational models, approaches, and measurement of PCC; and present a case study outlining PCC principles and approaches. The chapter will conclude with strategies geared toward evaluation of PCC.

DEFINITION AND ATTRIBUTES

PCC is a widely used term in nursing and healthcare research and practice, yet a recent review by Kogan, Wilber, and Mosqueda (2016) found as many as 15 definitions for PCC. In addition, the terms *patient-centered care*, *patient-directed care*, and *person-directed care* are frequently used as synonyms, yet they may have distinct meanings (Behrens et al., 2019; Kogan et al., 2016; Kumar & Chattu, 2018). Current convention suggests that patient-centered and patient-directed care is not limited to preference-based care for their medical conditions or illness; rather, it sees the individual as having unique social, mental, emotional, and other life goals and needs (Kumar & Chattu, 2018).

The American Geriatrics Society convened an interdisciplinary panel with the goal of defining PCC and key attributes (American Geriatrics Society Expert Panel on Person-Centered Care, 2016). They defined PCC as asking and allowing an individual to state his or her values and preferences that should then direct all healthcare choices and decisions to support not only the individual's health-related goals, but all other personal goals as well (American

Geriatrics Society Expert Panel on Person-Centered Care, 2016). In addition to defining PCC, the expert panel also determined eight essential elements to fully achieve PCC, which are listed and described in Table 4.1.

Further work has been done to identify essential elements of PCC for specific populations and settings. A 2019 study used concept mapping with an expert panel to identify domains important across various long-term settings, including assisted living, nursing home, and home and community-based care settings. The six domains identified are: (a) Enacting Humanistic Values (e.g., supporting autonomy and empowering individuals); (b) Direct Care Worker Values (e.g., respectfulness and understanding); (c) Engagement Facilitators (e.g., involvement of family and friends in care and activities); (d) Living Environment (e.g., homelike atmosphere); (e) Communication; and (f) Supportive Systems (e.g., care coordination; Behrens et al., 2019). Similarly, a research review identified components of PCC that impact outcomes for those with dementia. They suggested six practice recommendations for PCC for persons with dementia: (a) Know the Person; (b) Recognize and Accept the Person's Reality; (c) Identify Areas for Continued Engagement; (d) Relationship Building; (e) Develop Relationships Across All Involved; and (f) Review Outcomes and Make Changes as Needed (Fazio, Pace, Flinner, & Kallmyer, 2018).

Given that there is not one global definition of PCC to date, clinicians and researchers must be thoughtful when selecting their framework for PCC. In the absence of a consensus definition of PCC, regardless of the population or setting, the definition and key attributes must be clearly illustrated and explained to all, including older adults and informal caregivers involved in their care. Researchers evaluating the impact of PCC must provide comprehensive definitions of PCC and the measures used to evaluate the impact.

TABLE 4.1

Essential Elements of Person-Centered Care

Element	Description
1. Personalized Care Plan	Preference-based, holistic care plan including personal and social goals
2. Care Plan Reassessment	Addresses physical, mental, and social changes as well as changing personal and medical care goals
3. Interdisciplinary Team-Based Care	Evolving caregiver team including the patient and family
4. Team Leader	Primary contact person and team leader to ensure continuity of care
5. Care Coordination	Ensured by primary contact person across settings and disciplines of care
6. Constant Communication	Open dialogue between patients, families, and providers in person and through the electronic health record
7. Continuing Education	Focus on person-centered care
8. Measurable Outcomes	Reasonable outcomes based on the individual's goals

Source: Data from American Geriatrics Society Expert Panel on Person-Centered Care. (2016). Person-centered care: A definition and essential elements. *Journal of American Geriatrics Society, 64*(1), 15–18. doi:10.1111/jgs.13866

ORIGIN AND HISTORY

PCC is believed to have begun in the 1940s with the work of psychologist Carl Rogers (Flinner, Kallmyer, Pace, & Fazio, 2018). His work focused on the development of person-centered therapy, also referred to as person-centered psychotherapy or counseling, which helps individuals to gain greater self-awareness (Dewing, 2004; Li & Porock, 2014). About a decade later, in the 1950s, patient-centered care gained interest in medicine and healthcare-related practice and research. Although distinct from PCC, patient-centered care was part of the paradigm shift from focusing on disease processes to focusing on the person (Groene, 2011). Additional terms used for patient-centered care include patient- and family-centered care, relationship-centered care, personalized care, and user- or client-centered care (Santana et al., 2018). Person-centered nursing is a term used to describe the person-centered approach to building therapeutic nurse–patient relationships during the delivery of nursing care (McCormack & McCance, 2006).

Most of our understanding of PCC derives from practice initiatives with older adults in long-term care (LTC) and those with dementia. Kitwood (1998) further advanced the concept by using the term *PCC* in the late 1980s to contrast the need for holistic dementia care versus the disease-based, medical approach (Flinner et al., 2018; Kitwood, 1998). Kitwood reasoned that PCC was the interaction between the individual's health, social context, and environment and emphasized the need for communication and relationship building among all those involved in the care of the person with dementia.

PCC in primary healthcare, including medicine and nursing, is thought to have been a movement from patient-centered care or medicine (Hakansson et al.,

2019). Often the terms *PCC* and *patient-centered care* are used interchangeably in the literature, yet there are differences in the goals of care (Hakansson et al., 2019; Kumar & Chattu, 2018). The goal of PCC is holistic and focused on quality of life, whereas patient-centered care focuses on treating the illness or condition to maintain or improve function. At the heart of person- and patient-centered care are similar values, including empathy, respect, engagement, relationship building, communication, shared decision-making, holism, personalization, and coordinated care (Hakansson et al., 2019).

More recently, the phrases *precision medicine*, *personalized medicine*, and/or *individualized medicine* have been used to describe individualized care (Jameson & Longo, 2015). The term *4P Medicine*, which stands for predictive, preventative, personalized, and participatory medicine, has also been proposed, but not as widely accepted (Jameson & Longo, 2015). Personalized medicine, and associated terms as noted previously, are based within a biomedical framework, whereas PCC is derived from a holistic perspective (El-Alti, Sandman, & Munthe, 2019). Personalized medicine may or may not result in improved outcomes and care for an individual, whereas precision medicine is thought to be a combination of the best available treatments and care based on genetic, environmental, and social factors both for the individual and for society as well (Jameson & Longo, 2015). Future exploration of how patient-centered care and personalized, precision, individualized medicine can work together to improve outcomes and care is expected.

FEDERAL AND STATE INITIATIVES

The Centers for Medicare and Medicaid Services (CMS), the payer for most LTC supports and services, supports PCC practices and policies. The CMS 2016 Quality Strategy includes six priorities to improve individual and family engagement in care design and delivery (CMS, 2016a, 2016b). A tenet of this change was to incorporate preferences and values into care as a way to improve health, the experience of healthcare delivery and services, and promote self-management (CMS, 2016a, 2016b). In 2018, proposed changes to the payment programs for Medicare included shifting payment from volume to quality of care indicators. Reimbursement in this model would be linked to patient-centered, or driven, quality indicators of care (CMS, 2018). The new structure for payments was designed to treat the person as a whole being, emphasizing the unique needs, values, and preferences of each individual.

At the state level, the agencies that monitor nursing homes in Kansas and Ohio have adopted PCC practices. Promoting Excellent Alternatives in Kansas (PEAK) began in 2002 as a way to promote culture change among LTC providers across the state (Kansas State University, 2019). PEAK is supported by the Kansas State University and the Kansas Department for Aging and Disability Services (KDADS). In 2012, PEAK underwent a transition to PEAK 2.0, with an increased emphasis on PCC practices rather than culture change. PEAK 2.0 is a Medicaid pay-for-performance incentive program and focuses on the following five domains of PCC: (a) Foundation, (b) Resident Choice, (c) Staff Empowerment, (d) Home Environment, and (e) Meaningful Life (Kansas State University, 2019).

The Ohio Person-Centered Care Coalition (OPCCC) was formed in 2005 by an interdisciplinary group of stakeholders in LTC, including representatives from groups of healthcare providers, consumers, and regulatory agencies (OPCCC, n.d.-a). Administered by the Ohio Health Care Association (OHCA), the OPCCC strives to influence change in LTC settings that transform the culture based on the following principles and values: (a) Each person has something to contribute; (b) Every person has goals; (c) Individuals know themselves the best; (d) Every person has the ability to make his or her choices known; and (e) Choices and preferences should always be considered (OPCCC, n.d.-b). In July 2016, legislation was introduced in Ohio, making it mandatory for skilled nursing facilities to implement the Preferences for Everyday Living Inventory, a measure of individual preferences across multiple domains into routine care to be reimbursed by Medicaid for services rendered (OHCA, 2016).

NURSING STRATEGIES

A core value in the nursing process is providing care. To achieve this, nurses develop therapeutic relationships with patients, family members, and other members of the healthcare team (McCormack, 2003, 2004; McCormack & McCance, 2006). Nurses are able to create these relationships through evaluation of the overall satisfaction and involvement with care and the creation of a therapeutic milieu (McCormack & McCance, 2006). This focus on creation of meaningful relationships to improve person-specific outcomes fits within the tenets of PCC.

Nurses can use strategies embedded within the framework of PCC to enhance relationship building and, ideally, patient outcomes over time. One way to do this is through the assessment of individual preferences, which is a critical tenet of PCC (Van Haitsma et al., 2019). Preferences can be thought of as an expression of how well a decision addresses individual values and personal goals (Van Haitsma et al., 2019). Knowing and being able to

meet preferences are ways to operationalize and measure the extent to which PCC is provided (Reid, Chappell, & Gish, 2007). Currently, there is a lack of evidence to support how assessment and knowledge of an individual's preferences results in improved individual outcomes. Both the Preference-Based Model of Care (Van Haitsma et al., 2019) and the Person-Centered Care Model (Santana et al., 2018) provide a framework for implementing and measuring PCC. The latter includes processes of care as well as preference congruence, or how care that is provided across settings matches a person's expressed preferences (Reid, Chappell, & Gish, 2007).

Engagement of the individual in his or her care is critical to PCC. The person should be involved in assessment strategies, care planning, and evaluation of outcomes important to the individual (Santana et al., 2018). Family members recognized as important to the person should also be included in all of these processes, as appropriate. In addition to their own care, individuals and their families should be included on the healthcare organization's planning committees such as patient and family advisory councils that engage key stakeholders in practice and quality improvement projects (Sharma et al., 2016). Additional approaches include tools such as the "All About Me Board," which is a way to organize general information on what names the individual prefers to be called, favorite hobbies, what makes them feel calm, past work experience, and also names of family members and/or important pets (Fick, DiMeglio, McDowell, & Mathis-Halpin, 2013).

SETTING-SPECIFIC APPROACHES

PCC may differ depending on the unique population and setting. The latter includes long-term, home and community-based, and acute care settings.

Long-Term Care

The movement toward PCC in LTC settings began as a widely adopted "culture-change" movement in the United States (Li & Porock, 2014). Principles of PCC are at the core of the culture-change movement and provide a platform to promote resident choice, dignity, respect, and quality of life. In the 1990s in the United States, the culture-change movement began to shift toward models of care that guided not only direct care, but also the physical environment (Li & Porock, 2014). Culture-change models include the Pioneer Network, the Eden Alternative, and The Green House Project, which are summarized in Table 4.2.

The Pioneer Network is composed of interdisciplinary members in five broad categories: (a) Policy Makers, (b) Healthcare Consumers, (c) Academia, (d) Healthcare Providers, and (e) Partners (Pioneer Network, n.d.). To accomplish systems change, The Pioneer Network strives to create avenues for communication; develop and foster relationships; change practice, research, and policy; and provide information to all stakeholders (Pioneer Network, n.d.). The Pioneer Network has fostered a coalition across most states to help with lasting change.

The Eden Alternative is perhaps the most widely known model in the United States and was founded by

TABLE 4.2

Approaches to Person-Centered Care in Long-Term Care Settings

Title	Description	Link
Pioneer Network	Recognized as the national leader of the culture-change movement in long-term care with the goal of shifting long-term care to person-directed practices across the country.	www.pioneernetwork.net
Eden Alternative	International organization to improve the lives of older adults by decreasing loneliness, helplessness, and boredom through creation of elder-centered communities ranging from long-term care settings and beyond.	www.edenalt.org
The Green House Project	Transformation of long-term and post-acute care settings to smaller-scale, "homelike" settings focused on improving quality of life and engagement in meaningful relationships.	www.thegreenhouseproject.org

Bill Thomas. Currently, it is an international organization focused on improving quality of life for older adults regardless of where they may reside through the use of person-centered and person-directed practices (Eden Alternative, n.d.-a). Quality of life is measured by the three "plagues" of loneliness, helplessness, and boredom and the implementation of 10 Eden Principles to alleviate these plagues (Thomas, 1996). The Eden Alternative is shaped by a framework of seven Domains of Well-Being: (a) Identity, (b) Growth, (c) Autonomy, (d) Security, (e) Connectedness, (f) Meaning, and (g) Joy (Eden Alternative, n.d.-b). A key approach within The Eden Alternative is a transformation of the physical environment to a homelike environment with plants, animals, and intergenerational activities (Li & Porock, 2014).

The Green House Project, also known as the Small House Model, aims to promote PCC through drastic transformation of the physical environment. Communities are formed with small numbers of residents, approximately 10 or less, to promote social and therapeutic interactions (Li & Porock, 2014; Rabig, Thomas, Kane, Cutler, & McAlilly, 2006; Robinson & Gallagher, 2008).

The impact of person-centered models of care or approaches to care in LTC settings has received some attention, but more work remains to be done. Results on resident, family, and staff outcomes is mixed (Ausserhofer et al., 2016). Reports suggest that direct resident time per resident day and staff interaction with residents may be improved with the use of models such as The Green House (Sharkey, Hudak, Horn, James, & Howes, 2011). There is also evidence to suggest that direct care providers and staff may benefit from the movement toward smaller-scale, more homelike LTC environments, resulting in higher job satisfaction and less turnover (Vermeerbergen, Van Hootegem, & Benders, 2017). This result may be achieved through increased social support in the work environments of alternatives like The Green House, but no clear association exists to date.

Home and Community-Based Care

The provision of PCC within the context of home and community-based care services and supports has been seen through the fairly widespread adoption of the Patient-Centered Medical Home (PCMH; Hong, Huo, & Mainous, 2018; Jackson et al., 2013). The PCMH seeks to transform primary care by improving patient and informal caregiver experiences, outcomes, and interactions within the healthcare system (Jackson et al., 2013). Although PCMH has varying conceptual and operational definitions, basic tenets include a patient-centered focus, care coordination across healthcare team members and settings, and emphasis on care quality and safety (Jackson et al., 2013).

The PCMH was initially supported by the American Academy of Pediatrics (AAP), where the pediatrician was considered as a gatekeeper and the person responsible for restoring the health of children who were chronically ill (Arend, Tsang-Quinn, Levine, & Thomas, 2012). The definition was later expanded by the AAP to focus on patient- and family-centered comprehensive care provided by the primary care practitioner. The Institute of Medicine (IOM), now known as the National Academies of Science, supported the notion of patient care homes, including improved access to care, continuity of care, team-based care, and the patient being involved in his or her own care (Arend et al., 2012). In addition, support for PCMH came from other organizations such as the American Academy of Family Practice (AAFP), American College of Physicians (ACP), American Osteopathic Association, National Committee for Quality Assurance (NCQA), the Joint Commission, and others (Arend et al., 2012). In general, PCMH homes have been shown to provide increased access to care, better continuity of care across providers and settings, care that is more patient-centered, improved patient self-management and involvement of care, and also increased use of health information technology in care (Arend et al., 2012). The bulk of data supporting PCMH focuses on one aspect rather than the implementation of a comprehensive package including all elements.

There is some evidence to support improved outcomes with the use of a PCMH. In terms of disease-specific measures and outcomes, recent research has linked PCMH with better control of chronic health conditions such as diabetes and hypertension (Rosland et al., 2018). Some evidence supports systematic outcomes such as improved patient and caregiver satisfaction, lowered burnout and stress among healthcare staff, and fewer hospitalizations and emergency department visits (Nelson et al., 2014). Both of these studies, which were conducted within Veterans Affairs settings, found that outcomes were dose dependent. Facilities with improved uptake of PCMH principles fared better with regard to outcomes than those that were not as successful in implementing the model. Future work may focus on understanding barriers to and facilitators of implementation across organizations and different types of settings in an effort to improve outcomes.

Acute Care

Embedded PCC within the context of acute care hospitals is a challenging arena and is gaining increased attention.

This interest comes from an increasingly complex, chronically ill population, who are the largest population being seen in acute care. Expectations of patients and families, as well as their self-care knowledge and skills, have risen over the years, creating a need to change the way that acute care is delivered. At the same time, acute care hospitals are seeing increased costs, with fewer and more expensive resources. This has led to many changes that have been labeled as patient centered (Gabutti, Mascia, & Cicchetti, 2017). The bulk of the work done in acute care emphasizes patient-centered care, rather than PCC. For the purpose of this chapter, work using both patient-centered care and PCC are described.

Strategies for how acute care facilities are providing PCC have emphasized systemic shifts. Gabutti et al. (2017) described change as three pillars: (a) the progressive patient care model, (b) the patient-centered approach, and (c) the lean approach (Gabutti et al., 2017). The progressive patient care model is a shift from traditional clustering of patients on the basis of a specific disease process, such as telemetry, to a pooling of patients together on the basis of the amount of care they require. Examples of this may include assigning levels of care to patients using a numerical rating scale or grouping patients by more standard sets such as outpatient and inpatient surgeries, further stratifying inpatient surgical candidates on the basis of expected length of stay (Gabutti et al., 2017; Villa, Barbieri, & Lega, 2009; Villa, Prenestini, & Giusepi, 2014). Patient-centered approaches to change emphasize the need for improved communication and continuity of care across care providers and settings of care (Gabutti et al., 2017). With the exception of emergency departments, relatively little of this work is focused on within acute care communication and care transfers (Gabutti et al., 2017). Lean methods were originally created as a way to eliminate unnecessary steps and waste in engineering and manufacturing processes, beginning with the Toyota Production System (Nicosia, Park, Gray, Yakir, & Hung, 2018). In acute care settings, lean principles focus on improving patient flow by redefining roles and expectations of healthcare team members, changing staffing models and scheduling, improving communication among staff, and redesigning workspaces (Gabutti et al., 2017). Gabutti et al. (2017) further explain that information communication technology (ICT) tools, managerial accounting tools, and human resource management tools are the ways to achieve these changes.

Additional recent work by Fiorio, Gorli, and Verzillo (2018) suggests the following six changes that are required in order to move acute care facilities toward PCC: (a) organizational models of care delivery, (b) patient care needs, (c) nursing models of care delivery, (d) resources, (e) roles and responsibilities, and (f) physical space (Fiorio et al., 2018). Changes suggested by Gabutti et al. (2017) and Fiorio et al. (2018) can be summarized as two main themes. The first is change in organizational and nursing models of care, and the second is changes within the physical environment and structure.

Current organizational and nursing models of care delivery in hospitals are focused on tasks, with set roles and responsibilities of medical, nursing, and all healthcare team members. To shift toward PCC, a process-driven model such as primary nursing is needed to reduce fragmented care (Vos et al., 2011). Functional or team nursing involves a group of nurses being responsible for the care of each patient. In contrast, primary nursing means a primary nurse holds responsibility for the coordination and delivery of care throughout the course of hospitalization with the goal of providing continuity of care (Dal Molin et al., 2018; Fiorio et al., 2018; Vos et al., 2011). The role of the nurse may also shift from providing direct care to a nurse liaison or advocate, where the focus is on care coordination and communication between the patient, family, and all healthcare team members (Gabutti et al., 2017).

Evidence on patient and nursing staff outcomes related to implementation of primary care nursing has been relatively positive, with some mixed results. Patient outcomes such as pressure ulcers, falls, and urinary catheter infections may be positively impacted (Dal Molin et al., 2018). An even more recent study, using questionnaire data, found that patients felt primary nursing resulted in nursing care that was more tailored to their individual needs and preferences and that their needs were promptly addressed (Naef, Ernst, & Petry, 2019). In contrast, this same study reported that primary nursing resulted in decreased care coordination, which may ultimately impact patient outcomes. Evidence also suggests that changes within organizational and nursing care delivery models may result in increased workload and burden on healthcare staff, particularly nurses (Bohmer, Beyersdorger, & Harrow, 2010; Gabutti et al., 2017). Long-term work needs to evaluate whether this continues after the initial change.

Staff outcomes such as decreased turnover may be a result of the move to primary nursing care models (Butler et al., 2011). A potential explanation of the variance in outcomes related to primary care nursing is similar to those explored with other PCC setting-specific approaches; the implementation and uptake of primary care nursing is inconsistent and often done without appropriate system and organization supports (Goode & Rowe, 2001; Korhonen & Kangasniemi, 2013; Naef et al., 2019). Additional evidence is also needed to explore how primary nursing care

impacts outcomes for older adult patients and their informal, family caregivers, particularly in those with cognitive impairment such as dementia and/or delirium as this is an understudied area.

The second theme of change in acute care toward PCC has been within the physical space of facilities. These changes to the space where care is provided often coincide with organizational changes to the way that it is delivered. Changes in the acute care environment are now being designed to meet the needs of patients, families, and healthcare providers. Historically, hospitals have been built around fixed spaces, with isolated units. Each unit is often devoted to specialty care or procedural care, such as telemetry or surgery. This means that each unit is responsible for separate pieces, including beds, medical equipment, and staff. Recent changes with the PCC movement include physical spaces meant to capitalize on shared resources. Each unit has flexibility in design, equipment, and staff (Fiorio et al., 2018; Vos et al., 2011). All of these changes work together to promote a space that is focused on the patient and family and their needs, rather than what works best for the clinician and the healthcare organization as advocated by organizations such as *Planetree* (Frampton, 2009). Outcomes associated with changes in the physical environment have not been fully evaluated, but there is some evidence to suggest that redesign can improve patient flow throughout facilities and has been linked to increased patient satisfaction, decreased wait times in settings such as the emergency department, and shorter lengths of stay (Gabutti et al., 2017).

Future work on PCC needs to focus on how to operationalize and effectively implement changes (Gabutti et al., 2017). Current definitions of person-centered changes in acute care are broad and not properly defined in a way that direct healthcare staff, such as nurses, and also organizational managers and leaders can use them. Additional work needs to clearly outline effective approaches for policy makers as well (Gabutti et al., 2017).

MEASUREMENT OF PERSON-CENTERED CARE IN PRACTICE AND RESEARCH

PCC is complex, and until recently there was no standard approach in defining the term and essential elements. Given this, there has also been variation in measurement. Table 4.3 presents several tools to assess preferences for care and aspects of PCC.

There are also several global initiatives to facilitate patient engagement. The World Health Organization (WHO) has established a Health Evidence Network (HEN) to help patients, families, and their providers make healthcare decisions (WHO, 2019; Winn, Ozanne, & Sepucha, 2015). The International Patient Decision

TABLE 4.3

Tools to Measure Person-Centered Care

Name of Tool	Completed By	Number of Items	Aspects of Person-Centered Care Measured	Initial Development and Country of Origin
Client-Centered Care Questionnaire (CCCQ; De Witte, Schoot, & Proot, 2006)	Client	15	1. Client values and expectations 2. Aspects of care demands 3. Aspects of care relationship	Three home care organizations in the Netherlands
Individualized Care (IC; Chappell, Reid, & Gish, 2007)	Long-term care nursing staff of residents with dementia	13 IC-KNOW; 15 IC-AUTONOMY; 7 IC-COMMUNICATION-SR; 11 IC-COMMUNICATION-SS	1. Staff knowledge of residents (IC-KNOW) 2. Resident autonomy (IC-AUTONOMY) 3. Communication between staff and residents and also staff to staff (IC-COMMUNICATION-SR; IC-COMMUNICATION-SS)	Six long-term care settings in Canada
Patient-Centered Care in Primary Care Scale (Radwin et al., 2019)	Primary care clinic clients	36; 23 Short Form	1. Provider knowledge of person/individualizing care 2. Nurse knowing the person 3. Nurse individualizing care 4. Continuity of care	Veterans Affairs outpatient clinics in United States

TABLE 4.3

Tools to Measure Person-Centered Care (*continued*)

Name of Tool	Completed By	Number of Items	Aspects of Person-Centered Care Measured	Initial Development and Country of Origin
Person-Directed Care (PDC; White, Newton-Curtis, & Lyons, 2008)	Long-term care nursing staff	50	1. Knowing the person 2. Comfort care 3. Autonomy 4. Personhood 5. Support relations 6. Staff work with residents 7. Personal environment for residents 8. Management/Structure	Eight long-term care settings in Oregon
Preferences for Everyday Living Inventory (PELI-NH-Full Version 2.0; Curyto, Van Haitsma, & Towsley, 2016)	Long-term care resident	72	1. Social contact 2. Growth activities 3. Diversionary activities 4. Self-dominion 5. Enlisting others in care	Two long-term care settings across the Northeastern United States

PCC, person-centered care.

Aid Standards (IPDAS) Collaboration is a network of researchers, practitioners, and key stakeholders that also aims to improve PCC through evidence-based development of patient decision aids (Elwyn et al., 2006; IPDAS, 2019; Winn et al., 2015). Key stakeholders in this group include patients.

Understanding an individual's preferences for care is a component of PCC. Owing to constraints within the healthcare system, it has been difficult to measure the extent to which these preferences are adhered to (Winn et al., 2015). Work has been done to understand how to define and also measure the agreement between patient preferences and medical treatments provided, which is a key tenet of patient-centered care (Sepucha & Ozanne, 2010); however, no clear method is available for determining this match, and additional work is needed in this area (Winn et al., 2015).

CASE STUDY 4.1

Mr. H. is an 80-year-old widower who came to the nursing home (NH) for rehabilitation following a hospitalization for a head injury. He has dementia, which at times causes problems with his short-term memory. Mr. H. ambulates independently. He desires to spend unsupervised time outside whenever he wants during nicer weather. The NH has a courtyard that is secure, but Mr. H. prefers to go out in front of the building because he likes to scavenger hunt for coins. Staff members are worried for his safety. Staff are particularly concerned that Mr. H. will sustain an unwitnessed fall, get hit by a car, or wander away and forget his way back. Beyond the physical safety of Mr. H., staff are troubled by the potential for a regulatory deficiency or a lawsuit related to a preventable harm. They have asked Mr. H. to refrain from going outside unattended until the situation can be further evaluated by the interprofessional team and a risk mitigation plan can be established. Mr. H. told staff members that he does not share the same worries and that he enjoys scavenger hunting because it helps to take his mind off his illness and keeps him physically active. He does not understand the staff's request and as a result has become angry, less talkative, and has begun to refuse clinical care and involvement in other activities. The goal is for Mr. H. to return home with LTC services and supports for his head injury and progressing dementia.

The interprofessional team has identified this circumstance as an opportunity to reevaluate Mr. H's care plan to ensure it is person-centered. The following actions are taken:

- The nurse assesses Mr. H's cognitive status.
- The physical therapist assesses Mr. H's physical function.

(*continued*)

CASE STUDY (*continued*)

- The nurse clarifies with Mr. H. his preference to go outside, identifying why it is so important to him.
- During an interdisciplinary care team meeting, the team explicitly discusses Mr. H's goal to be discharged home; preference to go outside unsupervised; and the potential benefits, harms, and alternative options to honoring Mr. H.'s preference.
- The nurse educates Mr. H. and his family on the risks and documents the discussion. The nurse invites Mr. H. and his family to a care planning meeting to determine how to best honor his preference.
- The interdisciplinary team, along with the resident and the family, construct a personalized, preference-based PCC plan using the Rothschild Process for Care Planning Resident Choice process and documentation form.

Based on the improvement noted in Mr. H's physical function and that he has previously been outside to scavenger hunt without supervision and was able to return independently, the interdisciplinary collaborative practice team has agreed that it would be in Mr. H's best interest to continue his hobby. Mr. H stays in the NH for two more weeks and then is discharged back home.

Case Study Discussion

In this case study, person-centered care was established by personalizing Mr. H's care plan to his specific preference to go outside unattended. The interdisciplinary team worked together to assess Mr. H's health status and create an open and continuous line of communication with Mr. H. and his daughter about his preference. Going outside independently is a reasonable outcome for Mr. H as the goal is to have him remain independent enough to continue care for his head injury and sequelae at home.

SUMMARY

PCC is a global, national, and local priority for nurses and interdisciplinary healthcare team members. PCC assessment includes, but is not limited to, personal and medical background, preferences, values, and beliefs. The evidence supports the effectiveness of PCC models in long-term and acute care settings. Future work will continue on evaluation of models in home and community-based care settings.

Ongoing evaluation with the person and family to assess preference congruence, understand their engagement in decision-making, and evaluate the impact of preference assessment on respect and dignity will be future areas to focus on in research and practice. Additional evaluation of the physical environments in acute, LTC, primary care, and community-based care with regard to how well they help to promote PCC should also be an area where we continue to focus and develop evidence-based approaches to meeting different needs. The provision of PCC is considered a global best practice for healthcare delivery. There has been considerable progress made in understanding PCC from all stakeholder perspectives, and we will continue to see the important role that nurses play in implementation and evaluation strategies moving forward.

NURSING STANDARD OF PRACTICE

Protocol 4.1: Implementation of Person-Centered Care

I. GOAL

To facilitate the implementation of person-centered care (PCC) for individuals as they move across settings of care and receive care from all interdisciplinary healthcare team members.

II. OVERVIEW

PCC is conceptually defined, and major tenets have been identified. Global and local movements toward PCC are seen at theoretical and operationalized levels. Changes moving toward PCC in acute, long-term, and home and

(*continued*)

Protocol 4.1: Implementation of Person-Centered Care (*continued*)

community-based care settings have been identified and include shifts in both how care is provided and the environments in which care takes place. Measurement of preferences can be accomplished using various standardized tools. The congruence between preferences for care and care provided continues to be an area where additional work is needed to understand how to achieve best practices. Nurses play an integral role in the implementation of PCC across settings and in involving both the patient and the family. Clinicians and researchers selecting a PCC framework must clearly outline and describe how they will measure PCC and evaluate the impact of any interviews.

III. BACKGROUND

A. Definition
   PCC is generally defined as asking and allowing an individual to indicate his or her values and preferences that should then direct all healthcare choices and decisions to support not only their health-related goals, but all other personal goals as well to the fullest extent possible.
B. Attributes
   I. Personalized Care Plan
   II. Continued Assessment of Preferences and Care Plan
   III. Interdisciplinary Team Care
   IV. Team Leader or Gatekeeper for All Healthcare Information and Decisions Made
   V. Care Coordination Across Healthcare Team Members
   VI. Continued Communication Across All Team Members
   VII. Continuing Education
   VIII. Measurable Outcomes

IV. HISTORY

PCC is rooted in psychology and is considered to be a more holistic concept than similarly used terms such as *patient-centered care*. In the 1980s, Thomas Kitwood advanced our understanding and acceptance of PCC in particular in persons with dementia. Kitwood proposed that PCC was the interaction between the individual's health, social context, and environment and emphasized the need for communication and relationship building among all those involved in the care of the person; these are all tenets of the currently accepted definitions of PCC.

V. FEDERAL AND STATE INITIATIVES

At the federal level, PCC is supported by the Centers for Medicare & Medicaid Services. At the state and local levels, early adopters have included Kansas and Ohio with Promoting Excellent Alternatives in Kansas (PEAK) in 2002 and the Ohio Person-Centered Care Coalition (OPCCC) beginning in 2005. Evaluation of both of these programs continues.

VI. NURSING STRATEGIES

A. Assessment of preferences and promoting congruence between preferences and care provided
B. Knowing the person by using "All About Me" or similar approaches
C. Engagement of the person in assessment, planning, and evaluation
D. Inclusion of family in assessment, planning, and evaluation, as desired by the person
E. Including the person and family in organizational planning/initiatives (e.g., committees, councils)

VII. ORGANIZATIONAL MODELS AND APPROACHES

A. Acute Care
   I. PCC shifts in acute care include changes in both organizational and nursing care delivery models and also changes to the physical environment and structure within these settings. Shifts in organizational and nursing models of care include a shift from task-oriented, fragmented care to primary care nursing delivery models. Environmental and structural changes include movements toward flexible designs, shared resources, and staff across hospital units.

(*continued*)

Protocol 4.1: Implementation of Person-Centered Care (*continued*)

B. Long-Term Care
   I. Models of PCC in long-term care (LTC) began as a "culture-change" movement in the United States. Common culture-change models include The Pioneer Network, the Eden Alternative, and The Green House Project. The Pioneer Network is a national leader of person-centered practices in the United States. The Eden Alternative is focused on decreasing loneliness, helplessness, and boredom through elder-centered communities in LTC and also other settings. Transformation of long-term and postacute care settings to smaller, more homelike settings emphasizing quality of life and meaningful relationships is the crux of The Green House Project.
C. Home and Community-Based Care Services
   I. The Patient-Centered Medical Home (PCMH) is the primary model used to promote patient-centered care in home and community-based care settings. In general, the PCMH emphasizes care coordination among interdisciplinary healthcare team members with a focus on care quality and safety.

VIII. EVALUATION OF EXPECTED OUTCOMES

A. PCC assessment initiated, including personal and medical background, preferences, values, and beliefs
B. Ongoing and transitional evaluation with person and family to describe preference congruence, engagement in decision-making, respect and dignity, and environment
C. Evaluation of the physical environment
D. Audits of personalized care plans to address preference congruence
E. Staff orientation includes importance of PCC, assessment of preferences, preference congruence, team-based care, including the person and family, and the focus on interpersonal communication with older adults, families, and other clinicians

Environmental Approaches to Support Aging-Friendly Care

5

Rana Sagha Zadeh

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Define the three key components of the "aging-friendly physical environment of care."
2. Identify recent, current, and upcoming trends in evidence-based healthcare design.
3. Understand the role of the physical environment in safe and effective care delivery.
4. Summarize the existing evidence on the role of the physical environment in healthcare, especially for older adults.
5. Describe the process for successfully applying evidence about the physical environment into healthcare practice.

OVERVIEW

The physical environment is a key component of aging-friendly care models that can facilitate or hinder safe and effective care (Boltz, Capezuti, & Shabbat, 2010; Huang, Larente, & Morais, 2011). Therefore, management of the physical environment becomes an essential consideration in achieving optimal care, supporting physical and behavioral health, and maximizing physical and functional performance for older adults. In this chapter, we provide a framework for an "aging-friendly physical environment of care," describe its essential components, share a brief summary of recent trends and foundational evidence, and present key considerations for successful application of the evidence into practice.

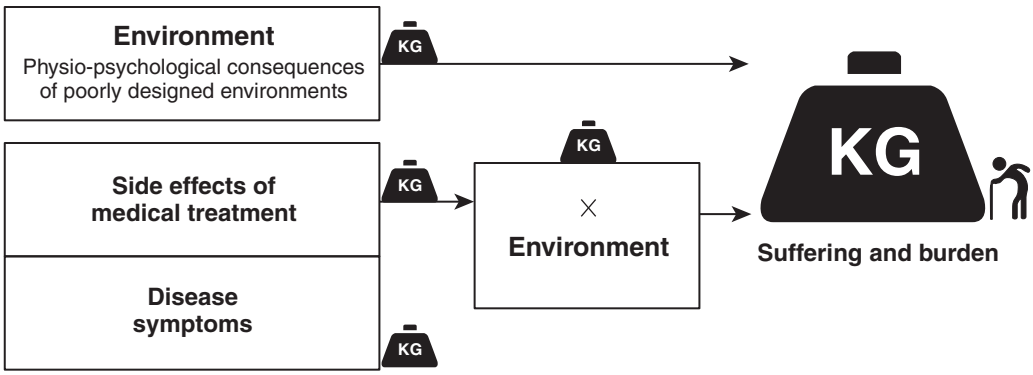
BACKGROUND AND STATEMENT OF PROBLEM

By the combined work of researchers from design, nursing, and medicine, the evidence-based practice and evidence-based medicine (Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996) decision-making frameworks have recently been expanded to include decisions on the healthcare built environment. This trend was formalized by the term *evidence-based design* (EBD), defined as "basing design decisions on credible research to achieve the best possible outcome" (Center for Health Design, 2008a, p. 3; Hamilton, 2003, p. 20). Over 3,000 studies to date have been identified on the role of the physical environment on healthcare outcomes, ranging from safety issues to the pace and quality of recovery. For patients and families, the physical environment has been shown to be a factor in improving experiences and quality of care by providing comfort, dignity, privacy, and control. Thus, the creation of a positive environment of care requires attention to the built environment.

For patients with multiple comorbidities, advanced illness, or life-limiting illness, the physical environment can be either a source of suffering or a refuge that provides

relief from suffering, a symbol of care or a cause of stigma. The term *palliative design* was coined in 2018 to highlight the growing body of evidence on "the design and management of the physical environment to improve quality of life and minimize suffering (including physical, psychological, social, and spiritual symptoms) for patients, their families, and their caregivers" (Sagha Zadeh & Eshelman, 2019, p. 183). Palliative design is the conscious design of the environment to meet the varied needs of the patients, manage symptoms, and safeguard quality of life. It is intended to work alongside, and in integration with, medical care to achieve the desired care outcomes (Sagha Zadeh & Eshelman, 2019).

Particularly for seniors who may be experiencing combined levels of physical and cognitive impairments, the institutional physical environment sometimes becomes the underlying reason for health and safety issues independent of the disease or medical treatment consequences. It can also exacerbate negative disease or treatment symptoms (Figure 5.1).



Examples of the former are sleep and restlessness issues resulting from noise pollution in the hospital environment (e.g., from equipment, verbal distress of neighboring patients, alarms, and conversations). These sleep disturbances can even develop in healthy adults exposed to the auditory and sensory aspects of hospital environments in laboratory studies (Stanchina, Abu-Hijleh, Chaudhry, Carlisle, & Millman, 2005; Topf, 1992; Topf, Bookman, & Arand, 1996; Wallace, Robins, Alvord, & Walker, 1999) and can persist after hospitalization. Unfortunately, falls and infections can be other devastating direct consequences of a physical environment of care that has not been optimized (Hall & Kamerow, 2013; Taylor & Hignett, 2016). The physical environment was shown to be the root cause of nearly half of hospital patient falls in 2005 (Taylor & Hignett, 2016).

Delirium provides an example of a situation in which the environment is not the root cause of the symptom but can worsen or ease suffering. Although age, illness, and drugs are typically the causes of delirium (Fong, Tulebaev, & Inouye, 2009), the condition is significantly intensified by the physical environment, which in some cases can even cause a doubling in the rate of delirium occurrence (Ghaeli, Shahhatami, Mojtahed Zade, Mohammadi, & Arbabi, 2018). Management of environmental factors (e.g., circadian light variation, room exposure to outside views and light) has been shown to reduce delirium in older adults considerably (Ghaeli et al., 2018; Williams, Campbell, Raynor, Mlynarczyk, & Ward, 1985).

As seen in these examples, a portion of the suffering and harm experienced by patients, as well as the burden placed on staff, can be an unintended consequence of the physical environment. These environment-induced consequences of hospitalization could be avoided by conscientious design of the physical environment. Overlooking the physical environment is not only a threat to staff productivity but can also prolong hospitalization, increase medication use, and reduce patient satisfaction. As the growing body of evidence continues to clarify the role of the environment as a nonpharmacological strategy for safe and high-quality care delivery, the allocation of resources to optimize the physical environment is moving from being desirable to being absolutely necessary.

FIGURE 5.1

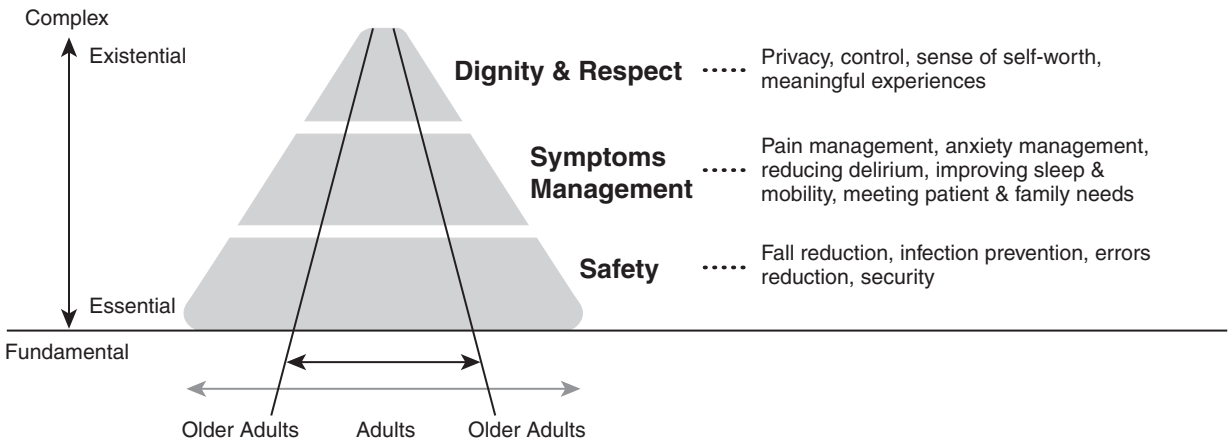
Causes of suffering for older adults as related to the physical environment.

AGING-FRIENDLY PHYSICAL ENVIRONMENT OF CARE

Older adults may experience mobility loss, cognitive dependencies, and comorbidities. They are therefore more vulnerable to falls, infections, and injuries. If overlooked, the architecture of the care environment can threaten their safety; erode their sense of confidence, dignity, and control; and impair their quality of life (Brereton et al., 2012).

In this section, we describe a proposed framework that synthesizes the latest evidence on desired qualities of the environment of care for older adults. An aging-friendly physical environment of care should support the multiple needs of the senior patient population and protect them from harm. An aging-friendly physical environment can be defined as a set of nonpharmacological interventions marked by the ability to support the following outcomes for older adults: (a) protecting their safety, (b) meeting their essential needs and managing their symptoms, and (c) supporting their sense of dignity, control and respect (Figure 5.2). Nursing assessment and evaluation of environmental strategies to improve care, whether performed as a single intervention or in combination with other strategies, can result in determining effective nonpharmacological interventions (Kline, 2009).

These three criteria are further explained in this section. It is notable that although the literature on the general population highlights the impact of environmental factors on health outcomes, the effectiveness of these strategies is highly dependent on the customization of the solutions to patient characteristics, such as age and health condition. It also depends on the type and quality of the intervention. The documented complex interaction of individual characteristics (e.g., age, health) with environmental factors calls for individualized response (Kline, 2009).



Safety (e.g., Preventing Falls, Infections, Errors, and Incidents)

Safety and injury prevention must be considered as the most fundamental criteria of aging-friendly care environments. In long-term and acute-care settings, injuries usually result from a combination of factors, including the physical environment.

Falls are the most frequently reported adverse events in in-patient settings (Beyea, 2005) and are a threat to elderly patients in particular (Morse, 2008). Analysis of hospital data shows that almost all fall incidents are preventable, yet falls have remained a key concern in nursing practice for the past several decades (Currie, 2006), probably because of the numerous factors involved in fall incidents. The risk factors leading to falls include both intrinsic factors (e.g., age, mental status, mobility) and extrinsic factors (e.g., environment, nursing practice, medication; Brambilla, Rebecchi, & Capolongo, 2019; Currie, 2006; Jensen, Lundin-Olsson, Nyberg, & Gustafson, 2002; Joint Commission, 2015). Hospital data show that

FIGURE 5.2

The aging-friendly physical environment.

Note: This framework is organized from the most fundamental needs to the most complex needs, as inspired by Maslow's hierarchy of needs (Maslow, 1943).

the physical environment is the root cause of 40% of fall incidents in U.S. hospitals (Taylor & Hignett, 2016). Yet environmental strategies have been widely underutilized in practice. However, with the recent push for improving safety by agencies such as the Agency for Healthcare Research and Quality (AHRQ), these trends are changing. The most effective approaches to preventing falls are multilevel interventions, as single interventions have shown mixed results (Cumming, 2002; Currie, 2006; Taylor, Hignett, & Joseph, 2014).

A combination of environmental strategies and nursing practices (nonpharmacological factors) and medication adjustments (pharmacological factors) that is then tailored to patient characteristics is deemed the most effective plan for fall prevention, according to multiple systematic reviews (Abdalla et al., 2018; Cumming, 2002; Currie, 2008). Examples of relevant physical environmental interventions include grab bars, open-circulation pathways, toilet height and design, flooring materials, flooring irregularities, and spatial design aspects, including proximity and visibility of the patient areas from staff work areas (Brambilla et al., 2019; Melo, 2018; Taylor & Hignett, 2016). With such a strategic and informed approach, areas of high risk for falls could be transformed to improve patient safety. The selection of the correct strategies requires combining experience and evidence and working closely with architects and engineers. Exhibit 5.1 displays an example of such an effort at The Villages Regional Hospital in The Villages, Florida. Environmental solutions for fall prevention are not necessarily expensive. According to the principal architect in the case described in Exhibit 5.1, Sam Burnette, some of the strategies used (e.g., eliminating depressed slab) actually saved costs during construction compared to conventional approaches.

EXHIBIT 5.1

Examples of Fall-Prevention Strategies in a Shower Stall at The Villages Regional Hospital, The Villages, FL

- Removed trip hazards in shower areas
- Above-slab shower system eliminates curb
- No depressed slab required

The major patient population demographic at The Villages Regional Hospital is older adults. Therefore, the facility specifically adopted aging-friendly design strategies. Safety was a key goal of the project. The architecture firm implemented the following fall-prevention strategies:

1. Minimized site tripping obstacles (e.g., parking lot wheel stops and raised curbs at pedestrian crosswalk).
2. Eliminated flooring trip hazards at flooring material transitions (e.g., flooring between patient room and bathroom, hard tile and carpet transitions, and high thresholds at entry vestibules). Replaced bathroom shower units that had raised curbs with showers that have roll-in transitions.
3. Provided handrails and grab bars at key areas where seniors need the wall support for walking assistance.

—Sam Burnette, Principal, ESa

Infections are another key safety concern for all patients (Clancy, 2008), especially those with compromised immune system function. As in the case of falls, combined multilevel interventions (education, physical environment, clinical practice, and technology) are deemed the most effective infection prevention measures (Neo, Sagha-Zadeh, Vielemeyer, & Franklin, 2016; Zimring et al., 2013). Examples of physical environmental strategies that were found effective for preventing infection transmission include the use of single-occupancy rooms, sink and toilet redesign, surface redesign with antibacterial solutions or easy-to-clean finishes, strategic placement and numbering of hand-sanitizing stations, electronic reminders for hand cleaning, and air filtering (Bartley & Streifel, 2010; Hall & Kamerow, 2013; Memarzadeh, 2011; Neo & Sagha-Zadeh, 2017, Ulrich et al., 2008).

Recently, multidisciplinary partnerships among clinical and nonclinical stakeholders have led to the systematic development of multilevel interventions that include evaluation and recommendation of environmental measures, including, for example, the tools developed by the U.S. Department of Veterans Affairs and the Joint Commission Center for Transforming Healthcare (Department of Veterans Affairs, 2014; Joint Commission Center for Transforming Healthcare, n.d.). Another useful safety framework is the Conceptual Framework for the Chain of Transmission, supported by AHRQ; its chain of transmission interventions model provides an evidence-based guide for research and practice on environmental interventions to control pathogens in healthcare settings (Zimring et al., 2013).

Safety Risk Assessment (SRA) is an example of a recent systematic toolkit specifically focused on the optimization and refinement of the physical environment for injury prevention (Taylor, Quan, & Joseph, 2015). Developed by the Center for Health Design and funded by AHRQ, SRA encompasses evidence-based safety measures targeting infections, falls, medication errors, security, injuries of behavioral health, and patient handling (Taylor, Joseph, & Quan, 2012; Taylor, Joseph, Quan, & Nanda, 2014). SRA is specifically designed to be used in combination with nursing practices and adapted to specific populations and contextual needs. It is composed of measures that help assess and prioritize safety hazards and offers design recommendations to mitigate these identified risks.

Symptom Management

Physical environmental strategies can be used to provide comfort but can also reduce symptoms of a disease or its treatment, especially when combined with medication and customized to the population and context. The physical environment, paired with social context, feeds sensory functions (visual, auditory, tactile, olfactory, and gustatory) and leads to biological and psychological responses that can vary according to an individuals' age, gender, and health conditions (Kline, 2009).

Evidence supports the idea that, when combined with clinical interventions, the management of physical environmental factors can be used as an effective strategy to manage pain and anxiety (Diette, Lechtzin, Haponik, Devrotes, & Rubin, 2003; Lee et al., 2004; Nelson, West, & Goodman, 2005; Ulrich, 1991; Ulrich et al., 2008; Ulrich, Zimring, Quan, & Joseph, 2006; Walch et al., 2005). Table 5.1 shows the relationship between patient pain and suffering and individual, social, clinical, and environmental factors modified from the human response model framework (HRM; Heitkemper & Bond, 2003; Heitkemper, Levy, Jarrett, & Bond, 1995; Kline, 2009).

One well-studied environmental strategy is positive distraction therapy. Humans have a predisposition to respond well to pleasant surroundings (Ulrich, 2001).

TABLE 5.1

Multiple Factors Influencing Patient Outcomes and Their Indicators

	Factors (Modifiable and Nonmodifiable)	Patient Symptoms and Indicators
Individual characteristics	Age, gender, genetics, attitude, health condition, sensory function	1. Physiological (blood pressure, heart rate) 2. Experiential (pain, State Trait Anxiety Index, patient satisfaction) 3. Clinical (medication use, length of stay)
Social, clinical, and environmental factors	Physical environment, amenities and resources, season of the year, social support, medical care practices, pharmaceuticals	

Note: HRM is an approach developed originally for nursing science for irritable bowel syndrome and later for pain to explain the complex relationship between the symptom and its contributors (Heitkemper & Bond, 2003; Heitkemper et al., 1995; Kline, 2009).

Source: Data from Kline, G. A. (2009). Does a view of nature promote relief from acute pain? *Journal of Holistic Nursing, 27*(3), 159–166. doi:10.1177/0898010109336138

Positive distractions are defined as environmental or social conditions marked by a capacity to restore mental health (Ulrich, 1991, 2001). They nudge the individual's attention away from internal and external suffering and stressors toward a more restorative state of mind (Shepley, 2006). In one example, Johns Hopkins researchers evaluated the effect of environmental audiovisual distraction therapy in a randomized controlled trial (Diette et al., 2003). The intervention consisted of exposure to nature scenes at the bedside paired with nature sounds before, during, and after a bronchoscopy procedure. This resulted in significantly less pain for older adults who received the intervention than in those who did not (Diette et al., 2003). The study concluded that such noninvasive strategies must be considered for use along with medication for pain management during painful and invasive treatments (Diette et al., 2003). Exhibit 5.2 displays the application of a similar intervention for pain and symptom management at Lee Health Hospital in Cape Coral, Florida.

EXHIBIT 5.2

Noninvasive Visual and Auditory Intervention for Pain and Symptom Management at Lee Health Hospital, Cape Coral, Florida

The application of combined visual and auditory interventions to reduce pain for patients during an invasive and painful procedure at Lee Health Hospital in Cape Coral, Florida. Researchers recommend that clinicians consider using this nonintrusive strategy along with conventional analgesic medication for patients who undergo painful treatments (Diette et al., 2003).

Photo credit: Bedscapes/Healing Environments International (www.bdscapes.com), Jenny Drew and Lee Health.

Another study by researchers at the University of Pittsburgh evaluated the analgesic effect of sunlight on patients recovering from elective cervical and lumbar spinal surgeries at Montefiore Hospital in Pittsburgh, Pennsylvania. Patients were randomly assigned to bright (more sunlight) or dim rooms of the ward. Those with bright rooms used 20% less analgesic medications and experienced less pain and anxiety. The effect was significant for all age groups, including older patients (Walch et al., 2005). Various forms of positive distractions could be used for such therapy, including art, music, nature, trees, flowers, birds, water, sky, smiling faces, virtual reality, videos, animation, comedy and laughter, caring, and social interaction (Ulrich, 2001).

Visual or physical access to nature is one of the most studied environmental variables in relation to pain and stress management in the general population, especially in older adults (Sagha Zadeh et al., 2018a). The benefits of exposure to nature can be generated either by providing views (e.g., window to natural scenery, indoor plants) or by allowing patients to go out in nature (e.g., access to a balcony, patio, or garden). These strategies can be used to reduce a sense of confinement and create a sense of refuge. A landmark randomized controlled trial of postsurgical patients compared hospitalized patients whose windows looked out on nature with patients whose views showed a brick wall. The patients with nature views had less use of analgesic medication, higher pain tolerance, and lower average length of hospital stay; they also expressed fewer negative comments about staff (Ulrich, 1984). Another study, focused on older adults residing in a long-term care facility, documented that engaging in a brief activity in a garden significantly reduced acute cortisol levels compared to doing the same activity in an indoor classroom (Rodiek, 2002). Also, a study investigating the transfer of older patients from home to in-patient hospice facilities found that the presence of nature at the institutional facility provided patients and their families with an easier transition and resulted in higher satisfaction (Evans, Cutson, Steinhauser, & Tulsky, 2006).

Noise control and lighting design are other well-studied components of healing environments (Sagha Zadeh-et al., 2018a; Stanchina et al., 2005; Topf et al., 1996; Ulrich et al., 2008). Unwanted noise is linked to negative physical and psychological symptoms, including increased stress, sleep loss, and aggression. One study showed that nursing home residents with functional and cognitive impairments tended to have less social interaction when noise levels were elevated (Garre-Olmo et al., 2012). For dementia patients, noise intensity has been associated with agitation and disruptive behavior (Algase, Beattie, Antonakos, Beel-Bates, & Yao, 2010; Joosse, 2009).

Noise can be effectively controlled by applying sound-absorbing finish surfaces, improving wall and door insulation, and altering room layouts, as well as addressing noise from equipment, food delivery, medication carts, and alarms. Exhibit 5.3 demonstrates an architectural approach to noise control in an aging-friendly patient room. The use of ear plugs or quiet protocols for staff conversations should be considered only as secondary solutions for this issue, as they add additional steps for staff and patients and could potentially interfere with care. Studies on older adults have shown that effective management of sleep and circadian disturbances is possible by optimizing day and night light exposure, either as a single intervention (Chong, Tan, Tay, Wong, & Ancoli-Israel, 2013; Fukuda et al., 2001; Kobayashi et al., 2001) or in combination with other clinical interventions (e.g., mind–body approaches and complementary health practices; McDowell, Mion, Lydon, & Inouye, 1998; Robinson, Weitzel, & Henderson, 2005).

Temperature is another environmental variable that is likely to help with patient comfort and symptom management. Room temperature that is adjustable on the basis of patient needs was identified in one systematic review as a factor that can reduce agitation in dementia patients (Marquardt, Bueter, & Motzek, 2014). Older patients and those with mobility and cognitive impairment are more sensitive than young, healthy patients to thermal conditions (Klenk, Becker, & Rapp, 2010; U.S. National Institutes of Health, 2011; Vassallo, Gera & Allen, 1995).

Environmental factors may be used in conjunction with clinical practice and medication to treat pain and other symptoms (Kline, 2009). However, the effectiveness of physical environmental therapies is highly dependent on individual and social context, and the qualities of the intervention itself must be carefully designed and adapted to the population of interest. For example, a 2011 study found that displaying realistic artwork depicting nature in the waiting room of a psychiatric facility significantly reduced the occurrence of agitated episodes requiring medication administration and medical staff interventions (Nanda, Eisen, Zadeh, & Owen, 2011). Blank walls and abstract art did not produce such positive health effects. One systematic review concluded that sensory stimulations are more likely to be effective in pain reduction when multiple types are combined (e.g., auditory and visual; Kline, 2009).

Dignity

Evidence indicates that the built environment surrounding patients and families is a symbol of care quality and can enhance their sense of respect, dignity, self-worth,

EXHIBIT 5.3

Noise Reduction Strategies in a Patient Room at The Villages Regional Hospital, The Villages, Florida

The Villages Regional Hospital, North Tower and Procedural Center additions completed in 2016.

The Villages Regional Hospital invested in developing a specialized physical environment that is supportive of elderly patients' needs.

The following strategies for noise reduction were used:

1. Incorporated an NRC (noise reduction coefficient) rating in the drywall and acoustical ceiling tile materials. These provide acoustical benefits for a modest material cost.
2. Selected acoustically quieter flooring options, such as luxury vinyl tile or cushioned sheet flooring as opposed to older vinyl composite tile or stone/porcelain flooring. Hard-soled shoes, dropped clipboards, and other instruments can be noisy, disturbing distractions on hard floors.
3. Minimized equipment noise and unnecessary monitoring alarms in patient rooms.
4. Replaced or repaired squeaky wheels on mobile equipment and mop buckets.

and social value while reducing fear, shame, and stigma (Borhani, Abbaszadeh, & Rabori, 2016; Edvardsson, 2005; Matiti & Trorey, 2008). Patients with diminished cognitive, social, and physical abilities especially require environmental accommodations that afford them autonomy and meet their needs. Absence of these elements puts them at heightened risk for physical and emotional stress.

Promoting dignity, respect, and a sense of value and control (Baillie, 2009) has always been a primary goal of nursing care (Chochinov et al., 2008; International Council for Nurses, 2006; Mains, 1994). Elderly patients and those with health problems are most likely to feel a loss of dignity when receiving care (Baillie, 2009). In addition to nursing practice, other factors affect patients' perception of dignity, including the physical environment, safe care, holistic care, and individual traits (Baillie, 2009; Borhani et al., 2016; Webster & Bryan, 2009). A well-designed environment is flexible and adaptable to support patient mobility and allow personalization, is well-maintained and clean, and is supportive of privacy. Such an environment is likely to safeguard patients' personhood, dignity, and respect.

When it comes to the physical environment, privacy and control are considered by patients to be symbols of care and dignity (Baillie, 2009; Matiti & Trorey, 2008). Two qualitative studies, one of cardiac patients in an intensive care unit and one in three hospital wards (medical, acute surgical, and orthopedic), found that environmental cleanliness, privacy, and quiet surroundings were perceived as facilitators of dignity and that lack of those factors was perceived as a threat to patients' dignity (Borhani et al., 2016; Matiti & Trorey, 2008).

These studies also found that meeting the varying needs of patients and families was another effective method to promote a sense of respect. One example is environmental sensory needs: "The sounds of the air conditioner and the utility room are not good for those who suffer from heart disease. Some put up with it, but some don't. I myself get very annoyed, but nobody cares. This shows that the hospital does not think about the patients very much," said one patient. Another patient commented on the importance of providing space for family members: "I come from a long way. My daughter came with me. They told her to go and sit outside. Having visitors is not permitted in this ward. How sad I am. Where will my daughter sleep tonight? I'm upset. No matter how many sleeping pills they give me, they don't work. I'm so uncomfortable; they should comfort me" (Borhani et al., 2016).

A qualitative study of 133 caregivers on their perception of strategies to manage quality of life for patients with advanced illness found that a sense of worth and dignity can be supported by promoting feelings of independence, providing privacy, and creating meaningful experiences through a combination of strategies related to clinical practices and the environment. "Providing privacy translates [into] trust and being valued as an individual," said a caregiver in the study (Sagha Zadeh, Eshelman, Setla, & Sadatsafavi, 2018b). Patients' sense of dignity can be increased by taking all possible measures in the environment and care practices to "make the patient feel useful if ambulatory" and support them "doing as much as they can." Examples include giving the patient "control over [the] environment and who comes and goes"; "offering choices [of] linens, music, TV, etc."; and minimizing distractions such as "noise, motion, vibration, and door movement" (Sagha Zadeh et al., 2018b).

Environments that encourage personalization may also facilitate dignified care. Being stripped of one's identity in a sterile healthcare environment can harm one's sense of dignity, especially for older patients (Hubbard et al., 2018). An Australian study of older patients in a rehabilitation ward provided resources for all patients to decorate their room with personal photos. The intervention enhanced the connection between staff and patients and promoted patients' sense of dignity and identity (Hubbard et al., 2018). Another study of 44 medical residents showed that personalizing the physical environment by bringing in patients' belongings led to elderly patients being treated more positively than those who were treated in typical hospital rooms with no such intervention (Millard & Smith, 1981). Exhibit 5.4 shows an example of an architect's visualization of a room in a long-term care facility for patients with dementia.

In summary, factors other than care by nursing and medical professionals can influence a patient's perception of dignity, respect, and identity. Optimizing these factors, including the physical environment, is likely to not only improve patient satisfaction but also to reduce the burden on clinical staff.

APPLICATION OF RESEARCH ON THE PHYSICAL ENVIRONMENT INTO PRACTICE FOR AGING-FRIENDLY CARE

Although research on the role of the physical environment in providing better care for older adults is promising, its seamless and effective application into care practice requires an integrative and holistic approach. The best evidence must be gathered and combined with the voices and experiences of medical and design practitioners. The resulting solutions need to be adapted and customized to the specific context, patient population, and setting. This

EXHIBIT 5.4

Conceptual Rendering for Resident Room for a Dementia Care Facility

Allowed room customization with personal belongings

- Provided access to nature, daylight, and the outdoors
- Provided space for bringing personal furniture, improved ambulation, and minimized trip hazards

FIGURE 5.3

Proposed translational framework for successful implementation of healing environments for aging patients.

Note: Informed by "EBD Steps" from the Center for Health Design (2008a, 2008b) and the active design and injury prevention translational guides from the Johns Hopkins Center for Injury Research and Policy (2013).

process requires collaboration among multiple disciplines, as well as support and buy-in from leadership. Communication between staff, patient representatives, designers, and engineers will not only ensure successful design, application, and evaluation of the solutions but also create a sense of ownership, mutual trust, and teamwork among the personnel and leadership. Figure 5.3 provides a proposed framework for the successful implementation of

healing environments for aging populations as informed by existing translational processes for the physical environment, including "Evidence-Based Design Steps" (Center for Health Design, 2008b, p. 3) and Active Design Guide translational reports (Johns Hopkins Center for Injury Research and Policy, 2013).

According to the AHRQ, a systems approach with involvement of multiple groups is needed for the development of an efficient and safe care environment (Shekelle et al., 2013). This requires looking at the problem from multiple perspectives and implementing a combined solution tailored to the problem at hand. This is the reason for today's worldwide trend toward the formation of innovative, multidisciplinary partnerships among practitioners in nursing, medicine, business, and engineering. Intended to produce a disruptive transformation of healthcare into a user-friendly service with accountability and affordability, these movements combine hospitality, design, engineering, nursing, medicinal, and business practices.

CASE STUDY 5.1

RS is a 78-year-old female patient with Alzheimer's disease diagnosed 6 years ago. She presented to the hospital from her home with worsening agitation that could not be adequately managed in the community. On admission, underlying medical issues were ruled out with laboratory and imaging tests. Geriatrics and Psychiatry Services were consulted for her behavioral symptoms. She was started on olanzapine 5 mg twice a day and 2.5 mg daily as needed for intermittent agitation. Despite the medications, her behavior continued to be difficult to manage and presented daily disruptions to her medical care. She was unable to participate in physical therapy or consume meals owing to her behavioral disturbances. On further questioning of her caretakers, it was noted that her routine sleep schedule at home was 1 a.m. to 10 a.m. With this information, the medical team intervened by implementing a modified sleep schedule paired with environmental and medical care modifications. The early-morning vital sign check and phlebotomy were postponed to the afternoon if feasible, and her meals and physical therapy sessions were restructured to accommodate her waking hours. She was transferred to a private room in an effort to minimize auditory, visual, and traffic disruptions. Lighting was minimized during her sleep hours, and family members brought familiar objects to her bedside. With these interventions, the behavioral outbursts gradually lessened, ultimately leading to her successful discharge to a skilled nursing facility.

(*continued*)

Discussion

This case illustrates how environmental interventions combined with medical care can be highly effective in the medical management of behavioral disturbance in dementia patients in the hospital setting. Efforts to control the amount of noise and light, the activities of care personnel, and the objects in the immediate surroundings should be considered in addition to medication management when dealing with behavioral disturbances in the hospital setting.

Case study credit: Cynthia Lien, MD

SUMMARY

The physical environment is one of the standing criteria in aging-friendly care models (Boltz et al., 2010; Huang et al., 2011) and can hinder or promote safe and effective care. Environmental interventions are most likely to yield positive outcomes if they are applied in combination with clinical practice and adapted to specific patient populations and settings. Providing an optimized physical environment of care is not without cost but provides great value in supporting clinical practices to reduce suffering and burden on patients, families, and staff. The development of environments that successfully meet the needs of seniors and staff requires commitment from the administration. Clarity on the value of investing time and resources toward developing a geriatric-friendly environment is critical to informing upper-level management in their strategic capital investment decisions.

The optimization of the environment for aging-friendly care and other nonpharmacological strategies needs to be considered for use together with pharmacological strategies to improve patient outcomes and ensure quality and accountability of care.

Age-Related Changes in Health*

Marianne Logan Fingerhood

6

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe the structural and functional changes in multiple body systems that occur during the normal aging process.
2. Understand the clinical significance of these age-related changes regarding the health and disease risks of the older adult.
3. Discuss the components of a nursing assessment for the older adult in light of the manifestations of normal aging.
4. Identify care strategies to promote successful aging in older adults, with consideration of age-related changes.

OVERVIEW

The process of normal aging, independent of disease, is accompanied by a myriad of changes in body systems. As evidenced by longitudinal studies, such as the Baltimore Longitudinal Study of Aging (www.blsa.nih.gov), modifications occur in both structure and function of organs and are most pronounced at an advanced age of 85 years or older (Dumic et al., 2019). Many of these alterations are characterized by a decline in physiological reserve. Although baseline function is preserved, organ systems become progressively less capable of maintaining homeostasis in the face of stresses imposed by the environment, disease, or medical therapies (Lederer & Nayak, 2017). Age-related changes are strongly impacted by genetics (Harada, Natelson Love, & Triebel, 2013), as well as by long-term lifestyle factors, including physical activity, diet, alcohol consumption, and tobacco use (Kitzman, Upadhya, Haykowsky, & Taffet, 2017). Furthermore, great heterogeneity occurs among older adults; clinical manifestations of aging can range from stability to significant decline in function of specific organ systems (Denic, Glassock, & Rule, 2016).

The clinical implications of these age-related alterations are important in nursing assessment and care of the older adult for several reasons (Smith & Cotter, 2012). First, changes associated with normal aging must be differentiated from pathological processes in order to develop appropriate interventions (Saxon, Etten, & Perkins, 2015). Manifestations of aging can also adversely impact the health and functional capability of older adults and require therapeutic strategies to correct (Matos et al., 2018; Miller, 2015). Age-associated changes predispose older persons to selected diseases (Kitzman et al., 2017; Matos et al., 2018).

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

Thus, nurses' understanding of these risks can serve to develop more effective approaches to assessment and care. Finally, aging and illness may interact reciprocally, resulting in altered presentation of illness, response to treatment, and outcomes (Dumic et al., 2019).

This chapter describes age-dependent changes for several body systems. Clinical implications of these alterations, including associated disease risks, are then discussed, followed by nursing assessment and care strategies related to these changes.

CARDIOVASCULAR SYSTEM

Cardiac reserve declines in normal aging. This alteration does not affect cardiac function at rest, and resting heart rate, ejection fraction, and cardiac output remain virtually unchanged with age (van Riet et al., 2016). However, under physiological stress, the ability of the older adult's heart to increase both rate and cardiac output, in response to increased cardiac demand, such as physical activity or infection, is compromised (Paneni, Canestro, Libby, Luscher, & Camici, 2017). Such diminished functional reserve results in reduced exercise tolerance, fatigue, shortness of breath, slow recovery from tachycardia (Bettelli, 2018), and intolerance of volume depletion (Johanning, 2017). Furthermore, because of the decreased maximal attainable heart rate with aging, a heart rate greater than 90 beats per minute (bpm) in an older adult indicates significant physiological stress (Kitzman et al., 2017).

Age-dependent changes in both the vasculature and the heart contribute to the impairment in cardiac reserve. An increase in the wall thickness and stiffness of the aorta and carotid arteries results in diminished vessel compliance and greater systemic vascular resistance (Heckman, Forman, & Cheng, 2017). Elevated systolic blood pressure (BP) with constant diastolic pressure follows, increasing the risk of isolated systolic hypertension and widened pulse pressure (AlGhatrif & Lakatta, 2015). Strong arterial pulses, diminished peripheral pulses, and increased potential for inflamed varicosities commonly occur with age. Reductions in capillary density restrict blood flow in the extremities, producing cool skin (Johanning, 2017).

As an adaptive measure to increased workload against noncompliant arteries, the left ventricle and atrium hypertrophy and become rigid. The ensuing impairment in relaxation of the left ventricle during diastole places greater dependence on atrial contractions to achieve left ventricular filling (Paneni et al., 2017). In addition, sympathetic response in the heart is blunted because of diminished beta-adrenergic sensitivity, resulting in decreased myocardial contractility (van Riet et al., 2016).

Additional age-related changes include sclerosis of atrial and mitral valves, which impairs their tight closure and increases the risk of dysfunction. The ensuing leaky heart valves may result in aortic regurgitation or mitral stenosis, which present on examination as heart murmurs (Kitzman et al., 2017). Loss of pacemaker and conduction cells contributes to changes in the resting electrocardiogram (EKG) of older adults. Isolated premature atrial and ventricular complexes are common arrhythmias, and the risk of atrial fibrillation is increased (Karamichalakis et al., 2015). Because of atrial contractions in diastole, an extra heart sound, S_4, frequently develops, occurring immediately before the normal S_1 and S_2 (Paneni et al., 2017).

Baroreceptor function, which regulates BP, is impaired with age, particularly with change in position. Postural hypotension with orthostatic symptoms may follow, especially after prolonged bed rest, dehydration, or cardiovascular drug use, and can cause dizziness and the potential for falls (Butt & Harvey, 2015).

Cardiac assessment of an older adult includes performing an EKG and monitoring heart rate (40–100 bpm within normal limits), rhythm (whether it is regular or irregular), heart sounds (S_1, S_2, and extra heart sounds S_3 and S_4), and murmurs (noting location where loudest). The apical impulse is displaced laterally. In palpation of the carotid arteries, asymmetric volumes and decreased pulsations may indicate aortic stenosis and impaired left cardiac output, respectively. Auscultation of a bruit potentially suggests occlusive arterial disease. Peripheral pulses should be assessed bilaterally at a minimum of one pulse point in each extremity. Assessment may reveal asymmetry in pulse volume, suggesting insufficiency in arterial circulation (Johanning, 2017). The nurse should examine lower extremities for varicose veins and note dilation or swelling. In addition, dyspnea with exertion and exercise intolerance are critical to note (Bettelli, 2018).

BP should be measured at least three times on three different occasions or by ambulatory BP monitoring to appropriately diagnose hypertension. The reading should be performed in a comfortably seated position with back supported and feet flat on the floor, with the appropriate size cuff. The BP should then be repeated after 5 minutes of rest. Measurements in both supine and standing positions evaluate postural hypotension (Supiano, 2017).

Nursing care strategies include referrals for older adults who have irregularities of heart rhythm and decreased or asymmetric peripheral pulses. The risk of postural hypotension emphasizes the need for safety precautions (Bettelli, 2018) to prevent falls. These include avoiding prolonged recumbency or motionless standing and encouraging the older adult to rise slowly from lying or sitting positions and wait for 1 to 2 minutes after a position change to

stand or transfer. Overt signs of hypotension, such as a change in sensorium or mental status, dizziness, or orthostasis, should be monitored, and fall-prevention strategies should be instituted. For optimal cardiac functioning, sufficient fluid intake is advised to ensure adequate hydration and prevent hypovolemia (Bettelli, 2018; Miller, 2015).

Older adults should be encouraged to adopt lifestyle practices for cardiovascular fitness with the aim of ensuring a healthy body weight (body mass index [BMI] 18.5–24.9 kg/m^2; Lichtenstein et al., 2006) and normal BP (James et al., 2014). These practices involve eating a healthful diet (Schwingshackl et al., 2018), physical activity appropriate for age and health status (Puts et al., 2017), and elimination of the use of and exposure to tobacco products (National Center for Chronic Disease Prevention and Health Promotion [NCCDPHP] Office on Smoking and Health, 2014).

PULMONARY SYSTEM

Respiratory function deteriorates slowly and progressively with age. This decline in ventilatory capacity seldom affects breathing during rest or customary limited physical activity in healthy older adults (Schroder, Storbeck, Rabe, & Weber, 2015); however, with greater than usual exertional demands, pulmonary reserve against hypoxia is readily exhausted and dyspnea occurs (Taylor & Johnson, 2010).

Several age-dependent anatomic and physiological changes combine to impair the functional reserve of the pulmonary system. Respiratory muscle strength and endurance deteriorate to restrict maximal ventilatory capacity (Sillanpaa et al., 2014). Secondary to calcification of rib-cage cartilage, the chest wall becomes rigid (Brandsma et al., 2017), limiting thoracic compliance. Loss of elastic fibers reduces recoil of small airways, which can collapse and cause air trapping, particularly in dependent portions of the lung. Decreases in alveolar surface area, vascularization, and surfactant production adversely affect gaseous exchange (Schroder et al., 2015).

Additional clinical consequences of aging include an increased anteroposterior chest diameter caused by skeletal changes. An elevated respiratory rate of 12 to 24 breaths per minute accompanies reduced tidal volume for rapid, shallow breathing. Limited diaphragmatic excursion and decreased chest/lung expansion, as a consequence of kyphosis, can result in less effective inspiration and expiration (Lorbergs et al., 2017). Because of decreased cough reflex effectiveness and deep-breathing capacity, mucus and foreign matter clearance is restricted, predisposing to aspiration, infection, and bronchospasm (Brandsma et al., 2017). Furthermore, elevating the risk of infection is a decline in ciliary and macrophage activities and drying of the mucosal membranes with more difficult mucus excretion (Shanker, Rojas, & Caufield, 2017). With the loss of elastic recoil comes the potential for atelectasis. Because of reduced respiratory center sensitivity, ventilatory responses to hypoxia and hypercapnia are blunted (Schroder et al., 2015), putting the older adult at risk of developing respiratory distress with illness or administration of narcotics (Clayton, 2008; Miller, 2015).

The modifications in ventilatory capacity with age are reflected in changes in pulmonary function tests measuring lung volumes, flow rates, diffusing capacity, and gas exchange. Whereas the total lung capacity remains constant, the vital capacity is reduced, and the residual volume is increased (Sillanpaa et al., 2014). Reductions in all measures of expiratory flow (forced expiratory volume in 1 second [FEV_1], forced vital capacity [FVC], FEV_1/FVC, peak expiratory flow rate [PEFR]) quantify a decline in useful air movement (Shanker et al., 2017). Because of impaired alveolar function, the diffusing capacity of the lung for carbon monoxide (DLCO) declines as does pulmonary arterial oxygen tension (PaO_2), indicating impaired oxygen exchange; however, arterial pH and partial pressure of arterial carbon dioxide ($PaCO_2$) remain constant (Bush, 2016). Reductions in arterial oxygen saturation and cardiac output restrict the amount of oxygen available for use by tissues, particularly in the supine position, although arterial blood gas seldom limits exercise in healthy subjects (Hassel et al., 2015).

Respiratory assessment includes determination of breathing rate, rhythm, regularity, volume (hyperventilation/hypoventilation), depth (shallow, deep; Bush, 2016), and effort (dyspnea; Hassel et al. 2015). Auscultation of breath sounds throughout the lung fields may reveal decreased air exchange at the lung bases (Gonzalez del Castillo & Sanchez, 2017). Thorax and symmetry of chest expansion should be inspected. A history of respiratory disease (tuberculosis, asthma), tobacco use (expressed as pack years), and extended exposure to environmental irritants through work or avocation are contributory (Bush, 2016).

Subjective assessment of cough includes questions on quality (productive/nonproductive), sputum characteristics (note hemoptysis; purulence indicating possible infection), and frequency (during eating or drinking, suggesting dysphagia and aspiration; Gonzalez del Castillo & Sanchez, 2017).

Secretions and decreased breathing rate during sedation can reduce ventilation and oxygenation. Oxygen saturation can be followed through arterial blood gases and pulse oximetry, whereas breathing rate (>24 respirations per minute), accessory muscle use, and skin color (cyanosis, pallor) should also be monitored (Tran, Rajwani, & Berlin, 2018). The inability to expectorate secretions, the appearance of dyspnea, and decreased saturation of oxygen (SaO_2) levels

suggest the need for suctioning to clear airways (Cao, White, & Ma, 2017). Optimal positioning to facilitate respiration should be regularly monitored with the use of upright positions (Fowler's or orthopneic position) recommended (Clayton, 2008). Pain assessment may be necessary to allow ambulation and deep breathing (Cao et al., 2017). See the "Atypical Presentation of Disease" section of this chapter for assessment of pneumonia, tuberculosis, and influenza.

Nursing care strategies useful in facilitating respiration and maintaining patent airways in the older adult include positioning to allow maximum chest expansion through the use of semi- or high-Fowler's or orthopneic position (Clayton, 2008). Additionally, frequent repositioning in bed or encouraging ambulation, if mobility permits, is advised (Cao et al., 2017). Analgesics may be necessary for ambulation and deep breathing (Clayton, 2008).

Hydration is maintained through fluid intake (6–8 oz/d) and air humidification, which prevent desiccation of mucous membranes and loosen secretions to facilitate expectoration (Miller, 2015). Suctioning may be necessary to clear airways of secretions, and oxygen should be provided as needed (Clayton, 2008). Incentive spirometry, with the use of sustained maximal inspiration (SMIs) devices, can improve pulmonary ventilation, mainly inhalation, as well as loosen respiratory secretions, particularly in older adults who are unable to ambulate or are declining in function (Cao et al., 2017).

Deep-breathing exercises, such as abdominal (diaphragmatic) and pursed-lip breathing, in addition to controlled and huff coughing, can further facilitate respiratory function. Techniques for healthy breathing, including sitting and standing erect, nose breathing (Cao et al., 2017), and regular exercise, should be promoted. Education on eliminating the use of and exposure to tobacco problems should be emphasized (NCCDPHP Office on Smoking and Health, 2014).

RENAL AND GENITOURINARY SYSTEMS

In normal aging, the mass of the kidney declines with a loss of functional glomeruli and tubules in addition to a reduction in blood flow. Concomitantly, changes occur in the activity of the regulatory hormones, vasopressin (antidiuretic hormone), atrial natriuretic hormone, and the renin–angiotensin–aldosterone system (Lederer & Nayak, 2017; Weinstein & Anderson, 2010). These alterations combine to result in diminished glomerular filtration rate (GFR), with a 10% decrement per decade starting at age 30 years, as well as impaired electrolyte and water management (Denic et al., 2016).

Despite these changes, the older adult maintains the ability to regulate fluid balance under baseline conditions; however, with age, the renal system is more limited in its capacity to respond to externally imposed stresses. This reduced functional reserve increases vulnerability to disturbances in fluid homeostasis as well as to renal complications and failure (Weinstein & Anderson, 2010), particularly from fluid/electrolyte overload and deficit, medications, or illness (Lederer & Nayak, 2017).

The decline in functional nephrons emphasizes the risk from nephrotoxic agents, including nonsteroidal anti-inflammatory drugs (NSAIDs), beta-lactam antibiotics, and radiocontrast dyes. Reduced GFR impairs the older adult's ability to excrete renally cleared medications, such as aminoglycoside antibiotics (e.g., gentamicin) and digoxin, increasing the risk of adverse drug reactions (Cutler & Clark, 2018). Dosages should be based on GFR estimated by the Cockcroft–Gault equation for creatinine clearance (Péquignot et al., 2009) or the modification of diet in renal disease (MDRD), rather than by serum creatinine concentration (Lederer & Nayak, 2017). Values of serum creatinine remain unchanged despite an age-associated decline in GFR because of the parallel decrease in both older adults' skeletal muscle mass, which produces creatinine, and GFR for creatinine elimination. Thus, serum creatinine levels overestimate GFR to result in potential drug overdose (Denic et al., 2016).

Increased risk of electrolyte imbalances can result from an age-dependent impairment in the excretion of excessive sodium loads, particularly in heart failure and with NSAID use, leading to intravascular volume overload. Clinical indicators include weight gain (>2%); intake greater than output; edema; change in mental status; tachycardia; bounding pulse; pulmonary congestion with dyspnea, rales; increased BP and central venous pressure (CVP); as well as distended neck/peripheral veins (Denic et al., 2016).

Conversely, sodium wasting or excess sodium excretion when maximal sodium conservation is needed can occur with diarrhea (Miller, 2015). Hypovolemia and dehydration may ensue, manifesting as acute change in mental status (may be the initial symptom), weight loss (>2%), decreased tissue turgor, dry oral mucosa, tachycardia, decreased BP, postural hypotension, flat neck veins, poor capillary refill, oliguria (<30 mL/hr), increased hematocrit and specific gravity of urine, and blood urea nitrogen (BUN); plasma creatinine ratio greater than 20:1; and serum osmolality greater than 300 mOsm/kg (Miller, 2015).

Impaired potassium excretion puts the older adult at risk for hyperkalemia, particularly in heart failure and with use of potassium supplements, potassium-sparing diuretics, NSAIDs, and angiotensin-converting enzyme (ACE)

inhibitors (Rich, 2017). Clinical indicators include diarrhea, change in mental status, cardiac dysrhythmias or arrest, muscle weakness and areflexia, paresthesias and numbness in extremities, EKG abnormalities, and serum potassium greater than 5.0 mEq/L (Denic et al., 2016).

Limited acid excretion capability can cause metabolic acidosis during acute illness in the older adult. This condition presents as Kussmaul's respirations, change in mental status, nausea, vomiting, arterial blood pH less than 7.35, serum bicarbonate less than 22 mEq/L, and $PaCO_2$ less than 38 mmHg with respiratory compensation (Denic et al., 2016).

Causes of abnormal water metabolism with age include diminution in maximal urine concentrating ability (Sands, 2012), which, in concert with blunted thirst sensation and total body water, can result in hypertonic dehydration and hypernatremia (Miller, 2015). Often associated with insensible fluid loss from fever (Lederer & Nayak, 2017), hypernatremia presents with thirst; dry oral mucosa; dry, furrowed tongue; postural hypotension; weakness; lethargy; serum sodium less than 150 mEq/L; and serum osmolality less than 290 mOsm/kg. Disorientation, seizures, and coma occur in severe hypernatremia (Grattagliano, Mastronuzzi, & D'Ambrosio, 2018).

Impaired excretion of a water load, exacerbated by ACE inhibitors, thiazide diuretics (Lederer & Nayak, 2017), and selective serotonin reuptake inhibitors (SSRIs; Miller, 2015), predisposes the older adult to water intoxication and hyponatremia (Denic et al., 2016). Clinical indicators involve lethargy, nausea, muscle weakness and cramps, serum sodium less than 135 mEq/L, and serum osmolality less than 290 mOsm/kg. Confusion, coma, and seizures are seen in severe hyponatremia (Grattagliano et al., 2018).

Changes in the lower urinary tract with age include reduced bladder elasticity and innervation, which contribute to decreases in urine flow rate, voided volume, and bladder capacity, as well as increases in postvoid residual and involuntary bladder contractions. A delayed or decreased perception of the signal from the bladder to void and decline in pelvic floor functioning (Ellsworth, Marschall-Kehrel, King, & Lukacz, 2013) translate into urinary urgency. Increased nocturnal urine flow, which results from altered regulatory hormone production, impaired ability to concentrate urine (Sands, 2012), and bladder-muscle instability, can lead to nocturnal polyuria (Lederer & Nayak, 2017). In older men, benign prostatic hyperplasia (BPH) can result in urinary urgency, hesitancy, and frequency (Rabijewski, Papierska, Kuczerowski, & Platkiewicz, 2015). All these changes combine to increase the risk of urinary incontinence in the older adult. Furthermore, urgency and nocturia increase the risk of falls. Changes with age in the physiology of the urinary tract, such as increased vaginal pH and decreased antibacterial activity of urine, in addition to the functional changes of the bladder, contribute to the development of bacteriuria, with potential for urinary tract infection (UTI; Gray, 2017; Rowe & Juthani-Mehta, 2017).

Renal assessment includes monitoring for renal function (GFR) based on creatinine clearance, particularly in acute and chronic illnesses (Lederer & Nayak, 2017; Péquignot et al., 2009). The choice, dose, need, and alternatives for nephrotoxic and renally excreted agents should be considered (Cutler & Clark, 2018).

Dehydration, volume overload, and electrolyte status are assessed first by screening for risk of fluid and electrolyte imbalances based on the older adult's age, medical and nutritional history, medications, cognitive and functional abilities, psychosocial status, and bowel and bladder patterns. Data on fluid intake and output; daily weights; and vital signs, including orthostatic BP measurements, are needed. Heart rate is a less reliable indicator for dehydration in older adults because of the effects of medications and heart disease (Miller, 2015).

Physical assessment for fluid/electrolyte status focuses on skin for edema and turgor. Note that turgor in older adults is a less reliable indicator for dehydration because of poor skin elasticity, and assessment over the sternum or inner thigh is recommended. Additional assessment involves the oral mucosa for dryness as well as cardiovascular, respiratory, and neurological systems. Acute changes in mental status, reasoning, memory, or attention may be initial symptoms of dehydration (Gray, 2017; Miller, 2015). Pertinent laboratory tests include serum electrolytes, serum osmolality, complete blood count (CBC), urine pH and specific gravity, BUN, hematocrit (Miller, 2015), and arterial blood gases (Denic et al., 2016).

Evaluations of urinary incontinence, UTI, and nocturnal polyuria using a 72-hour voiding diary are recommended. See the "Atypical Presentation of Disease" section that follows the UTI discussion. Voiding history and rectal examination are required to diagnose BPH (see Chapter 25, Urinary Incontinence in the Older Adult). Fall risk should be addressed when nocturnal or urgent voiding is present (see Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care).

Ongoing care involves monitoring for renal function (Lederer & Nayak, 2017; Péquignot et al., 2009) and for levels of nephrotoxic and renally cleared drugs (Cutler & Clark, 2018). Maintenance of fluid/electrolyte balance is paramount (Denic et al., 2016), especially if fluids are given intravenously (Bettelli, 2018). To prevent dehydration,

older adults weighing between 50 and 80 kg (110 and 176 lb) are advised to have a minimum fluid intake of 1,500 to 2,500 mL/d (unless contraindicated by the medical condition; Miller, 2015) from both fluids and food sources, including fruits, vegetables, soups, and gelatin, with avoidance of high salt and caffeine content (Miller, 2015; Ney, Weiss, Kind, & Robbins, 2009).

Incontinence care and exercise can contribute to management of voiding problems, including reduced incontinence, of older adults (Lukacz, Santiago-Lastra, Aldo, & Brubaker, 2017). Behavioral interventions recommended for nocturnal polyuria include limited fluid intake in the evening, avoidance of caffeine and alcohol, and a prompted-voiding schedule (Lederer & Nayak, 2017). Institution of safety precautions and fall-prevention strategies are needed in nocturnal or urgent voiding (see Chapter 19, Late Life Depression).

OROPHARYNGEAL AND GASTROINTESTINAL SYSTEMS

Age-specific alterations in the oral cavity can adversely affect the older adult's nutritional status. Deterioration in the strength of muscles of mastication as well as potential for tooth loss and xerostomia because of dehydration or medications may reduce food intake (Hall, 2017). Contributing to poor appetite are an altered taste perception and a diminished sense of smell (see Chapter 11, Oral Healthcare in the Older Adult; Landi, Picca, Calvani, & Marzetti, 2017; Visvanathan & Chapman, 2009).

Changes in the esophagus with age include delayed emptying in addition to decreases in upper and lower esophageal sphincter pressures, sphincter relaxation, and peristaltic contractions. Swallowing becomes slower and less efficient (Logemann, Curro, Pauloski, & Gensler, 2013). Although these alterations rarely impair esophageal function and swallowing sufficiently to cause dysphagia or aspiration in normal aging, such conditions can develop in conjunction with disease or medication side effects in older adults (Gregersen, Pedersen, & Drewes, 2008; Landi et al., 2017). Diminished gastric motility with delayed emptying contributes to altered oral-drug passage time and absorption in the stomach, elevated risk of gastroesophageal reflux disease (GERD; Commisso & Lim, 2019), and decreased postprandial hunger, leading to diminished food intake and possible malnutrition (Visvanathan & Chapman, 2009). Reduced mucin secretion impairs the protective function of the gastric mucosal barrier and increases the incidence of NSAID-induced gastric ulcerations (Hall, 2017). Although the motility and most absorptive functions of the small intestine are preserved with age, absorption of vitamin B12, folic acid, and carbohydrates declines (Hall, 2017). In addition, malabsorption of calcium and vitamin D contributes to the risk of osteoporosis. Supplementation with calcium and vitamins D and B12 is now recommended for older adults (U.S. Department of Agriculture [USDA] & U.S. Department of Health and Human Services [USDHHS], 2015; Visvanathan & Chapman, 2009).

Age-dependent weakening of the large-intestine wall predisposes older adults to diverticulosis and may lead to diverticulitis (Hall, 2017). Because motility of the colon appears to be preserved with age, increased self-reports of constipation in older adults may be attributed instead to altered dietary intake, medications, inactivity, or illness. Diminished rectal elasticity, internal anal sphincter thickening, and impaired sensation to defecate contribute to the risk of fecal incontinence in older adults (Roque & Bouras, 2015), although this condition is found primarily in combination with previous bowel surgery or disease and not in normal aging (Hall, 2017).

Pancreatic exocrine output of digestive enzymes is preserved to allow normal digestive capacity with aging (Hall, 2017). Regarding endocrine function, aging changes in carbohydrate metabolism allow a genetic predisposition for diabetes to become manifest (Meneilly, 2010). An age-related decrease in gallbladder function increases the risk of gallstone formation. Although liver size and blood flow decline with age, reserve capacity maintains adequate hepatic function, and values of liver function tests remain stable; however, the liver is more susceptible to damage by stressors, including alcohol and tobacco. Associated with changes in the hepatic and intestinal cytochrome P450 system (Hall, 2017), clearance of a range of medications, including many benzodiazepines, declines to result in increased potential for dose-dependent adverse reactions to these drugs (Cutler & Clark, 2018).

Reductions in antimicrobial activity of saliva and immune response of the gastrointestinal tract with age contribute to a high risk for infectious and inflammatory diseases of this system (Scannapieco & Cantos, 2016). Furthermore, impaired enteric neuronal function may blunt the older adult's reaction to infection and inflammation and result in atypical presentation of disease (see "Atypical Presentation of Disease" section; Dumic et al., 2019).

In the gastrointestinal evaluation, the abdomen and bowel sounds are assessed. Liver size, as well as reports of pain, anorexia, nausea, vomiting, and altered bowel habits, should be noted (Visvanathan & Chapman, 2009). Assessment of the oral cavity includes dentition and chewing capacity (Patil et al., 2018).

Weight is monitored with calculation of BMI and compared to recommended values (Lichtenstein et al., 2006; Sullivan & Johnson, 2017; Visvanathan & Chapman, 2009). Deficiencies in diet can be identified through comparisons of dietary intake, using a 24- to 72-hour food intake record, with nutritional guidelines (USDA & USDHHS, 2010; Wallace, 2017). In addition, laboratory values of serum albumin, prealbumin, and transferrin are useful nutritional indicators. Low albumin concentration can also affect efficacy and potential for toxicity of selected drugs, including digoxin and warfarin (Cutler & Clark, 2018). Several instruments for screening the nutritional status, eating habits, and appetite of older adults are available (see "Resources" section and Chapter 13, Nutrition in the Older Adult; Landi et al., 2017).

Signs of dysphagia, such as coughing or choking with solid or liquid food intake, should be reported for further evaluation. If aspiration from dysphagia is suspected, the lungs must be assessed for the presence of infection, typically indicated by unilateral or bilateral basilar crackles in the lungs, dyspnea, tachypnea, and cough (Bush, 2016). A decline in function or change in mental status may signal atypical presentation of respiratory infection from aspiration (Landi et al., 2017). Evaluation of GERD is based on typical and atypical symptoms (see "Atypical Presentation of Disease" section; Hall, 2017).

To assess constipation or fecal incontinence, a careful history with a 2-week bowel log noting laxative use is needed. Fecal impaction is assessed by digital examination of the rectum as a hardened mass of feces, which can be palpated. The impaction may also be palpated through the abdomen (Roque & Bouras, 2015).

For continuing care, referrals should be provided to a registered dietitian for poor food intake, unhealthy BMI (healthy BMI: 18.5–24.9 kg/m^2; overweight: 25–29.9 kg/m^2; obesity: 30 kg/m^2 or greater; Lichtenstein et al., 2006), and unintentional weight loss of 10% or greater in 6 months (Landi et al., 2017). Drug levels and liver function tests are monitored if drugs are metabolized hepatically (Cutler & Clark, 2018). Explanation of normal bowel frequency, the importance of diet and exercise, and recommended types of laxatives address constipation problems (Roque & Bouras, 2015). Mobility should be encouraged to prevent constipation, and prophylactic laxatives should be provided if constipating medications, such as opiates, are prescribed (Mounsey, Raleigh, & Wilson, 2015). Community-based food and nutrition programs (Visvanathan & Chapman, 2009) and education on healthful diets using the food pyramid for older adults may be useful in improving dietary intake (see Chapter 13, Nutrition in the Older Adult; USDA & USDHHS, 2015).

MUSCULOSKELETAL SYSTEM

Musculoskeletal tissues undergo age-associated changes that can negatively impact function in the older adult. Sarcopenia is defined as reduced muscle mass, physical performance, and grip strength (Cederholm & Morley, 2015). A decline in the size, number, and quality of skeletal muscle fibers occurs with aging, and lean body mass is replaced by fat and fibrous tissue so that by age 75 years, only 15% of the total body mass is muscle compared to 30% in a young, healthy adult (Shad, Wallis, van Loon, & Thompson, 2016). The decline can be as high as 0.5% per year, with a rate of strength loss as high as 3% per year (Tieland et al., 2017). These alterations result in diminished contractile muscle force with increased weakness and fatigue plus poor exercise tolerance. Age-specific physiological alterations contributing to sarcopenia include reductions in muscle innervation, insulin activity, and sex steroid (estrogen and testosterone) and growth hormone levels. Additionally, individual factors, such as weight loss, protein deficiency, and physical inactivity, including hospitalization and other periods of forced limited activity, can accelerate development of this condition so it progresses to a clinically significant problem (Fuggle, Shaw, Dennison, & Cooper, 2017; Shad et al., 2016). Sarcopenia has been documented to affect function adversely in older adults by increasing the risk of disability, falls, unstable gait, and need for assistive devices (Ko, Jerome, Simonsick, Studenski, & Ferrucci, 2018). Physical activity, particularly strength training, and adequate intake of energy and protein can prevent or reverse sarcopenia (Liguori et al., 2018; Robinson et al., 2017; Woo, 2018).

Age-dependent bone loss occurs in both sexes and at all sites in the skeleton. Whereas bone mass peaks between ages 30 and 35 years, density decreases thereafter at a rate of 0.5% per year. This decrement, caused by reduced osteoblast activity in the deposition of new bone, is accompanied by deterioration in bone architecture and strength (Manini, Gundermann, & Clark, 2017). Furthermore, from 5 to 7 years following menopause during estrogen decline, bone loss in women accelerates to a 3% to 5% annual rate. This loss, resulting from osteoclast activation with elevated bone breakdown or resorption (Maruotti, Corrado, & Cantatore, 2017), occurs mainly in cancellous or trabecular bone, such as the vertebral body, and may develop into type I osteoporosis in women aged 51 to 75 years, who risk vertebral fractures (Ensrud & Crandall, 2017). Decreased serum 25-hydroxy vitamin D at levels of less than 20 ng/mL in this age group have an increased risk of fracture during the menopausal transition period (Cauley, 2015). Following this postmenopausal period,

bone loss slows again in women and involves cortical bone in the long bones of the extremities. With aging, both women and men may develop type II osteoporosis and are susceptible to hip fractures and kyphosis from vertebral compression fractures in later life (Qaseem, Forciea, McLean, & Denbert, 2017).

An age-associated decline in the strength of ligaments and tendons, which are integral to normal joint function, predisposes to increased ligament and tendon injury, more limited joint range of motion (ROM), and reduced joint stability, leading to osteoarthritis (Collins, Diekman, & Loeser, 2018). Degeneration of intervertebral disks caused by dehydration and poor nutrient influx elevates the risk of spinal osteoarthritis, spondylosis, and stenosis with aging (Galbusera et al., 2014).

Age-related changes in articular cartilage, which covers the bone endings in joints to allow smooth movement, involve increased dehydration, stiffening, crystal formation, calcification, and roughening of the cartilage surface (Manini et al., 2017). Although these alterations have a minor effect on joint function under baseline conditions, the aging joint is less capable of withstanding mechanical stress, such as the stress caused by obesity or excess physical activity, and is also more susceptible to diseases, including osteoarthritis (Loeser, 2010).

Age-dependent changes in stature include dorsal kyphosis, reduction in height, flexion of the hips and knees, and a backward tilt of the head to compensate for the thoracic curvature (Manini et al., 2017). A shorter stride, reduced velocity, and broader base of support with feet more widely spaced characterize modifications in gait with age (Cruz-Jimenez, 2017; Ko et al., 2018).

The musculoskeletal assessment includes inspection of posture, gait, balance, symmetry of body parts, and alignment of extremities. Kyphosis, bony enlargements, or other abnormalities should be noted. The clinician should palpate bones, joints, and surrounding muscles, evaluating muscle strength on a scale of 0/5, and noting symmetry and signs of atrophy of major upper and lower extremity muscle groups. Active and passive ROM for major joints are evaluated, noting pain, limitation of ROM, and joint laxity. Joint stabilization and slow movements in ROM examinations are advised to prevent injury. Functionality, mobility, fine and gross motor skills, balance, and fall risk should be assessed (see Chapter 10, Assessment of Physical Function in the Older Adult, and Chapter 19, Late Life Depression; Cruz-Jimenez, 2017).

For continuing care, referrals to physical or occupational therapy may be appropriate. Increased physical activity, including aerobic (Chodzko-Zajko et al., 2009) and ROM exercise plus training programs to increase muscle strength and power (i.e., ability to produce force; Shad et al., 2016), is recommended to maintain maximal function. Interventions to promote such behavior in older adults involve health education, goal setting, and self-monitoring (Shad et al., 2016). Pain medication may be needed to enhance functionality (see Chapter 22, Pain Management in the Older Adult; Lim, Musa, Fredrick, & Ousman, 2017). Strategies to prevent falls (see Chapter 19, Late Life Depression) and avoid physical restraints (see Chapter 27, Physical Restraints and Side Rails in Acute and Critical Care Settings) are appropriate.

To prevent and treat osteoporosis, adequate daily intake of calcium (1,200 mg for women aged 50 years and older) and vitamin D (400 IU for women aged 50–70 years and 600 IU for women aged 71 years and older), physical exercise, and smoking cessation are recommended (Bijelic, Milicevic, & Balaban, 2017; JafariNasabian, Inglis, Reilly, Kelly, & Ilich, 2017). In addition, routine bone mineral density screening for osteoporosis is advised for women aged 65 years and older, as well as for women aged 60 to 64 years at increased risk for osteoporotic fractures (Agency for Healthcare Research and Quality [AHRQ], 2014; Curry et al., 2018).

NERVOUS SYSTEM AND COGNITION

Age-related alterations in the nervous system can affect function and cognition in older adults. Changes include a reduced number of cerebral and peripheral neurons (Lim et al., 2017; Todorova & Blokland, 2017), modifications in dendrites and glial support cells in the brain, and loss and remodeling of synapses (Bennett & Madden, 2014). Decreased levels of neurotransmitters, particularly dopamine, as well as deficits in systems that relay signals between neurons and regulate neuronal plasticity also occur with aging (Puglielli & Mattson, 2017).

Combined, these neurological changes contribute to decrements in general muscle strength; deep tendon reflexes; sensation of touch, pain, and vibration; and nerve conduction velocity (Lim et al., 2017; Todorova & Blokland, 2017), which result in slowed coordinated movements and increased response time to stimuli (Tieland et al., 2017). These clinical consequences, although relatively mild in normal aging, cause an overall slowing of motor skills with potential deficits in balance, gait, coordination, reaction time, and agility (Cruz-Jimenez, 2017; Ko et al., 2018). Such decline in function can adversely affect an older adult's daily activities, notably ambulation and driving, and predispose to falls and injury (Chodzko-Zajko et al., 2009; Cholerton, Reger, & Craft, 2017).

Neurological changes, along with thinning of the skin, compromise thermoregulation in the older adult.

These result in decreased sensitivity to ambient temperature as well as impaired heat conservation, production, and dissipation with predisposition to hypothermia and hyperthermia (Kuchel, 2017). Febrile responses to infection may be blunted or absent (see "Atypical Presentation of Disease" section; High, 2017; Liang, 2016).

With age, the speed of cognitive processing slows (Harada et al., 2013), and some degree of cognitive decline is common, but not universal in the older adult population (Kirova, Bays, & Lagalwar, 2015). Older adults demonstrate significant heterogeneity in cognitive performance, which may be positively impacted by education, good health, and physical activity (Coetsee & Terblanche, 2017; Collins et al., 2018; Young, Angevaren, Rusted, & Tabet, 2015).

Specific cognitive abilities exhibit differing levels of stability or decline with age. For example, crystallized intelligence, or the information and skills acquired from experience, remains largely intact, whereas fluid intelligence, or creative reasoning and problem -olving, declines (Harada et al., 2013). Sustained attention is unaffected by aging, although divided attention, or the ability to concentrate on multiple tasks concurrently, deteriorates. The mild decline in executive function, which includes the capability of directing behavior and completing multistep tasks, usually has minimal impact on an older adult's ability to manage daily activities. Although language abilities and comprehension appear stable, spontaneous word finding may deteriorate and is often a complaint of older adults. Remote memory, or recalling events in the distant past, and procedural memory, or remembering ways to perform tasks, remain intact but declarative memory, or learning new information, is slowed (Cholerton et al., 2017). However, despite some deficits, memory functions are adequate for normal life in successful aging (Klaming, Annese, Veltman, & Comijs, 2017).

Changes in the nervous system increase the risk of sleep disorders (Moraes et al., 2014) and delirium in the older adult, especially in acute care (see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment). Neural changes affect the perception, tolerance, and response to treatment of pain (Lim et al., 2017). In addition, age-specific alterations predispose neurons to degeneration, contributing to Alzheimer's disease (Caseli, Beach, Knopman, & Graff-Radford, 2017), Parkinson's disease, and Huntington's disease (Paladina, Conte, Caggiano, Pieratoni, & Faraonio, 2018; Puglielli & Mattson, 2017).

Assessment, with periodic reassessment, of baseline functional status (see Chapter 9, Assessing Cognitive Function in the Older Adult) should include evaluation of fall risk, gait, and balance (see Chapter 10, Assessment of Physical Function in the Older Adult, and Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care) as well as basic, instrumental, and advanced activities of daily living (ADL). During acute illness, functional status, pain (see Chapter 18, Preventing Functional Decline in the Acute Care Setting), and symptoms of delirium (see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment) should be monitored. Evaluation of baseline cognition with periodic reassessment (see Chapter 9, Assessing Cognitive Function in the Older Adult) and sleep disorders (Moraes et al., 2014) is warranted. The impact of physical and cognitive changes of aging on an older adult's level of safety and attentiveness in daily tasks should be determined (Cholerton et al., 2017; Harada et al., 2013; Klanning et al., 2017). Temperature indicating hypothermia (<95°F or <35°C) or hyperthermia (>105°F or >40.6°C) must be closely watched (Kuchel, 2017; Lu, Leasure, & Dai, 2010).

For care of the older adult, fall-prevention strategies should be implemented (see Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care). If delirium is identified, nursing interventions for its treatment are needed (see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment). Particularly during surgery, procedures, such as the use of warmed intravenous fluids, humidified gases, and temperature-regulating blankets (Bettelli, 2018), should be instituted to maintain normal temperatures and prevent hypothermia in the older patient (Kuchel, 2017). Lifestyle modifications recommended to improve cognitive function include regular physical exercise (Coetsee & Terblanche, 2017; Collins et al., 2018), intellectual stimulation (Harada et al., 2013), and a healthful diet (USDA & USDHHS, 2015). Behavioral interventions for sleep disorders may be warranted (Spira et al., 2014).

IMMUNE SYSTEM AND VACCINATION

Immunosenescence, or the age-related dysfunction in immune response, is characterized by reduced cell-mediated immune function and humoral immune responses (Castelo-Branco & Soveral, 2014), as well as increased inflammatory response (High, 2017). In older adults, immunosenescence is responsible, in part, for the increased susceptibility to and severity of infectious diseases (Liang, 2016), the lower efficacy of vaccination (Castelo-Branco & Soveral, 2014), and the chronic inflammatory state, which may contribute to chronic disease with age (Hunt et al., 2010).

Infectious diseases are a critical threat to older adults, especially because vaccination efficacy declines with age. Mortality rates for infectious diseases are highest for adults older than 85 years, whereas reactivation of viruses, particularly varicella zoster leading to herpes zoster, occurs

significantly more frequently in older adults (High, 2017). Immunosenescence, by dampening the induction of adaptive immune responses, results in reduced response rates to vaccination. For example, influenza vaccination has a protection rate of only 56% in older persons. Furthermore, antibody titers following booster vaccinations, such as against tetanus, are lower and decline faster with diminished antibody function in older adults compared to younger individuals (Castelo-Branco & Soveral, 2014).

Current immunization recommendations for older adults are available from the Centers for Disease Control and Prevention (CDC, 2018). Vaccination with pneumococcal polysaccharide for pneumococcal infections is recommended for individuals 65 years of age and older, with one-time revaccination indicated if the patient was vaccinated 5 or more years previously and was aged younger than 65 years at the time of primary vaccination. For seasonal influenza, all individuals 50 years of age and older should be vaccinated with the inactivated vaccine just prior to influenza season each year. High-dose influenza vaccines have been found to be more efficacious (Dunkle et al., 2017). A single dose of zoster vaccine is recommended for all adults 60 years of age and older regardless of prior zoster history. A complete tetanus vaccine series is indicated for individuals having an uncertain history of tetanus immunization or having received fewer than three doses. Boosters should be given at 10-year intervals or more frequently with high-risk injuries. Hepatitis vaccines should also be considered for older adults, depending on circumstances such as potential exposure and travel (CDC, 2018; High, 2017).

ATYPICAL PRESENTATION OF DISEASE

Diseases, particularly infections, often manifest with atypical features in older adults. Signs and symptoms are frequently subtle in the very old (Gentleman, 2014). These may initially involve nonspecific declines in functional or mental status, anorexia with reduced oral intake, incontinence, falls (Liang, 2016), fatigue, or exacerbation of chronic illness such as heart failure or diabetes (High, 2017; Scannapieco & Cantos, 2016).

As a presenting sign of infection, fever is often blunted or absent, particularly in very old (High, 2017), frail, or malnourished (Kuchel, 2017) adults. Compared to young adults with a normal mean baseline body temperature of 98.6°F (37°C), frail older adults have a lower mean oral baseline temperature of 97.4°F (36.3°C; Lu et al., 2010). A blunted response to inflammatory stimuli in combination with lower basal temperature can result in a lack of measurable febrile response. Increasing age is a predisposing factor for the absence of fever (Liang, 2016).

Assessment of the older patient should note any changes from baseline (including those that are subtle and nonspecific) in functioning, mental status, and behavior (e.g., increased/new-onset confusion), appetite, or exacerbation of chronic illness (High, 2017). This is especially important in individuals with cognitive impairment who are unable to describe symptoms.

To detect fever, normal temperature should be established for the older adult and monitored for changes of 2°F to 2.4°F (1.1–1.3°C) above baseline (Liang, 2016). Oral temperatures of 99°F (37.2°C) or greater on repeated measurements also can be used to signify fever. The difficulty of diagnosing infection based on signs and symptoms may result in greater reliance on laboratory and radiologic evaluations (High, 2017).

In the assessment of disease, both typical and atypical symptoms must be considered. Evaluation for pneumococcal pneumonia includes monitoring for typical symptoms, such as productive cough, fever, chills, and dyspnea, as well as insidious, atypical symptoms, including tachypnea, lethargy (Mandell et al., 2007; Tran et al., 2018), weakness, falls, decline in functional status, delirium, or increased/new-onset confusion with absent high fever. Decreased appetite and dehydration may be the only initial symptoms in the older adult (Talbot, 2017). Although chest radiograph is basic to diagnosis, the older adult who is dehydrated may not show infiltrate or consolidation, and these findings may appear only after hydration (Miller, 2015).

Clinical features of tuberculosis in the older person are often atypical and nonspecific. Presenting symptoms may include dizziness, nonspecific pain, or impaired cognition rather than the typical manifestations of fever, night sweats, cough, or hemoptysis (High, 2017). Typical influenza symptoms of cough, fever, and chills may be combined with altered mental status in older adults (Talbot, 2017).

In an acute myocardial infarction, the classic presentation of severe chest pain and diaphoresis may be replaced by dyspnea, confusion, and anxiety (Gray-Vickrey, 2010).

UTI in older adults may present with classical symptoms of dysuria, flank or suprapubic discomfort, hematuria, and urinary frequency and urgency, or atypical symptoms of new-onset/worsening incontinence, anorexia, confusion, nocturia, or enuresis (Rowe & Juthani-Mehta, 2017).

For peritonitis, atypical symptoms, such as confusion and fatigue, may be manifest rather than the typical symptoms of rigidity (Lim et al., 2017). Evaluation of GERD is based on typical presenting symptoms of heartburn (pyrosis) and acid regurgitation, as well as atypical symptoms in the older adult of dysphagia, chest pain, hoarseness, vomiting, chronic cough, or recurrent aspiration pneumonia (Hall, 2017).

CASE STUDY 6.1

Ms. M is an 89-year-old woman presenting with productive cough, dyspnea, fatigue, and increased confusion over the past week. Her vital signs are pulse, 96 bpm; temperature, 98.6°F; respiration, 31 breaths per minute; and BP, 110/55 mmHg. A chest radiograph shows multilobe infiltrates with a diagnosis of pneumonia. How severe is her pneumonia?

Ms. M's symptoms of a respiratory rate greater than 30 respirations per minute, multilobe infiltrates on a chest radiograph, and diastolic BP of less than 60 mmHg characterize her pneumonia as severe (Mandell et al., 2007), and she is likely to require admission to an intensive care unit. However, several age-related changes affect her symptoms of pneumonia. Pneumonia may present in the older adult with typical symptoms of productive cough, fever, and dyspnea or with more insidious, atypical symptoms of tachypnea, lethargy (Mandell et al., 2007), weakness, falls, decline in functional status, or increased/new-onset confusion. Decreased appetite and dehydration may be the only initial symptoms (Talbot, 2017).

Because of reduced sympathetic innervation of the heart with age, the heart rate of an older adult does not increase in response to stress comparable to that of a younger individual (Kitzman et al., 2017). Thus, 96 bpm in an 89-year-old person is tachycardic and indicates a severe stress reaction. Furthermore, because of a blunted febrile response to infection, particularly in a very old, frail, or malnourished adult, a fever may not be manifest even with severe infection (High, 2017; Liang, 2016; Lu et al., 2010).

SUMMARY

Changes that occur with age strongly impact the health and functional status of older adults. Thus, recognition of and attention to these alterations are critically important in nursing assessment and care. Armed with knowledge of age-related changes and using the clinical protocol described in this chapter, nurses can play a vital role in improving geriatric standards of practice. Designing interventions that take age-related changes into consideration, educating patients and family caregivers on these alterations, and sharing information with professional colleagues will all serve to ensure optimal care of older adults.

NURSING STANDARD OF PRACTICE

Protocol 6.1: Age-Related Changes in Health

I. GOAL

To identify anatomical and physiological changes, which are attributed to the normal aging process

II. OVERVIEW

Age-associated changes are most pronounced in advanced age of 85 years or older, may alter the older person's response to illness, show great variability among individuals, are often impacted by genetic and long-term lifestyle factors, and commonly involve a decline in functional reserve with reduced response to stressors.

III. STATEMENT OF PROBLEM

Gerontological changes are important in nursing assessment and care because they can adversely affect health and functionality and require therapeutic strategies; must be differentiated from pathological processes to allow development of appropriate interventions; predispose to disease, thus emphasizing the need for risk evaluation of the older adult; and can interact reciprocally with illness, resulting in altered disease presentation, response to treatment, and outcomes.

IV. AGE-ASSOCIATED CARDIOVASCULAR CHANGES

A. Definition
   1. Isolated systolic hypertension: Systolic BP 140 mmHg and diastolic BP 90 mmHg

(*continued*)

Protocol 6.1: Age-Related Changes in Health (*continued*)

B. Etiology
   1. Arterial wall thickening and stiffening, decreased compliance
   2. Left ventricular and atrial hypertrophy; sclerosis of atrial and mitral valves
   3. Strong arterial pulses, diminished peripheral pulses, cool extremities

C. Implications
   1. Decreased cardiac reserve
      a. At rest: No change in heart rate, cardiac output
      b. Under physiological stress and exercise: Decreased maximal heart rate and cardiac output, resulting in fatigue, shortness of breath, slow recovery from tachycardia
      c. Risk of isolated systolic hypertension; inflamed varicosities
      d. Risk of arrhythmia, postural, and diuretic-induced hypotension; may cause syncope

D. Parameters of cardiovascular assessment
   1. Cardiac assessment: EKG; heart rate, rhythm, murmurs, heart sounds; palpate carotid artery and peripheral pulses for symmetry (Bush, 2016)
   2. Assess BP (lying, sitting, and standing) and pulse pressure (Bettelli, 2018; Butt & Harvey, 2015)

V. AGE-ASSOCIATED CHANGES IN THE PULMONARY SYSTEM

A. Etiology
   1. Decreased respiratory muscle strength; stiffer chest wall with reduced compliance
   2. Diminished ciliary and macrophage activity, drier mucous membranes; decreased cough reflex
   3. Decreased response to hypoxia and hypercapnia

B. Implications
   1. Reduced pulmonary functional reserve
      a. At rest: No change
      b. With exertion: Dyspnea, decreased exercise tolerance
   2. Decreased respiratory excursion and chest/lung expansion with less effective exhalation; respiratory rate of 12 to 24 breaths per minute
   3. Decreased cough and mucus/foreign matter clearance
   4. Increased risk of infection and bronchospasm with airway obstruction

C. Parameters of pulmonary assessment
   1. Assess respiration rate, rhythm, regularity, volume, depth (Bush, 2016), and exercise capacity (Hassel et al., 2015). Ascultate breath sounds throughout lung fields (Mick & Ackerman, 2004).
   2. Inspect thorax appearance, symmetry of chest expansion. Obtain smoking history.
   3. Monitor secretions, breathing rate during sedation, positioning (Clayton, 2008;), arterial blood gases, pulse oximetry (Bush, 2016).

D. Nursing care strategies
   1. Maintain patent airways through upright positioning/repositioning (Clayton, 2008).
   2. Provide oxygen as needed (Tran et al., 2018); maintain hydration and mobility (Miller, 2015).
   3. Assess incentive spirometry as indicated, particularly if immobile or declining in function (Cao et al., 2017; Clayton, 2008).
   4. Educate patient on cough enhancement (Cao et al., 2017), smoking cessation (NCCDPHP Office on Smoking and Health, 2014).

VI. AGE-ASSOCIATED CHANGES IN THE RENAL AND GENITOURINARY SYSTEMS

A. Definitions
   1. To determine renal function (GFR):
      a. *Cockcroft–Gault equation:* Calculation of creatinine clearance in older adults (Péquignot et al., 2009). For men:

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{Age in years}) \bullet (\text{Body weight in kg})}{72 \bullet (\text{Serum creatinine, mg/dL})}$$

(*continued*)

Protocol 6.1: Age-Related Changes in Health (*continued*)

For women, the calculated value is multiplied by 85% (0.85).

b. *MDRD:* See National Kidney Disease Education Program calculator (National Kidney Disease Education Program, 2012).

B. Etiology
   1. Decreases in kidney mass, blood flow, GFR (10% decrement/decade after age 30 years); decreased drug clearance
   2. Reduced bladder elasticity, muscle tone, capacity
   3. Increased postvoid residual, nocturnal urine production
   4. In males, prostate enlargement with risk of BPH

C. Implications
   1. Reduced renal functional reserve; risk of renal complications in illness
   2. Risk of nephrotoxic injury and adverse reactions from drugs
   3. Risk of volume overload (in heart failure), dehydration, hyponatremia (with thiazide diuretics), hypernatremia (associated with fever), and hyperkalemia (with potassium-sparing diuretics); reduced excretion of acid load
   4. Increased risk of urinary urgency, incontinence (not a normal finding), UTI, nocturnal polyuria; potential for falls

D. Parameters of renal and genitourinary assessment
   1. Assess renal function (GFR through creatinine clearance; Lederer & Nyak, 2017; National Kidney Disease Education Program, 2012; Péquignot et al., 2009).
   2. Assess choice/need/dose of nephrotoxic agents and renally cleared drugs (Cutler & Clark, 2018; see Chapter 24, Reducing Adverse Drug Events in the Older Adult).
   3. Assess for fluid/electrolyte and acid/base imbalances (Miller, 2015).
   4. Evaluate nocturnal polyuria, urinary incontinence, and BPH (Lederer & Nayak, 2017). Assess UTI symptoms (see "Atypical Presentation of Disease" section; Rowe & Juthani-Mehta, 2017).
   5. Assess fall risk if nocturnal or urgent voiding (see Chapter 19, Late Life Depression).

E. Nursing care strategies
   1. Monitor nephrotoxic and renally cleared drug levels (Cutler & Clark, 2018).
   2. Maintain fluid/electrolyte balance (Bettelli, 2018). Minimum ingestion of 1,500 to 2,500 mL/d from fluids and foods for 50- to 80-kg adults to prevent dehydration (Miller, 2015).
   3. For nocturnal polyuria, limit fluids in evening, avoid caffeine, use prompted-voiding schedule (Lederer & Nayak, 2017).
   4. Institute fall prevention strategies for nocturnal or urgent voiding (see Chapter 19, Late Life Depression)

VII. AGE-ASSOCIATED CHANGES IN THE OROPHARYNGEAL AND GASTROINTESTINAL SYSTEMS

A. Definition(s)
   1. BMI: Healthy, 18.5 to 24.9 kg/m^2; overweight, 25 to 29.9 kg/m^2; obese, 30 kg/m^2 or greater

B. Etiology
   1. Decreases in strength of muscles of mastication, taste, and thirst perception
   2. Decreased gastric motility with delayed emptying
   3. Atrophy of protective mucosa
   4. Malabsorption of carbohydrates, vitamins B12 and D, folic acid, calcium
   5. Impaired sensation to defecate
   6. Reduced hepatic reserve; decreased metabolism of drugs

C. Implications
   1. Risk of chewing impairment, fluid/electrolyte imbalances, poor nutrition
   2. Gastric changes: Altered drug absorption, increased risk of GERD, maldigestion, NSAID-induced ulcers
   3. Constipation not a normal finding; risk of fecal incontinence with disease (not in healthy aging)
   4. Stable liver function tests; risk of adverse drug reactions

(*continued*)

Protocol 6.1: Age-Related Changes in Health (*continued*)

D. Parameters of oropharyngeal and gastrointestinal assessment
   1. Assess abdomen, bowel sounds.
   2. Assess oral cavity (see Chapter 8, Sensory Changes in the Older Adult); chewing and swallowing capacity, dysphagia (coughing, choking with food/fluid intake; Landi et al., 2017). If aspiration occurs, assess lungs (rales) for infection and typical/atypical symptoms (High, 2017; Mandell et al., 2007; see "Atypical Presentation of Disease" section, www.consultgerirn.org).
   3. Monitor weight, calculate BMI, and compare to standards (Lichtenstein et al., 2006). Determine dietary intake and compare to nutritional guidelines (USDA & USDHHS, 2015; Visvanathan & Chapman, 2009; see Chapter 10, Assessment of Physical Function in the Older Adult).
   4. Assess for GERD, constipation and fecal incontinence, and fecal impaction by digital examination of rectum or palpation of abdomen.

E. Nursing care strategies
   1. Monitor drug levels and liver function tests if on medications metabolized by liver. Assess nutritional indicators (USDA & USDHHS, 2015; Visvanathan & Chapman, 2009).
   2. Educate patient on lifestyle modifications and OTC medications for GERD.
   3. Educate patient on normal bowel frequency, diet, exercise, and recommended laxatives. Encourage mobility, and provide laxatives if on constipating medications (Mounsey et al., 2015).
   4. Encourage participation in community-based nutrition programs (Visvanathan & Chapman, 2009); educate on healthful diets (USDA & USDHHS, 2015).

VIII. AGE-ASSOCIATED CHANGES IN THE MUSCULOSKELETAL SYSTEM

A. Definition

Sarcopenia: Reduced muscle mass, physical performance, and grip strength associated with aging

B. Etiology
   1. Sarcopenia evokes increased weakness and poor exercise tolerance
   2. Lean body mass replaced by fat with redistribution of fat
   3. Bone loss in women and men after peak mass at age 30 to 35 years
   4. Decreased ligament and tendon strength; intervertebral disc degeneration; articular cartilage erosion; changes in stature with kyphosis, height reduction

C. Implications
   1. Sarcopenia: Increased risk of disability, falls, unstable gait (Ko et al., 2018)
   2. Risk of osteopenia and osteoporosis
   3. Limited ROM, joint instability, risk of osteoarthritis

D. Nursing care strategies
   1. Encourage physical activity through health education and goal setting (Fuggle et al., 2017) to maintain function (Chodzko-Zajko et al., 2009).
   2. Administer pain medication to enhance functionality (see Chapter 18, Preventing Functional Decline in the Acute Care Setting). Implement strategies to prevent falls (see Chapter 19, Late Life Depression and Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care).
   3. Prevent osteoporosis by adequate daily intake of calcium and vitamin D, physical exercise, and smoking cessation (Bijelic et al., 2017; NCCDPHP Office on Smoking and Health, 2014). Advise routine bone mineral density screening (AHRQ, 2014; Curry et al., 2018).

IX. AGE-ASSOCIATED CHANGES IN THE NERVOUS SYSTEM AND COGNITION

A. Etiology
   1. Decrease in neurons and neurotransmitters
   2. Modifications in cerebral dendrites, glial support cells, synapses
   3. Compromised thermoregulation

(*continued*)

Protocol 6.1: Age-Related Changes in Health (*continued*)

B. Implications
   1. Impairments in general muscle strength, deep tendon reflexes, nerve conduction velocity; slowed motor skills and potential deficits in balance and coordination
   2. Decreased temperature sensitivity; blunted or absent fever response
   3. Slowed speed of cognitive processing. Some cognitive decline is common but not universal. Most memory functions are adequate for normal life
   4. Increased risk of sleep disorders, delirium, neurodegenerative diseases

C. Parameters of nervous system and cognition assessments
   1. Assess, with periodic reassessment, baseline functional status (Cholerton et al., 2017; see Chapter 9, Assessing Cognitive Function in the Older Adult, Chapter 10, Assessment of Physical Function in the Older Adult, and Chapter 19, Late Life Depression). During acute illness, monitor functional status and delirium (see Chapter 17, Advance Care Planning).
   2. Evaluate, with periodic reassessment, baseline cognition and sleep disorders (Moraes et al., 2014).
   3. Assess impact of age-related changes on level of safety and attentiveness in daily tasks (Klaming et al., 2017).
   4. Assess temperature during illness or surgery (Kuchel, 2017).

D. Nursing care strategies
   1. Institute fall-prevention strategies (see Chapter 19, Late Life Depression).
   2. To maintain cognitive function, encourage lifestyle practices of regular physical exercise (Harada et al., 2013) intellectual stimulation (Puglielli & Mattson, 2017), and healthful diet (Schwingshackl, et al., 2018).
   3. Recommend behavioral interventions for sleep disorders.

X. AGE-ASSOCIATED CHANGES IN THE IMMUNE SYSTEM

A. Etiology
   1. Immune response dysfunction, reduced efficacy of vaccinations (Liang, 2016), and chronic inflammatory state (Hunt et al., 2010).

B. Nursing care strategies
   1. Follow CDC immunization recommendations for the older adult for pneumococcal infections, seasonal influenza, zoster, tetnaus, and hepatitis (CDC, 2018: High 2017).

XI. ATYPICAL PRESENTATION OF DISEASE

A. Etiology
   1. Diseases, especially infections, may manifest with atypical symptoms in older adults.
   2. Symptoms/signs are often subtle and include nonspecific declines in function or mental status, decreased appetite, incontinence, falls (Liang, 2016), fatigue, and exacerbation of chronic illness (Gentleman, 2014; High, 2017).
   3. Fever blunted or absent in very old (High, 2017), frail, or malnourished (Tieland et al., 2017) adults. Baseline oral temperature in older adults is 97.4°F (36.3°C) versus 98.6°F (37°C) in younger adults (Lu et al., 2010).

B. Parameters of disease assessment
   1. Note any change from baseline in function, mental status, behavior, appetite, or chronic illness (High, 2017).
   2. Assess fever. Determine baseline and monitor for changes 2°F to 2.4°F (1.1°C–1.3°C) above baseline (Liang, 2016). Oral temperatures above 99°F (37.2°C) or greater also indicate fever (High, 2017).
   3. Note typical and atypical symptoms of pneumococcal pneumonia (Liang, 2016; Mandell et al., 2007), tuberculosis (Kuchel, 2017), influenza (Talbot, 2017), acute myocardial infarction (Gray-Vickrey, 2010), UTI (Rowe & Juthani-Mehta, 2017), peritonitis (Dumic et al., 2019; Scannapieco & Cantos, 2016), and GERD (Hall, 2017).

(*continued*)

Protocol 6.1: Age-Related Changes in Health *(continued)*

XII. EVALUATION/EXPECTED OUTCOMES (FOR ALL SYSTEMS)

A. The older adult will experience successful aging through appropriate lifestyle practices and healthcare.
B. Healthcare provider will
   1. Identify normative changes in aging and differentiate these from pathological processes.
   2. Develop interventions to correct for adverse effects associated with aging.
C. Institution will
   1. Develop programs to promote successful aging.
D. Provide staff education on age-related changes in health.

XIII. FOLLOW-UP MONITORING OF CONDITION

A. Continue to reassess effectiveness of interventions.
B. Incorporate continuous quality-improvement criteria into existing programs.

ABBREVIATIONS

AHRQ	Agency for Healthcare Research and Quality
BMI	Body mass index
BP	Blood pressure
BPH	Benign prostatic hyperplasia
CDC	Centers for Disease Control and Prevention
EKG	Electrocardiogram

Healthcare Decision-Making*

Joanne Roman Jones and Marie Boltz

7

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Define informed consent and its supporting bioethical and legal principles.
2. Understand the role of culture in healthcare decision-making.
3. Differentiate between competence and capacity.
4. Understand the process of decisional capacity assessment.
5. Describe the nurse's role and responsibility as an advocate for the patient's voice in healthcare decision-making.

OVERVIEW

Healthcare is about decisions—how they are made, who makes them, and according to what standards. Until the latter half of the 20th century, patients were told what healthcare interventions would benefit them, and they rarely questioned the doctor's instructions. The rise of the rights movement in most areas of society promoted the idea that patients would benefit from robust participation in decision-making affecting their health outcomes. Building on the well-established doctrine of informed consent, as well as statutory and case law, all states came to require that patient goals, values, and preferences be central to healthcare decision-making. The result was a greater degree of clinician–patient collaboration in planning and implementing care decisions. Although all healthcare activities deserve principled and thoughtful decision-making, the benefit–burden–risk calculus associated with treatment and diagnostic interventions typically requires specific informed consent by or on behalf of the patient. For this reason, the determination of patients' decision-making capacity, as well as applicable standards, becomes a pressing issue that arises daily in the clinical setting.

BACKGROUND AND STATEMENT OF PROBLEM

Ethical Principles and Professional Obligations

Core ethical principles that underlie the healthcare decision process and give rise to clinician obligations include:

- Respect for autonomy: supporting and facilitating the capable patient's exercise of self-determination regarding healthcare
- Beneficence: promoting the patient's best interest and well-being and protecting the patient from harm
- Nonmaleficence: avoiding actions likely to cause the patient harm

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

- Justice: allocating fairly the benefits and burdens related to healthcare delivery and ensuring that decisions are based on clinical need rather than ethically irrelevant characteristics, such as race, religion, or socioeconomic status

The tension between and among these ethical principles can create dilemmas for clinicians when their obligations conflict. For example, care providers have a duty to respect patients' autonomy by honoring their decisions *and* a duty to protect them from the harm of risky choices. Care providers are also expected to provide care to patients who need it *and* be responsible stewards of limited resources. Clinical, legal, and ethically valid decisions by or for patients invoke a careful balancing of information, principles, rights, and responsibilities in light of medical realities, cultural factors, and, increasingly, concerns about resource allocation and access to care.

Autonomy and Capacity

The well-settled right to determine what happens to one's own body has two equally important components: the right to *consent* to treatment and the right to *refuse* treatment. Grounded in the ethical principle of respect for persons, this right to bodily integrity is considered so fundamental that it is protected by the U.S. Constitution, state constitutions, and decisions of the U.S. Supreme Court (*Cruzan v. Director,* 1990). All persons are considered to have the potential for autonomy, expressed in the clinical setting through informed decision-making. The threshold question is whether they have the *capacity to exercise autonomy*.

Respect for autonomy is widely considered to be the ethical principle most central to healthcare decision-making because of its emphasis on self-governance and choices that reflect personal values. This heightened emphasis on self-determination is largely a Western phenomenon, however, and is not universally shared. Even capable patients who are from cultures that value collective rather than individual decision-making may not be comfortable with pure autonomous decision-making. Instead, they may involve trusted others in planning their care, thus demonstrating *assisted*, *supported*, or *delegated* autonomy as their preferred method of decision-making. If this is their customary dynamic and if it appears to be effective for them, there is no reason to encourage them to adopt an unfamiliar decision-making style in the mistaken belief that only self-governance is authentic. For these patients, autonomy may be reflected not in self-determined decision-making about treatment, but in expressions of values and goals of care. Drawing on the assistance or support of trusted others does not diminish the integrity of the process. Voluntarily delegating decision-making authority to others is also an autonomous choice, but it is one that must be explicitly confirmed, not inferred.

Diminished or fluctuating capacity is not a reason to ignore the patient's voice but is a signal to attend more carefully to what is being communicated. The "what" and "how" of the treatment may be a decision for others to make; the "why" or the rationale in the patient's voice must be heard.

Capacity and Competence

Decisional capacity refers to a set of skills related to healthcare decision-making, including the ability to:

- Understand and process information about diagnosis, prognosis, and treatment options.
- Weigh the benefits, burdens, and risks of the proposed options.
- Apply a set of personal values to the analysis.
- Arrive at a decision that is consistent over time.
- Communicate the decision (Roth, Meisel, & Lidz, 1997).

Capacity runs along a continuum rather than being all on or all off. Some patients are able to make all their own decisions—personal, legal, financial, healthcare—and some, like infants and adults with profound cognitive impairment, are unable to make any decisions. Because capacity is decision specific rather than global, most people are able to make some decisions and not others.

Although the terms *capacity* and *competence* are often used interchangeably, in the healthcare setting their distinctions go beyond semantics. Competence is a *legal* presumption that an adult has the mental ability to negotiate various legal tasks, such as entering into a contract, making a will, and standing for trial. Incompetence is a judicial determination that because a person lacks this ability, she or he should be prevented from doing certain things. In contrast, capacity is a *clinical* determination that a person has the ability to understand, make, and take responsibility for the consequences of healthcare decisions. Because the legal system should rarely be involved in medical decisions, the patient's capacity for decision-making is an assessment made by clinicians.

Consent and Refusal

In the clinical setting, the principle of respect for autonomy is most clearly expressed in the doctrine of informed

consent and refusal. Because therapeutic and diagnostic interventions typically involve a range of benefits, burdens, and risks, express consent is almost always required before interventions are implemented. Informed consent is a process over time rather than a single event or a signed document. Among adults with a language barrier associated with education and/or ethnicity, comprehension might be limited (Fink et al., 2010). Providing adequate time for the informed consent discussion(s) and the opportunity to ensure understanding and voluntariness are essential to a valid decision about whether to authorize a proposed intervention. As an expression of autonomy, the most effective consent process is a collaborative interaction that includes consultation with clinicians and trusted others.

Informed consent and refusal engage capable patients or surrogates acting on behalf of patients without capacity in a process that requires:

- Patient decisional capacity
- Disclosure of sufficient material information relevant to the decision in question
- Understanding of the information provided
- Voluntary choosing among the options
- Consent to or refusal of the proposed intervention (Lo, 2000)

Education can improve decisional capacity to give safe, informed consent even for clinically depressed older adults (Lapid, Rummans, Pankratz, & Appelbaum, 2004). In one study, depressed patients' involvement in healthcare decision-making not only increased the likelihood of their receiving treatment congruent with depression treatment guidelines, but also showed reduced symptoms of depression over an 18-month period (Clever et al., 2006). "Framing" can be persuasive; a clinician's emphasis on the distinctions about the efficacy of a treatment and whether it would be curative or palliative can influence a patient's decision even more than information given about the disease or treatment options (Van Kleffens, van Baarsen, & van Leeuwen, 2004).

Decision-Making Authority

Treatment decisions are typically made by capable patients based on their health goals, values, and preferences in response to information they receive about their diagnosis, prognosis, and therapeutic options. These decisions are, thus, an expression of autonomy, reflecting the view that healthcare is not something that is *done to* patients; rather, it is a collaborative endeavor in which patients and clinicians contribute to the shared goal of recovery, rehabilitation, or palliation.

Readiness for decision-making has a temporal, as well as a contextual, component. Asked in focus groups why they had or had not been involved in any advance care planning (ACP), older adults and their caregivers revealed considerable variability in their readiness for discussion of different components of the ACP process such as advance directive creation, communication with family and physicians, and consideration of their treatment goals (Fried, Bullock, Iannone, & O'Leary, 2009). Participants identified barriers and benefits to ACP and said that it was not the only way to prepare for decline in health or death. Prior experience with healthcare decision-making for others influenced older adults' propensity to engage in ACP. Having an active role in shared decision-making is associated with enhanced cancer-specific quality of life, satisfaction, and more likely use of adjuvant therapy for women with breast cancer but not for men with prostate cancer (Hack et al., 2010; Mandelblatt, Kreling, Figeuriedo, & Feng, 2006).

Perceptions of ACP are crucial in determining readiness to engage in the process of proactive consideration of healthcare options. If "ACP" is perceived as synonymous with "end of life," it is not surprising that individuals, families, and care professionals are reluctant to initiate or participate in "the discussion." The common response is, "No one is dying here, so we don't have to deal with these matters now."

When patients are not capable of making decisions about their treatment, others are asked to choose for them, basing their decisions as much as possible on what is known of the patients' preferences or what is considered to be in their best interest. The determination of decision-making authority is among the most critical tasks in the clinical setting. When patients lack the ability to make treatment decisions, authority to act on their behalf must be vested in others—appointed agents, family, or other surrogates. The threshold determination, then, is of the patient's decisional capacity: an assessment of an individual's ability to make decisions about healthcare and treatment.

DECISION AIDS

Especially because the older adult population is expected to double during the next 20 years, capacity assessments in settings that care for them are likely to be requested and relied on with increasing frequency. Given that decisional capacity is an important marker of an individual's ability to complete specific tasks or make specific decisions, the

reliability of capacity assessments is crucial in evaluating what individuals are able to do for themselves. Although decisional capacity is an index of patient ability to make decisions and, therefore, involves cognitive processes, its assessment requires more than a test of mental acuity or a psychiatric examination (Post & Blustein, 2015).

Given the importance of assessing decision-making capacity, the desire for a precise method of measurement is understandable. "Decisional capacity assessments are important tools in optimizing safety and autonomy when there are questions about an older adult's ability to make decisions related to healthcare, independent living, financial management, and other areas that are essential to daily functioning" (Braun & Moye, 2010, p. 204). Decision aids assist, guide, and support a decision-making process that requires consideration of benefits, burdens, risks, and options. Studies indicate that decision aids lead to decisions that are value based, more informed, less conflicted, and characterized by a process that is more participatory than passive compared with standard decision-making approaches (O'Connor et al., 2004). Decision aids made a difference in physician–patient discussions about the use of adjuvant therapy for women with breast cancer (Siminoff, Gordon, Silverman, Budd, & Ravdin, 2006); clarified values and options, and increased knowledge regarding breast and ovarian genetic testing counseling (Wakefield et al., 2008); and improved men's knowledge on the risks and benefits of prostate-specific antigen (PSA) testing (Watson et al., 2006). An "order effect" was discerned regarding the sequence in which information was presented in a decision aid to women with breast cancer (Ubel et al., 2010). The order of presentation of information about the risks and benefits of tamoxifen influenced their perceptions. Bias was eliminated by the simultaneous presentation of information of competing options and risks.

A comprehensive review of several additional capacity assessment instruments (Racine & Billick, 2012) concluded that sensitivity and specificity tend to be in tension with efficiency and ease of use. Some can be administered in less than 10 minutes but may be more general, whereas others, which are more specific and in depth, require considerably more time and complicated scoring systems. Although none of the instruments are considered to be the gold standard, the literature indicates that their use in clinical practice could improve accuracy in capacity determination. Especially in the older adult population, where capacity issues may be complex and multifactorial, these tools may be useful adjuncts to clinical interviews, medical record reviews, interviews, neuropsychological testing, and functional assessment.

ASSESSMENT OF THE PROBLEM

Determination of Decision-Making Capacity

The importance of capacity determination resides in the presumption that adults have decisional capacity, and, absent contrary evidence, treatment decisions typically defer to patient goals, values, and preferences. This deference usually extends to all decisions made by capable individuals, including those decisions that appear risky or ill advised. Capacity assessment is important because patients who lack the ability to appreciate the implications of, and accept responsibility for, their choices are vulnerable to the risks of deficient decision-making. Indeed, the reason capacity determination is considered so important and receives so much attention is that honoring the decisions of a capable patient demonstrates respect for the person, whereas honoring the decisions of a patient without capacity can be seen as an act of abandonment. Thus, clinicians have an obligation to ensure that capable patients have the opportunity to make treatment decisions that will be implemented and that incapacitated patients will be protected by having decisions made for them by others who act in their best interest.

Fulfilling this obligation requires that clinicians appreciate the characteristics of decision-making capacity, the elements of which include the ability to:

- Understand and process information about diagnosis, prognosis, and treatment options.
- Weigh the relative benefits, burdens, and risks of the care options.
- Apply a set of values to the analysis.
- Arrive at a decision that is consistent over time.
- Communicate the decision (Roth et al., 1997).

Capacity assessment depends on interaction with the patient over time rather than on specific tests. There is no gold standard instrument or "capacimeter" that assesses decisional capacity (Kapp & Mossman, 1996). The Mini-Mental State Examination (MMSE) estimates orientation, long- and short-term memory, and mathematical and language dexterity. It is not a test of executive function (an assessment more likely to capture reasoning and recall) and is, therefore, less helpful in gauging the patient's ability to understand the implications of a decision (Allen et al., 2003). It has been suggested, however, that an MMSE score of less than 19 or more than 23 might be able to distinguish those with and without capacity for decision-making (Karlawish, Casarett, James, Xie, & Kim, 2005). The Assessment of Capacity for Everyday Decision-making (ACED) is a valid and reliable

instrument to assess everyday decisional capacity in those with mild to moderate cognitive impairment (Lai et al., 2008). The ACED is useful for assessing the capacity to solve functional problems of older persons with mild to moderate cognitive impairment from disorders such as Alzheimer's disease. Common clinical examples are persons who have problems performing an IADL, such as cooking, but refusing help to manage that IADL. The ACED provides patient-specific assessments of decisional abilities needed to make that informed refusal. It can also inform the assessment of complex cases of "self-neglect syndrome" (Baruth & Lapid, 2017). The SPACED is the Short Portable ACED (Karlawish & Lai, 2009). The shorter version allows the examiner to interview a person with a functional problem that has at least one possible solution (e.g., an older adult is forgetting to take his medication and home care can provide a weekly pill box).

Although there is no consistent standardized definition of decisional capacity, there is evidence that safe and sufficient decision-making is retained in early-stage dementia (Kim, Karlawish, & Caine, 2002). Persons with mild to moderate dementia can make or at least participate in making treatment decisions, but impaired memory recall might be a barrier to their demonstrating understanding of treatment options (Moye, Karel, Azar, & Gurrera, 2004). Standard assessment of appreciation of diagnostic and treatment information should focus on the patient's ability to state the importance or implications of the choice on his or her future health. Specific neuropsychological tests (e.g., MacArthur Competence Assessment Tool and Hopemont Capacity Assessment Interview) can predict decisional capacity for those with mild to moderate dementia, although reasoning and appreciation might differ among those with mental illness (Gurrera, Moye, Karel, Azar, & Armesto, 2006).

In one study, the standard of decision-making most highly valued by a group of geriatricians, psychologists, and ethics committee members was the ability to appreciate the consequences of a decision, followed by the ability to respond "yes" or "no" to a question; the standard least supported was that the decision had to seem reasonable (Volicer & Ganzini, 2003).

Clinical Importance of Decisional Capacity

Accurate and useful capacity assessment depends on the recognition that capacity is decision specific rather than global and works on a sliding scale based on the notion of risk. The greater the risk attached to a decision, the higher the level of capacity required to make a decision that will be honored. For example, a person with diminished capacity may be able to decide what to have for lunch or when to shower without undue risk of harm. A patient who asks to be removed from life support, however, is someone whose level of capacity would need to be considerably higher, demonstrating comprehension of the risk–benefit ratio and appreciation of the consequences.

Evidence also suggests that adults with mild to moderate mental retardation are able to make and provide a rationale for their treatment decisions and evaluate the risks and benefits of treatment options (Cea & Fisher, 2003). Because most people have the ability to make some decisions and not others, respect for autonomy requires clinicians to identify the widest range of decisions each patient is capable of making. A note in the chart saying, "Patient lacks decision-making capacity" is extremely unhelpful because it implies that the individual is unable to make any decisions about anything. This inhibits the exercise of autonomy by arbitrarily precluding decision-making when, in fact, the patient may lack only the ability to make complex treatment decisions. Far more helpful would be an entry that says, "Patient lacks the capacity to make decisions about participation in a drug study" or "Patient lacks the capacity to make decisions about dialysis."

Likewise, decisional capacity may not be constant but may fluctuate, depending on the patient's clinical condition, medication, and/or time of day. Among gerontological nurses, protecting the right of older adults with diminished capacity or physical function to make those healthcare decisions that they can appropriately make is among their top practice concerns (Alford, 2006). Precisely because decisional capacity is not static, it is imperative for the protection of those with mild to moderate dementia that their understanding and reasoning about treatments and interventions are periodically assessed (Moye, Karel, Gurrera, & Azar, 2006). Approaching patients for discussions and decisions when they are at their most capable (e.g., during the patient's "window of lucidity") enhances their opportunities to participate in planning their healthcare.

Although disagreement with a proposed care plan or refusal of recommended treatment does not by itself demonstrate incapacity, risky or potentially harmful decisions should be carefully scrutinized to protect vulnerable patients from the consequences of deficient decision-making. Because appointing a healthcare agent requires a lower level of capacity than that needed to make the often complex decisions the agent will make, even patients with diminished capacity may be able to select the persons they want to speak for them (Mezey, Teresi, Ramsey, Mitty, & Bobrowitz, 2002).

Decision-Making in the Absence of Capacity

The more difficult clinical scenario is decision-making on behalf of patients who have lost or never had the capacity to make decisions for themselves. Two approaches have been developed in response to the needs of incapacitated patients: advance directives and surrogate decision-making. Advance directives (see Chapter 17, Advance Care Planning) include the *instruction directive*, also known as a living will, which is a list of interventions the patient does or does not want in specified circumstances, and the *appointment directive*, also known as a healthcare proxy or durable power of attorney for healthcare (DPOAHC), which is the legal designation of a healthcare agent with the same decision-making authority as the patient. A related type of prospective care planning is the Practitioner/Physician Orders for Life-Sustaining Treatment (POLST) or Medical Orders for Life-Sustaining Treatment (MOLST), which are consolidated sets of medical orders specifically for patients with life-limiting illnesses (Bomba, 2011; Fromme, Zive, Schmidt, Olszewski, & Toll, 2012).

Despite the advantages of ACP, it is estimated that only one third of the adult population in the United States has an advance directive (American Bar Association Commission on Law and Aging, 2014). For that reason, the majority of healthcare decisions for incapacitated patients are made by surrogates, usually family or others close to the patient, who are asked by the care team to participate in making treatment decisions. Absent explicit instructions from the patient (verbally or in an advance directive), decisions by others are based on either *substituted judgment* (when the patient's wishes are known or can be inferred) or the *best interest standard* (when the patient did not have or articulate treatment preferences). Substituted judgment determines what the *patient* would choose based on prior statements and patterns of decision-making. In contrast, the best interest standard invokes the *surrogate's* evaluation of the proposed intervention's benefits and burdens to the patient.

A healthcare surrogate may be any capable person 18 years of age or older who, although not specifically chosen or legally appointed, assumes the responsibility for making healthcare decisions on behalf of a person who lacks the capacity to make those decisions. Informal surrogates are individuals, typically family members, who are presumed to know the patient best and to act in his or her best interest. Formal surrogates may be specified by state law in a hierarchy, typically in descending order of relation to the patient. *Family consent laws* are state-specific statutes that set out the state-approved decision-making hierarchy—the order in which persons are authorized to make decisions on behalf of a patient who lacks decisional capacity and has not appointed a healthcare agent by means of an advance directive or DPOAHC. To gain as much insight as possible into the patient's goals, values, and preferences, and approximate as closely as possible the decisions he or she would make if capable, the ethical imperative is to engage the decision-making efforts of individuals who know the patient best before moving to those with a less vested relationship to him or her. For that reason, a good-faith effort is typically required to contact members in each level of the hierarchy in turn, moving to a lower level only when it has been determined that no one at a higher level is able or willing to assume decision-making responsibilities**.** Most states accord considerable latitude to surrogates, especially next of kin, in consenting to treatment. Decisions about limiting treatment are more problematic and may be significantly restricted, depending on the state in which the patient is receiving care (see the "Resources" section, American Bar Association Commission on Law & Aging, for state guidelines).

Context of Healthcare Decision-Making

Healthcare goals and the treatment preferences for achieving them typically change as an individual's health and functional status change (Fried et al., 2006). Previously unacceptable conditions may become more or less acceptable as they are experienced. For example, patients already in pain may be less likely to refuse a treatment outcome that includes being in pain than patients who are not currently suffering moderate to severe pain (Fried et al., 2006). Likewise, patients' treatment and comfort goals may differ from those of their family caregivers and professional providers (Steinhauser et al., 2000).

Just as there is the right to learn one's medical information, there is also a right not to be burdened with unwanted information. Older adults or those from cultures that traditionally shield patients from knowledge of their illness may prefer to have information disclosed to a particular family member, the family as a group, or trusted others, who will use it to make decisions on the patient's behalf. With the implementation of the Health Insurance Portability and Accountability Act of 1996 (HIPAA), most hospitals have a form for patients to sign, designating their preferred decision-maker(s). Another approach is to ask, "You're here because you're not feeling well. We're going to do some tests and examinations, and then decisions about treatment will need to be made. Some patients like to have all the information; others don't. What would make you comfortable? Whom would you like us

to talk to? Would you like to be part of those discussions and decisions?"

It is not uncommon for even capable patients to say, "Talk to my daughter. She makes all my decisions about important things. Just do whatever she thinks is right." This is an autonomous decision, delegating a trusted person to be the decision-maker; if this is the dynamic the patient prefers, it would be inappropriate to try to change it. However, although it is important to respect patient preferences and cultural traditions, a patient's waiver of the right to have information must be explicitly confirmed, not presumed.

Trust is a critical element in the patient–provider relationship, especially in decision-making situations in which information is disclosed and questions are answered. Various factors influence information exchange and shared decision-making (Edwards, Davies, & Edwards, 2009). Providers may be influenced by their perceptions of informed patients and their interest in participatory decision-making, their limited knowledge of patients' cultures, or a tendency to stereotype patients rather than view them as individuals. Patients may be influenced by their personal motivations to obtain and use information, cultural identity and expression, health literacy, and ability to cope with the possibility of receiving distressing information. Of note, a shared influence reported by providers and patients is the sick-role expectation (Edwards et al., 2009). African American patients have been shown to be significantly more likely than Caucasian patients to report low trust of the U.S. healthcare system, unrelated to age or socioeconomic status (Halbert, Armstrong, Gandy, & Shaker, 2006), as well as little interest in ACP and advance directives (Cox et al., 2006). This is not, however, an indication that patients of color and minority ethnic populations do not want to participate in healthcare decision-making, including decisions at the end of life.

Quality-of-Life Considerations in Decision-Making

Although there is almost universal acknowledgment of the patient's desire to be comfortable (i.e., relieved of pain and suffering) and to achieve a sense of completion, other quality-of-life considerations elicit more varied responses. Attitudes about the importance of clergy, being physically touched, and using all available technology may differ among patients, families, and caregivers. Older adults with varying degrees of functional impairment and past experiences with treatment decision-making were found to be more interested in the outcome of a serious medical event than with curative interventions and whether the intervention could restore or maintain their ability to participate in activities they valued (Rosenfeld, Wenger, & Kagawa-Singer, 2000). Among older adults with end-stage renal disease, the decision to begin dialysis was found to be influenced by their family caregiving responsibilities, feeling that they had no other options, and their current enjoyment of life that inhibited contemplation of their death (Visser et al., 2009). Those who rejected dialysis were more often older, male, and widowers compared with those who accepted dialysis. The former group imagined that they would experience a loss of autonomy and a continuing trajectory of functional loss, have difficulty getting to the dialysis center, and have to start thinking about the future—a prospect that was unappealing to them at the time. These findings speak to the contextual and temporal nature of healthcare decision-making that has been explored by others (Fried et al., 2009).

INTERVENTIONS AND CARE STRATEGIES

Assessing the patient's orientation and understanding can provide critical information about decision-making behavior in different circumstances, as well as the ability to articulate care wishes. Reporting that a patient is "disoriented to time and place" is helpful only in establishing the context in which more focused and useful decisional capacity assessment should take place.

Documentation needs to be specific and descriptive. The entry should describe the circumstances or interaction(s) that led to the conclusion about the patient's ability to make decisions. Because capacity is decision specific, accurate and useful statements are "Patient appears to lack the capacity to make decisions about discharge; she is unable to describe how she will cook or get to the bathroom at home" or "Patient lacks the capacity to make decisions about surgery; he was unable to name the type of surgery, what the surgery is supposed to correct, or what is involved or to be expected during recovery."

Communicating information includes determining what the patient and/or surrogate(s) understand, what they need or want to know, and how involved they want to be in decision-making. Providing the relevant medical facts in lay language and avoiding medical jargon that creates distance are essential. It is also important to consider the participants in the decision-making. Who should be present? What is their relationship to the patient? What is their decisional authority? What information is necessary, at what level of detail, and how will it be used? When is the information to be provided and over what period of time (Popejoy, 2005)?

Whenever language barriers or preferences are identified, certified interpreters are essential. Trained interpreters might be the only healthcare staff who recognize that patients, families or other surrogates, and the physician or healthcare professionals have differing interpretations of illness, treatment, and health; inconsistent understandings of the goals and plan of care; and disparate views about death and dying. Moreover, these varied parties may use language and decision-making frameworks differently. An interpreter may realize that truth telling might not only be perceived as disrespectful and dangerous but may also potentially shorten the patient's life span, as believed in certain cultures. A trained interpreter is more than a word-for-word translator; rather, he or she can serve as a mediator, culture broker, patient advocate, witness, educator, and participant who interprets both fact and nuance.

CASE STUDY 7.1

Mr. Peters is an 85-year-old man with advanced Alzheimer's disease who has been living in a nursing home for the past 6 months. When he stopped eating several weeks ago, he was hospitalized for placement of a percutaneous endoscopic gastrostomy (PEG) tube to provide artificial nutrition and hydration. He returned to the nursing home briefly but developed uncontrolled diarrhea and apparent abdominal discomfort. Two days ago, his PEG tube fell out, and he has been readmitted to the hospital for treatment of the diarrhea and possible replacement of the PEG.

Mr. Peters opens his eyes and responds to painful stimuli but does not interact and appears not to recognize family members. He is clearly incapable of participating in discussions or decisions about his care. His close family includes his son and granddaughter, who are visiting from California, and his grandson, Jason, who has been very involved for several years in providing and deciding about Mr. Peters' care.

A clinical ethics consultation has been convened, including Mr. Peters's family, his two attending physicians, the house and nursing staff who have cared for him most consistently, and the bioethicist. Discussion focuses on clarifying his condition and probable clinical course, the goals of care, and his likely care preferences.

Jason describes his grandfather as very active and fiercely independent until age 78, when his dementia was apparent. With his wife, he had raised Jason, and, when she died, he continued to raise the boy alone until Jason left for college. When the dementia worsened several years ago, Jason arranged for his grandfather and a team of 24-hour caregivers to move into an apartment next to his. That arrangement continued until Mr. Peters required care that could best be provided in a skilled nursing facility.

All three family members agree that, given Mr. Peters's personality, values, and lifetime behavior pattern, he would not have wanted to be maintained in his current condition, certainly not dependent on artificial nutrition and hydration. Nevertheless, they express concern about the ethics, legality, and clinical effect of not replacing the PEG tube and are especially uncomfortable about whether it would be considered "starving" him to death.

According to the care team, Mr. Peters's advanced dementia is not reversible, and he will continue to deteriorate mentally and physically until death. The doctors referred to the considerable literature demonstrating that, in patients with advanced dementia, artificial nutrition and hydration can cause gastrointestinal (GI) distress, including nausea, bloating, gas, and diarrhea, which appears to have happened to Mr. Peters. In the opinion of the care team, continued artificial nutrition and hydration would only contribute to the patient's suffering and prolong the dying process. The doctors also explain that, far from suffering, Mr. Peters appears more comfortable because the PEG fell out and the diarrhea has stopped. They assure the family that the patient could be admitted to the nursing home's hospice unit, where he will receive comfort care, including pain and other symptom management. The bioethicist addressed the relevant ethical issues discussed here.

Discussion

The ethics analysis of this case focuses on decision-making for an incapacitated patient, promoting the patient's best interest and protecting him from harm, and forgoing life-sustaining treatment, specifically artificial nutrition and hydration, at the end of life.

Surrogate decision-making on behalf of patients lacking capacity uses the following standards.

- The patient's wishes as expressed directly through discussions with others or in advance directives
- Substituted judgment (when the patient's wishes are known or can be inferred)
- The best interest standard (when the patient's wishes are not known or inferable)

(*continued*)

CASE STUDY 7.1 (*continued*)

Mr. Peters has not left any explicit instructions; however, his family, knowing him very well, is able to predict with confidence what he would and would not have wanted based on his characteristic patterns of behavior and decision-making. In this case, the family's substituted judgment is consistent with what was considered by the family and the care team to be in the patient's best interest—protecting him from continued artificial nutrition and hydration that would have increased his suffering without providing benefit and prolonged his dying. Framing this as *protecting* the patient from the burdens and risks of an intervention rather than *depriving* him of necessary treatment can make this decision more tolerable for distressed families.

One of the most difficult surrogate decisions is forgoing life-sustaining treatment and, because providing nourishment is so intimately associated with love and nurturing, forgoing artificial nutrition and hydration is especially wrenching for families and caregivers. Clinicians, ethicists, and courts have agreed that artificial nutrition and hydration are medical treatments, the benefits, burdens, and risks of which should be assessed like those of any other intervention.

Capable patients and the appointed healthcare agents of incapacitated patients have a well-established right to refuse any unwanted treatment, including those that are life sustaining. Absent capacity or advance directives, the family's authority to make end-of-life decisions, including forgoing artificial nutrition and hydration, depends on the laws of the state in which the patient is treated. Many states permit family and surrogates authorized by case or statutory law to make these decisions based on substituted judgment or their assessment of the patient's best interest in light of the patient's condition and prognosis. Other states require surrogates, even next of kin, to provide explicit evidence that the patient would have refused artificial nutrition and hydration in order to authorize withholding or withdrawing the interventions. Because of the jurisdictional variations, the completion of advance directives, including the legal appointment of healthcare agents and alternative agents, should be strongly encouraged by healthcare professionals.

SUMMARY

The notion of "ownership" of one's body applies to healthcare decision-making even in times of crisis. Patients with diminished or fluctuating decisional capacity should not be denied the opportunity to make the specific healthcare decisions they are capable of making. A vulnerable patient who lacks capacity, despite some social or conversational skills, needs to be protected from the potentially harmful effects of uninformed, poorly reasoned, and potentially risky healthcare decisions. It is suggested that the best way for nurses to learn older adults' informational needs, avoid undue paternalism, and promote their patients' best interests is to engage them in discussion about their health goals, values, and preferences (Tuckett, 2006). The ethical obligations that must be assumed by healthcare professionals are skillfully assessing the clinical situation; assessing the benefits, burdens, and risks of the therapeutic options; the patient's capacity to make and take responsibility for the relevant decisions; and the surrogate's need for information, guidance, and support.

NURSING STANDARD OF PRACTICE

Protocol 7.1: Healthcare Decision-Making

I. GOALS

To ensure nurses in acute care:

A. Understand the supporting bioethical and legal principles of informed consent
B. Are able to differentiate between competence and capacity
C. Understand the issues and processes used to assess decisional capacity
D. Can describe the nurse's role and responsibility as an advocate for the patient's voice in healthcare decision-making

II. OVERVIEW

A. Persons with decisional capacity have a well-established right, grounded in law and Western bioethics, to determine what is done to their bodies.
B. In any healthcare setting, the exercise of autonomy (self-determination) is seen in the process of informed consent to and refusal of treatment and/or care planning.
C. Determination of decision-making capacity is a compelling clinical issue because treatment and diagnostic interventions have the potential for significant benefit, burden, and/or risk.
D. Honoring the decisions of a capable patient demonstrates respect for the person; honoring the decisions of a patient without capacity is an act of abandonment.

III. BACKGROUND AND STATEMENT OF THE PROBLEM

A. Introduction
   1. Core ethical principles that are the foundation of clinician obligation are the following:
      a. Respect for autonomy, beneficence, nonmaleficence, and distributive justice.
      b. Clinically, legally, and ethically valid decisions by or for patients require a careful balancing of information, principles, rights, and responsibilities in light of medical realities, cultural factors, and, increasingly, concerns about resource allocation.
      c. Even capable patients, including those who are older adults, easily confused, or from cultures that do not consider autonomy a central value, as well as patients with diminished or fluctuating capacity, may not be capable of or comfortable with exercising purely autonomous decision-making.
      d. Care professionals have an obligation to be alert to questionable or fluctuating capacity both in patients who refuse and those who consent to recommended treatment. Capable individuals may choose to make their own care decisions, or they may voluntarily delegate decision-making authority to trusted others. Delegation of decisional authority must be explicitly confirmed, not inferred.
      e. The context of decision-making can include cultural imperatives and taboos; perceptions of pain, suffering and quality of life, and death; education and socioeconomic status; language barriers; and advance healthcare planning.
B. Definitions
   1. *Consent:* The informed consent process requires evidence of decisional capacity, disclosure of sufficient information, understanding of the information provided, voluntariness in choosing among the options, and, on those bases, consent to or refusal of the intervention.
   2. *Competence:* A *legal* presumption that an adult has the mental ability to negotiate various legal tasks (e.g., entering into a contract, making a will).
   3. *Incompetence:* A *judicial* determination that a person lacks the ability to negotiate legal tasks and should be prevented from doing so.

(*continued*)

Protocol 7.1: Healthcare Decision-Making (*continued*)

4. *Decisional capacity:* A *clinical* determination that an individual has the ability to understand and to make and take responsibility for the consequences of health decisions. Because capacity is not global but decision specific, patients may have the ability to make some decisions but not others. Capacity may fluctuate according to factors, including clinical condition, time of day, medications, and psychological and comfort status.

C. Essential elements
   1. Decisional capacity reflects the ability to understand the facts, appreciate the implications, and assume responsibility for the consequences of a decision.
   2. The elements of decisional capacity: The ability to understand and process information; weigh the relative benefits, burdens, and risks of each option; apply personal values to the analysis; arrive at a consistent decision; and communicate the decision (Roth et al., 1997).
   3. Standards of decision-making
      a. Prior explicit articulation: A decision based on the previous expression of a capable person's wishes through oral or written comments or instructions.
      b. Substituted judgment: A decision by others based on the formerly capable person's wishes that are known or can be inferred from prior behaviors or decisions.
      c. Best interests standard: A decision based on what others judge to be in the best interest of an individual who never had or made known healthcare wishes and whose preferences cannot be inferred.

IV. ASSESSMENT OF DECISIONAL CAPACITY

A. There is no gold standard instrument to assess capacity.
B. Assessment should occur over time, at different times of day, and with attention to the patient's comfort level.
C. The MMSE or Mini-Cog Test are not tests of capacity.
D. Clinicians agree that the ability to understand the consequences of a decision is an important indicator of decisional capacity.
E. Safe and sufficient decision-making is retained in the early stages of dementia and by adults with mild to moderate mental retardation.

V. NURSING CARE STRATEGIES

A. Communicate with the patient and family or other surrogate decision-makers to enhance their understanding of treatment options.
B. Be sensitive to racial, ethnic, religious, and cultural mores and traditions regarding end-of-life care planning, disclosure of information, and care decisions.
C. Be aware of conflict-resolution support and systems available in the care-providing organization.
D. Observe, document, and report the patient's ability to:
   1. Articulate his or her needs and preferences.
   2. Follow directions.
   3. Make simple choices and decisions (e.g., "Do you prefer the TV on or off?" "Do you prefer orange juice or water?").
   4. Communicate consistent care wishes.
E. Observe period(s) of confusion and lucidity; document the specific time(s) when the patient seems more or less "clear." Observation and documentation of the patient's mental state should occur during the day, evening, and at night.
F. Assess the patient's understanding relative to the particular decision at issue. The following probes and statements are useful in assessing the degree to which the patient has the skills necessary to make a healthcare decision.
   1. "Tell me in your own words what the physician explained to you."
   2. "Tell me which parts, if any, were confusing."

(*continued*)

Protocol 7.1: Healthcare Decision-Making (*continued*)

3. "What do you feel you have to *gain* by agreeing to (the proposed intervention)?"
4. "Tell me what you feel you have to *lose* by agreeing to (the proposed intervention)."
5. "Tell me what you feel you have to gain or lose by refusing (the proposed intervention)."
6. "Tell me why this decision is important (difficult, frightening, etc.) to you."

G. Select (or construct) appropriate decision aids.
H. Help the patient express what he or she understands about the clinical situation, the goals of care, and his or her expectation of the outcomes of the diagnostic or treatment interventions.
I. Help the patient identify who should participate in diagnostic and treatment discussions and decisions.

VI. EVALUATION AND EXPECTED OUTCOME(S)

A. Referrals to the ethics committee or ethics consultant in situations of decision-making conflict between any of the involved parties
B. The use of interpreters in communication of, or decision-making about, diagnostic and/or treatment interventions
C. Plan of care: instructions regarding frequency of observation to ascertain the patient's lucid periods, if any
D. Documentation
   1. Is the process of the capacity assessment described?
   2. Is the assessment specific to the decision at issue?
   3. Is the informed consent and refusal interaction described?
   4. Are the specifics of the patient's degree or spheres of orientation described?
   5. Is the patient's language used to describe the diagnostic or treatment intervention under consideration recorded?
   6. Is the patient's demeanor during this discussion recorded?
   7. Are the patient's questions and the clinician(s)' answers recorded?
   8. Are appropriate mental status descriptors used consistently?

ABBREVIATION

MMSE Mini-Mental State Examination

Sensory Changes in the Older Adult*

Pamela Z. Cacchione

8

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe the normal changes of aging that affect the senses in the older adult.
2. Identify common disorders that impact the senses in the older adult.
3. Understand the increased risk of morbidity and mortality in sensory-impaired older adults.
4. Determine how best to assess the sensory status in the older adult.
5. Identify nursing strategies to manage sensory impairment in the older adult.
6. Collaborate with interprofessional team members who can assist the older adults with sensory impairment.

OVERVIEW

Understanding how to assess for and manage sensory deficits is essential to holistic nursing. A goal of *Healthy People 2020* is to decrease the prevalence and severity of disorders of vision, hearing, balance, smell, and taste, as well as voice, speech, and language (Office of Disease Prevention and Health Promotion [ODPHP], n.d.). With the growing evidence of increased morbidity and mortality related to sensory impairment, *Healthy People 2030* continues to focus on sensory disorders, as evidenced by their proposed objectives for *Healthy People 203*0 (Secretary's Advisory Committee for Healthy People 2030, 2019). This chapter on sensory changes addresses common age-related changes associated with the senses as well as disease states and injuries to the senses occurring more commonly with aging. Nursing care related to the *Healthy People 2020* goals regarding sensory changes are also addressed.

BACKGROUND AND STATEMENT OF PROBLEM

Individuals experience and interact with their environments through their senses. Vision, hearing, smell, taste, and peripheral sensation allow us to safely experience and enjoy the world around us. Changes in sensory function (vision, hearing, smell, taste, and peripheral sensation) are common as people age. These sensory changes can negatively impact the older adult's ability to interact safely within the environment and interpret and respond to sensory information, putting an older adult's health at risk and decreasing quality of life. For example, changes in hearing can impact an older person's communication skills; changes in vision can impact his or her health literacy by limiting the ability to take medications safely. Researchers have determined that sensory impairment is more dangerous than previously thought (Cacchione, 2014). Sensory impairment, particularly vision and hearing impairment,

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

has been linked to increased mortality (Cugati et al., 2007; Gopinath et al., 2013; Karpa et al., 2010). A decrease in sense of smell has been linked to increased risk of mortality within 5 years (Pinto, Wroblewski, Kern, Schumm, & McClintock, 2014). *Healthy People 2020* emphasizes the importance of healthy senses, including vision, hearing, balance, smell, and taste. Vision and hearing abilities are essential to language, whether spoken, signed, or read (ODPHP, n.d.). Decreases in sense of smell can interfere with an older adult's ability to smell smoke in a fire or recognize spoiled food. Many adults report a decrease in taste that impacts their desire to eat. Decreased peripheral sensation sets up an individual for injury and falls.

NORMAL CHANGES OF AGING SENSES

The senses—vision, hearing, taste, smell, balance, and peripheral sensation—change with aging, usually presenting primarily with a slowing of function. A summary table is presented describing age-related changes and the functional outcomes for each sense (Table 8.1).

Vision

There are several changes that occur with vision as people age. The eyelids start lagging, potentially obscuring vision; the pupil takes longer to dilate and contract, slowing

TABLE 8.1

Normal Changes of Aging

Sense	Change With Aging	Functional Outcome
Vision	■ Decreased dark adaptation ■ Decreased upward gaze ■ Eyes become drier and produce fewer tears ■ Cornea becomes less sensitive ■ Pupils decrease in size ■ Visual fields become smaller	■ Increased safety risk in changing environmental light ■ Decreased field of vision ■ Dry, irritated eyes ■ Slow to recognize injury to the cornea ■ Inability to adjust to glare and change in lighting conditions ■ Safety risk for driving and maneuvering in the environment
Hearing	■ Eardrum thickens ■ Loss of high-frequency hearing acuity ■ Decreased ability to process sounds after age 50 ■ Increased cerumen impactions ■ Ossification of the stapes	■ Thickened eardrum decreases sound moving across the ear canal ■ Decreased ability to hear sounds, such as/p/,/w/,/f/,/sh/, and women's and children's voices ■ Requires more time to process and respond to auditory stimuli ■ Decreased hearing because of blockage of sound
Smell	■ Decreased ability to identify odors ■ Impacts ability to taste	■ Inability to identify spoiled food or smoke ■ Limits enjoyment in eating
Taste	■ Decreased number of taste buds ■ Limited decrease in taste supported by studies ■ Less saliva production	■ Decreased sensitivity to flavors ■ Dry mouth affects ability to swallow
Sensation	■ Decreased vibratory sense ■ Decreased two-point discrimination ■ Decreased temperature sensitivity ■ Decreased balance ■ Decreased proprioception ■ Changed pain sensation	■ Increased risk for injury ■ Decreased ability to sense pressure ■ Decreased protective response to withdraw from hot objects ■ Risk of falls ■ Decreased protective mechanism

accommodation after age 50 because of the hardening of the lens; and presbyopia is widespread.

Presbyopia

Presbyopia results in the inability to focus on close objects (National Eye Institute [NEI], 2015). It is an age-related progressive decline in the crystalline lens' ability to accommodate, resulting in the inability to focus on near objects (Arines, Almaguer, & Acosta, 2017). Functionally, presbyopia occurs when the normal age-related reduction in the eyes' focusing range reaches a point, when optimally corrected for distance vision, where the clarity of near vision is insufficient to satisfy an individual's near vision requirements (Wolffsohn & Davies, 2019).

Hearing

Normal changes of aging impacting hearing acuity include the decrease in function of the hair fibers in the ear canal that normally aid in the natural removal of cerumen and the protection of the ear canal from external elements. Conduction of sound is limited by the ossification of the stapes, decreasing the vibration of the stapes and thickening of the tympanic membrane, making it less flexible (Wallhagen, Pettengill, & Whiteside, 2006).

Presbycusis

Presbycusis or age-related hearing is characterized by increased hearing thresholds, impaired processing of high-pitched sounds, including reduced frequency and temporal resolution, and difficulty understanding speech, especially in noisy or complex listening environments (Blazer, Domnitz, & Liverman, 2016). Presbycusis affects more than 50% of older adults by the age of 75 years and nearly 100% of adults aged 90 and older (Blevin, 2018). This high-frequency sensorineural hearing loss is a multifactorial process associated with aging and varies in severity (Blevin, 2018). Presbycusis usually has a bilateral progressive onset and has both intrinsic, including genetic, and extrinsic causes such as environmental exposures (Tawfik, Klepper, Saliba, & Friedman, 2019). Risk factors include heredity, vascular insults, environmental exposure, free radicals, hormones, and mitochondrial deoxyribonucleic acid (DNA) damage (Huang & Tang, 2010; Tawfik et al., 2019). Presenting symptoms of this irreversible condition include high-frequency hearing loss and difficulty hearing high-pitched sounds such as /t/,/p/,/k/,/s/,/z/,/sh/, and/ch/ (Blazer et al., 2016; Huang & Tang, 2010). Background noise further aggravates this hearing deficit (Blazer et al., 2016).

Smell

Changes in smell are common as we age but are not considered a normal part of aging. Frequently, older adults complain of distortions of smell. Factors associated with loss of sense of smell include age and gender, with older males being more prone to smell loss (Hoffman, Rawal, Li, & Duffy, 2016). The environment, head trauma, diseases, or illness can diminish the sense of smell (Hoffman et al., 2016). Changes in the sense of smell have also been found to correlate with neurological conditions, such as Parkinson's disease, and genetically with Alzheimer's disease. The rhinencephalic brain regions are thought to be vulnerable to Alzheimer's disease pathology (Daulatzai, 2015; Doty, 2018; Hoffman et al., 2016; Lafaille-Magnan et al., 2017; Oleson & Murphy, 2015).

Taste

Common changes in taste include a decreased ability to detect the intensity of taste thought to be partially due to a decline in taste buds (Doty, 2018). There is no decrease in somatic sensations, such as touch and burning pain in the tongue, when compared with the case in younger adults (Fukunaga, Uematsu, & Sugimoto, 2005). However, complete loss of taste is rare, and changes in taste are more often related to poor dentition and dental care; decreased sense of smell, diseases, or illness, such as rhinitis, allergies, or infections; and medications (Doty, 2018; Hoffman et al., 2016; Ogawa, Annear, Ikebe, & Maeda, 2017). Even though taste is processed by cranial nerves VII, IX, and X, there is little known about the central nervous system's impact on sense of taste (Doty, 2018; Ogawa et al., 2017).

Peripheral Sensation

Aging is associated with a decline in peripheral sensory nerve function (Breen et al., 2016). Two-point discrimination and vibratory sense both decrease with age. The ability to perceive painful stimuli is preserved in aging (Riley et al., 2017). However, older adults perform movements more slowly than younger adults, precipitating a slowed reaction time for pulling away from painful stimuli (Landelle, El Ahmadi, & Kavounoudias, 2018).

ASSESSMENT OF THE PROBLEM

Vision

The leading causes of vision impairment and blindness are age-related eye diseases (Prevent Blindness America, 2012). The prevalence of visual impairment increases with age and the settings in which older adults live, with vision impairment affecting approximately 2.6 million adults older than 65 years in the United States (Prevent Blindness America, 2012). According to data from the National Health and Nutrition Examination Survey (NHANES; Dillon, Gu, Hoffman, & Ko, 2010; Schiller, Lucas, & Peregoy, 2012; Swenor, Ramulu, Willis, Friedman, & Lin, 2013), 3.4% of older adults aged 70 to 79 years and 15.9% of older adults 80 years and older were found to be visually impaired (Swenor et al., 2013), but this varied by race and ethnicity with non-Hispanic Whites (13.8%), non-Hispanic Blacks (21.1%), and Mexican Americans (24%). The National Health Interview Survey from 2014 to 2015 reported prevalence rates for vision impairment even when wearing glasses or contact lenses for older adults between 65 and 84 years old of 13.0% and 85 years and older of 23.5% (Lamuda, Wittenborn, & Rein, 2018). Additionally, a study investigating socioeconomic factors in vision found that increasing age and lower socioeconomic status were associated with vision impairment (Zheng et al., 2012). Adults aged 85 years and older were found to have a 12.3% prevalence of blindness in the National Health Interview Study (Okeke et al., 2018). This is worrisome because this is the fastest growing segment of our population.

Studies evaluating older adults in long-term care settings demonstrate prevalence rates of visual impairment from 27% to 57% of older adults (Bron & Caird, 1997; Cacchione, Culp, Dyck, & Laing, 2003; Swanson, McGwin, Elliott, & Owsley, 2009). The NHIS study estimated national prevalence rates for people who wear glasses and found that 83.5% of older adults between 65 and 84 years old and 84.9% of those aged 85 and older wear glasses (Okeke et al., 2018). Despite this prevalence rate, uncorrected refractive error was common in visually impaired older adults. In one study, of the 8.8% of the older adults found to be visually impaired, 59% were impaired because of an uncorrected refractive error (Vitale, Cotch, & Sperduto, 2006). Leading causes of blindness by race and ethnicity were found to be age-related macular degeneration in Whites and Hispanics compared with cataracts and open-angle glaucoma in Blacks (American Academy of Ophthalmology [AAO], 2020a).

The definition of visual impairment varies by different groups and by country (Agency for Healthcare Research and Quality [AHRQ], 2004, 2012). The United States defines low vision as *best corrected visual acuity*:

- Normal vision: visual acuity of 20/20 or better
- Mild vision impairment: 20/25 to 20/50
- Moderate visual impairment: 20/60 to 20/160
- Severe visual impairment (legally blind): 20/200 to 20/400
- Profound vision impairment: 20/400 to 20/1,000
- Near-total vision loss: less than or equal to 20/1,250
- Total blindness: no light perception

Low vision can also be defined based on visual field limitations. *Severe visual impairment* is defined as best corrected field less than or equal to 20° (legal blindness). *Profound visual impairment* is defined as visual field less than or equal to 10 degrees (AHRQ, 2004, 2012).

Nursing Assessment of Vision

Health history is an essential part of vision assessment. Several health conditions predispose older adults to visual impairment. In the United States, diabetes is a common cause of disease-related blindness associated with diabetic retinopathy, with 40% to 45% of diabetics having some stage of diabetic retinopathy (NEI, 2019c). Hypertension carries with it the risk of hypertensive retinopathy. Ascertaining a thorough baseline health history with yearly reviews and updates is essential in maintaining visual health. Health questions related to visual health include the questions shown in Box 8.1 (Cacchione, 2007; Wallhagen et al., 2006).

Examination of the Eye

The external structures can cause decreased vision if the lids lag because of laxity of the skin of the upper eyelid. Lid lag can interfere with visual acuity and fields and may require surgery. A decreased level of tear function can negatively impact visual acuity. In severe cases, cataracts can be visible to the naked eye and appear as a whitish gray pupil instead of black. Cloudiness of the whole cornea of the eye is indicative of a corneal problem, not a cataract. If the person has had cataract surgery, the lens implant may be visible on close inspection.

Fundus Exam. Using an ophthalmoscope, a nurse can visualize the red reflex and, with experience and practice, the fundus of the eye. This is often difficult with small pupils. Darkening the room may help with dilating the pupils. Optometrists, ophthalmologists, and nurses with training can dilate the pupils to allow for a better view of

BOX 8.1

Vision History Questions

- When was your last eye exam?
- How would you describe your eyesight?
- Any change in your eyesight?
- When did you notice this change?
- Are you experiencing any blurred vision?
- Are you having any double vision?
- Are you bothered by glare?
- Are you experiencing any eye pain?
- Are you using any eye drops for any reason?
- Any history of trauma or injury to your eyes?
- Have you had any eye surgeries?
- Do you have cataracts?
- Any family history of eye problems?

Source: Data from Cacchione, P. Z. (2007). Nursing care of older adults with age-related vision loss. In S. Crocker-Houde (Ed.), *Vision loss in older adults: Nursing assessment and care management* (pp. 131–148). New York, NY: Springer Publishing Company; Whiteside, M. M., Wallhagen, M. I., & Pettengill, E. (2006). Sensory impairment in older adults: Part 2. Vision loss. *American Journal of Nursing, 106*(11), 52–61. doi:10.1097/00000446-200610000-00030

the fundus. Cataracts will appear as a dark shadow in the anterior portion of the lens in front of the retina.

Vision Testing. Vision testing should be completed before the eyes are dilated and assessed in each eye, then both eyes together for both uncorrected and corrected (with glasses or contacts) vision.

Distance Vision. The "gold standard" in eye charts, the Snellen chart, is one of the most commonly used to assess distance vision. Visual acuity is tested at 20 feet. The individual is asked to read the letters on the chart until he or she misses more than two on a line. Acuity equals the line above the line with more than two errors. Acuity measures range from 20/10 to 20/800 on the Snellen chart.

Early Treatment Diabetic Retinopathy Study. The Early Treatment Diabetic Retinopathy Study (ETDRS; Ferris, Kassoff, Bresnick, & Bailey, 1982) eye chart is also used frequently and can be used at a distance of 4 meters. At this distance, the greatest visual acuity measured is 20/200—the equivalent of legal blindness.

Pinhole Test. With best vision, with or without glasses, a multiple pinhole occluder or shield can be placed in front of the eye, allowing light rays to reach the retina without the interference of optical problems of the eye (AAO, 2020b). This test identifies refractive error of the peripheral cornea of the lens of the eye by allowing only perpendicular light into the lens (Kalinowski, 2008). If the individual can read farther down the chart with the pinhole, his or her vision may be improved with better refraction of his or her eyeglasses, or, if he or she does not have glasses, vision could be improved with eyeglasses. If the pinhole acuity is worse than 20/60, the individual's visual impairment is not correctable with glasses (Kumar et al., 2018).

Near Vision. Near vision is important for health literacy, especially regarding reading food or medication labels. There are several ways to assess near vision. Two commonly used tools are the Rosenbaum Pocket Eye Screener and the Lighthouse for the Blind Near Vision Screener. The Rosenbaum Pocket Eye Screener is a noncopyrighted tool based on the Snellen chart that can be useful in assessing near vision in the acute care and primary care settings. The Rosenbaum is true to scale when compared with the Snellen chart at the 20/200, 20/400, and 20/800 acuity levels. However, the other levels are slightly too large, causing an overestimation of visual acuity (Horton & Jones, 1997). The Lighthouse for the Blind Near Vision Screener (Lighthouse for the Blind, Owsley et al., 2007) is a handheld vision screener with a cord that can be used at 40 and 20 centimeters to measure the proper distance for testing near vision. This near vision screener mimics the ETDRS eye chart in a smaller version but is not pocket size. It does not, however, have the concern that the Rosenbaum Pocket Eye Screener has over the scale matching of the ETDRS distance acuity level. For research purposes, it has the added feature of the cord for measuring a consistent distance.

Contrast Sensitivity. Contrast sensitivity is the ability to discriminate between two luminance levels in a static image and is often compromised by aging and diseases or conditions of the eye (Saftari & Kwon, 2018). Decreases in contrast sensitivity occur with cataracts, glaucoma, and retinopathies (Khan, Petropoulous, Ponirakis, & Malik, 2017; Owsley, 2016). Low-contrast sensitivity despite normal visual acuity creates a situation where a person has difficulty detecting hazards in the environment, particularly at night (Saftari & Kwon, 2018). Decline in contrast sensitivity impacts one's ability to distinguish when one step ends and another begins, identify light switches on the wall, read materials not made in high-contrast font, or identify the buttons on the remote. Intact contrast sensitivity is important for day-to-day safety and function within the environment. Impaired contrast sensitivity has been associated with falls, decreased

physical function, and nursing home placement in older adults (Saftari & Kwon, 2018).

The Pelli–Robson Contrast Sensitivity Chart (Pelli, Robson, & Wilkins, 1988) is read at the 1- or 3-meter distance. All letters are presented at the 20/200 acuity level but in decreasing shades of black to gray. The Pelli–Robson Contrast Sensitivity Chart is widely used in practice and works well for older adults who are experienced in recognizing letters (Hirvelä & Laatikainen, 1995; Morse & Rosenthal, 1997). The MARS Letter Contrast Sensitivity Test is another validated screener for contrast sensitivity (Arditi, 2005). Additionally, the Melbourne Edge Test (Verbaken & Johnston, 1986) is helpful in identifying persons at risk for falls. Persons who have difficulty identifying the orientation of a line defined by the contrast between two abutted surfaces are likely to be at risk for falls (Lord, Delbaere, & Sturnieks, 2018).

Visual Fields. *Fields of vision* refers to the area of peripheral vision visible when the individual is focusing straight ahead (Cassin & Rubin, 2001). The vision in visual fields can be affected by many eye conditions, specifically glaucoma, macular degeneration, and retinopathies (Jessa, Evans, Thomson, & Rowlands, 2007), as well as neurological disorders that inhibit eye movement or affect the blood supply to the optic nerve. Intact visual fields are necessary to function safely in one's environment. A good bedside gross measure of visual fields can be done by assessing visual fields by confrontation. The examiner faces the patient and determines whether the patient can identify the number of examiner's fingers as they are moving into the patient's field of view (Leat et al., 2018). Although subjective and dependent on the examiner having normal fields of vision, the confrontation test is useful in quickly identifying large losses in visual fields.

The Humphrey Visual Field Test is completed by an ophthalmologist and assesses visual fields using a static type of perimetry (Gianutsos & Suchoff, 1997). This instrument provides a more reliable measure of functional visual fields. The Goldman VI4e kinetic perimetry visual field testing, on the other hand, assesses the kinetic type of functional visual fields (Hepworth & Rowe, 2018). Kinetic perimetry entails the introduction of a moving stimulus, moving from a nonvisible area toward the fixed point of view. The Goldman VI4e kinetic perimetry visual field testing is hard to standardize because it is operator dependent (Hepworth & Rowe, 2018). Because these automated methods are more widely used, the location of the visual field deficit may clue the examiner about the type of eye condition. For example, unilateral visual field deficits may be related to a cerebral vascular accident, glaucoma will affect the peripheral fields, and macular degeneration has associated loss of central field of vision.

Stereopsis. Stereopsis is the process in which humans have the ability to construct spatial relationships between objects using different viewpoints provided by their eyes to produce a vivid perception of depth and three-dimensional shapes (Read, Phillipson, Serrano-Pedraza, Milner, & Parker, 2010, Saftari & Kwon, 2018). The ability to perceive depth, judge distances, and perceive spatial relationships is necessary for safe negotiation of the environment (Lord et al., 2018). There are multiple clinical methods of measuring stereopsis and stereoacuity; however, these tests are much more effective in identifying intact stereoacuity than a decline in stereoacuity (O'Connor & Tidbury, 2018). Stereopsis and stereoacuity are not thought to be affected by aging but may be negatively impacted by distance acuity and eye diseases (O'Connor & Tidbury, 2018).

Visual Function Questionnaire

The NEI Visual Function Questionnaire (VFQ-25) is a 25-item survey that assesses the functional impact of visual impairment. It provides a subjective report on 12 functional subscales: general vision, near vision, distance vision, driving, peripheral vision, color vision, ocular pain, general health, vision-specific role difficulties, dependency, social function, and mental health (Revicki, Rentz, Harnam, Thomas, & Lanzetta, 2010). The NEI VFQ-25 has sound psychometric properties in cognitively intact older adults (Mangione et al., 2001).

Conditions of the Eye

Diseases That Alter Vision Seen More Frequently as People Age

Cataracts. Age-related cataracts gradually cloud the crystalline lens and may present either unilaterally or bilaterally as painless, progressive loss of vision (Owsley, 2011). Cataracts are usually age related, but they can be secondary to glaucoma, diabetes, Alzheimer's disease, congenital or smoking injury, or injuries related to medications such as steroids or sunlight exposure (NEI, 2019b). The management of cataracts includes early identification and monitoring followed by surgical extraction and lens implantation once vision is affected.

Age-Related Macular Degeneration (ARMD)

This involves the development of lipid deposits (drusen) beneath the retina in the retinal pigmented epithelium.

ARMD is the leading cause of central vision loss and legal blindness in older adults (Alavi, 2016). ARMD is more common in fair-haired, blue-eyed individuals. Other risk factors include smoking and excessive sunlight exposure. There are wet and dry forms of macular degeneration. The wet form is more easily treated than the dry form. Treatment is available for the wet form of ARMD and consists of injectable medications that target neovascularization to slow the progression of dry macular degeneration (Alavi, 2016, NEI, 2019a). In addition, photodynamic therapy and laser surgery are used to target leaky blood vessels (NEI, 2019a). The Age-related Eye Disease Study AREDs and AREDS2 found that a combination of supplements could slow the progression of ARMD by 25%; these include 500 mg of vitamin C, 400 international units of vitamin E, 80 mg zinc oxide, 2 mg cupric oxide, 10 mg lutein, and 2 mg zeaxanthin (NEI, 2019a).

Glaucoma. Glaucoma is the most common cause of irreversible blindness (Khan et al., 2017). It is a progressive, chronic, serious form of eye disease that is considered an optic neuropathy, where the loss of retinal ganglion cells negatively impacts the function of the optic nerve resulting in vision loss and blindness (Alavi, 2016). Primary open-angle glaucoma is the most common form of glaucoma in older adults (NEI, 2019d). Increased intraocular pressure causes atrophy and cupping of the optic nerve head, which leads to visual field deficits that can progress to blindness. In addition, glaucoma causes an intolerance to glare, decreased perception of contrast, and decreased ability to adapt to the dark. Treatments are available to delay vision loss, but no cure is available. African Americans and Mexican Americans are five times more likely than Caucasians to develop glaucoma (NEI, 2019d). Treatment for open-angle glaucoma includes medications to lower the eye pressures, laser trabeculoplasty, conventional surgery, or a combination of these treatments (NEI, 2019e). Closed angle glaucoma is a medical emergency and presents with acute increase in eye pressure, causing pain, nausea, blurred vision, and redness of the eye (NEI, 2019d). Persons with these symptoms should go to the nearest emergency department.

Diabetic Retinopathy. In persons with diabetes, diabetic retinopathy is the leading cause of serious vision loss (Khan et al., 2017). Diabetic retinopathy starts, because of high levels of blood sugar, as mild nonproliferative retinopathy with microaneurysms on the retina and progresses to moderate to severe nonproliferative retinopathy, in which blood vessels in the retina are blocked, depriving the retina of adequate blood supply, and then progresses to proliferative retinopathy, in which the growth of new abnormal fragile blood vessels that leak can cause blindness (NEI, 2019c). The risk can be reduced by effecting tight blood sugar control. As many as 45% of diabetics develop diabetic retinopathy (NEI, 2019c). Diabetic retinopathy is treated with tight blood sugar control, antivascular endothelial growth factor injections (anti-VEGF), laser surgery, and corticosteroids by a retinal specialist (NEI, 2019c).

Hypertensive Retinopathy. Similarly to diabetic retinopathy, hypertensive retinopathy is caused by end-organ damage from poorly controlled hypertension, causing background and, eventually, proliferative retinopathy. Hypertensive retinopathy is usually treated with laser photocoagulation and tight blood pressure control.

Temporal Arteritis. This is an autoimmune disorder that causes inflammation of the temporal artery, also known as *giant cell arteritis*. It presents as malaise, scalp tenderness, unilateral temporal headache, jaw claudication, and sudden vision loss (usually unilateral). This vision loss is a medical emergency but is potentially reversible if identified immediately. The client should see an ophthalmologist or go to the emergency department immediately if symptoms develop.

Detached Retina. This condition can occur in patients with cataracts or recent cataract surgery or trauma, or it can occur spontaneously. A detached retina presents as a curtain coming down across a patient's line of vision. An individual experiencing this should see an ophthalmologist or proceed to the closest emergency department immediately. See Box 8.2 for implications of vision changes on an older adult's function.

BOX 8.2

Implications of Vision Changes in Older Adults

Impact on safety
- Inability to read medication and food labels
- Decreased health literacy
- Difficulty navigating stairs or curbs
- Difficulty driving
- Difficulty crossing streets

Impact on quality of life
- Reduces ability to remain independent
- Difficulty or unable to read
- Falls

INTERVENTIONS AND CARE STRATEGIES

Vision

The nurse should obtain a past medical history to avoid disruption in the management of chronic eye conditions, ensuring continuation of ongoing regimens, such as eye drops for glaucoma. Without the continuation of the individual's eye drops, eye pressures could precipitously increase, causing an acute exacerbation of the glaucoma, potentially dramatically limiting vision. If an acute change in an individual's vision occurs, the primary care provider should be notified immediately. Depending on the signs and symptoms present, the individual may need to see an ophthalmologist or go to the emergency department to receive treatment to restore the vision or limit the deterioration. Many cities have ophthalmological emergency rooms.

Proper lighting is essential to optimize vision within an environment. Too little light can limit an individual's vision. Too much light, depending on the individual's eye condition, such as cataracts, macular degeneration, or glaucoma, may cause eye pain and glare. It is important to ascertain whether an individual is sensitive to light. If he or she is sensitive to light, indirect light and night lights may be helpful to provide a safe environment. The majority of older adults benefit from improved lighting. To avoid glare, directing incandescent lamps directly on a task, such as sewing or reading, often improves visual acuity and is well tolerated. Glare occurs when a light shines directly into the eye or reflects off a shiny surface. Therefore, people with glaucoma, diabetic retinopathy, and cataracts may benefit from additional lighting that is properly directed to avoid problems with glare (Perlmutter et al., 2013). Low-vision specialists recommend trying different positions and wattage of lighting to find what works best for each individual. There are lighting assessments, but more evidence is needed to support their use (Wittich, Amour, Jarry, & Seiple, 2018).

Encourage the use and proper fitting of eyeglasses. Older adults' eyeglasses should be labeled with the person's name so they can be returned to the owner if they are set down and left behind. Even with eyeglasses, magnification may be helpful. Additional lighted magnification can improve functional vision. (Large lighted magnifiers are available from low-vision centers.) A low-vision optometrist or specialist can assist in recommending the appropriate level of magnifier.

Contrast sensitivity is associated with several eye conditions, including cataracts, glaucoma, and macular degeneration. Adding contrast to the edge of each step, fixtures in the home, light switches that blend into the wall, or faucets that blend into the sink can create a safer and more functional environment. In addition, having contrasting colors in bathrooms, particularly around toilets and sinks, facilitate higher functioning with activities of daily living.

Annual screening is not recommended by the U.S. Preventive Services Task Force (2016) in the older adult. However, nurses should encourage an annual dilated eye exam either with an optometrist or ophthalmologist, particularly for those with hypertension, diabetes, or complaints of vision changes (AAO, 2020a). More frequent eye exams may be needed for older adults with diabetes or hypertension, glaucoma, and macular degeneration (AAO, 2020a). Nurses are members of the interprofessional team responsible for preventing unnecessary disability. Therefore, nurses should make sure that there is a mechanism in place to trigger eye exams on an annual basis.

Hearing Impairment

Owing to the slow, insidious development of hearing impairment, surveys to identify older adults with hearing impairment often suffer from underreporting on self-report instruments. The latest version of the NHANES included audiometric testing in older adults and found a prevalence rate of 45.6% in those between 70 and 74 years, and 80% of adults 85 years and older have disabling hearing loss (Blazer et al., 2016; Lin et al., 2013; National Institute on Deafness and Other Communication Disorders [NIDCD], 2018). Hearing loss has been found to be greater in men and progresses more quickly than in women (Chao & Chen, 2009, 2018). And less than a third of those who could benefit from a hearing aid have ever used them (NIDCD, 2018). This dramatic increase in prevalence rates is magnified in the nursing home population. Prevalence rates of hearing impairment in the nursing home are similar to rates of visual impairment, at approximately 24% (Warnat & Tabloski, 2006). When hearing is tested through audiometry, the prevalence rates increase to 42% to 90% (Bagai, Thavendiranathan, & Detsky, 2006; Cacchione et al., 2003; Tolson, Swan, & Knussen, 2002). The American Academy of Audiology defines hearing loss based on decibels or loudness and the Hertz or the pitch of sound. Normal speech is in the 0 to 25 dB range, mild hearing loss is defined as hearing between the 26-40 dB range. Hearing loss between the 41-55 dB range is moderate; 56-70 dB is considered moderately severe and 71 to 90 dB is severe hearing loss. Hearing loss 91 dB and over is considered profound hearing loss (Clark, 1981). Aging impairs the processing of sound through the ear canal peripherally as well as through central auditory processing, making it more difficult to hear the higher frequencies, including women's and children's voices (Patel & McKinnon, 2018).

Assessment of Hearing

Despite the U.S. Preventive Services Task Force not having sufficient evidence to recommend routine hearing screening in older adults, it is essential that older adults are assessed for hearing impairment (Bainbridge & Wallhagen, 2014; Wallhagen & Reed, 2018). Older adults with age-related hearing loss (ARHL) have greater difficulty hearing consonants within words that convey the meaning within a word, are used to separate syllables, and indicate separation of words (Patel & McKinnon, 2018). Often, it is easy to determine when an older adult is hard of hearing just by having a conversation with him or her. The older adult may lean in closer in an attempt to hear better, turn the head to the "good ear," or cup a hand behind the ear. Older adults may have to ask for things to be repeated; they may report having trouble hearing their grandchildren's or others' high-pitched voices. Older adults often complain that people are mumbling. Any or all of these signs may be present. Regardless of whether any of these signs are present, all older adults should have their hearing screened annually at their primary care visit (Patel & McKinnon, 2018). Primary care providers play an important role in screening for hearing loss and making appropriate referrals for older adults for an evaluation by a specialist (Patel & McKinnon, 2018). Methods of screening are described herein.

Hearing Handicap Inventory for the Elderly—Screen

The Hearing Handicap Inventory for the Elderly—Screen (HHIE-S; Ventry & Weinstein, 1983) is a 10-item scale used to determine how hearing is impacting an older adult's daily life and to assist in identifying who might benefit from a hearing aid and an audiology referral. The scale takes approximately 5 minutes to complete and is targeted for community-dwelling older adults. This scale is available online through the Hartford Foundation Institute for Geriatric Nursing "Try This: Best Practices in Care for Older Adults" (Demers, 2001). The HHIE-S has reported excellent sensitivity and specificity for severe hearing loss, but the sensitivity and specificity decrease as the level of hearing impairment lessens (Adams-Wendling, Pimple, Adams, & Titler, 2008).

Whisper Test

The whisper test involves covering the tragus of the opposite ear canal, and, from a distance of 2 feet, whispering a three-syllable word or a combination of three letters and numbers on an exhale. The person being tested then either correctly or incorrectly repeats the word or letter–number combination back (Strawbridge & Wallhagen, 2017). An incorrect response triggers a repeat attempt to see whether the older adult can identify a different three-syllable word or number–letter combination. The consistency of the level of the whispered word makes this test difficult to compare from examiner to examiner (Strawbridge & Wallhagen, 2017).

Finger Rub Test

Nurses can perform this quick and reliable assessment in any quiet setting (Wallhagen & Reed, 2018). With the person seated comfortably in the chair, the tester stands behind the person, and first rubs his or her fingers together next to the seated person's ear, one ear at a time, to familiarize the person with the sound. Then, the tester performs a finger rub test with his or her arms extended approximately 27 inches on each side (Strawbridge & Wallhagen, 2017). The person being tested has three trials to hear the finger rub on each ear. They must successfully hear the sound either on the first or second finger rubs even though three trials are performed. If they do not hear a finger rub on the first two trials, it is considered a positive screen for possible hearing loss. This test has a sensitivity of 91% and a specificity of 68%, and a positive predictive value of 88% and a negative predictive value of 74% (Strawbridge & Wallhagen, 2017).

Handheld Audioscope

The handheld audioscope is a device developed to specifically screen for hearing impairment. It has a test tone that is presented at the 60-dB level. The decibel levels that may be tested include the 20-, 25-, and 40-dB levels at the 500-, 1,000-, 2,000-, and 4,000-Hz levels (Strawbridge & Wallhagen, 2017). The audioscope has an otoscope that allows for the direct inspection of the tympanic membrane or cerumen impactions, which can result in conductive hearing loss present in up to 30% of older adults (Lewis-Cullinan & Janken, 1990; Yueh, Shapiro, MacLean, & Shekelle, 2003). Testing using the audioscope should be performed in a quiet setting and may not be as useful in the long-term care environment with high noise levels. Strawbridge and Wallhagen (2017) recommend screening in the primary care setting using the finger rub test or a direct question: "Do you feel you have any difficulty with your hearing?" If they fail the finger rub test or answer yes to the direct question, an otoscopic exam should be performed, and if cerumen is not blocking the canal, a referral for audiometry is indicated.

Pure Tone Audiometry

Pure tone audiometry is the gold standard of hearing tests, particularly if completed in a soundproof booth with 92% sensitivity and 94% specificity in detecting sensorineural

hearing loss (Frank & Petersen, 1987). Pure tone audiometry allows for testing of a wide range of decibels and Hertz levels, or loudness and pitch or frequencies, allowing for testing in the 5- to 120-dB range and 250 to 4,000 Hz. Portable pure tone audiometers with noise-reduction earphones are available and can be used in the community, outpatient, and long-term care settings when access to an audiologist is limited. This wide range of tones allows for a better understanding of the individual's functional hearing. Pure tone audiometry by an audiologist is the next step after screening has identified a hearing deficit (Strawbridge & Wallhagen, 2017).

Hearing Changes Common in Older Adults

Conductive hearing loss usually involves abnormalities or injury to the middle or external ear, including the ear canal, tympanic membrane, and ossicular chain of bones in the middle ear; air conduction thresholds will be higher than bone conduction thresholds (Blazer et al., 2016). Causes of conductive hearing impairment include cerumen impactions or foreign bodies, ruptured eardrum, otitis media, and otosclerosis (Wallhagen et al., 2006; Yueh et al., 2003).

Sensorineural hearing loss is the most common form of hearing loss in older adults and is identified when air conduction and bone conduction thresholds are similar but below normal hearing (Blazer et al., 2016). Sensorineural hearing loss involves damage to the inner ear, the cochlea, or the fibers of the eighth cranial nerve. The hearing loss is usually a bilateral, progressive onset, and is caused by gradual loss of hair cells and fibrous changes in the small blood vessels that supply the cochlea. Risk factors include heredity, environmental exposure, free radical, and mitochondrial DNA damage (Huang & Tang, 2010, National Institute on Aging [NIA], n.d.). Sudden sensorineural hearing loss can occur rapidly or over a period of 3 days. It is a medical emergency, and an individual should seek medical attention immediately (NIA, n.d.).

Central auditory processing disorder is an uncommon disorder, with prevalence ranging from 0.75% to 14.3% (Gates, Cooper, Kannel, & Miller, 1990; Quaranta et al., 2014). This disorder is defined as difficulties in the perceptual processing of auditory information in the central nervous system and the neurobiological activity that underlies the processing and gives rise to the electrophysiologic auditory potentials (Atcherson, Nagaraj, Kennett, & Levisee, 2015). Older adults with this condition have an inability to process incoming signals and may be found among patients with stroke and other neurological conditions such as Alzheimer's disease and Parkinson's disease (Atcherson et al., 2015). The person's hearing is often intact, but his or her ability to process the sound is impaired, resulting in impaired speech understanding (Quaranta et al., 2014). Persons with central auditory processing changes have been identified through the following behavioral tests: speech-in-noise processing, dichotic processing, and temporal processing (Atcherson et al., 2015).

Tinnitus, otherwise known as *ringing in the ear*, is the perception of sound without an external source and has an estimated prevalence of 10% to 15% (NIDCD, 2017e; Tunkel et al., 2014). There are two classifications of tinnitus: primary or secondary. Primary tinnitus is idiopathic or associated with sensorineural hearing loss. Secondary tinnitus is associated with a specific underlying cause or condition (Tunkel et al., 2014). Subjective ringing in the ears may fluctuate and can be caused by noise-induced damage to the hair receptors of the cochlear nerve and age-related changes in the organs of hearing and balance. Secondary tinnitus can be caused by hormonal changes, thyroid disorders, and tumors (NIA, n.d.; Tunkel et al., 2014). Patients with tinnitus should be referred to an ear, nose, and throat (ENT) specialist.

Ménière's disease is characterized by fluctuating hearing loss, dizziness, vertigo, tinnitus, and a sensation of pressure in the affected ear (Hussain, Murdin, & Schilder, 2018; NIDCD, 2017b). Ménière's disease typically begins between ages 40 and 60 years, and sometimes it resolves on its own (NIDCD, 2017b). Unfortunately, the fluctuating hearing loss can become permanent hearing loss over time. Possible causes of Ménière's disease include vascular constriction similar to that found in migraines, as well as viral infections, allergies, and autoimmune disorders, and may have a genetic component as Ménière's disease tends to run in families (NIDCD, 2017b). Persons who report the previous signs and symptoms should be referred to an otolaryngologist.

Implications of Hearing Changes

Older adults who have hearing impairment experience a decreased quality of communication, social isolation, low self-esteem, and generally lower quality of life. More recently, older adults with hearing impairment have been identified as being at higher risk of poor physical functioning, falls, healthcare expenditures, and dementia, as well as higher mortality rates (Goman & Lin, 2018; Karpa et al., 2010; Lin et al., 2013; Tahden, Giesler, Meis, Wagener, & Colonius, 2018). Decreased hearing impacts an individual's word recognition, decreasing the ability to communicate. This, in turn, can lead to significant safety issues. For example, if patient education about medication

administration is provided only verbally, key information can be misheard and misinterpreted. Difficulty understanding the spoken word can lead to fatigue and speech paucity of friends and loved ones, decreasing social engagement (Tahden et al., 2018).

Speech paucity is described as decreased attempts to have meaningful conversations because of the difficulty in getting the message through to a hearing-impaired loved one. Speech paucity (Wallhagen et al., 2006) leads to social isolation of the hearing impaired because only the necessary information is transferred and no everyday social information is shared (Wallhagen et al., 2004). This can lead to depression and low self-esteem in the hearing-impaired individual and the partner. Other factors that lead to social isolation in hearing-impaired older adults include the inability to hear the phone or the doorbell ringing or knocking at the door.

Ideally, older adults who develop hearing loss will see an audiologist and obtain unilateral or bilateral hearing aids or other audiological interventions to improve their ability to communicate with the people around them. Unfortunately, the stigma, cost, and delay in pursuing hearing aids are barriers to their success. Hearing aids should be pursued early in the course of hearing impairment. For example, hearing aids can be very helpful when hearing is impaired to the point that background noise interferes with understanding the spoken word. Success in using hearing aids at this level of hearing improves the chance that older adults will continue with hearing aids. Once an individual is offered a hearing aid, hearing rehabilitation should accompany the hearing-aid dispensing; this will increase the use of the hearing aid and positively impact his or her independent living and quality of life (Bainbridge & Wallhagen, 2014; Tahden et al., 2018). Once older adults become used to the silence, it is hard to adapt to the increased ambient noise heard with hearing aids. Often, older adults require extensive coaching from an audiologist to get through the transition phase of wearing hearing aids. Technological advancement has resulted in analog hearing aids that can be finely tuned to the individual's needs (Bainbridge & Wallhagen, 2014). In one intervention group of older adults fitted with hearing aids, 98% experienced benefit, and their caregivers perceived significant benefit as well (Tolson et al., 2002). University settings are often the most cost-effective locations to pursue hearing aids. The cost of hearing aids is an important factor because most insurance plans, including Medicare, do not cover hearing aids, but will cover cochlear implants.

Osseointegrated auditory implants are approved in the United States for unilateral hearing loss or those with conductive/mixed hearing loss (Blazer et al., 2016; Patel & McKinnon, 2018). These devices are similar to bone-anchored hearing aids (BAHA) that were developed following patients with dental implants reporting perceptions of sound through their dental implants (Patel & McKinnon, 2018). Older adults experience improved hearing and speech recognition in noisy settings but no improvement on sound localization after being fitted with a BAHA (Kim et al., 2017). As a result, they have become an alternative to traditional hearing aids in specific cases to improve function and quality of life in persons with unilateral conductive or mixed hearing loss (Kim et al., 2017; Patel & McKinnon, 2018).

Cochlear implants are another technological advancement that has demonstrated positive outcomes in profoundly deaf or severely hard-of-hearing older adults in the areas of speech recognition (NIDCD, 2017a). Cochlear implants are an effective intervention for older adults who do not benefit from amplification (Patel & McKinnon, 2018). A cochlear implant works by bypassing the damaged parts of the ear and stimulating the auditory nerve. These impulses are sent to the brain through the auditory nerve, and the brain recognizes them as sound (NIDCD, 2017a). Severe hearing impairment must be present unilaterally or bilaterally before this surgical intervention, under general anesthesia, is considered. In one study, cochlear implants were found to improve the ability to understand speech (NIDCD, 2017a). Currently, there is only evidence for unilateral cochlear implants in profoundly deaf adults rather than bilateral cochlear implants because of limited functional gain (Patel & McKinnon, 2018). Despite these improvements, relatively few adults have received this new technology. As of 2012, according to the U.S. Food and Drug Administration, nearly 58,000 adults have received cochlear implants (NIDCD, 2017a). Older cochlear implant users show greater confidence and participation in social situations than prior to their cochlear implant (Patel & McKinnon, 2018).

Smell and Taste

Smell and taste are two senses that are difficult to separate because they overlap, particularly when food is involved. These two senses are dependent on chemosensation, the ability of the nose, mouth, and throat to identify tastes and smells based on chemical reactions through receptors in the nasal airway; retronasal air flow; and taste buds on the tongue, palate, oropharynx, larynx, upper esophagus, and intestine (DeVere, 2017). Smell and taste ability decline later in life, with more than 75% of persons over age 80 exhibiting a significant decline in smell and taste (Doty, 2018). Often, when people go to their primary care provider as a result of having lost their sense of taste, they are

surprised to learn that they have a smell disorder instead (Doty, 2018). The sense of smell and ability to identify odors decrease owing to normal changes in aging. This can be problematic for safety reasons. One study found that persons who could not smell, anosmics, were three times more likely than those who could smell (normosmics) to have experienced a potentially life-threatening event, including ingestion of spoiled food or failure to detect smoke or leaking natural gas (Pence, Reiter, DiNardo, & Costanzo, 2014). Studies have also linked the loss of smell to Alzheimer's disease and Parkinson's disease (Devanand, 2016; Doty, 2017; Mesholam, Moberg, Mahr, & Doty, 1998; Vasavada et al., 2015). Taste problems are rare, with less than 20% of patients with altered taste actually having a primary taste disorder (DeVere, 2017).

Changes in Smell and Taste Common to Older Adults

There are four types of olfactory disorders: (a) *Hyposmia* is the reduction of the sense of smell, (b) *parosmia* is the distortion in the sense of smelling the presence of an odor, (c) *anosmia* is no sense of smell, and (d) *phantosmia* is the perception of an odor when no odor source is present (Doty, 2017; NIDCD, 2017c). Olfactory disorders impact quality of life and increase mortality in older adults (Devanand et al., 2015; Pinto et al., 2014). Common complaints from people with olfactory disorders include difficulty with cooking, decreased appetite, eating spoiled food, too little perception of body odor, and inability to detect gas leaks or smoke (DeVere, 2017).

Because of the impact disorders of taste and smell have on quality of life and mortality, it is important to take a complete history and physical examination with older adults. A thorough cranial nerve exam and head and neck examination should be included. In addition, neurological disorders such as head trauma, multiple sclerosis, Parkinson's disease, and Alzheimer's disease negatively impact smell (DeVere, 2017). If an older adult has a subjective complaint of decreased sense of smell or if an olfactory disorder is identified, the individual should be referred to an otorhinolaryngologist by the primary care provider.

Most changes in taste are thought to occur because of an oral condition, xerostomia (dry mouth), decreased sense of smell, medications, diseases such as diabetes, gastroesophageal reflux disease, hypothyroidism, liver and kidney disease, malnutrition, and tobacco use (DeVere, 2017; Doty, 2018). However, a thorough neuro exam is indicated. Cranial nerves V, VII, IX, and X play an important role in taste and tongue sensation (DeVere, 2017). Dysgeusia is defined as a condition in which a foul, salty, rancid, or metallic taste sensation persists in the mouth and can be associated with burning mouth syndrome (NIDCD, 2017d). Additional taste disorders include hypogeusia, which is the decreased ability to taste sweet, sour, bitter, salty, or savory tastes; and ageusia, which is the inability to detect any tastes (NIDCD, 2017d). However, because of the poor outcomes for older adults with taste disorders, referral for treatment is indicated either to an otolaryngologist, neurologist, or a subspecialist at a smell and taste center (DeVere, 2017; Doty, 2018).

As with olfactory disorders, disorders of taste are often identified on history, not by physical examination. There are very few tests to assess for taste disorders. Therefore, the history is essential. Substance abuse, including tobacco, alcohol, and cocaine, should be reviewed. The individual's dietary habits should be reviewed. Questions regarding recent dental work or procedures should also be asked. Ascertaining whether the individual has a history of gastric reflux could reveal manageable conditions impacting taste. Other potential causes of taste disorders include upper respiratory and middle ear infections, radiation therapy for head and neck cancers, exposure to chemical and certain medications, head injury, and poor oral hygiene (DeVere, 2017). A thorough review of medications is fundamental in the evaluation of a taste disorder (Doty, 2018).

Diseases That Alter Taste Seen More Frequently as People Age

Burning Mouth Syndrome

Burning mouth syndrome is a burning pain that is burning, scalding, or tingling in the mouth that lasts months or longer (National Institute of Dental and Craniofacial Research [NIDCR], 2017). This syndrome is most common in middle-aged and older women and is difficult to diagnose and may require evaluation by a dentist who specializes in oral medicine or oral surgery (NIDCR, 2017). Primary burning mouth syndrome is thought to be a neurological condition. Secondary burning mouth syndrome can be caused by vitamin B deficiencies, local trauma, gastrointestinal disorders causing reflux, allergies, salivary dysfunction, oral candida, medications, and diabetes (NIDCR, 2017).

Xerostomia

Xerostomia, the sensation of dry mouth, is common with many systemic conditions, medical management, radiation therapy, and prescribed medications used for older adults (Anil et al., 2016), including anticholinergic medications, antidepressants, antihistamines, angiotensin-converting enzyme inhibitors, lipid-lowering agents, antiparkinsonian

medications, and anticonvulsants, to name a few (Anil et al., 2016).

Implications of Taste and Smell Changes

Inability to smell limits some of the pleasures of everyday life, decreasing quality of life. The smell of a spring rain, of a Christmas tree, of flowers, or of coffee brewing may not be detectable. Taste is diminished because of the inability to smell. Of significant concern in older adults who have smell and taste disorders is malnutrition. Appetite is detrimentally affected because of the inability to smell and taste the food. Inability to smell is a safety hazard because of the inability to smell smoke in a fire or a gas leak. Decreased sense of taste may also result in inability to recognize spoiled food, resulting in nausea, vomiting, or infectious diarrhea. Because decreased sense of smell is associated with neurodegenerative diseases and increased mortality (DeVere, 2017; Doty, 2018), it is important to investigate potential reversible causes for a person's decreased sense of smell.

Peripheral Sensation

Peripheral sensation describes the way in which nerves send signals back and forth from the extremities to the central nervous system and back again (National Institute of Neurological Disorders and Stroke [NINDS], 2019). Sensation is disrupted due to over 100 different types of peripheral neuropathies, and symptoms vary depending on the type of nerves affected: motor, sensory, or autonomic (NINDS, 2019). In an NHANES study of older adults, older than 70 to 79 years, 28% reported the loss of feeling in their feet; this increased to 35% in adults older than 80 years (Dillon et al., 2010). Unfortunately, poor nerve function can increase late-life disability (Ward et al., 2014). Common disorders that increase the risk of peripheral neuropathy include diabetes; alcoholism; autoimmune disorders; osteoporosis with compression fractures; peripheral vascular disease; infections; nutritional deficiencies, particularly of vitamins (e.g., thiamine and B12); malignancies; and chemotherapy agents (NINDS, 2019). Mechanoreception (sense of touch) and thermoception (sense of temperature) along with pain provide critical environmental information that can be protective (Heft & Robinson, 2017). Therefore, it is essential to take complaints about decreased peripheral sensation seriously. Therefore, owing to the multitude of risk factors for peripheral neuropathy, a neurology consultation is recommended for complicated presentations of peripheral neuropathy to help determine the appropriate evaluation and management of the condition.

Changes in Peripheral Sensation Common to Older Adults

Conditions that alter peripheral sensation are seen more frequently as people age and include peripheral neuropathy, diabetic neuropathy, phantom limb pain, and acute sensory loss.

Peripheral Neuropathy. This is a heterogeneous group of disorders (Merkies, Faber, & Lauria, 2015) that present with nerve pain in the distal extremities related to nerve-fiber damage in the motor, large sensory, small sensory, and autonomic nerve fibers from underlying systemic illnesses, neurotoxic drugs, primary disorders of the immune system, and hereditary disorders (Merkies et al., 2015). The most commonly suspected causes are circulatory problems (peripheral vascular disease and diabetes) or vitamin deficiencies. Common vitamin deficiencies that impact peripheral nerves include thiamine and B12.

Diabetic Neuropathy. This is end-organ damage to the peripheral nerves from microvascular changes that occur with diabetes. It often leads to loss of sensation in the feet as well as balance and mobility deficits in diabetics, contributing to undetected skin trauma to the extremities and falls (Deshpande, Hewston, & Aldred, 2017). Diabetic neuropathy–related skin trauma often causes refractory infections because of poor vascular supply to the extremity. It is extremely important to teach diabetics and patients with peripheral neuropathy to provide special attention and care to their feet.

Phantom Limb Pain. This is the experience of pain that can range from dull ache to crushing pain where an amputated limb once was. The sensory cortex of the brain has influence in this mechanism. This pain is often chronic and requires special interventions for control and management, including electronic prosthetics, analgesics, and psychosocial support.

Acute Sensory Loss. Acute sensory loss may be caused by a stroke, acute nerve entrapment in the spine, traumatic nerve damage, or compartment syndrome, resulting from trauma to a limb. This sensory loss presents with acute onset of numbness, tingling, severe nerve pain, or lack of sensation and function in the affected extremity and is a medical emergency. Persons presenting with acute sensory loss should proceed to the nearest emergency department.

Implications of Peripheral Sensation Changes

Inability to recognize position sense, pressure, or to ascertain where feet are positioned on the floor can lead to falls,

burns, lacerations, calluses, and pressure ulcers. Intact peripheral sensation is essential for remaining safe in the environment.

Nursing Assessment and Care Strategies of Peripheral Sensation

Nurses should take appropriate health histories to ascertain the presence of decreased sensation or pain in limbs. In addition, a thorough inspection and physical examination of the individual's legs and feet or the affected extremity is also important. Diabetics and people known to have peripheral neuropathy should have thorough neurological exams, including vibratory sense with a tuning fork over bony prominences. The Semmes–Weinstein monofilament test is also recommended. This test was developed to identify persons at risk for neuropathic ulceration typically of the feet (Yildirim & Gunduz, 2015). Position sense and kinesthetic sense, the sense of movement, should also be tested (Landelle et al., 2018). A referral to neurology may be necessary for nerve conduction testing, which is the most important tool in the diagnostic workup of older adults with suspected peripheral neuropathy (Barrell & Smith, 2019).

Semmes–Weinstein Monofilament Test

This inexpensive simple procedure is used to screen for decreased sensation in several plantar sites on the foot. The Semmes–Weinstein monofilament is placed against the sole of the foot in eight different areas on the foot and not tested on calluses. The individual is asked to report when he or she perceives any sensations (Martinez-Hervás et al., 2017). The Semmes–Weinstein nylon monofilament 5.04 gauge buckles at a pressure of 10 g. Loss of sensation at this level of pressure indicates a risk for neuropathic ulcer development (Yildirim & Gunduz, 2015). Identification of this risk is important for improving the vigilance of foot care.

Vibratory Sense

This is assessed by using a 128-Hz vibrating tuning fork on a lower extremity bony prominence. The examiner places the vibrating tuning fork on the bony prominence and asks the individual whether he or she feels any vibration. Older adults should be able to feel the vibration.

Proprioception

This is the ability of individuals to determine where they are in space. To assess for deficits in proprioception in the feet that may set the older adult up for falls and local trauma, the examiner has the individual close his or her eyes and then holds the large toe on the sides and moves the toe up or down and asks the individual to identify which direction the toe was moved. Inability to correctly identify the direction is an indication of decreased proprioception.

CASE STUDY 8.1

Mr. Sweets is a 75-year-old African American male living by himself in the community. He lives in a senior apartment building, where he receives housekeeping services and can participate in a meal plan if he likes. He arrives on the acute care of the elderly (ACE) unit in your hospital with a diagnosis of hyperglycemia and a urinary tract infection. He also has a history of hypertension, hyperlipidemia, and osteoarthritis of the left hip. He is widowed and has three children: two live in the area, the other lives out of state. He is a retired aeronautical engineer. His medications include metformin, 1,500 mg daily increased from 1,000 mg; Zocor, 40 mg orally daily; lisinopril, 20 mg daily; hydrochlorothiazide (HCTZ), 25 mg daily; and Tylenol Extra Strength, 1,000 mg three times a day for his hip discomfort.

On your admission assessment, you discover that he remembers receiving verbal instructions to cut his diabetic pills in half. Thus, since that appointment, he has been taking only 500 mg of metformin instead of 1,500 mg. His primary care provider had instructed him to take one and one half tablets of his metformin, not just half a tablet. You were not sure whether this was just a misunderstanding or whether Mr. Sweets was having difficulty hearing. You are also concerned that his vision may be a problem as well because of his 5-year history of known diabetes.

After you complete taking your history, you gather your supplies to complete your physical exam. Your supplies include an audioscope; Lighthouse for the Blind Near Vision Screener; three plastic bags—one full of coffee, baby powder, and peppermint candies—a 128-Hz tuning fork; and a Semmes–Weinstein monofilament test. The audioscope reveals that Mr. Sweets's ear canals are completely occluded with cerumen and that he can hear only the test tone that is delivered at the 60-dB level. On the near vision screener, he scored 20/125 in both eyes with his dirty

(*continued*)

CASE STUDY 8.1 (*continued*)

glasses. Unfortunately, because his blood sugar currently is and has been elevated, it is unclear how much of the decreased vision is caused by his elevated blood sugar and how much is related to possible refractive error or diabetic retinopathy. Mr. Sweets was able to correctly identify each scent in the plastic bags. When you examine his feet, you identify that he has significant sensation loss on the bottom of his feet. He has intact vibratory sense in the ankle, but his vibratory sense is decreased in both great toes. His feet are currently free of any calluses, deformities, or open wounds. He does have some thickened toe nails.

Discussion

These assessments impact the care plan for Mr. Sweets. His sensory deficits most likely precipitated his hospital admission. Written instructions may have helped prevent this, but his near vision may have interfered with the understanding of the written directions as well. He should have written instructions in large font, because of his vision, ideally in 14- to 16-point type. Because of bilateral cerumen impactions, he will need to begin using cerumen softening drops and have the cerumen removed with a cerumen spoon or irrigation after a few days. If this is not successful, he may need to be seen by an otolaryngologist (ear–nose–throat [ENT] physician) to have the cerumen removed. If his hearing is still impaired after the cerumen is removed, Mr. Sweets should see an audiologist.

Based on your history, he was last seen by an ophthalmologist 3 years ago. He should be seen by an ophthalmologist to determine whether any treatments for his diabetic retinopathy are necessary. He should receive anticipatory guidance to see an ophthalmologist every 6 months to yearly because of his diabetes. He would qualify for low-vision services if his acuity remained at 20/125. He would also benefit from increased contrast. Older adults with diabetic retinopathy often need enhanced contrast. This can be achieved by adding red to light-colored fixtures and white to dark-colored fixtures, remote controls, and other electrical devices that are usually solid colors with limited contrast. A low-vision specialist could be very helpful here to make his home environment safe and user friendly.

Mr. Sweets should be evaluated by a diabetic foot nurse and a podiatrist to have his nails trimmed and to learn more about foot care. He will need to learn how to complete daily foot inspections as well as assistance learning what type of footwear is appropriate for his feet. His hip may cause him some difficulty reaching his feet. It will be important for him to use mirrors and palpation to assist him in his self-care. A diabetic nurse educator can assist him with further information on the management of the disease and empower him to ask more questions and clarify when information does not appear compatible with what his symptoms are.

Mr. Sweets was discharged from the hospital after 4 days. His metformin was increased to 1,500 mg; he is afebrile and discharged on oral antibiotics for his urinary tract infection. He had his glasses cleaned and ears cleaned out over those 4 days, so his hearing has improved to where he can hear at the 40-dB level. He has an appointment to see the audiologist. An appointment was also made for ophthalmology. Follow-up appointments have also been made with the endocrine staff, with the diabetic nurse educator, and diabetic foot nurse on the same visit. These appointments were written out on a 4- by 6-inch index card with a black marker that he could read with his glasses. Sensory impairment is an interprofessional healthcare problem. Good communication among disciplines is essential in maintaining Mr. Sweets's functional status and ability to stay in the community. Nurses are best prepared to help Mr. Sweets navigate and coordinate visits to the other disciplines. Screening completed by nurses either in the community, acute care, or long-term care settings can identify problems that have often been passed off by the older adult as the result of normal aging.

SUMMARY

Older adults, owing to normal changes of aging, chronic disease, and environmental factors, are prone to changes in their vision, hearing, sense of smell, taste, and touch. It is imperative that nurses assess for and enhance older adults' senses when possible to decrease the negative sequelae of sensory impairment. Sensory impairment has been linked to negative outcomes in older adults, including poor health literacy, cognitive impairment, falls, other safety risks such as eating spoiled food due to not smelling, and increased risk of death. Individualized-Sensory Enhancement for the Elderly provides a framework within which to address sensory impairment in older adults. This framework includes first assessing an older adult's sensory status, then recommending referrals as indicated, followed by assisting older adults with improving their environment, and using their adaptive equipment to improve the quality of their lives.

NURSING STANDARD OF PRACTICE

Protocol 8.1: Sensory Changes

I. OVERVIEW

The Individualized-Sensory Enhancement of the Elderly (I-SEE) program was developed to tailor nursing interventions to the type and level of sensory impairment experienced by the older adult (Cacchione, 2007). Originally developed to address hearing- and visually impaired older adults, the I-SEE can logically be extended to address sensory impairment in smell, taste, and peripheral sensation. There are three levels to the I-SEE program: nursing assessments, nursing actions, and nursing referrals.

II. NURSING SENSORY ASSESSMENTS

A. History
   1. Ask questions about changes in hearing, vision, sense of smell, and taste, as well as any numbness and tingling in extremities.
   2. Review medications that may be exacerbating the sensory problem, such as anticholinergic medications, antibiotics, aminoglycosides, and high-dose aspirin.
   3. Determine whether symptoms occurred suddenly or gradually.
   4. Clarify whether symptoms are unilateral or bilateral.
   5. Inquire whether the individual has had any prior treatment for sensory conditions.
   6. Ascertain whether sensory conditions interfere with daily function.
   7. Ask about ability to drive; both daytime and nighttime driving can be impacted by visual impairment as well as hearing and the peripheral nervous system.
   8. Determine interest in receiving treatment for these conditions.

B. For each positive symptom reported, gather more information by asking about the following: character, associated symptoms, radiation, location, intensity, and duration, as well as what makes it better, what medications the individual has tried for these symptoms, and what makes it worse. These questions can be easily remembered by using the acronym CAR LID BMW. Answers to these questions provide a better understanding of the individual's concerns.

III. PHYSICAL EXAM FOR ALL SYSTEMS

A. Inspect the external structures of the eyes and ears; examine the ear canal for cerumen using an otoscope.
B. Check visual acuity with a near vision screener and distance acuity measure and contrast sensitivity.
C. Perform whisper test to assess rough hearing. If available in your setting, use a handheld audioscope to assess up to 40-dB hearing. If a greater range of hearing testing is needed, use a portable audiometer with noise-reduction earphones—a referral to audiology may be indicated.
D. Assess the nares; determine whether they are patent using the otoscope.
E. Inspect the mouth and tongue for any obvious lesions, odors, or deviations from normal.
F. Perform a neurosensory exam of the extremities, including a monofilament test.
G. Complete a monofilament test on all diabetics. This test quantifies the level of sensory impairment in the feet of patients with diabetes.
H. Assess vibratory sense of the extremities with a 128-Hz tuning fork and proprioception.

IV. NURSING ACTIONS AND REFERRALS

A. Vision
   1. Avoid disruption in the management of chronic eye conditions by obtaining past history and ensuring continuation of ongoing regimens such as eye drops for glaucoma.
   2. Notify the primary care provider of any acute change in vision.

(*continued*)

Protocol 8.1: Nursing Standard of Practice (*continued*)

3. Encourage the use of good lighting in patient rooms. Avoid glare whenever possible.
4. Encourage the use of the patient's eyeglasses. Have family provide lighted magnification if needed. (These are the large magnifiers with a light attached; available for purchase on a sliding scale at low-vision centers.)
5. Add contrast to the fixtures and electronics in the room if light switches blend into the wall or faucets blend into the sink. Other low-contrast items in the environment include remote controls, television sets, and radios.
6. Encourage annual eye exams either with an optometrist or ophthalmologist.
7. Schedule an annual dilated exam for patients with diabetes and hypertension by an ophthalmologist.
8. Written materials should be provided in at least 14- to 16-point high-contrast fonts with generous white space to improve visual tracking.
9. Encourage use of adaptive equipment.
10. Reinforce referrals for low-vision intervention.

B. Hearing
1. Assess for cerumen impactions. Request cerumen softening drops followed by cerumen removal or ear, nose, and throat consultation.
2. Get the person's attention and face him or her before speaking to assist the individual with lip reading; if female, consider wearing red lipstick to increase the contrast of your lips, a common compensatory mechanism for older adults.
3. Have at least one pocket amplifier on the nursing unit to use with hard-of-hearing individuals.
4. Do not shout at people with hearing impairments, but rather use lower tones of your voice.
5. Provide written instructions (use thick, black marker if person is also visually impaired).
6. Encourage use and ensure appropriate care for hearing aids: remove batteries at night; use brush provided to gently clean the tubes to reduce wax accumulation. Before sending bed linens or clothing to the laundry, determine whether the patient's hearing aid is in his or her ear or in its designated location (bedside table or medication cart).
7. Notify the primary care provider of any sudden change in hearing, including tinnitus or sensations of fullness.
8. Referral to audiologist and/or ENT as indicated (e.g., complicated cerumen impactions, new-onset tinnitus, or vertigo).
9. Encourage use of adaptive equipment, particularly in social settings.

C. Taste and smell
1. Take all complaints of inability or decreased ability to smell or taste seriously. Do not pass them off to medications or poor dentition.
2. Notify the primary care provider of an abrupt change in taste or smell.
3. ENT referral for evaluation for change in smell or taste.
4. Patient teaching should focus on safety issues with odors of gas and spoiled food.
5. Educate seniors to have smoke and carbon monoxide detectors in their homes, date all food in the refrigerator, and evaluate food with methods other than sense of smell and taste.

D. Peripheral sensation
1. Educate every older adult to examine his or her feet daily, as well as to look inside his or her shoes before putting them on each day.
2. Educate the older adult to always wear shoes or protective slippers when he or she is ambulating to avoid unintentional injury to his or her feet.
3. The individual should be instructed to inform his or her primary provider of any lesions, calluses, or red areas.
4. Extremities should be kept clean and thoroughly dry before applying lotion.
5. Encourage the individual to bring in footwear for evaluation by the advanced practice nurse if he or she has concerns about safety. Most medical supply companies carry diabetic healing shoes that have wide toe boxes and Velcro straps that can be purchased for less than $50.
6. Refer diabetics to facilities with certified diabetes educators and foot care specialists.
7. Implement fall precautions and initiate referral to physical therapy for all diabetics with peripheral neuropathy.

(*continued*)

Protocol 8.1: Nursing Standard of Practice (*continued*)

8. Refer all older adults with decreased sensation or circulation to a podiatrist or foot care specialist for ongoing foot care.
9. Encourage a diet rich in thiamine and B12.

V. EXPECTED OUTCOMES

A. Baseline visual acuity and hearing acuity for all older patients will be performed before discharge from the hospital, and on admission to home care or nursing home.
B. Fall precautions should be in place for all older patients with sensory impairments. Older adults should avoid falls and injuries to extremities if they have decreased sensation of lower extremities.
C. Accidental exposure to toxins, either in the air or in food because of decreased sense of smell or taste, should be avoided.

VI. FOLLOW-UP MONITORING

A. Annual vision assessment: Medicaid in most states will pay for a new pair of eyeglasses every 2 years.
B. When vision is worse than 20/125, individuals should be referred to a low-vision specialist to provide training in the use of visual assistive devices.
C. Given that hearing can change significantly over time, an audiological evaluation for hearing-impaired older adults every 2 years is important. Primary care annual visits should ask about hearing impairment, complete an audioscope evaluation, and refer to audiology for positive screens for hearing loss. Some states will pay through Medicaid for one hearing aid under limited conditions. Hearing aids have been shown to be better accepted if older adults receive them when they start having difficulty with word finding with background noise. Encouragement and hearing rehabilitation are needed to improve the consistent use of hearing aids. Audiologists can help train older adults and their families in the use of hearing aids.
D. When abrupt changes in smell or taste are reported, a referral to a dentist or ENT is indicated.
E. Long-term adjustments must be made in the home when smell and taste are affected. First, food should be dated and discarded after 48 hours to avoid accidentally eating spoiled food. Smoke and carbon monoxide detectors must be present.
F. When xerostomia (severe dry mouth) is found, a referral to a dentist is indicated.
G. Older adults with decreased peripheral sensation should be referred to neurology for an accurate diagnosis and followed regularly by a podiatrist or foot care specialist.

VII. INTERPROFESSIONAL CARE OF SENSORY CHANGES

A. Care of the aging senses is an interprofessional endeavor. Nurses who frequently have the most contact with clients can take the lead in assessing and screening older adults for decreased sensory function.
B. Once these deficits are identified, it is important to take the appropriate steps and identify the resources available to the older adult.
C. Occupational therapists, low-vision specialists, audiologists, nutritionists, otolaryngologists, and neurologists are just some of the interprofessionals who may be part of the team caring for the sensory-impaired older adult.
D. Good communication among disciplines is essential to assist the older adult in benefitting from each specialist.

Assessing Cognitive Function in the Older Adult*

Donna M. Fick, Pieter Heeren, and Koen Milisen

9

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the importance of assessing cognitive function.
2. Describe the methods of assessing cognitive function.
3. Compare and contrast the clinical features of delirium, mild cognitive impairment, dementia, and depression.
4. Incorporate the assessment of cognitive function into daily practice.

OVERVIEW

Cognitive function comprises perception, memory, and thinking—the processes by which a person perceives, recognizes, registers, stores, and uses information (Foreman & Vermeersch, 2004). Although alterations in cognitive functioning are inherent to aging, there are criteria that define pathological conditions, such as delirium, mild cognitive impairment, dementia, and depression (American Psychiatric Association [APA], 2013). These disorders have diverse clinical features and causes, but are all characterized by decline from a previously attained level (Sachdev et al., 2014). Clinicians often fail to detect these disorders in older adults, when using only routine history and standard examination (Burton et al., 2012; Douzenis et al., 2010; Torisson, Minthon, Stavenow, & Londos, 2012). This might have serious consequences that include missed opportunities to treat correctable conditions that are impacting the older adult's daily life and to minimize or prevent unfavorable outcomes such as functional decline and death (Bradshaw et al., 2013; Torisson et al., 2012). Assessing cognitive functioning is paramount for the early detection of pathological conditions and for monitoring the effectiveness of interventions (McCarten et al., 2012). The Aging, Demographics, and Memory Study (ADAMS) estimates the prevalence of cognitive impairment of all types to be 14% in people older than 71 (Alzheimer's Association, 2018). Additionally, the Age-Friendly Health Systems initiative, whose goals include making at least 20% of all health systems age friendly by 2020, uses the 4Ms Framework, which includes *mentation* (the prevention, identification, and management of delirium, dementia, and depression across care settings) as an essential dimension of quality care for older adults (Allen & Ouslander, 2018; Fulmer, Mate, & Berman, 2018; Institute for Healthcare Improvement, n.d.).

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

BACKGROUND AND STATEMENT OF PROBLEM

Declines in cognitive function are a hallmark of aging (Gutta & Howell, 2018); however, most declines in cognition with aging have no or minor clinical impact, are not pathological, and do not necessarily indicate signs of neurodegenerative diseases such as Alzheimer's disease (Blazer, Yaffe, & Liverman, 2015). Examples of nonpathological changes include a diminished ability to learn complex information, a delayed response time, and minor loss of recent memory; declines are especially evident with complex tasks or with those requiring multiple steps for completion (Gutta & Howell, 2018). Older adults are diverse and have a lifetime of factors that may impact cognition, and thus, cognitive aging is also diverse, and cognitive functioning levels often vary by individuals and throughout the life span. Additionally, it is important to keep in mind that cognitive impairment and dementia involve much more than just memory problems and forgetfulness and that impairment may present as issues with behavior; ability to do what used to be familiar tasks; or other issues with language, thinking, or changes in behavior (Blazer et al., 2015).

Pathological conditions of cognitive impairment that are prevalent with aging include delirium, mild cognitive impairment, dementia, and depression (depression can also be present without cognitive impairment; please see Table 9.1 for a comparison of the clinical features). Chapters 19, 20, and 21 describe these conditions more

TABLE 9.1

A Comparison of the Clinical Features of Delirium, Mild Cognitive Impairment, Dementia, and Depression

Clinical Feature	Delirium	Mild Cognitive Impairment	Dementia	Depression
Onset	Sudden/abrupt (can be days, hours, or weeks); depends on cause; often at twilight but can occur at any time of day	Insidious/slow; often unrecognized, as impairment does not interfere with daily activities	Insidious/slow but recognizable, as impairment interferes with daily activities; depends on cause	Often coincides with major life changes; often abrupt, but can be gradual
Course	Short; diurnal fluctuations in symptoms; worse at night, in darkness, and on awakening	Long; no diurnal effects, symptoms can improve, stabilize, or progress, yet relatively stable over time, may see deficits with increased stress	Long; no diurnal effects, symptoms progressive yet relatively stable over time, may see deficits with increased stress	Diurnal effects, typically worse in the morning; situational fluctuations in symptoms, but less than that with delirium
Progression	Abrupt	Variable: possibly absent or slow but uneven	Slow but uneven	Variable, rapid, or slow, but generally even
Duration	Several hours to less than 1 month; longer if unrecognized and untreated (sometimes untreatable) and can be persistent or lead to dementia	Months to years	Months to years	At least 2 weeks, can be several months to years
Consciousness	Disturbed	Clear	Clear—possibly disturbed in advanced dementia	Clear
Alertness	Fluctuates from stuporous to hypervigilant	Normal	Normal—possibly disturbed in advanced dementia	Often disturbed
Attention	Inattentive, easily distractible; the person cannot focus on an idea or task. Often considered a "hallmark sign of delirium"	Generally normal; if attention is affected, the person might have difficulties with complex-attention tasks (e.g., complex-problem solving)	Generally normal, depending on the cause; shifting from one (rather simple) attention task to another can be problematic	Often disturbed

(*continued*)

TABLE 9.1

A Comparison of the Clinical Features of Delirium, Mild Cognitive Impairment, Dementia, and Depression *(continued)*

Clinical Feature	Delirium	Mild Cognitive Impairment	Dementia	Depression
Orientation	Generally impaired; disoriented to time and place, should not be disoriented to person	Generally normal	Generally disturbed—impaired in advanced dementia	Selective disorientation
Memory	Recent and immediate impairment, unable to recall events of hospitalization and current illness, forgetful, unable to recall instructions	If memory is affected, mild declines in memory (misplacing things, repeating questions, having troubles keeping track of dates/appointments)	Major declines in memory (unable to recall recent events)	Selective or "patchy" impairment, "islands" of intact memory, recall better if cued, evaluation often difficult because of low motivation
Thinking	Disorganized; rambling, irrelevant, and incoherent conversation; unclear or illogical flow of ideas	If thinking is disturbed, changes in language (e.g., word-finding difficulties) and visuospatial function (e.g., slow to identify roadway hazards) might occur	Difficulty with abstraction, thoughts impoverished; judgment impaired	Intact but with themes of hopelessness, helplessness, or self-depreciation
Perception	Perceptual disturbances, such as illusions and visual and auditory hallucinations; misperceptions of common people and objects common	Intact	Misperceptions usually absent	Intact; delusions and hallucinations absent except in severe cases
Psychomotor behavior	Variable; hypoactive, hyperactive, and mixed	Normal	Normal, may have apraxia	Variable; psychomotor retardation or agitation
Associated features	Variable affective changes; symptoms of autonomic hypo-hyperarousal	The person might attempt to conceal or laugh off cognitive deficits	Affect tends to be superficial, inappropriate; attempts to conceal deficits in intellect; personality changes, aphasia, agnosia may be present; often lacks insight	Affect depressed; dysphoric mood, exaggerated and detailed complaints; preoccupied with personal thoughts; insight present; verbal elaboration; somatic complaints, poor hygiene, and neglect of self
Assessment	Distracted from task; fails to remember instructions, frequent errors without notice	Although a person or relative might report failings, these are often difficult to differentiate from declines inherent to aging. Neuropsychological tests have fairly good norms to detect this difference	Failings highlighted by family, frequent "near miss" answers, struggles with test, great effort to find an appropriate reply, frequent requests for feedback on performance	Failings highlighted by individual; frequent "don't know" answers, little effort; frequently gives up; indifferent toward test: does not care or attempt to find answer

extensively. Several strategies exist to prevent, treat, or slow these conditions (Inouye, Westendorp, & Saczynski, 2014; Langa & Levine, 2014). However, these opportunities exist mainly when and if these conditions are detected early.

Clinicians often fail to evaluate cognitive function when using routine history and standard examination (Burton et al., 2012; Torisson et al., 2012). Hence, early detection of cognitive impairment exists only when cognitive function is assessed (McCarten et al., 2012). Without assessment, these pathological conditions are often un(der)diagnosed (Torisson et al., 2012), and the individuals with these conditions face much greater, accelerated, and long-term cognitive and functional decline and death (Bradshaw et al., 2013; Collard et al., 2018; Liu et al., 2017). Yet it is clear that the assessment of cognitive function is a crucial step in a cascade of strategies to prevent, reverse, halt, or minimize cognitive decline.

ASSESSMENT OF THE PROBLEM

Methods for Assessing Cognitive Function

A two-step approach is recommended for determining the nature of impairment (Cordell et al., 2013; Jackson, Naqvi, & Sheehan, 2013). The first step is screening or assessing for impairment, and the second includes a full diagnostic person-centered clinical and functional evaluation, if necessary. Screening is conducted to briefly determine the presence or absence of impairment. If the assessment results indicate possible impairment, a full evaluation is necessary to make a diagnosis of dementia, delirium, depression, mild cognitive impairment, or some other health problem. The content of a full evaluation varies depending on the patient's presentation and includes tests to find out the etiologies of impairment, rule out reversible conditions or issues, and assess its severity (Cordell et al., 2013).

When a diagnosis is made, appropriate reassessment or *monitoring* is necessary to track cognitive and global functioning over time as a means for following the progression or regression of impairment, especially in response to treatment (Cordell et al., 2013; Shenkin, Russ, Ryan, & MacLullich, 2014).

Instruments to Assess for Cognitive Impairment

Numerous instruments are available to assess cognitive functioning, of which Folstein's Mini-Mental State Examination (MMSE) is one of the most well-known tools (Folstein, Folstein, & McHugh, 1975; Lin, O'Connor, Rossom, Perdue, & Eckstrom, 2013; Tombaugh & McIntyre, 1992). The MMSE consists of 11 items assessing orientation, attention, memory, concentration, language, and constructional ability. Each question is scored as either correct or incorrect; the total score ranges from 0 to 30 and reflects the number of correct responses. A score of less than 24 is often considered demonstrative of impaired cognition. The performance on the MMSE can be influenced by education (individuals with less than an eighth-grade education commit more errors), language (nonnative English speakers commit more errors, which is related to sociocultural differences), verbal ability (the MMSE can be used only with individuals who can respond verbally to questioning), and age (older people do less well; Tombaugh & McIntyre, 1992). Furthermore, it is important to stress that the MMSE is not available for public use without cost (Lin et al., 2013).

The Montreal Cognitive Assessment (MoCA) is an instrument for detecting and monitoring cognitive impairment (Nasreddine et al., 2005). It assesses the following cognitive domains: attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation. The total score is 30 points, and a score of 26 or above is generally considered normal. Validation studies of the MoCA indicate its performance to be equivalent or superior to that of the MMSE, especially in patients with mild cognitive impairment (Dong et al., 2012; Liew, Feng, Gao, Ng, & Yap, 2015). Permission to use or reproduce the MoCA is required in research and commercial settings.

The St. Louis University Mental Status (SLUMS) Exam is an 11-item questionnaire with scores ranging from 0 to 30 (Tariq, Tumosa, Chibnall, Perry, & Morley, 2006). It is designed to identify individuals with mild or early dementia (scores 21–26) through measuring orientation, memory, attention, and executive functions. In a study comparing performance with the MMSE, it was found that although both were equally sensitive for identifying those individuals with dementia, the SLUMS was superior when identifying individuals with mild neurocognitive disorder (Tariq et al., 2006).

As the administration times of the MMSE, MoCA, and SLUMS are quite long (approximately 10–15 minutes for trained users), it is recommended to use a briefer test for screening purposes, such as the Mini-Cog (Borson, Scanlan, Brush, Vitaliano, & Dokmak, 2000), to decide whether it is appropriate to conduct the MMSE or the MoCA. The Mini-Cog is a four-item screening test consisting of a three-item recall and a clock-drawing item; for example, draw the face of a clock, number the clock face, and place the hands on the clock face to indicate a specific time such as 11:10. Although the Mini-Cog is widely used and well known, clinicians might select other brief tools to use in their clinical practice, because there is no optimal

tool to detect cognitive impairment in all settings and patient populations (Cordell et al., 2013; Lin et al., 2013).

Most cognitive screening tests, among the ones mentioned earlier, are initially developed as a measure for global cognitive abilities. Because it is often difficult to make a differential diagnosis (Is the impairment delirium, mild cognitive impairment, dementia or depression, or possibly one superimposed on another?), parallel use of other short instruments, such as the Confusion Assessment Method (CAM; Inouye et al., 1990), the Delirium Observation Screening Scale (DOSS; Detroyer et al., 2014; Schuurmans, Shortridge-Baggett, & Duursma, 2003), or the Geriatric Depression Scale (GDS; Yesavage et al., 1982), can be useful to determine the nature of impairment and to rule out reversible and treatable conditions like delirium and depression. See Chapters 19, 20, and 21 for a more detailed discussion about which screening tool to choose per condition.

It is critically important to rule out reversible and treatable conditions that may be causing the cognitive impairment such as delirium or acute confusion. There are several tools to assess for delirium. The most widely used tool is the CAM, which assesses for evidence of an acute change, inattention, disorganized thinking, and altered level of consciousness. The CAM requires training and the use of another cognitive tool such as the MMSE (Inouye et al., 1990). Another widely used tool, the 3D-CAM, operationalizes the CAM with 10 questions, has high sensitivity and specificity, and can be completed in only 3 minutes (Marcantonio et al., 2014). Another approach is to use a two-step approach with a shorter assessment tool followed up by a diagnostic assessment. The 4AT is a recently designed screening instrument for detecting both delirium and cognitive impairment (Bellelli et al., 2014). Its key features are brevity (administered in less than 2 minutes), no special training required, allows for assessment of "untestable" patients, does not require supplemental materials, and incorporates brief cognitive test items. The 4AT (v 1.2) is free to download and use (www.the4AT.com). Initial validity and reliability tests are promising (Bellelli et al., 2014; Lees et al., 2013), and 4AT accurately excluded delirium and dementia in older patients in the emergency department (O'Sullivan et al., 2018). Another shorter (less than 40 seconds) highly sensitive screen is the Two-Item Ultra-Brief Delirium screen (UB-2), which has a sensitivity to detect delirium of 93% and 96% in persons with dementia (Fick et al., 2015, 2018). The UB-2 uses all 12 months of the year, which has been found to be more sensitive than asking only 6 months backward, in combination with the question, "What is the day of the week?", requires very minimal training, and can be performed by nursing assistants with high reliability (Fick et al., 2018; Zhou et al., 2018). If older adults fail either question, they are positive for delirium, and it should be followed up with another tool such as the CAM or 3D-CAM. The UB-2 form and a video on how to use the UB-2 can be accessed at www.nursing.psu.edu/readi

It is also recommended that formal cognitive testing be supplemented with information from close relatives (Cordell et al., 2013; Langa & Levine, 2014). This information assists in determining the duration of impairment—which is crucial for making a diagnosis—and can be obtained through history taking or the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE; Jorm & Jacomb, 1989) and/or the Family Confusion Assessment Method (FAM-CAM; Steis et al., 2012). Another brief informant interview is the Eight-Item Interview to Differentiate Aging and Dementia (AD8; Galvin et al., 2005). Memory, orientation, judgment, and function questions assess any change in the ability of the patient to remember appointments, keep track of current events, express level of interest in hobbies, and balance a checkbook. The AD8 has documented face validity, established in clinical research citing the Clinical Dementia Rating (CDR) and the IQCODE as evidence. The AD8 was also validated as a direct assessment independently administered from an informant interview (Galvin, Roe, Xiong, & Morris, 2006). The Neuropsychiatric Inventory (NPI; Kaufer et al., 2000) and caregiver burden assessments (Adelman, Tmanova, Delgado, Dion, & Lachs, 2014) can also be used to obtain information from relatives.

Formal screening is not always possible. When a patient is too sick for formal testing (e.g., inattentive or responding unusually or inappropriately to conversation or questioning), naturally occurring observations during daily and routine contacts with the patient (e.g., during bathing, feeding, transferring the patient) can be used to evaluate an individual's cognitive functioning easily and in a nonthreatening way. The Nurses' Observation Scale for Cognitive Abilities (NOSCA) was developed and validated to standardize the reporting of these observations (Persoon, Banningh, van de Vrie, Rikkert, & van Achterberg, 2011; Persoon et al., 2012).

When time is scarce, at minimum, it is necessary to establish whether a patient fulfills the criteria for delirium (Inouye et al., 1990), because delirium is reversible in most cases, and older adults with delirium have the highest risk for severe short-term adverse outcomes (Witlox et al., 2010). Therefore, in expectation of formal screening results, the use of the instruments mentioned earlier should temporarily be substituted by assessment of orientation (to time and place) and attention (e.g., naming of days of the week, no errors should be allowed; or months of the year backward, no errors should be allowed; serial sevens [i.e.,

in subsequently subtracting 7 from 100], one error should be allowed for five subtractions; or digit spans backward [i.e., the length of the longest list of digits that a person can recite backward, normally three or more]). Any suspected or uncertain cases should be handled as delirious until proven otherwise (Inouye et al., 2014).

When screening results indicate impairment, referral to a specialist setting (e.g., memory clinic, neuropsychologist, psychiatrist, advanced practice nurse) is necessary for more diagnostic workup (i.e., extensive history taking, clinical and neurological examination, extended neuropsychological assessment, brain imaging, blood sampling, etc.). If an impairment is detected, it is critical to provide follow-up and community support with resources for the older adult and his or her caregiver or family. Chapters 19, 20, and 21 describe more extensively how a differential diagnosis can be made.

When to Assess Cognitive Function

As there is insufficient evidence supporting universal screening for cognitive impairment in older patients (Moyer, 2014), screening interventions are usually applied to a smaller group of persons with specific risk factors (i.e., case finding). Recommendations for assessing cognition with standardized and validated tools include presence of signs, symptoms, or complaints of cognitive impairment (Lin et al., 2013; Moyer, 2014) with behavior that is inappropriate to a situation or unusual for the individual (including functional decline); when there is no informant to confirm absence of signs or symptoms (Cordell et al., 2013); and before making important treatment decisions as an adjunct to determining an individual's capacity to consent and capacity to adhere to treatment guidelines (see Chapter 21, Dementia: Assessment and Care Strategies).

When and how frequently cognitive functioning needs to be (re-)assessed is in part a function of the purpose of the assessment, the condition of the patient (e.g., unusual/inappropriate behavior), and the results of prior or current testing. Of course, patients with delirium or at high risk of delirium need to be monitored frequently (e.g., every 4–8 hours) because of the possible course and complications of this condition. When assessing for delirium it is important to have a prevention plan in place and best practices for delirium management (Fick, 2018). In case of reassessment after onset of treatment, it is important to know that delirium interventions might need only a few hours before effects can be measured, whereas effects of interventions to improve complaints and signs related to depression or dementia might be measured only after 2 or more weeks, if possible. The Gerontological Society of America has developed a guideline for assessing for cognitive impairment that includes a toolkit with resources for caregivers, recommendations for fitting the assessment into the annual wellness visit, and tips for brain health (www.geron.org/kaer).

Cautions for Assessing Cognitive Function

Various characteristics of the physical environment should be considered to ensure that the results of the cognitive assessment accurately reflect the individual's abilities and not extraneous factors. Overall, the ideal assessment environment should maximize the comfort and privacy of both the assessor and the individual. The environment should enhance performance by maximizing the individual's ability to participate in the assessment process (Dellasega, 1998). To accomplish this, the room should be well lit and of comfortable ambient temperature. The assessor should sit at eye level and be sure to provide and clean sensory devices as needed. Lighting must be balanced to be sufficient for the individual to see the examination materials adequately, while not being so bright as to create glare. Also, the environment should be free from distractions that can result from extraneous noise, scattered assessment materials, or brightly colored and/or patterned clothing and flashy jewelry on the assessor (Lezak, Howieson, & Loring, 2004).

It will be vital to prepare the individual for the assessment—explaining what will take place and how long it will take—hence reducing anxiety and creating an emotionally nonthreatening environment and a safe individual–assessor relationship (Engberg & McDowell, 2000). Therefore, it is essential to avoid counterproductive statements that describe the assessment as consisting of "simple," "silly," or "stupid" questions. These tend to diminish motivation to perform and heighten anxiety when errors are committed.

Performing the assessment in the presence of others should be avoided when possible, as the other individual may be distracting. If the other individual is a relative, additional problems may arise. For example, when the individual fails to respond or responds in error, significant others tend to provide the answer, or to say such things as "Now, you know the answer to that," or "Now, you know that's wrong." Because older adults are especially sensitive to any insinuation that they may have some "memory problem," it is important for the assessor in these cases to stress the importance of the assessment without increasing the individual's anxiety. An informant questionnaire, like the IQCODE (Jorm & Jacomb, 1989), can be a creative solution to deal with disturbing others.

The assessment can be perceived by the individual as intrusive, intimidating, fatiguing, and offensive; characteristics that can seriously and negatively affect performance.

Consequently, an initial period to establish a rapport with the individual is recommended (Lezak et al., 2004). This period also allows a determination of the individual's capacity for assessment; for example, do conditions exist that could alter the performance of the individual or interpretation of results such as sensory decrements? As a consequence, the assessor can alter the testing environment through simple methods; for example, by taking a position across from the individual or a little to the side. In this position, the individual can readily use the assessor's nonverbal communication as well as read the assessor's lips. Positioning also is important relative to lighting and glare. The assessor must also be careful not to cue the older adult or make excuses for why he or she may not be performing well, but instead should be aware of signs of fatigue or discomfort from overtesting. If needed, the assessor can encourage the older adult by saying things such as "You are doing fine, and we are almost done, or do you need a little break?"

Finally, avoid assessment periods immediately on awakening from sleep (wait at least 30 minutes) and immediately before and after meals or medical procedures (Foreman, Fletcher, Mion, & Trygslad, 2003). In addition, it should be said that even in perfect circumstances and in the absence of pathological conditions, patients may perform poorly on cognitive screening tests for other reasons, including acute illness, sleep deprivation, cultural issues, and so on (Shenkin et al., 2014). Therefore, it is paramount that screening results are reported with the appropriate context in which these were obtained. Otherwise, at a future date, patient charts might falsely reflect chronic impairment (Cordell et al., 2013; Shenkin et al., 2014).

CASE STUDY 9.1

Before

Mrs. O, a 72-year-old retired farmer's wife, was referred to the emergency department (ED) because her primary care provider (PCP) judged her to be slow in responding. For more than 10 weeks, she has been complaining about intolerable pain in her right hip, which could not be managed effectively by the PCP with acetaminophen and tramadol hydrochloride. An x-ray had revealed that the 15-year-old hip prosthesis needed replacement, and surgery had been scheduled in the upcoming week. As a result of this problem, Mrs. O became dependent on her husband for several activities of daily living (bathing, dressing, toileting, and transferring).

In the ED

The triage nurse in the ED reports to his colleague on the observational ward that Mrs. O is a gentle, cooperative lady who needs upgrading of pain therapy in anticipation of surgery. As intolerable pain is her main complaint, he administered an intravenous bolus of 5 mg piritramide.

The admitting nurse of the observational unit decides to assess Mrs. O's cognitive functioning, because her husband reports being overwhelmed by his wife's condition. He reports that his wife's cognitive status was known to be problematic—she was diagnosed with mild cognitive impairment a year ago (MMSE: 22/30), but it worsened dramatically since the funeral of her sister 2 weeks ago. He also added that she had been talking nonsense from time to time since then. In brief, there are arguments for the presence of delirium, depression, and dementia, or possibly one superimposed on another.

Some instances later, Mrs. O starts shouting for help. She is agitated, disoriented to time and place, and fails to recite the months of the year backward. Blood test results show that she was experiencing multiple problems: low sodium levels, high creatinine level, and presence of inflammation. It is likely that the intravenous bolus of piritramide triggered or worsened the delirium, as it is known that opiates should be administered with caution in people at risk of delirium (American Geriatrics Society, 2019)—which was probably not considered by the triage nurse, as he did not assess Mrs. O's cognitive functioning before administering the drug. A transfer to the intensive care unit is necessary owing to tachycardia and delirium, and surgery needs to be postponed until the aforementioned problems are corrected.

2 Weeks Later

When there were no more arguments for the presence of delirium (e.g., no fluctuating behavior, inattention, or disorganized thinking for at least a week), Mrs. O's cognitive functioning (MMSE 21/30) and depressive symptoms (GDS: 2/30) were assessed to evaluate her capacity to adhere to rehabilitation following surgery and to establish a baseline post hospitalization.

Mrs. O had an uncomplicated postoperative course and regained functional independence after participating in a patient-centered rehabilitation program targeting patients with cognitive impairment. After discharge from rehabilitation, Mrs. O and her caregiver were connected to local resources, including the Alzheimer's Association and the Area Agency on Aging.

SUMMARY

The determination of an individual's cognitive status is critical in the process and outcomes of illness and its treatment. Being competent in the assessment of cognitive functioning requires (a) knowledge and skill as they relate to the performance of the assessment of cognitive functioning, (b) sensitivity to the issues that can negatively bias the results and interpretation of this assessment, (c) accurate and comprehensive documentation of the assessment, and (d) the incorporation of the results of the assessment in the development of the individual's plan of care.

NURSING STANDARD OF PRACTICE

Protocol 9.1: Assessing Cognitive Function

I. GOALS

The goals of cognitive assessment include the following:

A. To determine an individual's cognitive abilities
B. To recognize early and diagnose the presence of cognitive impairment
C. To monitor an individual's cognitive response to various treatments

II. OVERVIEW

A. Detecting cognitive impairment in older patients is important because of the impairment's association with adverse events (Bradshaw et al., 2013).
B. Assessing cognitive function is necessary for early detection and prompt treatment of impairment (McCarten et al., 2012).

III. BACKGROUND AND STATEMENT OF PROBLEM

A. Definition of cognitive functioning includes the processes by which an individual perceives, registers, stores, retrieves, and uses information.
B. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*) provides criteria for diagnosing declines from a previously attained level (see *DSM-5* for specific criteria; APA, 2013; Sachdev et al., 2014).
    1. *Delirium* is a disturbance in attention and awareness that develops over a short period of time and tends to fluctuate in severity during the course of a day, combined with a disturbance in cognition (e.g., disorientation, memory deficit, etc.), neither of which are better explained by another neurocognitive disorder, but by one or multiple physiological effects (APA, 2013).
    2. *Mild neurocognitive disorder* (or *mild cognitive impairment*) is characterized by a modest cognitive decline from a previous level of performance in at least one cognitive domain (e.g., executive function, complex attention) that does not interfere with capacity for independence in everyday activities if the decline is not exclusively present in the context of a delirium or attributable to another mental disorder (APA, 2013).
    3. *Major neurocognitive disorder* (or *dementia*) is characterized by a significant cognitive decline from a previous level of performance in at least one cognitive domain (e.g., learning and memory, language) that interferes with independence in everyday activities if the decline is not exclusively present in the context of a delirium or attributable to another mental disorder (APA, 2013).
    4. *Depression* is a disorder represented by several symptoms. At the very least, one symptom needs to be the presence of a depressed mood or loss of interest or pleasure during a 2-week period, which causes clinically significant distress and leads to a decline from previous functioning; these symptoms cannot be attributed to direct physiological effects of a substance or a general medical condition (APA, 2013).

(*continued*)

Protocol 9.1: Assessing Cognitive Function (*continued*)

IV. ASSESSMENT OF COGNITIVE FUNCTION

A. Methods for assessing cognitive function
   1. *Screening*: to determine the absence or presence of impairment
   2. *Full evaluation*: to make a diagnosis if screening results indicate impairment
   3. *Monitoring*: to track cognitive status over time, especially in response to treatment

B. Instruments to assess for cognitive impairment
   1. *MMSE* (Folstein et al., 1975) is the most well-known and best studied instrument. It can be used to screen for or monitor cognitive impairment. However, performance on the MMSE is adversely influenced by education, age, language, and verbal ability. The MMSE is not available for public use without cost.
   2. *MoCA* and *SLUMS* can both detect and monitor cognitive impairment. Its performance is reported to be equivalent or superior to that of the MMSE, especially in patients with mild cognitive impairment.
   3. *Mini-Cog* is a widely used and recommended instrument that is often preferred over MMSE, MoCA, and SLUMS for detecting impairment because MMSE, MoCA, and SLUMS administration time is quite long. Depending on the setting, many other tools are available to briefly screen for the presence or absence of cognitive impairment.
   4. *Differential diagnosis*: Parallel use of other short instruments, such as the CAM (Inouye et al., 1990), the UB-2 (Fick et al., 2015), or the GDS (Yesavage et al., 1982), can be useful to rule out issues of delirium or depression and determine the nature of impairment.
   5. *Heteroanamnesis*: Information from relatives assists in determining the duration and nature of impairment. IQCODE, AD8, NPI, and FAM-CAM can be used to obtain this information.
   6. *Naturally occurring observations*: NOSCA standardizes the reporting of observations and conversations during naturally occurring care interactions (Persoon et al., 2011). The use of NOSCA is especially relevant when a patient's condition does not allow the use of other aforementioned instruments.
   7. *When screening results indicate impairment*: Referral to a specialist setting (e.g., memory clinic, neuropsychologist, psychiatrist, advanced practice nurse) is necessary for more diagnostic workup (i.e., extensive history taking, clinical and neurological examination, extended neuropsychological assessment, brain imaging, blood sampling, etc.).

C. When to assess cognitive function
   1. Presence of signs, symptoms, and/or complaints of cognitive impairment
   2. With behavior that is inappropriate to a situation and/or unusual for the individual (including functional decline)
   3. Lack of an informant to confirm absence of signs or symptoms
   4. Before making important treatment decisions as an adjunct to determining an individual's capacity to consent and capacity to adhere to treatment guidelines

D. Cautions for assessing cognitive function
   1. Physical environment (Dellasega, 1998)
      a. Comfortable ambient temperature
      b. Adequate lighting (not glaring)
      c. Free of distractions (e.g., should preferably be conducted in the absence of others and other activities)
      d. Position self to maximize individual's sensory abilities
   2. Interpersonal environment (Engberg & McDowell, 2000)
      a. Prepare individual for assessment
      b. Initiate assessment within nonthreatening conversation
      c. Let individual set pace of assessment
      d. Be emotionally nonthreatening

(*continued*)

Protocol 9.1: Assessing Cognitive Function (*continued*)

3. Timing of assessment (Foreman et al., 2003)
   a. Select time of assessment to reflect actual cognitive abilities of the individual
   b. Avoid the following times:
      i. Immediately on awakening from sleep (wait at least 30 minutes)
      ii. Immediately before and after meals
      iii. Immediately before and after medical diagnostic or therapeutic procedures
      iv. In the presence of unstable and/or interfering medical conditions (e.g., fever, nausea)
4. Reporting of assessment results (Shenkin et al., 2014)
   a. Report screening results with the context in which they were obtained.

V. EVALUATION/EXPECTED OUTCOMES

A. Patient
   1. Is assessed at recommended moments
   2. Any impairment detected early
   3. Care tailored to appropriately address cognitive status/impairment
   4. Satisfaction with care improved
B. Healthcare provider
   1. Competent to assess cognitive function
   2. Able to differentiate among delirium, mild cognitive impairment, dementia, and depression
   3. Uses standardized cognitive assessment protocol
   4. Satisfaction with care improved
C. Institution
   1. Improved documentation of cognitive assessments
   2. Impairments in cognitive function identified promptly and accurately
   3. Improved referral to appropriate advanced providers (e.g., geriatricians, geriatric nurse practitioners, neurologists, psychiatrists, memory clinics) for additional assessment and treatment recommendations
   4. Decreased overall costs of care

VI. FOLLOW-UP MONITORING

A. Provider competence in the assessment of cognitive function
B. Consistent and appropriate documentation of cognitive assessment
C. Consistent and appropriate care and follow-up in instances of impairment
D. Timely and appropriate referral for diagnostic and treatment recommendations

Assessment of Physical Function in the Older Adult*

Denise M. Kresevic

10

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Identify common components of standardized functional assessment instruments for older adults.
2. Identify unique challenges to gathering and communicating information from older adults regarding functional assessments.
3. Describe evidence-based nursing care interventions to promote, maintain, and restore functional health and quality of life outcomes in older adults in acute care settings.
4. Acknowledge the relationship between an individual's function, goals, and available resources in planning.

OVERVIEW

Physical functioning, the ability to manage day-to-day functioning (e.g., bathing, dressing, ambulating, managing medications), rather than the absence of disease, is the cornerstone of health for older adults. Maintaining a safe level of independent functioning may pose a challenge for older adults dealing with acute illness or exacerbations of chronic illnesses.

Functional assessment instruments provide a common language of health for patients, family members, and healthcare providers across settings, especially for the care of older adults. These assessments also serve as important parameters for goal setting and interprofessional collaboration, and an objective measurement of outcomes of care.

The consequences of not assessing for changes in status and intervening in a timely fashion are significant and often include major changes in quality of life and lifestyle (Hoogerduijn, Schuurmans, Duijnstee, de Rooij, & Grypdonck, 2006). Acute changes in functional ability often signal an acute illness and an increased need for assistance to maintain safety. Likewise, improvements in function signal recovery and a return to health. These changes have important implications for nursing care across settings, but especially during hospitalization. The ability to assess functional status is critical in accurately identifying normal aging changes, illness, and disability and in developing an individualized plan for continuity of care across settings. The failure to assess function can lead to increased risk of complications (e.g., malnutrition, falls); hospital readmissions; likelihood of being discharged to a nursing home setting (Fortinsky, Covinsky, Palmer, & Landefeld, 1999); and mortality (Boyd, Xue, Guralnik, & Fried, 2005; Rozzini, Sabatini, & Trabucchi, 2005) as well as decreased functional recovery (Boyd et al., 2005; Boyd,

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

Ritchie, Tipton, Studenski, & Wieland, 2008; Gill, Allore, & Guo, 2004; Volpato et al., 2007) and quality of life.

BACKGROUND AND STATEMENT OF PROBLEM

Physical functioning is a dynamic process of interaction between individuals and their environments. The process is influenced by motivation, physical capacity, illness, cognitive ability, pain, and the external environment, including social supports. Management of these day-to-day activities (e.g., eating, bathing, ambulating, managing money) serves as the foundation for safe, independent functioning of all adults.

Hospitalization can also contribute to functional decline, with decline experienced by an estimated 20% to 40% of hospitalized older adults (Landefeld, Palmer, Kresevic, Fortinsky, & Kowal, 1995). Functional decline is a common complication in hospitalized older adults, even in those with good baseline function (Gill, Allore, Gahbauer, & Murphy, 2010). The cause of this decline appears multifactorial and includes individual as well as environmental factors. Evidence that targeted interventions are effective in preventing and reversing functional decline continues to mount (Barnes et al., 2012; Resnick et al., 2016). Hospitalization provides a unique opportunity to treat acute conditions as well as assess function and provide evidence-based interventions to maintain function, plan for services, and promote "successful aging."

Educational intervention has demonstrated improvements in caregiver knowledge and patient outcome (Resnick et al., 2016; Resnick, Galik, Boltz, & Pretzer-Aboff, 2011).

Patient risk factors for functional decline include prehospitalization functional loss; the presence of two or more comorbidities; taking five or more prescription medications; having had a hospitalization or emergency room visit in the previous 12 months (McCusker, Kakuma, & Abrahamowicz, 2002); depression, (Covinsky et al., 1998); impaired cognition, including delirium (Inouye, Schlesinger, & Lydon, 1999; Narain et al., 1988); pain (Reid, Williams, & Gill, 2005; Von Rueden et al., 2017); nutritional problems; adverse medication effects (Graf, 2006); fear of falling (Boltz, Capezuti, & Shabbat, 2011); low self-efficacy and outcome expectations (McAuley et al., 2006; Resnick, 2002); and attitudes and goals toward functional independence and views on hospitalization (Boltz et al., 2011; Boltz, Capezuti, Shabbat, & Hall, 2010; Boyd, Landefeld, et al., 2008; Brown, Williams, Woodby, Davis, & Allman, 2007; Liebzeit, King, Bratzke, & Boltz, 2018).

These risk factors for functional decline are also associated with common risk factors for functional decline, including falls, injuries, acute illness, medication side effects, depression, malnutrition, baseline functional impairment, and decreased mobility associated with iatrogenic complications such as incontinence, falls, and pressure sores (Creditor, 1993). In one randomized clinical trial of hospitalized older adults, the daily nursing assessment of ability to perform bathing, dressing, grooming, toileting, transferring, and ambulation during routine nursing care yielded information necessary for maintenance of function in self-care activities (Landefeld et al., 1995).

Studies over the past 20 years have found that the use of multidisciplinary assessments and nursing protocols can reduce hospital length of stay and costs while maintaining patient outcomes and not increasing hospital readmission rates (Barnes et al., 2012).

This chapter addresses the need for and goals of functional assessment of older adults in acute care and provides a clinical practice protocol to guide nurses in this assessment (Protocol 10.1).

ASSESSMENT OF THE PROBLEM

Assessment of function includes an ongoing systematic process of identifying the older person's physical abilities and need for help or assistance. Functional assessment also provides the opportunity to identify individual strengths and measures of "successful aging" and also promotes maintenance of health. This information is especially important for nurses in planning for transitions of care, including discharge to other facilities or home and evaluating continuity of care. Nurses are in a pivotal position in all care settings, but particularly during hospitalization, to assess the functional status of older adults by direct observation during routine care and through information gathered from the individual patient, the patient's family, and any other long-term caregivers.

Including critical components of functional assessments into routine assessments in the acute care setting can provide (a) baseline functional capacity and recent changes in level of independence indicative of possible illness, especially infections; (b) baseline information to benchmark patients' response to treatment as they move along the continuum from acute care to rehabilitation or from acute to subacute care (e.g., following a new stroke or hip replacement surgery); (c) information regarding care needs and eligibility for services, including safety, physical therapy, and posthospitalization needs; and (d) information on quality of care. The ongoing use of a standardized functional assessment instrument promotes systematic communication of the patient's health status between care settings. It also allows units to compare their level of care with other units in the facility, measure outcomes, and plan for continuity of care (Campbell, Seymour, Primrose, & ACMEPLUS Project, 2004; see Table 10.1).

TABLE 10.1

Functional Assessment of Older Adults

Dimension	Assessment Parameter	Standardized Instrument	Nursing Strategy
ADL Bathing Dressing Eating Toileting Hygiene Transferring	Self-report of patient Surrogate report Observation during hospitalization	Katz ADL index (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963)	Orient to environment Encourage active participation in ADL Range-of-motion exercises Encourage to be out of bed Promote continence Consult PT/OT for strengthening exercises
Mobility Balance sitting and standing Gait steadiness Turns	Self-report Surrogate report Observation	"Get Up and Go" test (Mathias, Nayak, & Isaacs, 1986)	Ambulate PT/OT consult Mobility aids Community referrals
IADL Housework Finances Driving Shopping Meal preparation Reading Medication adherence Current events awareness Hobbies Employment Volunteer work	Self-report (include normal daily routine) Surrogate report (able to balance check book, traffic violations)	Lawton IADL scale (Gurland et al., 1994; Lawton & Brody, 1969) DAFA—for patients with dementia (Karagiozis, Gray, Sacco, Shapiro, & Kawas, 1998)	Assess ability to: ■ Find hospital room ■ Read newspaper ■ Read pill bottles ■ Order hospital meals from menu Facilitate as needed: ■ Community referrals for transportation and/or meals on wheels ■ OT consult to assess home management skills (cooking, laundry, etc.) ■ Home care referral, including medication management, follow-up medical care, rehabilitation, home safety management, and ADL support
Frailty **Hospital admission risk profile** **Patient perception of health**	Self-report Self-report—ADL IADL Chart review age diagnoses Cognitive status MMSE Self-report	Fried Frailty Scale (Fried et al., 2009) HARP (Sager et al., 1996) SF-36v2, SF-6D (Brazier, Roberts, & Deverill, 2002; Ware, Snow, Kolinski, & Gandeck, 1993)	Weight loss, fatigue, handgrip, physical activity, and walking speed Early referral OT PT home services Early identification of at risk for functional decline referral OT PT home care services physical functioning, role limitations due to physical and emotional problems, bodily pain, vitality, social functioning, and mental health; a single question on the SF-36—general health assists in planning of patient-centered care and discharge planning needs

ADL, activities of daily living; DAFA, Direct Assessment of Functional Abilities; HARP, hospital admission risk profile; IADL, instrumental activities of daily living; PT/OT, physical therapist/occupational therapist.

Although gathering information about functional status is a critical indicator of quality care in geriatrics, it requires significant time, skill, and knowledge. Older persons often present to the care setting with multiple medical conditions resulting in fatigue and pain. Acute illnesses may be superimposed on multiple interrelated medical comorbidities. In addition, sensory aging changes, particularly vision and hearing, can threaten the accuracy of responses. Ideally, information regarding functional status should be elicited as part of the routine history of older adults and incorporated into daily care routines of all caregivers. In addition, comprehensive assessment of function provides an opportunity to teach patients and families about normal aging as well as indicators of pathology.

Assessment Instruments

Collecting systematic information regarding tasks of daily living (e.g., bathing, dressing, ambulating, using a phone, taking medications, managing finances) can be

accomplished by the use of standardized instruments. The use of standardized instruments serves to ensure inclusive assessments, the ability to communicate in a common language, and the ability to benchmark information over time. Several instruments have been developed over the years to measure function. Although all measure components of function, the decision as to which instrument to use depends on the primary purpose of the assessment and the institutional preferences and resources (Kane & Kane, 2000). No single instrument will meet the needs of all care settings (Hoogerduijn et al., 2006).

While institutions and care settings may choose from a myriad of instruments to use in clinical practice, nurses should be familiar with the most commonly used. Many performance-based measures and observational instruments can be incorporated into routine care practices without significantly burdening caregivers. Incorporating electronic medical record templates into routine documentation can function as a prompt for providers, decreasing the time and increasing the communication of the results of these assessments.

The Katz Index of Independence in Activities of Daily Living (commonly referred to as the Katz ADL index) assesses activities of daily living (ADL), including bathing, dressing, transferring, toileting, continence, and eating (Katz et al., 1963). This scale is used widely to assess the functioning of older adults in all settings, including during hospitalization (Mezey, Rauckhorst, & Stokes, 1993). Originally, the Katz ADL index was proposed as an observation tool, with scores ranging from 1 to 3, indicating *independent ability*, *limited assistance*, and *extensive assistance* for each activity. Over time, the instrument has evolved into a dichotomized tool with independent versus dependent ability of each task (Kane & Kane, 2000). With established reliability (0.94–0.97), it is easy to use either as an observational or as a self-reported measure of level of independence (Kane & Kane, 2000). The Katz ADL index is easily incorporated into history and physical assessment flowsheets and takes little time to complete. Many other tools exist to assess ADL, including the Barthel index for physical functioning and the Older Americans Resources and Services ADL scale (OARS-ADL; Burton, Damon, Dillinger, Erickson, & Peterson, 1978; Mahoney & Barthel, 1965; Mezey et al., 1993).

In addition to ADL tools, instruments to measure more complex physical function called *instrumental activities of daily living* (IADL) have been proposed to be included in a comprehensive assessment of function in older adults. The majority of these instruments assess the individual's function in relation to the environment. Common IADL skills identified include using a phone, shopping, meal preparation, housekeeping, laundry, medication administration, transportation, and money management (Kane & Kane, 2000). Although assessment of ADL provides useful information for nursing care needs both during and after hospitalization, IADL information helps target critical posthospital care needs. Although direct observation of the patient's IADL may not occur during an acute hospitalization, it is important for the nurse to assess this information to plan for the patient's discharge. Common instruments used to measure IADL include the Lawton IADL scale, the Older Americans Resources and Services Instrumental Activities of Daily Living (OARS-IADL) scale, and the Direct Assessment of Functional Abilities (DAFA) scale.

Perhaps the most widely used IADL instrument for hospitalized older adults is the Lawton IADL scale. This scale assesses eight items, with each scored from 0 (dependence) to 8 (independent self-care). Reliability coefficients have been reported to be 0.96 for men and 0.93 for women (Kane & Kane, 2000).

More recently, scales that address frailty have been developed to assist in the assessment of at-risk individuals. Frailty is characterized by five components: weight loss, fatigue, handgrip, physical activity, and walking speed (Fried et al., 2009). The most widely used is the Fried Frailty scale (see Chapter 27, Physical Restraints and Side Rails in Acute and Critical Care Settings). This scale uses objective and self-report data. Baseline frailty is an important predictor of functional decline during acute illness and hospitalization that necessitates early aggressive interventions to maintain, if not improve, mobility and nutrition.

Assessment of function in individuals with dementia presents a unique challenge. The DAFA, a 10-item observational measure of IADL, has been found to be useful in assessing function in the presence of dementia (Karagiozis et al., 1998; see www.consultgerirn.org/resources and the Resources section of this chapter for assessment instruments).

Regardless of the instrument used, basic ADL and IADL function should be assessed for each patient, including capacity for dressing, eating, transferring, toileting, hygiene, ambulation, and medication adherence (see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment). Appropriate assessment instruments should be readily available on the acute care unit for reference and/or incorporated into routine documentation instruments for history, daily assessment, and discharge planning. To adequately assess function, sensory and cognitive capacity should be established and environmental adaptations, such as magnifying glasses or hearing amplifiers, may be necessary and should be accessible to nursing staff.

Although standardized instruments are useful for describing health status and planning for care, they must also be used in conjunction with individual observation and clinical judgment (Glenny, Kuspinar, & Naglie, 2017).

Despite age, functional status, and acute and chronic illness, the patients' perceptions of their functioning and overall health are paramount to planning and evaluating care. Many instruments have been developed to measure patients' perceptions of their health and overall functioning. One instrument that has demonstrated the ability to capture patients' perceptions and is easy to administer is the SF-36v2.

This instrument was derived from the General Health Survey of the Medical Outcomes Study by Stewart and colleagues (2007). A single question, "Is your health: excellent, very good, good, fair or poor," measures subjective health. In addition, the SF-6D, a shorter form of the SF-36v2 health survey, addresses six subscales: physical functioning, role limitations due to physical and emotional problems, bodily pain, vitality, social functioning, and mental health. Two summary scores can be calculated—physical component summary and the mental component summary.

Direct Assessment of Patients

Although nurses often rely on reports of physical functioning and capacity for ADL and IADL from other healthcare providers, patients, and family members, direct observation provides strong evidence for current capacity versus past ability.

Functional assessments are constantly conducted by nurses every time they notice that a patient can no longer pick up a fork or has difficulty walking. A comprehensive functional assessment leads to more than simply noticing a change in activity or ability, however. In a systematic manner, nurses need to assess the ability of a patient to perform ADL in the context of the patient's baseline functional and hospitalization status.

While assessing functional status, the patient should be made as comfortable as possible, given sufficient time to ask questions, and provided with frequent rest periods when needed. The need and availability of adaptive aids, such as glasses and hearing aids, should be applied. Often, family members accompany the older person and can assist in answering questions regarding function. However, an older person's perceptions of his or her ability are important and the individual should be encouraged to express his or her ideas. It is important for patients and family members to understand that baseline functional levels as well as any recent changes in function need to be reported. Many older adults may be reluctant to report decline in function, fearing that such reports will threaten their autonomy and independent living. Assessment of physical function by questioning or direct observation can seem overly intrusive to older adults who fear loss of independence. Creating a positive and open environment that acknowledges abilities, strengths, adaptations, and resources is essential.

Occasionally, the history and physical examination may reveal clues to further identify functional status. Muscle weakness and atrophy of legs may indicate lack of ability to safely ambulate independently. Temporal muscle wasting may indicate moderate to severe malnutrition resulting from inability to shop, prepare meals, or adequately consume sufficient calories. Hand contractures present with arthritis or cerebral vascular accidents alert the nurse to pay particular attention to performance versus self-report of ability to open pill bottles, dial a phone, or write checks. General appearance (e.g., hair, teeth, fingernails) and condition of clothing (e.g., clean and dry vs. urine-soaked undergarments) may give rise to information on bathing, dressing, continence, and ability to do laundry.

Specific Functional Assessments

Ambulation

Inherent in both ADL and IADL is ambulation, a critical parameter for functional assessment. Early nursing assessment of the hospitalized patient's ability to walk is very important in order to ensure safety and prevent falls and injuries. Identification of risks for falls can aid in the assessment of the individual's mobility needs and increase safe ambulation (see Chapter 19, Late Life Depression). The ability to safely ambulate is contingent on the ability to transfer, propel forward, and pivot with sufficient strength and balance. Ambulation is necessary for self-care both in the hospital and after hospital discharge. It is also a very sensitive indicator of acute health changes. Therefore, the ability to ambulate should be assessed by both self- or proxy report and/or by direct observation.

Some instruments used to assess ambulation, balance, and gait are sensitive measures of mobility (Applegate, Blass, & Franklin, 1990); however, they are also complex and time consuming to use. Therefore, direct observation of an individual's ability to get out of bed, sit in a chair, assume a standing position, and steadily walk a short distance—with or without assistive devices—is much simpler to do yet important to ensure safety (Applegate et al., 1990; Cress et al., 1995). However, acutely ill hospitalized older adults often tethered to equipment such as

intravenous lines or oxygen face unique challenges to demonstrate and maintain mobility and ambulation.

An efficient performance-based measure of ambulation, balance, and gait that can be observed during routine care of the hospitalized patient is the "Get Up and Go" test (Cress et al., 1995). To do a Get Up and Go test, patients are observed sitting in a chair, standing, walking, and pivoting. Direct observation of the patient should include an assessment of speed of performance, hesitancy, stumbling, swaying, grabbing for support, or unsafe maneuvers such as sitting too close to the edge of a chair or dizziness while pivoting (Tinetti & Ginter, 1998). Performance is scored from 1 (normal balance and steady gait) to 5 (severely abnormal balance and gait), which is clear evidence of fall risk (Kane & Kane, 2000). Assessment of unsafe transfers or ambulation indicates the need to begin immediate restorative therapies to prevent falls and injuries. These can include attention to environmental designs, such as walking paths free of clutter, handrails, and rest areas to encourage daily ambulation, as opposed to bed rest and immobility (Creditor, 1993). Although the Get Up and Go test is easy to perform, it is relatively subjective. Objectivity may be enhanced by timing the tasks (Kane & Kane, 2000).

Sensory Capacity

Evaluation of the potential impact of sensory changes on the performance of ADL is often underestimated. Impaired vision is especially important in medication adherence and safety. A simple test for functional vision is to have older adults read from a newspaper. A moderate impairment can be noted if only the headline can be read (Tinetti & Ginter, 1998). Another way to assess vision is to have older persons read prescription bottles. Functional assessment of safe medication administration includes the ability to read pill bottles and repeat directions for use, potential side effects, and instructions of when to contact a healthcare provider. Glasses should be available with clean lenses. Inability to read raises questions of literacy, undiagnosed vision difficulties, and safety for medication administration. Often overlooked is the number of older people who may not be able to read but are too embarrassed to reveal that information. As part of routine care, older adults should be encouraged to actively participate each day in learning about medications. In addition, at the time of discharge, nurses need to verify patient and family knowledge and skills regarding medications. This may include discussing medications as well as directly observing older adults opening pill bottles and identifying the correct pills.

Hearing ability is also essential for functioning and cognition. Individuals with decreased hearing may be inaccurately labeled as *cognitively impaired*. Hearing aids may not have been sent to the hospital with the older patient and should be obtained by the family. Hearing acuity may be validated by asking patients to identify the sound of a ticking watch. The "whisper test" may also be used. This is performed by whispering 10 words while standing 6 inches away from the individual. Inability to repeat five of the 10 words indicates a need for further assessment of hearing acuity. Occlusion of the external ear canal by cerumen, an easily treatable cause of decreased hearing acuity, may be evident with visualization (Mathias et al., 1986). Individuals with hearing deficits detected as part of bedside assessment should be referred for additional assessment and treatment. Amplifier devices may be useful and are an inexpensive item to stock on hospital nursing units.

Cognitive Capacity

Cognitive capacity includes a broad array of skills, including the ability to take in information, process it, make judgments, and act accordingly. This includes, but is not limited to, memory and decision-making.

Cognitive function is a major factor in a person's functional capacity, and baseline data regarding cognitive function should be gathered. However, such assessments most often initially rely on information provided by family members because acute illness may manifest as acute confusional states and not reflect baseline cognitive function (Kruianski & Gurland, 1976; see Chapter 6, Age-Related Changes in Health). Fluctuating attention may indicate an acute, reversible impairment (delirium) or temporary reactions to hospitalization. An acute change in cognition should be evaluated immediately for the presence of a potentially life-threatening, reversible medical condition (see Chapter 17, Advance Care Planning).

Cause of Functional Decline

All instances of functional decline should be assessed for an underlying reversible cause such as acute illness. With the resolution of acute illness (e.g., urinary tract infection [UTI], pneumonia, postoperative recovery), impaired ADL are expected to return to baseline with appropriate care and rehabilitation. Comprehensive musculoskeletal or neurological examination, laboratory tests, or referral for a therapeutic trial of physical or occupational therapy may be needed to boost recovery. In some cases, functional decline may accompany a predictable downward spiral associated with end-stage chronic diseases such as

Alzheimer's disease or terminal illnesses. However, even in individuals with these conditions, all potentially reversible causes should be fully explored.

INTERVENTIONS AND CARE STRATEGIES

Functional ability is a sensitive indicator of health in older adults. The need for assistance with ADL is an important nursing assessment to provide safe individualized care during hospitalization and also aids in care planning during and after a hospital stay. Sudden loss of function, including the ability to ambulate, is the hallmark of acute illness in older adults. Although recovery from illness may be associated with improvements in function, early nursing interventions to address care needs, refer to therapy, and modify environments of care help to ensure safety and decrease further loss of function. Therefore, all nurses must be skilled at incorporating a comprehensive functional assessment into all patient care assessments and communicating these assessments to the care team across transitions. Nurses need to be knowledgeable and skilled in assessment of function, implementing supportive environments, and providing geriatric-sensitive care to prevent functional decline. Geriatric-sensitive care incorporates strategies to prevent bed rest, encourage exercise and ambulation, ensure adequate nutrition, and encourage ongoing communication among all team members. Such care is essential in maximizing safe, independent functioning of hospitalized older adults (see Chapter 14, Family Caregiving).

CASE STUDY 10.1

Mrs. Hope, a 74-year-old retired night nurse, is admitted from her physician's office. Her admitting diagnosis is pneumonia, dehydration, and weakness. Her past medical history is significant for hypertension, congestive heart failure (CHF), and chronic obstructive pulmonary disease (COPD). Until the last few days she was very active, driving to church and the grocery store and volunteering several times a week at the library. Mrs. Hope is also a recent widow. She is extremely hard of hearing but has refused to wear her hearing aid. She smokes approximately 10 cigarettes a day, which she has done for more than 50 years. Her daughter who has accompanied her to the hospital admits that, lately, Mrs. Hope has not been taking most of her pills, although she has been taking aspirin for pain. She has also been losing weight and has poor appetite with little fluid intake. Laboratory values indicate anemia with a very low hematocrit and a urinary tract infection (UTI). A chest x-ray indicates a lung nodule.

Although on the unit, Mrs. Hope prefers to sleep in the recliner, saying she is most comfortable there and prefers to nap during the day. Despite intravenous (IV) fluids, blood transfusions, diuresis for fluid overload, oxygen therapy, occupational therapy for energy conservation, and round-the-clock acetaminophen for "aches and pains," Mrs. Hope continues to be weak and needs assistance with daily bathing and much encouragement and assistance to ambulate even short distances. She is able to communicate well using a hearing amplifier after her ears are cleaned of wax. She is assessed on rounds by the multidisciplinary care team over the next several days. Mrs. Hope acknowledges that she misses her husband but denies depression. After the team meeting, consultations are obtained for physical therapy, nutrition services, pharmacy, geriatric clinical nurse specialist, and social work, and the team begins to discuss Mrs. Hope's goals of care, including durable power of attorney for healthcare and advance directives. Over the next few days, with nutritional supplements and therapy, her fatigue improves, and she is able to be weaned from oxygen. Referrals for home care are made for nursing and therapy as well as for telehealth to monitor her CHF, weight, and blood pressure. Mrs. Hope's medication regimen is adjusted, substituting acetaminophen and an analgesic gel rather than aspirin, for her pain. She and her daughter are instructed on a high-calorie diet and are provided with information on senior centers, meals on wheels, and smoking-cessation programs. She is given vaccines for influenza and pneumonia. A future outpatient appointment for a comprehensive geriatric evaluation is made for a comprehensive geriatric assessment once her acute conditions resolve, including further testing of her lung nodule, anemia, cognitive status, and follow-up on advance directives.

Mrs. Hope is discharged home with her daughter after medications, diet, and exercises are reviewed using a teach-back method of education. She is given information on smoking cessation, pill boxes to aid with medication adherence and lifeline alert systems. The numbers for the home care agency and directions to the outpatient appointment are printed out for her at the time of discharge. A follow-up phone call confirms that Mrs. Hope is using her pill boxes and that she has made phone calls to her primary care physician and meals on wheels.

CASE STUDY 10.1 (*continued*)

Discussion

This case study indicates the need to assess baseline function, changes in function, and trajectory of function following acute care. Assessment in this case used components from several standardized functional assessment instruments and incorporated them into existing care routines. Care was enhanced by collaboration among multiple disciplines and across settings. Opportunities for assessment and resolution of impairment rely on institutional preferences and resources, as well as the functional level of the patient. Despite Mrs. Hope's impaired function, the hospital staff worked to enhance her physical functioning as much as possible within the current care setting and a context of safety. Although the focus of acute care is on resolving acute issues such as pneumonia and exacerbations of chronic diseases, such as CHF and pain, other issues, such as weight loss, anemia, fatigue, and advance directives, should also be addressed. In this case, follow-up of several issues will need to be done after hospitalization. Given the complexity of many large healthcare systems, ideally, these appointments can be arranged before the patient leaves the hospital. Referrals for home care and continued physical therapy were made as part of a coordinated transition of care and include information on other community resources.

CASE STUDY 10.2

Mr. Goode is an 86-year-old retired college history professor who is well known for his accomplishments as a collegiate football player. His wife of 60 years died last year. He lives alone in a one-floor condominium. His daughter and son live in the same city. He has a cleaning lady who comes once a week. He has been receiving meals on wheels; he admits to being a terrible cook. Mr. Goode has been driving only short distances during the daytime since his cataract surgery 15 years ago. He rides his stationary exercise bike daily to keep up his "boyish" figure.

Mr. Goode has a long history of cardiac disease, including two myocardial infarctions and a coronary bypass graft 20 years ago. He has degenerative joint disease that affects his hips and knees, and 10 years ago he underwent bilateral knee replacements. Twenty years ago, he had prostate surgery for enlargement. His current medications include lisinopril 5 mg, furosemide 20 mg, potassium chloride 8 mEq every other day, acetaminophen 650 mg twice a day, and analgesic balm as needed.

Mr. Goode is admitted to the emergency department extremely short of breath; the cleaning lady had called 911. He has crackles in his lungs and 4+ pitting edema of his legs. He is placed on oxygen and given IV Lasix. A Foley catheter is placed, and an IV of D5½NS at 50 mL/hr is started. On admission to the nursing unit, he requires assistance to move from the cart to the bed. He complains of nausea, weakness, and knee pain. His physician orders bed rest and Benadryl 25 mg at bedtime as needed for sleep.

On hospital day 2, Mr. Goode refuses to get out of bed because of knee pain. He requests assistance with his bathing and eating. His weight has decreased 2 pounds, and he has decreased crackles in his lungs. His daughter arrives with his glasses, hearing aids with batteries, and pillboxes. His medication boxes are still filled from the previous 5 days. His laboratory results return. His urine is positive for bacteria, red and white cells, and leukoesterase, confirming a UTI. An electrocardiogram is negative for an acute myocardial infarction. A chest x-ray confirms acute CHF and pneumonia. He is placed on antibiotics, and his diuretics are increased for 1 day. He cannot recall the last time he had a bowel movement.

During team rounds, his orders are changed to the following: out of bed and ambulate in hallway twice a day, discontinue Foley catheter and Benadryl, and wean oxygen. His nurses review his baseline ADL function and current function and request a physical therapy consultation to evaluate safe ambulation and a social work consultation to evaluate self-care ability and home care services. The patient requests analgesic balm for his knees. Fall precautions are initiated, including frequent prompted voiding. He is ordered a bowel stimulant and encouraged to drink warm prune juice for constipation.

On hospital day 4, Mr. Goode ambulates out to the nurse's station and announces that he feels much better and is ready to go home. His progress is reviewed on team rounds. The physical therapy evaluation reveals that he is capable of ambulating and transferring independently and safely, and the therapist recommends a continued home exercise program. He is given information on community arthritis programs, including water aquatics and tai chi. The social worker has shared information with Mr. Goode and his son regarding the "lifeline" and recommended check-in phone calls every evening. Nutrition services recommended a low-salt diet and used sample menus to practice food choices, and a nurse has reviewed medications with Mr. Goode and his daughter, using a "teach-back method." A pillbox is filled in the pharmacy. The daughter agrees to purchase a scale with large numbers. Mr. Goode's daughter will check

(*continued*)

CASE STUDY 10.2 (*continued*)

the pillbox weekly. Mr. Goode is ready for discharge from the hospital and will return to his condominium because he has returned to his baseline ADL. Before discharge, he agrees to update his vaccines for pneumonia and zoster. He is encouraged to schedule a visit with his primary care provider before he leaves the hospital.

Discussion

Similar to Case 10.1, this case stresses the importance of establishing baseline function and using standardized instruments to assess and communicate levels of function. Again, the critical collaboration with a multidisciplinary team that includes the patient is evident in planning and evaluating care needs.

This case illustrates the appropriate in-hospital interventions needed to reverse decline, such as early ambulation, attention to sensory needs, treatment of constipation, and judicious use of medications.

SUMMARY

Knowledge of ADL and IADL abilities, including eating, bathing, ambulation, shopping, housework, finances, food preparation, medication administration, and transportation, is an important part of providing individual nursing care for comprehensive discharge planning (Woolf, 1990). In summary, for older people, the evaluation of function represents the cornerstone of good nursing care and affords a sound baseline by which to provide information essential to plan for continued care across settings.

NURSING STANDARD OF PRACTICE

Protocol 10.1: Assessment of Physical Function

I. GOAL

To maximize physical functioning, ensure safety, and prevent or minimize decline in ADL function, and plan for transitions of care

II. OBJECTIVE

The following nursing care protocol has been designed to help bedside nurses to assess and monitor function in older adults, prevent decline, and maintain the function of older adults during acute hospitalization.

III. BACKGROUND

A. Functional status of individuals describes the capacity and performance of safe ADL and IADL (Applegate et al., 1990; Kane & Kane, 2000; Katz et al., 1963; Lawton & Brody, 1969) and is a sensitive indicator of health or illness in older adults. It is, therefore, a critical nursing assessment (Buurman et al., 2011; Byles, 2000; Campbell et al., 2004; Kresevic et al., 1998; Mezey et al., 1993).

B. Some functional decline may be prevented or ameliorated with prompt and aggressive nursing intervention (e.g., ambulation, toileting schedules, enhanced communication, adaptive equipment, attention to medications and dosages, and management of pain [Barnes et al., 2012; Bates-Jensen et al., 2004; Boltz et al., 2010; Brown, Redden, Flood, & Allman, 2009; Counsell et al., 2000; Kalisch, Soohee, & Dabney, 2013; Landefeld et al., 1995; Palmer, Counsell, & Landefeld, 1998; Zisberger et al., 2011]).

C. Some functional decline may occur progressively and is not reversible. This decline often accompanies chronic and terminal disease states such as degenerative joint disease, Parkinson's disease, dementia, heart failure, and cancer (Hirsch, Sommers, Olsen, Mullen, & Winograd, 1990). Interprofessional team care meetings may be helpful in clarifying the trajectory of illness and referring for appropriate follow-up.

(*continued*)

Protocol 10.1: Assessment of Physical Function (*continued*)

D. Functional status is influenced by physiological aging changes, acute and chronic illness, and adaptation to the physical environment. Functional decline is often the initial symptom of acute illness such as infections (e.g., pneumonia and UTI). These declines are usually reversible and require medical evaluation (Applegate et al., 1990; Sager & Rudberg, 1998). Functional status is contingent on motivation, cognition, and sensory capacity, including vision and hearing (Pearson, 2000).
E. Risk factors for functional decline include frailty injuries, acute illness, medication side effects, pain, depression, malnutrition, decreased mobility, prolonged bed rest (including the use of physical restraints), prolonged use of Foley catheters, and changes in environment or routines (Brown et al., 2009; Counsell et al., 2000; Landefeld et al., 1995; McCusker et al., 2002).
F. Additional complications of functional decline include loss of independence, falls, incontinence, malnutrition, decreased socialization, depression, and increased risk for long-term institutionalization and depression (Covinsky et al., 1998; Creditor, 1993; Landefeld et al., 1995; see related chapters).
G. Recovery of function can also be a measure of return to health, such as for those individuals recovering from exacerbations of cardiovascular or respiratory diseases and acute infections, from joint replacement surgery, or from new strokes (Katz et al., 1963).
H. Functional status evaluation assists patients and their families in planning future care needs post hospitalization, such as short-term skilled care, assisted living, home care, and need for community services (Boltz, Resnick, Chippendale, & Galvin, 2014; Graf, 2006; Landefeld et al., 1995), or long-term residential care.
I. Physical environments of care with attention to the special needs of older adults serve to maintain and enhance function (i.e., chairs with arms, elevated toilet seat, levers vs. door knobs, enhanced lighting; Capezuti et al. 2008; Kresevic et al., 1998; Landefeld et al., 1995).

IV. ASSESSMENT PARAMETERS

A. Comprehensive functional assessment of older adults includes independent performance of basic ADL, social activities, or IADL, the assistance needed to accomplish these tasks, and sensory ability, pain level, cognition, and capacity to ambulate (Campbell et al., 2004; Doran et al., 2006; Freedman, Martin, & Schoeni, 2002; Kalish et al., 2013; Kane & Kane, 2000; Katz et al., 1963; Lawton & Brody, 1969; Lightbody & Baldwin, 2002; McCusker et al., 2002; Tinetti & Ginter, 1998).
   1. Basic ADL (bathing, dressing, grooming, eating, continence, transferring)
   2. IADL (meal preparation, shopping, medication administration, housework, transportation, accounting)
   3. Mobility (ambulation, pivoting)
B. Older adults may view their health in terms of how well they can function rather than in terms of disease alone. Strengths should be emphasized as well as needs for assistance (Depp & Jeste, 2006; Pearson, 2000).
C. The clinician should validate, document, and communicate baseline functional status and recent or progressive decline in function (Boltz, Chippendale, Resnick, & Galvin, 2015; Gillis, MacDonald, & MacIssac, 2008; Graf, 2006).
D. Function should be assessed over time to validate capacity, decline, or progress (Applegate et al., 1990; Callahan, Thomas, Goldhirsh, & Leipzig, 2002; Kane & Kane, 2000).
E. Standard instruments selected to assess function should be efficient to administer and easy to interpret. They should provide useful practical information for clinicians and be incorporated into routine history taking and daily assessments, and documentation including electronic medical records (Hoogerduijn et al., 2006; Kane & Kane, 2000; Kresevic et al., 1998; see "Function" topic at www.consultgerirn.org for tools).
F. Interprofessional communication regarding functional status, changes, and expected trajectory should be part of all care settings and should include the patient and family whenever possible (Counsell et al., 2000; Covinsky et al., 1998; Kresevic et al., 1998; Landefeld et al., 1995).
G. Interprofessional rounds support promotion of function by addressing functional assessment (baseline and current), evaluating potential interventions, and helping develop a plan of care with measurable goals (Kresevic & Holder; 1998).
H. Patient's perceptions of function, quality of life, and goals of care should be assessed, documented, and communicated to the care team across all settings (Liebzeit et al., 2018).

(*continued*)

Protocol 10.1: Assessment of Physical Function (*continued*)

V. CARE STRATEGIES

A. Strategies to maximize functional status and to prevent decline
   1. Maintain individual's daily routine. Help to maintain physical, cognitive, and social function through physical activity and socialization. Encourage ambulation, encourage the individual to get out of bed for meals, allow flexible visitation, including pets, and encourage reading the newspaper. Encourage adjunctive interventions such as relaxation and music therapy (Boltz et al., 2015; Kresevic & Holder, 1998; Landefeld et al., 1995; Resnick et al., 2011).
   2. Educate older adults, family, and formal caregivers on the value of independent functioning and the consequences of functional decline (Graf, 2006; Kresevic & Holder, 1998; Vass, Avlund, Lauridsen, & Hendriksen, 2005); increased risk for complications such as malnutrition, falls, hospital readmissions, increased likelihood of being discharged to a nursing home setting (Fortinsky et al., 1999); increased mortality (Boyd et al., 2005; Rozzini et al., 2005); and decreased functional recovery (Boltz et al., 2015; Boyd et al., 2005, Boyd, Ritchie, et al., 2008; Gill et al., 2004; Gillis et al., 2008; Volpato et al., 2007), ultimately decreasing quality of life.
      a. Physiological and psychological value of independent functioning
      b. Reversible functional decline associated with acute illness (Hirsch et al., 1990; Sager & Rudberg, 1998)
      c. Strategies to prevent functional decline: exercise, nutrition, pain management, and socialization (Boltz, Resnick, Capezuti, Shuluk, & Secic, 2012; de Morton, Keating, & Jeffs, 2007; Kresevic & Holder, 1998; Landefeld et al., 1995; Siegler, Glick, & Lee, 2002; Tucker, Molsberger, & Clark, 2004)
      d. Sources of assistance to manage decline
   3. Encourage activity, including routine exercise, range of motion, and ambulation to maintain activity, flexibility, and function (Counsell et al., 2000; Landefeld et al., 1995; Pedersen & Saltin, 2006).
   4. Minimize bed rest (Bates-Jensen et al., 2004; Covinsky et al., 1998; Kresevic & Holder, 1998; Landefeld et al., 1995).
   5. Explore alternatives to physical restraint use (e.g., cover tubings; use distraction; Covinsky et al., 1998; Kresevic & Holder, 1998; see Chapter 23, Assessing, Managing, and Preventing Falls in Acute Care).
   6. Judiciously use medications, especially psychoactive medications, in geriatric dosages (Inouye, Rushing, Foreman, Palmer, & Pompei, 1998; see Chapter 17, Advance Care Planning).
   7. Assess and treat for pain (Covinsky et al., 1998). Consider alternative and nonpharmacological interventions.
   8. Design environments with handrails; wide doorways; raised toilet seats; shower seats; enhanced lighting; low beds; and chairs of various types and height, including recliners and rocking chairs (Cunningham & Michael, 2004; Kresevic et al., 1998).
   9. Help individuals regain baseline function after acute illnesses by using exercise, physical or occupational therapy consultation, nutrition, and coaching (Conn, Minor, Burks, Rantz, & Pomeroy, 2003; Covinsky et al., 1998; Engberg, Sereika, McDowell, Weber, & Brodak, 2002; Forbes, 2005; Hodgkinson, Evans, & Wood, 2003; Kresevic et al., 1998).

B. Strategies to help older individuals cope with functional decline
   1. Help older adults and family members determine realistic functional capacity based on health trajectory with interprofessional consultation (Kresevic & Holder, 1998).
   2. Provide caregiver education and support for families of individuals when decline cannot be ameliorated in spite of nursing and rehabilitative efforts (Graf, 2006). Palliative care consultation may offer the family and team important management strategies, particularly postacute care.
   3. Carefully document all intervention strategies and patient response (Graf, 2006).
   4. Provide information to caregivers on causes of functional decline related to acute and chronic conditions (Covinsky et al., 1998; Resnick et al., 2016).
   5. Provide education to address safety care needs for falls, injuries, and common complications. Short-term skilled care for physical therapy may be needed; long-term care settings may be required to ensure safety (Covinsky et al., 1998).
   6. Provide sufficient protein and caloric intake to ensure adequate intake and prevent further decline. Liberalize diet to include personal preferences (Edington et al., 2004; Landefeld et al., 1995).
   7. Provide caregiver support and community services, such as senior centers, meals on wheels, home care, nursing, and physical and occupational therapy services to manage functional decline (Covinsky et al., 1998; Graf, 2006).

(*continued*)

Protocol 10.1: Assessment of Physical Function (*continued*)

VI. EXPECTED OUTCOMES

A. Patients can
   1. Maintain safe level of ADL and ambulation.
   2. Make necessary adaptations to maintain safety and independence, including assistive devices and environmental adaptations.
   3. Strive to attain highest quality of life despite low functional level.
   4. Communicate preferences for care.

B. Providers can demonstrate
   1. Increased assessment, identification, and management of patients susceptible to or experiencing functional decline. Provide routine assessment of functional capacity despite level of care.
   2. Ongoing documentation (electronic medical record) and communication of capacity, interventions, goals, and outcomes
   3. Competence in preventive and restorative strategies for function
   4. Competence in assessing safe environments of care that foster safe independent function

C. Institution will experience
   1. System-wide incorporation of functional assessment into routine assessments
   2. A reduction in incidence and prevalence of functional decline
   3. A decrease in morbidity and mortality rates associated with functional decline
   4. Reduction in the use of physical restraints, prolonged bed rest, and Foley catheters use falls
   5. Decreased incidence of delirium
   6. An increase in prevalence of patients who leave the hospital with baseline or improved functional status
   7. Decreased readmission rate
   8. Increased early utilization of nutritional and rehabilitative services (occupational and physical therapy)
   9. Evidence of geriatric-sensitive physical care environments that facilitate safe, independent function such as low beds, comfortable chairs, and caregiver education on safe environmental design and exercise programs
   10. Evidence of continued interprofessional assessments, care planning, and evaluation of care related to function, including posthospital follow-up planning such as leadership support for interdisciplinary communication
   11. Leadership commitment to patient-centered care

VII. RELEVANT PRACTICE GUIDELINES

Several resources are now available to guide adoption of evidence-based nursing interventions to enhance function in older adults.

Oral Healthcare in the Older Adult*

11

Linda J. O'Connor

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the consequences of poor oral health.
2. Describe a thorough oral assessment in the older adult.
3. Describe the oral hygiene plan of care for nonintubated older adults.
4. Discuss nursing interventions for oral care.

OVERVIEW

Poor oral health and periodontal disease have been associated with malnutrition, dehydration, cardiovascular disease, pneumonia, aspiration pneumonia, ventilator-associated pneumonia, diabetes, chronic kidney disease, and chronic obstructive pulmonary disease (COPD; Ahn et al., 2016; Bascones-Martinez, Gonzalez-Febles, & Sanz-Esporin, 2014; Borgnakke, Anderson, Shannon, & Jivanescu, 2015; Carrizales-Sepulveda, Ordaz-Farias, Vera-Pineda, & Flores-Ramirez, 2018; Dietrich et al., 2017; Hajishengallis, 2015; Hong et al., 2017; Jung et al., 2014; Manger et al., 2017; Navarro, Sala, & Salas, 2017; Nguyen, Kim, Quan, Nguyen, & Tran, 2015; Ozcaka, Becerik, Bicakci, & Kiyak, 2014; Tabeta, Yoshie, & Yamazaki, 2014). Oral health also affects nutritional status, ability to speak, self-esteem, mental wellness, and overall well-being (Bilic et al., 2017; Ferreira, Dias-Pereira, Branco-de-Almeida, Martins, & Palva, 2017; Zucoloto, Maroco, & Campos, 2016). Many oral diseases are not part of the natural aging process but side effects of medical treatment and medications.

BACKGROUND AND STATEMENT OF PROBLEM

Plaque retention is a problem in older adults who have difficulty in mechanically removing plaque caused by diminished manual dexterity, impaired vision, or chronic illness (Brown, Goryakin, & Finlayson, 2009; Hakuta, Mori, Ueno, Shinada, & Kawaguchi, 2009). An older adult's functional ability and cognitive status affect his or her ability to perform oral care and denture care. Dental plaque harbors microorganisms, including *Streptococcus, Staphylococcus*, gram-positive rods, gram-negative rods, and yeasts (Coulthwaite & Verran, 2007). Dentures also have the potential to harbor *Streptococcus pneumoniae*, *Haemophilus influenza*, *Escherichia coli*, *Klebsiella*, and *Pseudomonas* secondary to spending time in nonhygienic environments (Coulthwaite & Verran, 2007). Dentures have been seen thrown in with patients' clothing, thrown in a washbasin

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

or other containers with bathing items, and so forth, instead of being properly cleaned and stored in a denture cup. Lack of good oral hygiene increases the risk of development of secondary infections, extended hospital stays, and significant negative health outcomes.

Multiple medications produce side effects that affect the oral cavity. Cardiac medications can cause salivary dysfunction, gingival enlargement, and lichenoid mucosal reactions. Steroid treatment can predispose a patient to oral candidiasis, and cancer treatments can cause a plethora of oral conditions such as stomatitis, salivary hypofunction, microbial infections, and xerostomia.

The mouth reflects the culmination of multiple stressors over the years, and, as the mouth ages, it is less able to tolerate these stressors. With an increase in chronic disease and medication usage as a person ages, periodontal problems may increase. Many of the oral health problems seen in older adults could be avoided with routine preventive care.

ASSESSMENT OF THE PROBLEM

Physical Assessment

The promotion of oral health through assessment and good oral hygiene is an essential part of nursing care. Oral assessment is part of the nurse's head-to-toe assessment of the older adult and is done on admission and at the beginning of each shift. The nurse assesses the condition of the oral cavity, which should be pink, moist, and intact; the presence or absence of natural teeth and/or dentures; ability to function with or without natural teeth and/or dentures; and the patient's ability to speak, chew, or swallow. Natural teeth should be intact, and dentures (partial or full) should fit comfortably and not be moving when the older adult is speaking. Any abnormal findings such as dryness, swelling, sores, ulcers, bleeding, white patches, broken or decayed teeth, halitosis, ill-fitting dentures, difficulty swallowing, signs of aspiration, and pain are documented by the nurse, and the healthcare team informed.

Poorly fitting dentures can cause ulcerations and candidiasis (oral fungal infection, masses, and denture stomatitis). Denture stomatitis presents as red, inflamed tissue beneath dentures, caused by fungal infections and insufficient oral hygiene. Some oral mucosal diseases that nursing may see are angular cheilitis (red and white cracked lesions in the corners of the mouth, caused by inflammation and a fungal infection), cicatricial pemphigoid (produces red, inflamed lesions on the gingival, palate, tongue, and cheek tissues), lichen planus (most common form presents as a lacy white appearance on the tongue and/or cheeks), and pemphigus vulgaris (red bleeding tissues that result from trauma but heal without scarring). Untreated lesions can develop into large, infected regions, which require immediate medical attention. Dental professionals diagnose oral mucosal diseases, but the nurse needs to be aware of any abnormal findings and report them immediately.

The nurse also needs to assess the patient for functional ability and manual dexterity to provide oral hygiene. The nurse needs to observe the older adult providing oral hygiene to make sure that it is effective. The primary focus for nurses is to maintain the older adult's function so that older adults may participate in their daily care. Once the older adult performs his or her oral hygiene, the nurse must follow up as appropriate to complete the oral hygiene.

Assessment Tools

The Kayser-Jones Brief Oral Health Status Examination (BOHSE) is a 10-category screening tool that can be used with cognitively intact or impaired older adults in any healthcare setting. The BOHSE provides an organized, efficient method for nurses to document their oral assessment. The 10 categories (lymph nodes, lips, tongue, gums, tissues, saliva, natural teeth, artificial teeth, pairs of teeth in chewing positions, and oral cleanliness) are scored from 0 (healthy) to 2 (unhealthy). Total scores range from 0 to 20; the higher the score, the poorer the older adult's oral health (Kayser-Jones, Bird, Paul, Long, & Schell, 1995). See the "Resources" section for access to this tool.

INTERVENTION AND CARE STRATEGIES

The gold standard for providing oral hygiene is the toothbrush. It is the mechanical action of the toothbrush that is important for plaque removal. If the older adult has any decrease in function or manual dexterity, the nursing staff needs to assess the older adult's ability to provide effective oral hygiene and then assist as needed. Foam swabs may be used for cleaning the oral mucus of an edentulous older adult. Alcohol-free commercial mouth rinses may be used. Lemon–glycerin swabs or swab sticks cause drying of the oral mucosa and erosion of the tooth enamel and thus should never be used.

The use of chlorhexidine (CHG) in the older adult is determined by the dentist. CHG has been found to be an effective means for the reduction of nosocomial pneumonia and ventilator-associated pneumonia (El-Rabbany, Zaghlol, Bhandari, & Azarpazhooh, 2015; Manger et al., 2017; Rabello, Araujo, & Magalhaes, 2018; Silvestri et al., 2014). A good oral assessment by the nurse during each shift is essential for the patient on CHG, and so is monitoring of nutritional intake.

Education of the nursing staff is imperative. Implementation of evidence-based protocols combined with ongoing educational training sessions have been demonstrated to have a positive impact on oral care being provided and on the oral health status of older adults (Catteau, Piaton, Nicolas, Hennequin, & Lassauzay, 2016; Deutsch et al., 2017; Gibney, Wright, Sharma, & Naganathan, 2015; Janssens, Vanobbergen, Lambert, Schols, & De Visschere, 2018; Kaneoka et al., 2015; Ory et al., 2017; Tynan, Deeth, & McKenzie, 2018). Staff needs to be instructed on oral hygiene and the proper care of different appliances. Dentures should be brushed before they are placed into a denture cup. Dentures should be removed at night, but some older adults prefer to keep their dentures in continuously. It therefore becomes even more important for the nurse to do an assessment of the oral mucosa. In the acute care and long-term care setting, the older adult may not have dental adhesive, and, therefore, there is a high risk of food particles getting caught underneath their dentures. It is important, therefore, that staff remember to take the dentures out after each meal, rinse them and the patient's mouth, and place the dentures back in. Complete denture care should be given morning, night, and as needed.

Nurses need to be educated in oral assessment, and nursing assistants need education on observation of the oral cavity and what to report to the nurse. Both nurses and nursing assistants need to be educated about the proper techniques for providing oral hygiene and caring for oral appliances. Patients and families need information about the importance of good oral health and hygiene and to dispel the oral health myths that exist about oral health and aging in general.

Education focused on the importance of good oral health and hygiene in the older adult, the myths about oral health and aging, evidence-based practice protocols, implementing these protocols, and the appropriate products for providing oral hygiene to their patients and residents must also be provided to managers and administrators. Without the proper supplies, it is impossible for the nursing staff to provide the oral hygiene care the older adult needs and to properly implement evidence-based protocols for oral health and hygiene in the older adult.

CASE STUDY 11.1

Mrs. Smith, an 84-year-old female with a history of Alzheimer's-type dementia, was admitted for recent decreased oral intake and percutaneous endoscopic gastrostomy (PEG) placement. Mrs. Smith was alert, oriented to herself, pleasant, cooperative with care, and able to follow simple directions. She lived at home with her family and received care from a home health aide. The initial oral assessment was done on day 2 of admission, and it was found that upper dentures and lower natural teeth were both covered with food particles. Her oral mucosa was noted to be dry. The upper dentures were difficult to remove and caused her pain. The upper denture was being "kept in place" by a collection of old food, which was found on removal. The oral mucosa under the upper denture was covered with sores and ulcers and was bleeding, infected, and very painful. The health team was notified, a dental consultant was called, and an oral hygiene plan of care was implemented. Mrs. Smith's diet was changed to puree while her oral mucosa was healing, and the PEG placement was put on hold. On inquiry, it was learned from the family that their long-time aide had just moved and that the new aide had been with them for only a few months. It was during this time that they noticed the decline in Mrs. Smith's nutritional intake. The family chose to hire a new aide, and both the family and the new aide were educated on proper oral hygiene for Mrs. Smith. Once Mrs. Smith's oral mucosa had healed, the upper denture was replaced, and she was returned to her regular diet. Her oral intake returned to baseline, and a PEG was no longer required.

Discussion

This case study illustrates how poor oral care often goes undetected, the importance of good oral care, the need for physical assessment by the nurse, and the need for staff and family education. This patient was being admitted for an invasive procedure secondary to poor oral health caused by poor oral care. Although the family was involved in Mrs. Smith's care (she had no contractures or skin breakdown), her lack of oral care had gone unnoticed by them. The admitting nurse documented that the patient had dentures on the admission form but did not do a physical oral assessment. The nurse caring for the patient on day 2 had attended an oral health seminar and included the physical oral assessment in her morning rounds. She also followed up with the nursing assistants to ensure that oral care had been provided to the patient after each meal. The implementation of an oral hygiene plan of care and education of nursing staff, family, and home care staff ensured that Mrs. Smith received the oral care required for her oral mucosa to heal, and her nutritional status to return to baseline, and prevented the unnecessary placement of a PEG.

SUMMARY

A healthy mouth is a vital part of general health and well-being, and it is imperative that healthcare professionals provide continuing education to patients and families, advocate for oral health prevention, and provide oral care to older adults in all settings. Well-developed evidence-based oral care protocols and educational training sessions have been demonstrated to have a positive impact on the oral health status of older patients.

NURSING STANDARD OF PRACTICE

Protocol 11.1: Providing Oral Healthcare to Older Adults

I. GOAL

The promotion of oral health through good oral hygiene is an essential part of nursing care. The RN or designee provides regular oral care for functionally dependent and cognitively impaired older adults.

II. BACKGROUND

A. Oral hygiene is directly linked with systemic infections, cardiac disease, cerebrovascular accident, acute myocardial infarction, glucose control in diabetes, nutritional intake, comfort, ability to speak, and the patient's self-esteem and overall well-being.
B. Definitions
   1. *Oral* refers to the mouth (natural teeth, gingival and supporting tissues, hard and soft palate, mucosal lining of the mouth and throat, tongue, salivary glands, chewing muscles, upper and lower jaw, and lips).
   2. *Oral cavity* includes cheeks, as well as hard and soft palate.
   3. *Oral hygiene* is the prevention of plaque-related disease, the destruction of plaque through the mechanical action of tooth brushing and flossing, or the use of other oral hygiene aids.
   4. *Edentulous* means that natural teeth have been removed.

III. PARAMETERS OF ASSESSMENT

A. The RN conducts an oral assessment or evaluation on admission and on every shift. The nurse assesses the condition of:
   1. The oral cavity; should be pink, moist, and intact
   2. The presence of or absence of natural teeth and/or dentures
   3. Ability to function with or without natural teeth and/or dentures
   4. The patient's ability to speak, chew, or swallow
   5. Any abnormal findings, such as dryness, swelling, sores, ulcers, bleeding, white patches, broken or decayed teeth, halitosis, ill-fitting dentures, difficulty swallowing, signs of aspiration, and pain
B. Assessment tool: The Kayser-Jones BOHSE. See the "Resources" section for access to this tool.

IV. NURSING CARE STRATEGIES

A. Oral hygiene plan of care: dependent mouth care of the edentulous patient
   1. Oral care is provided during morning care, evening care, and as needed.
   2. Wash hands and don gloves.
   3. Remove dentures.
   4. Brush dentures with toothbrush/toothpaste and rinse.
   5. Brush patient's tongue.
   6. Reinsert dentures.
   7. Apply lip moisturizer.

(*continued*)

Protocol 11.1: Providing Oral Healthcare to Older Adults (*continued*)

B. Dependent mouth care: patients with teeth or partial dentures
   1. Oral care is provided during morning care, evening care, and as needed.
   2. Wash hands and don gloves.
   3. Gently brush teeth in an up-and-down motion with short strokes using the toothbrush.
   4. Brush patient's tongue.
   5. Apply lip moisturizer.
C. For partial dentures, follow procedure for full denture cleaning and insertion.
D. Assisted or supervised care
   1. Oral care is provided during morning care, evening care, and as needed.
   2. Assess what patient can do and provide assistance as needed.
   3. Set up necessary items.

V. EVALUATION OF EXPECTED OUTCOMES

A. Patient will
   1. Receive oral hygiene a minimum of once every 8 hours while in the acute care, long-term care, or home care setting.
   2. Patients and families will be referred to dental services for follow-up treatment.
   3. Patients and families will be educated on the importance of good oral hygiene and follow-up dental services.
B. RN will
   1. Conduct an assessment or evaluation of the oral cavity on admission and every shift.
   2. Notify the physician of any abnormalities present in the oral cavity.
   3. Assess what each patient can do independently.
   4. Observe aspiration precautions while providing care.
   5. Provide oral care education to patients and families.
C. Institution will
   1. Provide access to dental services as appropriate.
   2. Provide ongoing education to healthcare providers.
   3. Provide a yearly oral health and dental care in-service to healthcare providers.

Managing Oral Hydration in the Older Adult*

12

Phyllis M. Gaspar and
Janet C. Mentes

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe older adults at risk of inadequate fluid intake and of dehydration.
2. Identify key aspects of a hydration assessment.
3. List specific interventions to promote hydration in older adults across care settings.
4. Identify outcomes of a hydration management program.

OVERVIEW

The incidence and prevalence of dehydration among older adults have been characterized as a public health issue for community-dwelling older adults (Picetti et al., 2017) and repeatedly noted as being far too commonly an avoidable diagnosis for those in long-term care (Paulis, Everink, Halfens, Lohrmann, & Schols, 2018). Studies using biomarkers (serum sodium, osmolality, and blood urea nitrogen [BUN]/creatinine ratio) for dehydration and volume depletion by the Established Populations for Epidemiologic Studies of the Elderly (EPESE; Stookey, Pieper, & Cohen, 2005) and National Health and Nutrition Examination Survey III (NHANES III; Stookey, 2005) found that the prevalence rate for these conditions in community-dwelling older adults could range from .5% to 60%, depending on the markers used. Several recent studies reported the occurrence of dehydration among community-dwelling older adults at 22% (Hooper et al., 2016) and 41.3% (Lesnik, Piko, Zeleznik, & Bevc, 2017).

The prevalence of dehydration among residents of long-term care (LTC) was reported in a systemic review, conducted by Paulis et al. (2018), to range from .8% to 38.5%. Hooper and team, who implemented the Dehydration Recognition in our Elders (DRIE; driestudy.appspot.com) study, reported that 19% of those in LTC were dehydrated. Yet that percentage is more than double that reported by Johnson and Hahn (2018) and Lesnik et al. (2017). In two separate studies, Murray, Doeltgen, Miller, and Scholten (2015, 2016) reported the rate of dehydration as 21% and 44% among individuals post stroke and in a rehabilitation facility.

Another line of investigation relevant to the occurrence of dehydration is the description of inadequate water intake among residents in LTC. Botigué et al. (2018), Gaspar (1988, 1999, 2011), Gaspar, Scherb, and Rivera-Mariani (2019), Marra et al. (2016), and Namasivayam-MacDonald et al. (2018) all reported that the intake of fluids was inadequate based on various

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

recommended parameters. The percentages of the sample that had less than the recommended parameter was over 90%, for all parameters used.

Admission and effects of hydration in the hospital setting have been explored by El-Sharkawy, Shahota, Maughan, and Lobo (2014), who found that 40% of older adults were dehydrated on admission to a hospital and 44% were found to be dehydrated at 48 hours. Fortes et al. (2015) reported that 21% of the hospitalized older adults population had water-loss dehydration and 19% presented with water solute dehydration. Bennett, Thomas, and Riegel (2004) found that 48% of older adults presenting with dehydration at an emergency department (ED) unit were from the community. Wolff, Stuckler, and McKee (2015) reported that those admitted from care homes had a ten times higher prevalence of hypernatremia as compared to those living in the community. Older adults have the highest rate of hospital admissions with dehydration as the primary diagnosis (AHRQ, 2015). Maintaining adequate fluid balance is an essential component of health across the life span; older adults are more vulnerable to shifts in water balance—both overhydration and dehydration—because of age-related changes and increased likelihood that an older individual has several medical conditions (Hooper, Bunn, Jimoh, & Fairweather-Tait, 2013). Dehydration is the more frequent occurrence in older adults (Warren et al., 1994; Xiao, Barber, & Campbell, 2004). In fact, avoidable hospitalizations for dehydration in older adults increased by 40% from 1990 to 2000, at a cost of $1.14 billion (Xiao et al., 2004) and is one of the Agency for Healthcare Research and Quality's 13 ambulatory care-sensitive conditions. When dehydration is considered as a comorbid condition, the cost of hospitalizations and rehospitalizations is even higher (Frangeskou, Lopez-Valcarcel, & Serra-Majem, 2015).

Careful attention to hydration requirements of older adults will not only help prevent hospitalizations for dehydration but also decrease associated conditions such as acute confusion and delirium (Foreman, 1989; Mentes & Culp, 2003; Mentes, Culp, Maas, & Rantz, 1999; Murray et al., 2015, 2016; O'Keeffe & Lavan, 1996; Seymour, Henschke, Cape, & Campbell, 1980), adverse drug reactions (Doucet et al., 2002), infections (Beaujean et al., 1997; Masotti et al., 2000; Murray et al., 2015, 2016), increased morbidity associated with bladder cancer (Michaud et al., 1999), coronary heart disease (Chan, Knutsen, Blix, Lee, & Fraser, 2002; Rasouli, Kiasari, & Arab, 2008), stroke (Lin, Lee, Hung, Chang, & Yang, 2014; Rodriguez et al., 2009), and other thromboembolytic events (Kelly et al., 2004). Furthermore, dehydration has been associated with longer hospital stays for rehabilitation (Frangeskou et al., 2015; Mukand, Cai, Zielinski, Danish, & Berman, 2003) and for readmission to the hospital (Frangeskou et al., 2015; Gordon, An, Hayward, & Williams, 1998). Even in healthy community-dwelling older adults, physical performance and cognitive processing are affected by mild dehydration (Ainslie et al., 2002).

Oral hydration of older adults is particularly complex for a variety of reasons. In the following review, issues of age-related changes, risk factors, assessment measures, and nursing strategies for effective interventions for dehydration are addressed.

BACKGROUND AND STATEMENT OF PROBLEM

Water is an essential component of body composition. Intricate cellular functions, such as gene expression, protein synthesis, and uptake and metabolism of nutrients, are affected by hydration status. Organ systems, specifically the cardiovascular and renal systems, are particularly vulnerable to fluctuating levels of hydration (Metheny, 2000).

Older individuals are at increased risk for hydration problems stemming from several converging age-related factors, including lack of thirst (Ainslie et al., 2002; Phillips, Bretherton, Johnston, & Gray, 1991; Phillips et al., 1984); changes in body composition, specifically loss of fluid-rich muscle tissue (Bossingham, Carnell, & Campbell, 2005); increasing inability to respond efficiently to physiological stressful events through which dehydration results (Farrell et al., 2008; Rolls, 1998); and renal changes, including a reduced renal capacity to handle water and sodium efficiently (Macias-Nuñez, 2008). Additionally, personal, often lifetime, hydration habits may contribute to risk but have not been explored in relation to underhydration. As a result, older adults are often at risk for a chronic state of underhydration. Several studies (Bossingham et al., 2005; Morgan, Masterson, Fahlman, Topp, & Boardley, 2003; Raman et al., 2004) of community-dwelling older adults suggest that under normal conditions, older adults maintain adequate hydration; however, when challenged by environmental stressors—physical or emotional illness, surgery, or trauma—they are at increased risk for dehydration and rapidly become dehydrated if they are already chronically underhydrated.

DEFINITIONS

Dehydration

Dehydration is the depletion in total body water (TBW) content caused by pathological fluid losses, diminished water intake, or a combination of both. It results in hypernatremia (more than 145 mEq/L) in the extracellular fluid

compartment, which draws water from the intracellular fluids. The water loss is shared by all body-fluid compartments, and relatively little reduction in extracellular fluids occurs. Thus, circulation is not compromised unless the loss is very large.

Underhydration

Underhydration is a precursory condition to dehydration associated with insidious onset and poor outcomes (Mentes, 2006; Mentes & Culp, 2003). Others have referred to this condition as *mild dehydration* (Stookey et al., 2005), *chronic dehydration* (Bennett et al., 2004), or *impending water-loss dehydration* (Hooper et al., 2011).

ASSESSMENT OF THE PROBLEM

Assessment of hydration status consists of determining adequacy of intake, risk identification with attention to specific populations at increased risk, assessment of hydration habits, and evaluation of specific biochemical and clinical indicators. Armstrong, Johnson, Armstrong, and Johnson (2018), in a review of the literature, indicated that the diagnosis of dehydration needs to be based on a combination of history, physical exam, laboratory values, and clinician experience.

Determining Adequate Intake

All older adults should have an individualized fluid goal determined on the basis of a documented standard for daily fluid intake. Numerous standards have been developed (Box 12.1), several based on fluid intake (liquid intake), while others are based on water intake that is inclusive of food and fluid. Gaspar (2011) has compared four of the standards and provides a rationale for the use of the following formula as a recommended water intake standard (from food and fluid): 1,600 mL/m^2 × .75. This formula provides the most individualized approach to the establishment of a water intake recommendation and should be attainable. A nomogram based on this formula was produced to enhance the clinical utilization of the standard and is available in the University of Iowa Guideline noted as a resource.

Risk Identification

Risk for inadequate fluid intake as well as risk for dehydration, primarily among ill or frail older adults across care settings, have been studied. Although there is no single outstanding risk factor for dehydration, several are repeatedly identified: Age, gender, ethnicity, class, and number of medications taken, level of activities of daily living (ADL) dependency, presence of cognitive impairment, presence of medical conditions such as infectious processes, and a prior history of dehydration have all been associated with dehydration in older adults (Mentes & Iowa–Veterans Affairs Nursing Research Consortium [IVANRC], 2000; Iowa Hydration Guideline). In a systematic review of 19 studies, 49 risk factors for dehydration were identified, but only cognitive impairment and fever were significantly associated with dehydration in more than one study (Paulis et al., 2018). Therefore, although single risk factors are discussed, it is likely that clusters of risk factors may be more helpful in clinical settings (Leibovitz et al., 2007).

Increasing age is associated with increased likelihood of dehydration (Ciccone, Allegra, Cochrane, Cody, & Roche, 1998; Lavizzo-Mourey, Johnson, & Stolley, 1988; Marra et al., 2016; Warren et al., 1994) and similarly for inadequate fluid intake (Gaspar, 1988). Namasivayam-MacDonald et al. (2018) reported that for residents in LTC settings, for every 1 year of age there was a decline in fluid intake of 6 mL/d. Ciccone et al. (1998) found that adults aged 85 years and older were three times more likely to have a diagnosis of dehydration on admission to an emergency department than adults aged 65 to 74 years. Older African American and Black adults have higher prevalence rates of dehydration on hospitalization than Caucasian adults (Lancaster, Smiciklas-Wright, Heller,

BOX 12.1

Daily Fluid Goal Formulas

- 1,600 mL/m^2 of body surface per day (Butler & Talbot, 1944; Gaspar, 1988, 1999); more recently, Gaspar (2011) recommended 75% of this standard and has developed a nomogram
- 30 mL/kg body weight with 1,500 mL/d minimum (Chernoff, 1994)
- 1 mL/kcal fluid for adults (National Research Council, 1989)
- 100 mL fluid/kg for the first 10 kg BW, 50 mL fluid/kg for the next 10 kg of BW, and 15 mL fluid/kg for the remaining kilograms of weight (Chidester & Spangler, 1997)
- 1,600 mL/d (Hodgkinson, Evans, & Wood, 2003)
- 1.6 L of drinks for women and 2.0 L of drinks for men daily (Volkert et al., 2018)

BW, body weight.

Ahern, & Jensen, 2003; Warren et al., 1994). A recent study by Mentes, DeVost, and Nandy (2019) reported that Black and African American community-dwelling older adults had better hydration than the Caucasians in the sample. Female gender has been associated with risk of dehydration in nursing home residents (Gaspar, 1988; Lavizzo-Mourey et al., 1988); however, male hospitalized patients had an increased risk for dehydration (Warren et al., 1994), and, more recently, no gender differences were detected in a large database study (Xiao et al., 2004).

In general, individuals in LTC settings are considered to be at increased risk (Lesnik et al., 2017), with one third of residents experiencing a dehydration episode in a 6-month period (Mentes, 2006). However, many of the factors are also characteristic of older adult hospitalized patients as well. See Protocol 12.1 for patient, staff, and family issues that serve as risk factors for dehydration. An example of a tool to determine risk is the Dehydration Risk Appraisal Checklist (Mentes & Wang, 2010) developed for use by nursing home staff members and based on information that could be retrieved from the Minimum Data Set (MDS; Exhibit 12.1).

A screening tool was developed by Oates, Vicky, Plank, and Price (2017) to identify those at risk for inadequate fluid intake among hospitalized older adults. The Northumbria Assessment of Hydration (NoAH) was used as part of a quality improvement project with positive outcomes.

At-Risk Populations

Several groups of patients, based on medical diagnosis, are at increased risk of dehydration. These groups include the chronically mentally ill and stroke, surgical, and end-of-life patients.

Chronically Mentally Ill Patients

Special consideration should be given to chronically mentally ill elders (e.g., individuals with schizophrenia, bipolar disorder, obsessive-compulsive disorder), as they may be at risk for both over- and underhydration. Their antipsychotic medications may blunt their thirst response and put them at increased risk in hot weather for dehydration and heat stroke (Batscha, 1997). In addition, even small increases in their antipsychotic medications may predispose them to neuroleptic malignant syndrome (NMS), of which hyperthermia and dehydration are prominent features (Bristow & Kohen, 1996; Jacobs, 1996; Sachdev, Mason, & Hadzi-Pavlovic, 1997). Polyuria due to lithium treatment in community-dwelling adults with bipolar disorder may also put them at risk for dehydration and

EXHIBIT 12.1

Dehydration Risk Appraisal Checklist

The greater the number of characteristics present, the greater the risk for hydration problems. Please check all that apply.	
>85 years	Female
Significant Health Conditions	
MMSE score <24 (indicating cognitive impairment)	Semidependent in ADL
Dementia diagnosis	Repeated infections
GDS score ≥6 (indicating depression)	History of dehydration
	Urinary incontinence
Medications	
Laxatives	Psychotropics: antipsychotics, antidepressants, anxiolytics
Diuretics	
Intake Behaviors	
BMI <21 or >27	Can drink independently but forgets
Requires assistance to drink	Poor eater
Has difficulty swallowing/chokes	

ADL, activities of daily living; BMI, body mass index; GDS, Geriatric Depression Scale; MMSE, Mini-Mental State Examination.

death (Kinahan et al., 2015). In addition, in individuals with persistent mental illness, risks of overhydration stem from a combination of the drying side effects of prescribed psychotropic medications and the individual's compulsive behaviors that result in excessive fluid intake (Cosgray, Davidhizar, Giger, & Kreisl, 1993).

Stroke Patients

There is increasing evidence that dehydration may play an important part in contributing to early cerebral ischemia (Rodriguez et al., 2009), as well as the early recovery from stroke (Kelly et al., 2004). In fact, Kelly et al. found that dehydration in stroke patients was hospital acquired and led to poorer outcomes for recovering stroke patients. Dehydration, signified by increased serum osmolality, led to a 2.8- to 4.7-fold increase in the risk of hospitalized stroke patients acquiring a venous thromboembolism (VTE). Hospitalized patients recovering from stroke should be carefully and continuously monitored for dehydration. Another sequela of stroke is dysphagia, which can cause dehydration (Murray et al., 2015; Whelan, 2001). This appears to be related not only to the dysphagia resulting from the stroke but also the poor palatability of the thickened fluids offered to patients to prevent aspiration (Lin et al., 2014; McGrail & Kelchner, 2015).

Surgical Patients

Prolonged NPO status prior to elective surgery has been linked to increased risk of dehydration and adverse effects such as thirst, hunger, irritability, headache, hypovolemia, and hypoglycemia in surgical patients (Smith, Vallance, & Slater, 1997; Yogendran, Asokumar, Cheng, & Chung, 1995). Crenshaw and Winslow (2002) have found that despite the formulation of national guidelines developed by the American Society of Anesthesiologists Task Force on Preoperative Fasting (Parameters, 2017), patients were still being instructed to fast too long prior to surgery (Crenshaw & Winslow, 2002). In fact, patients may safely consume clear liquids up to 2 hours before elective surgery using general anesthesia, regional anesthesia, or sedation-anesthesia (Parameters, 2017).

End-of-Life Patients

Maintaining or withholding fluids at the end of life remains a controversial issue. Proponents suggest that dehydration in the terminally ill patient is not painful and lessens other noxious symptoms of terminal illness, such as excessive pulmonary secretions, nausea, edema, and pain (dehydration acts as a natural anesthetic; Fainsinger & Bruera, 1997). Some suggest additional benefit from the decreased need to get up to use the restroom and receive bedpans or diaper changes, which could be difficult or painful for someone at the end of life (Mion & O'Connell, 2003). Opponents of this position suggest that associated symptoms of dehydration, such as acute confusion/delirium, are stressful and reduce the quality of life for the terminally ill elder (Bruera, Belzile, Watanabe, & Fainsinger, 1996).

Most research that has been done with terminally ill cancer patients has examined the discomforts of dehydration, including thirst, dry mouth, and agitated delirium. However, research has not demonstrated a link between biochemical markers of dehydration and these various symptoms in terminally ill patients (Burge, 1993; Ellershaw, Sutcliffe, & Saunders, 1995; Morita, Tei, Tsunoda, Inoue, & Chihara, 2001). It has been suggested that several confounding factors influence the uncomfortable dehydration-like symptoms that accompany the end of life. These include the use and dosage of opiates, type and location of cancer, hyperosmolality, stomatitis, and oral breathing (Morita et al., 2001). On the other hand, Bruera et al. (1996) has determined that small amounts of fluids delivered subcutaneously via hypodermoclysis plus opioid rotation were effective in decreasing delirium and antipsychotic use and did not cause edema in terminally ill patients. Bruera et al. (2005) also found, in a 2-day-long pilot study, that parenteral hydration in terminally ill cancer patients leads to statistically significant decreases in hallucination, myoclonus, fatigue, and sedation but that in a larger clinical trial, no benefit from parenteral hydration was found for cancer patients in a hospice setting (Bruera et al., 2012). However, research suggests that artificial hydration does not prolong life (Bruera et al., 2005; Bruera et al., 2012, Meier, Ahronheim, Morris, Baskin-Lyons, & Morrison, 2001; Mitchell, Kiely, & Lipsitz, 1997).

Therefore, it is recommended that maintaining or withholding fluids at the end of life be an individual decision that should be based on the etiology of illness, use of medications, presence of delirium, and family and patient preferences (Bruera et al., 2012, Fainsinger & Bruera, 1997; Morita et al., 2001; Schmidlin, 2008). Schmidlin (2008) and Bruera et al. (2012) recommend early discussions with patients and family on their wishes as well as educating patients on the current knowledge about artificial hydration so that proper, patient-centered care will be provided.

Hydration Habits

Hydration habits may indicate the level of risk for dehydration in older adults. Some hydration habits may have developed over a lifetime, and others are adaptations to

current health status. Four major categories of hydration habits have been identified (Mentes, 2006): those older adults who "can drink," "cannot drink," "will not drink," and older adults who are at the "end of life." Older adults who can drink are those who are functionally capable of accessing and consuming fluids but who may not know what is an adequate intake or may forget to drink secondary to cognitive impairment; older adults who cannot drink are those who are physically incapable of accessing or safely consuming fluids related to physical frailty or difficulty in swallowing. Older adults who will not drink are those who are capable of consuming fluids safely but who do not because of concerns about being able to reach the toilet with or without assistance or who relate that they have never consumed many fluids. Finally, older adults who are terminally ill comprise the end-of-life category. Hydration habits of community-dwelling older adults were explored by Mentes et al. (2019) in relation to hydration status measured by salivary osmolality. From these habits, two latent factors, physical barriers and psychological barriers, were identified. Significant deficiencies in hydration health literacy among community-dwelling elderly were identified by Picetti et al. (2017). Older adults' are not aware of how their habits adversely influence their hydration status. Understanding the hydration habits of older adults can help them and nurses to plan appropriate interventions to improve or ensure adequate intake (Mentes, 2006; Picetti et al., 2017).

Indicators of Hydration Status

A priority for nursing, regardless of clinical setting, is the prevention of dehydration. Unfortunately, many of the standard tests for detection of dehydration confirm a diagnosis of dehydration only after it is too late to prevent the episode. In our fast-paced nursing environments, it is difficult to monitor the fluid intake of all our older patients. Armstrong, Kavouras, Walsh, and Roberts (2016) found that a combination of approaches is needed to diagnose dehydration, and Mentes (2006) noted that serial measurements offer the greatest likelihood of accuracy.

Many studies have used a single test—either biochemical or clinical signs/symptoms—that have insufficient evidence to support diagnostic accuracy (Hooper et al., 2015). Hooper et al. (2016) found that serum osmolality, urine specific gravity, nor any other urinary test was useful to diagnosis dehydration. Yet others have found urine color and specific gravity are reliable indicators of hydration status (not dehydration) in older individuals with adequate renal function in nursing homes and a Veterans Administration Medical Center (Culp, Mentes, & Wakefield, 2003; Mentes, Wakefield, & Culp, 2006). Specifically, the use of urine color, as measured by a urine color chart, can be helpful in monitoring hydration status (Armstrong et al., 1994; Mentes & IVANRC, 2000). The urine color chart has eight standardized colors ranging from *pale straw* (number 1) to *greenish brown* (number 8), approximating urine specific gravities of 1.003 to 1.029 (Armstrong et al., 1994). The urine color chart is most effective when an individual's average urine color is calculated over several days for an individual referent value. If the older person's urine becomes darker from his or her average color, further assessment of recent intake and health status can be conducted, and fluids can be adjusted to improve hydration status before dehydration occurs. Limitations in using urine indices to estimate specific gravity include the following: (a) Certain medications and foods can discolor the urine (Mentes, Wakefield, & Culp, 2006; Wakefield, Mentes, Diggelmann, & Culp, 2002), (b) persons must be able to give a urine specimen for color evaluation, and (c) best results in the use of urine color as an indicator have been documented in older adults with adequate renal function (Mentes, Wakefield, & Culp, 2006). In addition, the timing of collection of urine is also important. In a recent study of younger adults, Perrier et al. (2013) found that a late afternoon (between 4:00 and 8:00 p.m.) specimen best reflected overall hydration status as measured by urine osmolality when compared to a 24-hour urine collection. This would need to be tested with a sample of older adults. Rodrigues et al. (2015) found a 24-hour urine osmolality was negatively associated with hydration score. Johnson and Hahn (2018) make the case for the use of renal indicators for hydration status as the renal system is more responsive to water deficiency as compared to blood levels. They created a composite index, the Fluid Retention Index (FRI), which includes urine color, specific gravity, and urine creatinine. The findings did not support an association of the FRI with serum osmolality.

Bioelectrical impedance analysis (BIA) is a measurement that has been used mostly in the fitness industry to estimate body composition, including body mass index (BMI), TBW, and intracellular and extracellular water. Several nursing studies have used impedance measurements to estimate TBW and intracellular and extracellular water (Culp et al., 2003, 2004). Although mostly used in research, BIA is a noninvasive, reliable method used to estimate body water (Ritz & Source Study, 2001). Because TBW is dependent on weight and body composition, this measure is best used after a baseline value of TBW, intracellular, and extracellular fluid in liters has been documented. Then, deviations from the individual baseline can be noted. In a recent Cochrane Review for diagnostic

accuracy, a single measure of bioelectrical impedance with resistance at 50 Hz was found to be diagnostic of impending dehydration in two studies and equivocal in two studies (Hooper et al., 2015). The findings of Goldberg et al. (2014) also supported the use of BIA as a measure of hydration. Yet the recommendations by the ESPEN Guideline state that the bioelectrical impedance shall not be used to assess hydration status in older adults (Volkert et al., 2018).

Salivary osmolality is an emerging clinical indicator of hydration status that is sensitive in younger healthy adults (Oliver, Laing, Wilson, Bilzon, & Walsh, 2008) and has been tested in a small sample of nursing home residents (Woods & Mentes, 2011) and older hospitalized adults with a mean age of 78 years (Fortes et al., 2015). Salivary osmolality demonstrated 70% sensitivity and 68% specificity for water-loss dehydration as well as 78% sensitivity and 72% specificity for water and solute dehydration in this study (Fortes et al., 2015). Salivary osmolality was recently used to measure hydration status among a group of community-dwelling older adults attending senior centers and one adult day health center. Salivary osmolality values were, on average, higher for these older adults than those reported in younger healthy adults. On average, salivary osmolality values were higher (signaling poorer hydration) in the morning than in the early afternoon, and higher values were associated with slower times on an ambulation test (Mentes et al., 2019).

Indicators of Dehydration

Dehydration is the loss of body water from intracellular and interstitial fluid compartments that is associated with hypertonicity (Mange et al., 1997). Therefore, the most reliable indicators of dehydration are elevated serum sodium, serum osmolality, and BUN–creatinine ratio (Table 12.1). The guidelines of nutrition and fluid intake of the ESPEN recommend that serum osmolality be used as the standard for determining dehydration and impending dehydration (Volkert et al., 2018). The most common clinical assessments of dehydration include the presence of dry oral mucous membranes, tongue furrows, decreased saliva, sunken eyes, decreased urine output, upper body weakness, a rapid pulse (Gross et al., 1992), and tongue dryness (Vivanti, Harvey, & Ash, 2010; Vivanti, Harvey, Ash, & Battistutta, 2008). The ESPEN does not recommend that these clinical indicators be used as a basis for determining hydration status unless the individual has experienced a volume loss as a result of vomiting, diarrhea, or blood loss. Decreased axillary sweat production as a clinical sign of dehydration

TABLE 12.1

Approximate Ranges of Laboratory Tests for Hydration Status

Value Ranges for:	Normal	Impending Dehydration	Dehydration
BUN/Creatinine ratio	20–24		>25
Hematocrit	Male 42%–52%		> normal
	Female 35%–47%		> normal
Serum osmolality	<295 mmol/kg	295–300 mmol/kg	>300 mmol/kg
Serum sodium	135–145 meq/L		>150 meq/L
Urine osmolality	500–700 mOsm	700–1,050 mOsm	>1,050 mmol/kg
Urine specific gravity	1.005–1.019	1.020–1.029	>1.029
Urine color	Pale to medium yellow	Dark yellow	Greenish brown
Amount of urine		800–1,200 mL/d	<800 mL/d

BUN, blood urea nitrogen.

has produced contradictory results, making it an unreliable indicator of dehydration (Eaton, Bannister, Mulley, & Connolly, 1994; Gross et al., 1992), yet recent studies of Kinoshita et al. (2013) and Okuyama and Nishida (2016) have found axillary moisture and temperature (respectively) to be accurate indicators of hydration status. The change in accuracy is probably based on the technology now available to measure these indicators. Assessment of sternal skin turgor as a sign of dehydration has been the mainstay of nursing practice; however, it is also an ambiguous indicator for dehydration in older individuals, with some researchers finding it unreliable because of age-related changes in skin elasticity (Gross et al., 1992) and others finding it reliable (Chassagne, Druesne, Capet, Ménard, & Bercoff, 2006; Vivanti et al., 2008). From a systematic review, Hooper et al. (2015) found that the clinical symptoms/signs of "expressing fatigue" and "missing drinks between meals" were the only measures with the ability to diagnose impending and current dehydration.

In conclusion, the current comparison standard for determining hydration status is serum osmolality, but this standard is not supported by all researchers or clinicians. The use of multiple clinical indicators is advocated by Armstrong et al. (2016) advocated the use of multiple clinical indicators in the assessment of hydration, with Mentes et al. (2006) advising the use of serial measures. The work of Hooper et al. (2015) has indicated that three single tests versus serial testing showed the ability to diagnose impending and current dehydration, including expressing fatigue, missing drinks between meals, and BIA with a resistance of 50 Hz. It was further concluded that a combination of two tests—fatigue and missing drinks—further increased diagnostic accuracy. The development of tools for capturing fluid intake, such as the Drinks Diary, is essential. The potential for technology advancements that will provide for reliable, valid real-time hydration monitoring would allow detection of issues earlier and decrease the risk of dehydration-related morbidity among at-risk populations (Garrett et al., 2018).

CASE STUDY 12.1

Mrs. Chung is an 87-year-old Chinese American woman who was admitted to the hospital for observation secondary to an episode of dehydration. She has resided at Sunny Days Assisted Living Facility for the past month. Staff describe her as fiercely independent despite experiencing some declines in her health recently. Her medical diagnoses include hypertension, for which she receives atenolol 25 mg daily and enalapril 20 mg daily; status post–mild cerebrovascular accident (CVA) with residual left-sided weakness, for which she is taking 80 mg of aspirin daily; osteoarthritis, for which she takes Tylenol Extra Strength twice daily; and cataracts, for which she is reluctant to have surgery. She is cognitively intact and requires only minor assistance with bathing.

Before hospitalization, Mrs. Chung had become more withdrawn and concerned about her health. Her family noticed that she has altered some of her daily routines. For example, she eliminated her daily tea because she is unfamiliar with the new microwave at the assisted care facility (ACF) and hence finds it difficult to heat her water. She stays in bed much of the day, complaining that she does not have any energy. When questioned, she reluctantly admits that she has been having more problems with her long-standing urinary incontinence and she is afraid to leave her room because she is fearful that she will not be able to make it to a bathroom on time. Consequently, she has further restricted the amount of fluid that she consumes on a daily basis.

Mrs. Chung is at high risk for dehydration given that she has recently begun to restrict her fluids because of unfamiliarity with the microwave to heat her water for tea. Older adults from different cultures may wish to have their beverages served at different temperatures. Especially when ill, ethnic older adults may prefer to have warmed beverages. In addition, Mrs. Chung is "treating" her urinary incontinence by restricting her fluids, which places her at risk for dehydration and urinary tract infections. This scenario is not uncommon in older adults struggling to maintain independence. One of the major reasons for admission to a nursing home is the presence of urinary incontinence. Finally, there is some evidence that Mrs. Chung is depressed, which would also place her at risk for dehydration often secondary to decreased food and fluid intake. Additional risk factors include her age (87 years old), gender, and use of an angiotensin-converting enzyme (ACE) inhibitor, which acts on the renin–angiotensin–aldosterone (RAA) system.

Discussion

Interventions to prevent dehydration in Mrs. Chung would include evaluating her for a urinary tract infection and offering her an evaluation for her urinary incontinence that could include use of medications, if indicated, and use of behavioral strategies, including

(*continued*)

CASE STUDY 12.1 (*continued*)

urge inhibition (strategies to prolong urge to urinate) and/or Kegel exercises. Education on the importance of maintaining adequate fluid intake to minimize urinary incontinence is indicated, which should include a discussion about the amount of daily fluids required and the provision of a graduated cup to help her ascertain appropriate amounts. Helping her simplify the use of the microwave and/or attendance at social events at the ACF where fluids are provided could be implemented. Lastly, an evaluation for depression may be indicated if the previous interventions do not improve her mood.

SUMMARY

Dehydration in older adults is a costly yet preventable health problem. Best practices for hydration management have been identified primarily in the nursing home population, with recent attention to the community-dwelling older adult. Establishment of the older adult's individualized goal for water intake and evaluation of the achievement of the goal especially for those identified as being at risk for inadequate intake are essential. Strategies for promoting fluid intake in older adults, regardless of setting, are straightforward yet so necessary. They include providing access to fluids at all times, regularly offering fluids throughout the day, use of a vessel that is easy to handle, assessing fluid preferences and providing the fluid of choice, increasing fluids with each scheduled medication administration, incorporating fluids into activities, and appropriate supervision of personnel who will be providing the fluids. Nursing personnel should assess the older adult's ability to self-manage hydration habits as well as preventing extended periods of time when the older adult does not have access to fluids (as in fasting for a diagnostic test). Regularly offering fluids through fluid rounds, a beverage cart, or other novel means, such as tea time, is another principle of good hydration practice. Accommodating older peoples' preferences for type of beverage and appropriate temperature of beverage has been shown to increase fluid intake. Education and supervision of staff in all aspects of hydration management is the foundation of quality care. Lastly, appropriate supervision of how much fluid per day is required and how assistance is given to older adults who are not capable of drinking themselves to ensure that required amounts are consumed is also key in maintaining adequate hydration. Attention to concerns about toileting is another important issue in helping older adults to maintain adequate hydration. The hydration practices of healthier, community-dwelling older adults are dependent on their hydration literacy. Further study in hydration literacy is needed.

NURSING STANDARD OF PRACTICE

Protocol 12.1: Managing Oral Hydration

I. GOAL

Manage oral hydration to minimize episodes of underhydration and dehydration in older adults

II. OVERVIEW

Maintaining adequate fluid balance is an essential component of health across the life span; older adults are more vulnerable to shifts in water balance, both overhydration and dehydration, because of age-related changes and increased likelihood that an older individual has several medical conditions. Underhydration and dehydration are the more frequently occurring problem.

III. BACKGROUND AND STATEMENT OF THE PROBLEM

A. Definitions
   1. *Dehydration* is depletion in TBW content caused by pathological fluid losses, diminished water intake, or a combination of both. It results in hypernatremia (more than 145 mEq/L) in the extracellular fluid compartment, which draws water from the intracellular fluids (Metheny, 2000). The water loss is shared by all

(*continued*)

Protocol 12.1: Managing Oral Hydration (*continued*)

body-fluid compartments, and relatively little reduction in extracellular fluids occurs. Thus, circulation is not compromised unless the loss is very large.

2. *Underhydration* is a precursory condition to dehydration associated with insidious onset and poor outcomes (Mentes & Culp, 2003). Others have referred to this condition as *mild dehydration* (Stookey, 2005; Stookey et al., 2005), *chronic dehydration* (Bennett et al., 2004), or *impending water-loss dehydration* (Hooper et al., 2011).

Etiological factors associated with dehydration	
Environment: Residing in long-term care as compared with community dwelling (Lesnik et al., 2017; Rodrigues et al., 2015)	
Staff and family characteristics	
Inadequate staff and professional supervision	Kayser-Jones, Schell, Porter, Barbaccia, & Shaw, 1999
Presence of more staff	Namasivayam-MacDonald et al., 2018
Family or caregivers not spending time with patient	Mentes, Chang, & Morris, 2006
Age-related risk factors	
Age-related changes in body composition with resulting decrease in TBW	Bossingham et al., 2005; Lavizzo-Mourey et al., 1988; Metheny, 2000
Decreasing renal function	Lindeman, Tobin, & Shock, 1985
Lack of thirst	Farrell et al., 2008; Kenney & Chiu, 2001; Mack et al., 1994; Miescher & Fortney, 1989; Phillips et al., 1984; Phillips et al., 1991
Poor tolerance for hot weather	Josseran et al., 2009
Risk factors	
Individual characteristics	
Older than 85 years of age	Ciccone et al., 1998; Gaspar, 1999; Goldberg et al., 2014: Lavizzo-Mourey et al., 1988; Mentes et al., 2019; Murray et al., 2015
Female	Gaspar, 1988; Lavizzo-Mourey et al., 1988; Marra et al., 2016; Namasivayam-MacDonald et al., 2018
Semidependent in eating	Gaspar, 1999; Gaspar et al., 2019
Functionally more independent	Gaspar, 1999; Mentes & Culp, 2003
Functionally more dependent (especially with eating)	Botigué et al., 2018; Marra et al., 2016; Mentes et al., 2019; Murray et al., 2015; Namasivayam-MacDonald et al., 2018
Few fluid ingestion opportunities	Gaspar, 1988, 1999; O. F. Jimoh, Brown, Bunn, & Hooper, 2019
Inadequate nutrient intake	Gaspar, 1999; McGrail & Kelchner, 2015
Alzheimer's disease or other dementias or cognitive impairment	Albert, Nakra, Grossberg, & Caminal, 1989, 1994; Botigué et al., 2018; Marra et al., 2016; McGrail & Kelchner, 2015; Namasivayam-MacDonald et al., 2018; Paulis et al., 2018
Four or more chronic conditions	Lavizzo-Mourey et al., 1988
Four medications	Lavizzo-Mourey et al., 1988
Fever	Pals et al., 1995; Paulis et al., 2018; Weinberg et al., 1994

(*continued*)

Protocol 12.1: Managing Oral Hydration (*continued*)

Vomiting and diarrhea	Wakefield, Mentes, Holman, & Culp, 2008
Individuals with infections	Warren et al., 1994
Individuals who have had prior episodes of dehydration	Mentes, 2006
Depression or loneliness associated with decreased fluid intake as identified by nursing staff	Mentes, Chang, & Morris, 2006
Diuretics: thiazide	Wakefield et al., 2008
Diuretics: loop and thiazide	Lancaster et al., 2003
Risk of pressure ulcer	Botigué et al., 2018
Texture modified diet	Botigué et al., 2018; Painter, Le Couteur, & Waite, 2017
Receiving oral nutritional supplement	Marra et al., 2016
Impaired swallowing and/or dysphagia	Botigué et al., 2018)
Diabetes	Marra et al., 2016

Interventions for Enhancing Hydration Status

A. Risk identification	Mentes & IVANRC, 2000
1. Identify acute situations: vomiting, diarrhea, or febrile episodes	Mentes & IVANRC, 2000
2. Use a tool to evaluate risk	Mentes & IVANRC, 2000
Dehydration Risk Appraisal Checklist (LTC)	Mentes & Wang, 2010
Northumbria Assessment of Hydration (acute care) Risk of insufficient fluid intake	Oates et al., 2017
3. Use a tool to evaluate adequacy of intake: Drink Diary	F. O. Jimoh, Bunn, & Hooper, 2015
B. Acute hydration management	
Monitor input and output	Weinberg et al., 1994
Provide additional fluids as tolerated	Weinberg et al., 1994
Minimize fasting times for diagnostic and surgical procedures	Parameters, 2017
Offer subcutaneous or intravenous fluid in parallel with encouraging oral fluid intake for those experiencing dehydration and who are unable to drink	Volkert et al., 2018

C. Chronic/long-term hydration management

Systematic reviews of evidence have not identified a specific intervention for the management of dehydration and/or inadequate fluid intake (Abdelhamid et al., 2016; Bunn et al., 2016; Herke et al., 2018; Volkert et al., 2018). An individualized resident-centered care plan that considers the following strategies is needed (Volkert et al., 2018)

Provide fluids consistently throughout the day	Bak, Wilson, Tsiami, & Loveday, 2018; Bunn, Jimoh, Wilsher, & Hooper, 2015; Ferry, 2005; Hodgkinson et al., 2003; F. O. Jimoh et al., 2015; O. F. Jimoh et al., 2019; Mentes, Chang, & Morris, 2006; Oates & Price, 2017; Robinson & Rosher, 2002; Simmons, Alessi, & Schnelle, 2001; Volkert et al., 2018
Specific Effective Strategies	
Plan fluid intake as follows: 75%–80% delivered at meals, and 20%–25% delivered during nonmeal times such as medication times and planned nourishment times	Volkert et al., 2018

(*continued*)

Protocol 12.1: Managing Oral Hydration (*continued*)

Offer a variety of fluids keeping in mind the individual's previous intake pattern	Bunn et al., 2015; Godfrey, Cloete, Dymond, & Long, 2012; Schnelle et al., 2010; Simmons et al., 2001; Volkert et al., 2018; Wilson et al., 2019: Zembrzuski, 1997
Integrate fluid rounds midmorning and late afternoon, where caregiver provides additional fluids	Spangler, Risley, & Bilyew, 1984
Standardize fluid with medication administrations to a prescribed amount; e.g. 180 mL (6 oz.) per administration time.	O. F. Jimoh et al., 2019; Mentes & Culp, 2003
Provide 2–8 oz. glasses of fluid in a.m. and p.m.	Robinson & Rosher, 2002
If taking thickened liquids, encourage intake (water intake lower when taking thickened liquids as compared with thin liquids)	McGrail & Kelchner, 2012, 2015; Painter et al., 2017
Select between-meal snacks that will increase water intake	Marra et al., 2016
Provide fluids between waking and breakfast	O. F. Jimoh et al., 2019
Provide reminders/prompts to drink fluids	Bak et al., 2018; Bunn et al., 2015; Godfrey et al., 2012; Oates & Price, 2017
Offer a variety of fluids with consideration for residents' preference	Godfrey et al., 2012; Mentes, Chang, & Morris, 2006; Robinson & Rosher, 2002; Schnelle et al., 2010; Simmons et al., 2001; Wilson et al., 2019

Interventions and Strategies	**References**
Make drinking opportunity a pleasurable and social experience	Abdelhamid et al., 2016; Cook, Hodgson, Hope, Thompson, & Shaw, 2019; Godfrey et al., 2012
Specific Effective Strategies	
"Happy Hours" in the afternoon, where residents can gather together for additional fluids and socialization	Mentes, Chang, & Morris, 2006; Musson et al., 1990
"Tea Time" in the afternoon, where residents come together for fluids, nourishment, and socialization	Mueller & Boisen, 1989
Encourage resident to have meals in the dining room	Reed, Zimmerman, Sloane, Williams, & Boustani, 2005; Volkert et al., 2018
Create a noninstitutional dining experience	Reed et al., 2005, Volkert et al., 2018
Create a drink-friendly environment	Cook et al., 2019
Ensure utensils and level of assistance are resident centered	
Specific Effective Strategies	
Use of modified fluid containers based on resident's intake behaviors (e.g., ability to hold cup, to swallow)	Bak et al., 2018; Mueller & Boisen, 1989; Reedy, 1988
Use high-contrast tableware during meals for residents with dementia	Dunne, Neargarder, Cipolloni, & Cronin-Golomb, 2004
Provide the appropriate level of assistance to enhance intake	Bunn et al., 2015; Godfrey et al., 2012; Marra et al., 2016
Increase toileting routine (in combination with other strategies)	Bunn et al., 2015; Schnelle et al., 2010; Spangler et al., 1984; Tanaka et al., 2009; Zembrzuski, 2006

Interventions and Strategies	**References**
Ensure care providers (formal and informal) are knowledgeable of hydration needs and management strategies	
Specific Effective Strategies	Bunn et al., 2015
Provide staff with education on hydration management (in combination with other strategies)	Beattie, O'Reilly, Strange, Franklin, & Isenring, 2014; Greene et al., 2018; Oates & Price, 2017; Volkert et al., 2018; Zembrzuski, 2006

(*continued*)

Protocol 12.1: Managing Oral Hydration (*continued*)

Coordinate staff communication about hydration such as certified nursing assistant (CNA) handoff reports or documentation in nursing care plan.	Mentes, Chang, & Morris, 2006; Ullrich & McCutcheon, 2008
Provide a staffing ratio that allows the needs of the residents to be met	Namasivayam-MacDonald et al., 2018; Reed et al., 2005
Encourage family involvement and support	Mentes, Chang, & Morris, 2006
Promote Self-Management of Hydration	
Provide education to improve individuals' hydration health literacy	Picetti et al., 2017
Individuals who are cognitively intact and physically capable can be taught to use the Drinks Diary to self-monitor their fluid intake.	Jimoh et al., 2015
Assist to establish individuals' fluid intake goal based on the calculated fluid recommendation.	Volkert et al., 2018
Individuals who are cognitively intact and visually capable can be taught how to note changes in their level of hydration through the use of a color chart, to compare with the color of their urine. The chart is most accurate in individuals with better renal function.	Armstrong et al., 1994, 1998; Mentes, Wakefield, & Culp, 2006
Fluid Regulation and Documentation	
Note: Frequency of documentation of fluid intake will vary from setting to setting and is dependent on an individual's condition.	
Document a complete intake recording, including hydration habits	Mentes & IVANRC, 2000
Create fluid volume list of each utensil to accurately calculate fluid consumption	Burns, 1992; Hart & Adamek, 1984
Implement use of the Drinks Diary	F. O. Jimoh et al., 2015

IV. PARAMETERS OF ASSESSMENT

A. Health history	Mentes & IVANRC, 2000
Specific disease states: dementia, congestive heart failure, chronic renal disease, malnutrition, and psychiatric disorders such as depression	Albert et al., 1989; Gaspar, 1988; Warren et al., 1994
Presence of comorbidities: more than four chronic health conditions	Lavizzo-Mourey et al., 1988
Prescription drugs: number and types	Lavizzo-Mourey et al., 1988
Past history of dehydration, repeated infections	Mentes, 2006
B. Physical assessments Complete an exam that includes vital signs, height, weight, BMI (Vivanti et al., 2008), review of systems,	Mentes & IVANRC, 2000
C. Focused assessment on indicators of hydration	
Chief complaint of fatigue	Hooper et al., 2015
D. Laboratory tests (Mentes & Gaspar, 2020)	
Urine specific gravity	Mentes, 2006; Wakefield et al., 2002
Urine color	Mentes, 2006; Wakefield et al., 2002
BUN–creatinine ratio	Mentes & Gaspar, 2020
Serum sodium	Mentes & Gaspar, 2020

(*continued*)

Protocol 12.1: Managing Oral Hydration (*continued*)

Serum osmolality and a serum osmolality estimation equation based on serum measures of urea, glucose, sodium, and potassium	Siervo, Bunn, Prado, & Hooper, 2014
Salivary osmolality	Fortes et al., 2015
E. Assessment of ingestion behaviors and hydration habits	
Individual fluid-intake behaviors	Mentes, 2006
Subcategory of hydration patterns (can drink, cannot drink, will not drink, end of life)	Mentes, 2006
Missing drinks between meals	Hooper et al., 2015
Screen hospitalized older adults using the NoAH	Oates et al., 2017

V. EVALUATION AND EXPECTED OUTCOMES

A. Maintenance of body hydration (Mentes & Culp, 2003; Robinson & Rosher, 2002; Simmons et al., 2001)
B. Decreased infections, especially urinary tract infections (McConnell, 1984; Mentes & Culp, 2003; Robinson & Rosher, 2002; Murry et al., 2015)
C. Improvement in urinary incontinence (Spangler et al., 1984)
D. Lowered urinary pH (Hart & Adamek, 1984)
E. Decreased constipation (Murray et al., 2015; Robinson & Rosher, 2002)
F. Decreased acute confusion (Mentes et al., 1999)
G. Improved fluid intake
H. Improved hydration health literacy (Picetti et al., 2017)

VI. FOLLOW-UP MONITORING OF CONDITION

A. Urine color chart monitoring in patients with better renal function (Armstrong et al., 1994, 1998; Wakefield et al., 2002)
B. Urine specific gravity checks (Armstrong et al., 1994, 1998; Wakefield et al., 2002)
C. Twenty-four-hour intake recording (Metheny, 2000)
D. Drinks Diary to document fluid intake in individuals who are cognitively intact (F. O. Jimoh et al., 2015)
E. Hydration Health literacy (Picetti et al., 2017)
F. Salivary Osmolality (Volkert et al., 2018)

VII. RELEVANT PRACTICE GUIDELINES

A. Hydration management evidence-based protocol available from the University of Iowa College of Nursing Gerontological Nursing Interventions Research Center, Research Dissemination Core. Authors: Janet Mentes and Phyllis Gaspar, revised 2019.
B. ESPEN (European Society for Clinical Nutrition and Metabolism) guideline on clinical nutrition and hydration in geriatrics (Volkert et al., 2018).
C. Dehydration and Fluid Maintenance in the Long-Term Care Setting Clinical Practice Guideline by The American Medical Directors Association, 2009.

ABBREVIATIONS

BMI	Body mass index
BUN	Blood urea nitrogen
IVANRC	Iowa–Veterans Affairs Nursing Research Consortium
MMSE	Mini-Mental State Examination
NoAH	Northumbria Assessment of Hydration
TBW	Total body water

Nutrition in the Older Adult*

Rose Ann DiMaria-Ghalili

13

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Recognize factors that place the older adult at risk for malnutrition.
2. Discuss methods to screen and assess nutritional status in the older adult.
3. Use appropriate nursing interventions in the hospitalized older adult who is either at risk for malnutrition or has malnutrition.
4. Identify the importance of screening for nutrition risk during transitions in care.

OVERVIEW

Nutritional status is the balance of nutrient intake, physiological demands, and metabolic rate (DiMaria-Ghalili, 2002). However, older adults are at risk of poor nutrition (DiMaria-Ghalili & Amella, 2005). Furthermore, malnutrition, a recognized geriatric syndrome (Institute of Medicine [IOM], 2008), is of concern because it can often be unrecognizable and impacts morbidity, mortality, and quality of life (Chen, Schilling, & Lyder, 2001), and is a precursor for frailty in the older adult. Malnutrition in older adults is defined as "faulty or inadequate nutritional status; undernourishment characterized by insufficient dietary intake, poor appetite, muscle wasting, and weight loss" (Chen et al., 2001, p. 139). In the older adult, malnutrition exists along the continuum of care (Furman, 2006). Older adults admitted to acute care settings from either the community or long-term care settings may already be malnourished or may be at risk for the development of malnutrition during hospitalization. A diagnosis of malnutrition during an acute care stay increases the length of stay (12.6 ± 5 vs. 4.4 ± 1 days), cost of hospitalization ($26,944 vs. $9,485), and services needed on discharge (e.g., home care, long-term care; Corkins et al., 2014). Bedrest is common during the hospital stay, and the associated loss of lean mass that accompanies bedrest can impact the already vulnerable nutritional status of older adults (English & Paddon-Jones, 2010). The IOM (2008) notes that although malnutrition is a problem in older adults, most healthcare professionals, including nurses, have little training concerning the nutritional needs of older adults. Therefore, it is imperative that acute care nurses carefully assess and monitor the nutritional status of older adults to identify the risk factors of malnutrition so that appropriate interventions are instituted in a timely fashion. The focus of this nursing protocol is the discussion of nutrition in aging as it relates to risk factors,

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

implications, and interventions for malnutrition in the older adults.

BACKGROUND AND STATEMENT OF PROBLEM

The prevalence of malnutrition in older adults varies across studies and settings. Using a large probability sample of community-dwelling older adults (60 years and older), 5.9% were malnourished and 56.3% were at risk of malnutrition (DiMaria-Ghalili, Michael, & Rosso, 2013). Researchers report the prevalence of malnutrition in older adults in nursing homes to be between 1.5% and 67% (Bell, Lee, & Tamura, 2015) and between 12% and 70% in hospitals (Heersink, Brown, DiMaria-Ghalili, & Locher, 2010). Limited information is currently available on the prevalence of malnutrition as older adults transition from the hospital to the home. However, older adults do experience declines in nutrition and health status after hospital discharge, which impact the ability to shop and prepare meals, placing them at further nutritional risk after discharge from the hospital (Anyanwu, Sharkey, Jackson, & Sahyoun, 2011).

Marasmus, kwashiorkor, and mixed marasmus–kwashiorkor originally described the subtypes of malnutrition associated with famine, and these terms eventually characterized disease-related malnutrition. In 2012, the Academy of Nutrition and Dietetics and the American Society for Parenteral and Enteral Nutrition published criteria for the identification of adult malnutrition (undernutrition; White et al., 2012). Inflammation is the cornerstone of the new adult disease-related malnutrition subtypes and include "starvation-related malnutrition" in the context of social and environmental circumstances (without inflammation), "chronic disease-related malnutrition" (with chronic inflammation of a mild to moderate degree; e.g., rheumatoid arthritis), and "acute disease or injury-related malnutrition" (with acute inflammation of a severe degree; e.g., major infections or trauma). Defining characteristics focus on energy intake, weight loss, physical findings (loss of body fat, muscle mass, and presence of fluid accumulation), and reduced grip strength. Visceral proteins (e.g., albumin, prealbumin) are negative acute-phase proteins, typically suppressed during an inflammatory state, and are not indicative of nutritional status during inflammation. Consequently, albumin is no longer recommended to identify malnutrition (White et al., 2012). The new adult malnutrition categories underscore the impact of a loss of lean body mass and skeletal muscle associated with the catabolic nature of the inflammatory process (Jensen et al., 2010). Although *sarcopenia* is an age-related loss of muscle mass and muscle strength (Rolland, Van Kan, Gillette-Guyonnet, & Vellas, 2011), bedrest during hospitalization is also associated with a loss of lean body mass, which adversely impacts functional capacity (Rowell & Jackson, 2010).

The risk factors for malnutrition in the older adult are multifactorial and include dietary, economic, psychosocial, and physiological factors (DiMaria-Ghalili & Amella, 2005). Dietary factors include little or no appetite (Carlsson, Tidermark, Ponzer, Söderqvist, & Cederholm, 2005), problems with eating or swallowing (Serra-Prat et al., 2012), eating inadequate servings of nutrients, and eating fewer than two meals a day (Ramic et al., 2011). Limited income may cause restriction in the number of meals eaten per day or dietary quality of meals eaten (Lee & Berthelot, 2010; Samuel et al., 2012). Isolation is also a risk factor as older adults who live alone may lose their desire to cook because of loneliness, and appetite often decreases after the loss of a spouse (Ramic et al., 2011; Stroebe, Schut, & Stroebe, 2007). Impairment in functional status can place the older adult at risk of malnutrition (Oliveira, Fogaca, & Leandro-Merhi, 2009) because adequate functioning is needed to secure and prepare food (DiMaria-Ghalili, 2014). Difficulty in cooking is related to disabilities, and disabilities can hinder the ability to prepare or ingest food (Anyanwu et al., 2011; DiMaria-Ghalili, 2014). Chronic conditions can negatively influence nutritional intake as well as cognitive impairment (Inelmen, Sergi, Coin, Girardi, & Manzato, 2010). Psychological factors are known risk factors of malnutrition. For example, depression is related to unintentional weight loss (Chen, Bai, Huang, & Tang, 2007; Engel et al., 2011). Furthermore, poor oral health (Palacios & Joshipura, 2015) and xerostomia (dry mouth caused by decreased saliva) can impair the ability to lubricate, masticate, and swallow food (Palacios & Joshipura, 2015). Antidepressants, antihypertensives, and bronchodilators can contribute to xerostomia (DiMaria-Ghalili & Amella, 2005). Change in taste (from medications, nutrient deficiencies, or taste bud atrophy) can also alter nutritional intake (DiMaria-Ghalili & Amella, 2005).

Body composition changes in normal aging include increase in body fat, visceral fat stores, and a decrease in lean body mass (Janssen, Heymsfield, Allison, Kotler, & Ross, 2002). Furthermore, the low skeletal muscle mass associated with aging is related to functional impairment and physical disability (Janssen, Heymsfield, & Ross, 2002).

The impact of malnutrition on the health of the hospitalized older adult is well documented. In this population, malnutrition is related to prolonged hospital stay, poor health status, institutionalization, and death (Corkins

et al., 2014). Malnutrition is also related to frailty and impaired functional status (Litchford, 2014).

ASSESSMENT OF THE PROBLEM

Areas of nutrition status assessment in the hospitalized older adult should focus on identification of malnutrition and risk factors for malnutrition not only during hospitalization, but also on hospital discharge. Previously The Joint Commission mandated a nutrition screening be performed within 24 hours of hospital admission for all patients; however, hospitals now determine the frequency for performing these assessments (The Joint Commission, 2018) per institutional policy or standard. The American Society for Parenteral and Enteral Nutrition's Adult Nutrition Care Pathway suggests that a validated nutrition screening tool be completed upon admission (Ukleja et al., 2018). In a recent survey of nurses' nutrition screening and assessment practices (n = 545), nurses reported they are primarily responsible for the initial nutrition screening (Guenter & DiMaria-Ghalili, 2013). Thirty-one percent reported using a validated nutrition assessment tool; the most frequently reported were the Mini Nutritional Assessment (MNA; 49.1%) and the Subjective Global Assessment (32.4%).

The MNA (Guigoz, Vellas, & Garry, 1994) is a comprehensive two-level tool that can be used to screen and assess the older hospitalized patient for malnutrition by evaluating the presence of risk factors for malnutrition in this age group (DiMaria-Ghalili & Guenter, 2008). The MNA-SF (short form) is based on the full MNA, the original 18-item questionnaire. The MNA-SF consists of six questions on food intake, weight loss, mobility, psychological stress or acute disease, presence of dementia or depression, and body mass index (BMI; Kaiser et al., 2010), and can be used as a screening tool. The full MNA provides a more detailed assessment. The validity and reliability of the MNA for use in hospitalized older adults is well documented (Salva et al., 2004). If a patient scores less than 12 on the screen (MNA-SF), then the assessment section should be completed in order to compute the malnutrition indicator score. The MNA-SF is easy to administer and is comprised of six questions. The assessment section requires measurement of midarm muscle and calf circumference. Although these anthropometric measurements are relatively easy to obtain with a tape measure, nurses may first require training in these procedures before incorporating the MNA as part of a routine nursing assessment. Protocols should be established to identify interventions to be implemented once the screening and assessment data are obtained and should include consultation with a dietitian. See "Nutrition in the Elderly" in the "Resources" section for the topic of MNA in nutrition and consultgerirn.org/resources for *Assessing Nutrition in Older Adults* (DiMaria-Ghalili, Sobieski, & Amella, 2019).

Additional assessment strategies include proper measurement of height and weight and a detailed weight history. Height should always be directly measured and never recorded via patient self-report. An alternative way of measuring standing height is knee height (Salva et al., 2004) with special calipers. An alternative to knee height measures is a demi-span measurement, meaning half the total arm span. (For directions on estimating height based on demi-span measurement, see Appendix 2 in *A Guide to Completing the Mini Nutritional Assessment* from the Nestle Nutrition Institute at www.mna-elderly.com/mna_forms.html.)

A calorie count or dietary intake analysis is a good way to quantify the type and amount of nutrients ingested during hospitalization (DiMaria-Ghalili & Amella, 2005). Traditionally, laboratory indicators of nutritional status included measures of visceral proteins such as serum albumin, transferrin, and prealbumin (DiMaria-Ghalili & Amella, 2005). However, these visceral proteins are also negative acute-phase reactants and are decreased during a stressed inflammatory state, limiting the ability to predict malnutrition in the acutely ill hospitalized patient. Monitoring inflammatory markers, such as C-reactive protein (Jensen, Hsiao, & Wheeler, 2012) or interleukin 6 (Jensen & Wheeler, 2012), can help to determine if depleted albumin reflects malnutrition or an inflammatory response. In spite of this, albumin is a strong prognostic marker for morbidity and mortality in the older hospitalized patient (Sullivan, Roberson, & Bopp, 2005).

INTERVENTIONS AND CARE STRATEGIES

The nursing interventions outlined in the protocol focus on enhancing or promoting nutritional intake and range in complexity from basic fundamental nursing care strategies to the administration of artificial nutrition via parenteral or enteral routes. Before initiating targeted nutritional interventions in the hospitalized older adult, it must first be determined whether the older adult cannot eat, should not eat, or will not eat (Sobotka et al., 2009; Ukleja et al., 2018; Volkert et al., 2019). Factors to consider include the gastrointestinal tract (starting with the mouth) working properly without any functional, mechanical, or physiological alterations that would limit the ability to adequately ingest, digest, and/or absorb food. Also, does the older adult have any chronic or acute health condition in which the normal intake of food is contraindicated? Or, is the older adult simply not eating, or is the appetite decreased? If the gastrointestinal tract is functional and can be used to

provide nutrients, then nutritional interventions should be targeted at promoting adequate oral intake.

Nursing care strategies focus on ways to increase food intake as well as ways to enhance and manage the environment to promote increased food intake. When functional or mechanical factors limit the ability to take in nutrients, nurses should obtain interdisciplinary consultations from speech therapists, occupational therapists, physical therapists, psychiatrists, and/or dietitians to collaborate on strategies that would enhance the ability of the older adult to feed himself or herself or to eat. Oral nutritional supplementation has been shown to improve nutritional status in malnourished hospitalized older adults (Joanna Briggs Institute, 2007; Volkert et al., 2019) and should be considered in the hospitalized older adult who is malnourished or is at risk of malnutrition. When used, oral liquid nutritional supplements should be given at least 60 minutes before meals (Wilson, Purushothaman, & Morley, 2002). Specialized nutritional support should be reserved for select situations. If the provision of nutrients via the gastrointestinal tract is contraindicated, then parenteral nutrition via the central or peripheral route should be initiated (Ukleja et al., 2018). If the gastrointestinal tract can be used, then nutrients should be delivered via enteral tube feeding (Ukleja et al., 2018). The exact location of the tube and type of feeding tube inserted depend on the disease state, length of time tube feeding is required, and risk of aspiration. Patients started on specialized nutritional support should be routinely reassessed for the continued need for specialized nutrition support and transitioned to oral feeding when feasible. Also, advance directives, if not completed, should be addressed before initiating specialized nutrition support (see Chapter 7, Healthcare Decision-Making and Chapter 17, Advance Care Planning).

CASE STUDY 13.1

Mr. J.B. is an 83-year-old male admitted to the hospital with community acquired pneumonia. He also has a chronic venous leg ulcer and a history of chronic obstructive pulmonary disease and hypertension. On admission, his standing height is 5 feet 8 inches and he weighs 140 pounds. His BMI is 21.33. He is a widow, describes his health as fair, and uses the community share-a-ride program to shop and attend medical appointments. While he is independent in activities of daily living on admission, he complains of tiring easily after light housekeeping and lost 10 pounds in the past 3 months due to decreased appetite. Upon admission, his MNA-SF score is 7 based on moderate loss of appetite, weight loss greater than 6.6 pounds during the last 3 months, goes out, has suffered an acute event, has no psychological problems, and has a BMI of 21.33. Because his score is below 11, he is at risk for malnutrition, and a complete assessment level of the MNA is performed. His total MNA assessment score is 17.5 based on an assessment score of 10.5 and a screening score of 7.0, indicating he is at risk for malnutrition. Although he is on a regular diet, he only takes in about 50% of his meals. Oral nutritional supplements are ordered twice daily between meals.

Three days into his hospitalization, Mr. J.B. develops sepsis and is transferred to the ICU for 7 days. He remained on a regular diet and his intake dropped to 25% of his meals, and he consumed only 100 mL/d of his oral nutritional supplement. He lost an additional 3 pounds during his hospitalization and became progressively weak due to prolonged bedrest. A decision was made to transfer him to a rehab facility for physical therapy. Upon admission to the rehab facility, his MNA score indicated he was malnourished. During the discharge planning meeting, concerns were raised by the nurse, dietitian, physical therapist, and social worker about Mr. J.B.'s nutritional status and his ability to be able to shop and cook for himself when he transitions to home from the rehab facility. Mr. J.B. was discharged with home care, and a home delivered meal service to provide 3 meals a day for the first 2 weeks after discharge, in addition to oral nutrition supplements. A dietitian reassessed Mr. J.B.'s condition 2 weeks after discharge. His appetite was slowly improving, and he had no further weight loss. While he was able to travel to his medical appointments with the share-a-ride program, he still felt too weak to shop and cook for himself. He continued to receive three home delivered meals per day for an additional month. Six weeks after discharge he gained 2 pounds and was able to shop and prepare light meals for himself. He continued to consume one serving of an oral nutritional supplement per day and was switched to a once daily home delivered meal service.

SUMMARY

Hospitalized older adults are at risk of malnutrition. Nurses should carefully assess and monitor the nutritional status of the older hospitalized patient so that appropriate nutrition-related interventions can be implemented in a timely fashion.

NURSING STANDARD OF PRACTICE

Protocol 13.1: Nutrition in Aging

I. GOAL

Improve in indicators of nutritional status in order to optimize functional status and general well-being and promote positive nutritional status.

II. OVERVIEW

Older adults are at risk of malnutrition, with 39% to 47% of hospitalized older adults being malnourished or at risk of malnutrition (Kaiser et al., 2010).

III. BACKGROUND/STATEMENT OF PROBLEM

A. Definition(s)
   1. Malnutrition: Any disorder of nutritional status, including disorders resulting from a deficiency of nutrient intake, impaired nutrient metabolism, or overnutrition

B. Etiology and/or epidemiology: Older adults are at risk for undernutrition because of dietary, economic, psychosocial, and physiological factors (DiMaria-Ghalili & Amella, 2005).
   1. Dietary intake
      a. Little or no appetite (Carlsson et al., 2005; Ramic et al., 2011)
      b. Problems with eating or swallowing (Serra-Prat et al., 2012)
      c. Eating inadequate servings of nutrients (Ramic et al., 2011)
      d. Eating fewer than two meals a day (Ramic et al., 2011)
   2. Limited income may cause restriction in the number of meals eaten per day or dietary quality of meals eaten (Samuel et al., 2012).
   3. Isolation
      a. Older adults who live alone may lose desire to cook because of loneliness (Ramic et al., 2011; Stroebe et al., 2007)
      b. Appetite of widows decreases (DiGiacomo, Lewis, Nolan, Phillips, & Davidson, 2013)
      c. Difficulty cooking because of disabilities (Anyanwu et al., 2011)
      d. Lack of access to transportation to buy food (DiMaria-Ghalili & Amella, 2005)
   4. Chronic illness
      a. Chronic conditions can affect intake (DiMaria-Ghalili, 2014).
      b. Disability can hinder ability to prepare or ingest food (Anyanwu et al., 2011; Litchford, 2014).
      c. Depression can cause decreased appetite (Engel et al., 2011).
      d. Poor oral health (cavities, gum disease, and missing teeth), and xerostomia, or dry mouth, impairs ability to lubricate, masticate, and swallow food (Palacios & Joshipura, 2015).
      e. Antidepressants, antihypertensives, and bronchodilators can contribute to xerostomia (DiMaria-Ghalili & Amella, 2005).
   5. Physiological changes
      a. Decrease in lean body mass and redistribution of fat around internal organs lead to decreased caloric requirements (Janssen, Heymsfield, Allison, et al., 2002)
      b. Change in taste (from medications, nutrient deficiencies, or taste bud atrophy) can also alter nutritional status (DiMaria-Ghalili & Amella, 2005)

(*continued*)

Protocol 13.1: Nutrition in Aging (*continued*)

IV. PARAMETERS OF ASSESSMENT

A. General: During routine nursing assessment, any alterations in general assessment parameters that influence intake, absorption, or digestion of nutrients should be further assessed to determine whether the older adult is at nutritional risk. These parameters include:
   1. General assessment, including present history, assessment of symptoms, past medical and surgical history, and comorbidities (DiMaria-Ghalili, 2014)
   2. Social history (DiMaria-Ghalili, 2014)
   3. Drug–nutrient interactions: Drugs can modify the nutrient needs and metabolism of older people. Restrictive diets, malnutrition, changes in eating patterns, alcoholism, and chronic disease with long-term drug treatment are some of the risk factors in older adults that place them at risk for drug–nutrient interactions (DiMaria-Ghalili, 2014)
   4. Functional limitations (DiMaria-Ghalili, 2014)
   5. Psychological status (DiMaria-Ghalili, 2014)
   6. Physical assessment: Physical examination with emphasis on oral examination (see Chapter 11, Oral Healthcare in the Older Adult); loss of subcutaneous fat, muscle wasting, and BMI (DiMaria-Ghalili, 2014); and dysphagia

B. Dietary intake: In-depth assessment of dietary intake during hospitalization may be documented with a dietary intake analysis (calorie count; DiMaria-Ghalili & Amella, 2005).

C. Risk assessment tool: The MNA should be performed to determine whether an older hospitalized patient is either at risk of malnutrition or has malnutrition. The MNA determines risk based on food intake, mobility, BMI, history of weight loss, psychological stress, or acute disease, and dementia or other psychological conditions. If score on the MNA-SF is 11 points or less, the in-depth MNA assessment should be performed (DiMaria-Ghalili & Guenter, 2008). See the "Resources" section or go to consultgerirn.org/resources for nutrition information.

D. Anthropometry
   1. Obtain an accurate weight and height through direct measurement. Do not rely on patient recall. If the patient cannot stand erect to measure height, then either a demi-span measurement or a knee-height measurement should be taken to estimate height using special knee-height calipers (DiMaria-Ghalili & Amella, 2005). Height should never be estimated or recalled because of shortening of the spine with advanced age; self-reported height may be off by as much as 2.4 cm (DiMaria-Ghalili & Amella, 2005).
   2. Weight history: A detailed weight history should be obtained along with current weight. Detailed weight history should include a history of weight loss, whether the weight loss was intentional or unintentional, and during what period. A loss of 10 pounds over a 6-month period, whether intentional or unintentional, is a critical indicator for further assessment (DiMaria-Ghalili & Amella, 2005).
   3. Calculate BMI to determine whether weight for height is within normal range: 23 to 30. A BMI below 23 is a sign of undernutrition (Centers for Medicare & Medicaid Services, 2019).

E. Visceral proteins: Serum albumin, transferrin, and prealbumin are visceral proteins traditionally used to assess and monitor nutritional status (DiMaria-Ghalili & Amella, 2005). However, keep in mind that these proteins are negative acute-phase reactants, so during a stress state, the production is usually decreased. In the older hospitalized patient, albumin levels may be a better indicator of prognosis than nutritional status (White et al., 2012). Consider using inflammatory markers (C-reactive protein or interleukin-6) to ascertain whether the changes in albumin are caused by nutritional alterations or an inflammatory state (Jensen et al., 2012; Jensen & Wheeler, 2012).

F. Functional status: Measure handgrip strength using a hand dynamometer (White et al., 2012); review ability to perform ADL and IADL (DiMaria-Ghalili, 2014).

G. Transitional care needs determine the ability of the patient to shop, cook, and feed self after discharge (DiMaria-Ghalili, 2014).

(*continued*)

Protocol 13.1: Nutrition in Aging (*continued*)

V. NURSING CARE STRATEGIES

A. Collaboration (DiMaria-Ghalili & Amella, 2005)
   1. Refer to a dietitian if the patient is at risk of undernutrition or has undernutrition.
   2. Consult with a pharmacist to review the patient's medications for possible drug–nutrient interactions.
   3. Consult with a multidisciplinary team specializing in nutrition.
   4. Consult with a social worker, an occupational therapist, and a speech therapist as appropriate.

B. Alleviate dry mouth
   1. Avoid caffeine; alcohol and tobacco; and dry, bulk, spicy, salty, or highly acidic foods.
   2. If the patient does not have dementia or swallowing difficulties, offer sugarless hard candy or chewing gum to stimulate saliva.
   3. Keep lips moist with petroleum jelly.
   4. Take frequent sips of water.

C. Maintain adequate nutritional intake

   Daily requirements for healthy older adults include 30 kcal/kg of body weight, and 1 to 1.2 g/kg of protein per day (Bauer et al., 2013), with no more than 30% of calories from fat. Caloric, carbohydrate, protein, and fat requirements may differ depending on degree of malnutrition and physiological stress.

D. Improve oral intake
   1. Assess each patient's ability to eat within 24 hours of admission (Jefferies, Johnson, & Ravens, 2011).
   2. Engage in mealtime rounds to determine how much food is consumed and whether assistance is needed (Jefferies et al., 2011).
   3. Limit staff breaks to before or after patient mealtimes to ensure that adequate staff are available to help with meals (Jefferies et al., 2011).
   4. Encourage family members to visit at mealtimes.
   5. Ask family to bring favorite foods from home when appropriate.
   6. Ask about patient food preferences and honor them.
   7. Suggest small, frequent meals with adequate nutrients to help patients regain or maintain weight (Joanna Briggs Institute, 2007).
   8. Provide nutritious snacks (Joanna Briggs Institute, 2007).
   9. Help patient with mouth care and placement of dentures before food is served (Jefferies et al., 2011).

E. Provide conducive environment for meals
   1. Remove bedpans, urinals, and emesis basins from rooms before mealtime.
   2. Administer analgesics and antiemetics on a schedule that will diminish the likelihood of pain or nausea during mealtimes.
   3. Serve meals to patients in a chair if they can get out of bed and remain seated.
   4. Create a more relaxed atmosphere by sitting at the patient's eye level and making eye contact during feeding.
   5. Order a late food tray or keep food warm if the patients are not in their rooms during mealtimes.
   6. Do not interrupt patients for round and nonurgent procedures during mealtimes.

F. Specialized nutritional support (Sobotka et al., 2009; Ukleja et al., 2018; Volkert et al., 2019)
   1. Start specialized nutritional support when a patient cannot, should not, or will not eat adequately and if the benefits of nutrition outweigh the associated risks.
   2. Before initiation of specialized nutritional support, review the patient's advance directives regarding the use of artificial nutrition and hydration.

G. Provide oral supplements
   1. Supplements should not replace meals but should be provided between meals and not within the hour preceding a meal and at bedtime (Joanna Briggs Institute, 2007; Wilson et al., 2002).
   2. Ensure that oral supplement is at the appropriate temperature (Joanna Briggs Institute, 2007).
   3. Ensure that the patient can open oral supplement packaging (Joanna Briggs Institute, 2007).

(*continued*)

Protocol 13.1: Nutrition in Aging (*continued*)

4. Monitor the intake of the prescribed supplement (Joanna Briggs Institute, 2007).
5. Promote a sip style of supplement consumption (Joanna Briggs Institute, 2007).
6. Include supplements as part of the medication protocol (Joanna Briggs Institute, 2007).

H. NPO orders
1. Schedule older adults for tests or procedures early in the day to decrease the length of time they are not allowed to eat and drink.
2. If testing late in the day is inevitable, ask the physician whether the patient can have an early breakfast.
3. See ASA practice guideline regarding recommended length of time patients should be kept NPO for elective surgical procedures.

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient will
1. Experience improvement in indicators of nutritional status.
2. Improve functional status and general well-being.

B. Provider should
1. Ensure that care includes food and fluid of adequate quantity and quality in an environment conducive to eating, with appropriate support (e.g., modified eating aids) for people who can potentially chew and swallow but are unable to feed themselves.
2. Continue to reassess patients who are malnourished or at risk for malnutrition.
3. Monitor for refeeding syndrome.

C. Institution will
1. Ensure that all healthcare professionals who are directly involved in patient care should receive education and training on the importance of providing adequate nutrition.

D. QA/QI
1. Establish QA/QI measures surrounding nutritional management in aging patients.

E. Educational
1. Provided education and training includes
   a. Nutritional needs and indications for nutrition support
   b. Options for nutrition support (oral, enteral, and parenteral)
   c. Ethical and legal concepts
   d. Potential risks and benefits
   e. When and where to seek expert advice
2. Patient and/or caregiver education includes how to maintain or improve nutritional status as well as how to administer, when appropriate, oral liquid supplements, enteral tube feeding, or parenteral nutrition.

VII. FOLLOW-UP MONITORING

A. Monitor for gradual increase in weight over time.
1. Weigh patient weekly to monitor trends in weight.
2. Daily weights are useful for monitoring fluid status.

B. Monitor and assess for refeeding syndrome (Skipper, 2012).
1. Carefully monitor and assess patients the first week of aggressive nutritional repletion.
2. Assess and correct the following electrolyte abnormalities: hypophosphatemia, hypokalemia, hypomagnesemia, hyperglycemia, and hypoglycemia.
3. Assess fluid status with daily weights and strict intake and output.
4. Assess for congestive heart failure in patients with respiratory or cardiac difficulties.

(*continued*)

Protocol 13.1: Nutrition in Aging (*continued*)

5. Ensure caloric goals will be reached slowly, over more than 3 to 4 days, to avoid refeeding syndrome when repletion of nutritional status is warranted.
6. Be aware that refeeding syndrome is not only exclusive to patients started on aggressive artificial nutrition, but may also be found in older adults with chronic comorbid medical conditions and poor nutrient intake started with aggressive nutritional repletion via oral intake.

Family Caregiving*

Deborah C. Messecar

14

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe characteristics and factors that put family caregivers at risk of unhealthy transitions into the caregiving role.
2. Identify key aspects of a family caregiving preparedness assessment.
3. List specific interventions to support family caregivers of older adults to take on their caregiving duties.
4. Identify family caregiver outcomes expected from the implementation of this protocol.

OVERVIEW

Family caregivers are a key link in providing safe and effective transitional care to frail older adults as they move across levels of care (e.g., acute to subacute) or across settings (e.g., hospital to home; Gibson, Kelly, & Kaplan, 2012; Gitlin & Wolff, 2012; Hirschman et al., 2017; Naylor et al., 2017; Toles, Colon-Emeric, Naylor, Asafu-Adjei, & Hanson, 2017). Frail older adults coping with complex chronic conditions are vulnerable to problems with care as they typically have multiple providers and move frequently between and among healthcare settings. Incomplete communication among providers and across healthcare agencies is linked to high-risk care transitions with adverse outcomes and an increased risk of hospital readmission and or length of hospital stay (Geary & Schumacher, 2012; Jencks, Williams, & Coleman, 2009; Kansagara et al., 2016; Naylor et al., 2017). Nurses in collaboration with family caregivers can bridge the gap between the care provided in the hospital and other settings and the care needed in the community. Transitional care for frail older people can be improved if interventions address family inclusion and education, communication exists between healthcare workers and family, and interprofessional communication and ongoing support are available after the transition.

Helping Caregivers Take on the Caregiving Role

Helping the caregiver with the role-acquisition process is a critical nursing function that facilitates good transitional care. Indicators of a healthy assumption of the caregiving role are those factors that either indicate a robust and positive role-acquisition process or signal potential difficulty with assuming the caregiver role. When trying to ascertain what those indicators might be, the following questions about the caregiver role-acquisition process can be posed: What is the nature of the transition? For example, the

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

transition can be changes in the caregiving role or changes in health/illness requiring different levels of care. What are the transition conditions that facilitate or inhibit a healthy transition? What are the patterns of responses that indicate healthy movement through a transition (Geary & Schumacher, 2012)? Because the role-transition process unfolds over time, identifying process conditions that move patient and family members either in the direction of health or on the way to vulnerability and risk allows early assessment and intervention to facilitate healthy outcomes of the caregiving role acquisition (Geary & Schumacher, 2012; Gitlin & Wolff, 2012). If unhealthy role-taking transitions can be identified, then they can be either prevented or ameliorated.

Who Is Likely to Be or Become a Caregiver?

Being a family caregiver is a widespread experience in the United States. Depending on how family caregiving is defined, national surveys estimate that up to 43.5 million people, or 18.2% of the U.S. population, provide care for a chronically ill, disabled family member or friend during any given year (National Alliance for Caregiving [NAC] & American Association of Retired Persons [AARP], 2015). Reflecting an increasing trend, 40% of all family caregivers of adults older than 18 years are men, 60% are women, and the majority are older than 49 years (NAC & AARP, 2015). Among the primary family caregivers of disabled or ill adults older than 65 years, the proportion of male caregivers is lower (about 36.3%, but this number has increased from prior years). Among millennial caregivers of dementia patients, 53% are women and 47% are men, indicating closer gender parity than what is noted among older caregivers (Vega, Aranda, & Rodriguez, 2017). Primary family caregivers usually take care of relatives (85%), and of these, most (49%) care for a parent or in-law (NAC & AARP, 2015). Older adults receiving care were incrementally younger, more diverse, and better educated, compared with the case in prior national caregiving surveys in 2015 versus 2004 and 2009 (Wolff et al., 2018). Their caregivers are primarily spouses and children. The most common caregiver arrangement remains that of an adult female child providing care to an elderly female parent (NAC & AARP, 2015). Many caregivers are older and are at risk of chronic illness themselves. Caregiving duration of 4 years or longer among caregivers is increasing, from 44.8% in 1991 to 60.5% by 2015 (Wolff et al., 2018). In addition, national surveys indicate a trend of a substantial need gap for caregivers to be engaged in conversation with health providers about the care of the care receiver and self-care. More than 84% of caregivers state they could use more information on caregiving topics (NAC & AARP, 2015), yet many barriers to obtaining needed information exist (Werner et al., 2017). Family and friends continue to provide more than 80% of all long-term care services in the country (NAC & AARP, 2015), acting as a critical resource for providing long-term care (National Academies of Sciences, Engineering, and Medicine [NASEM], 2016).

Impact of Unhealthy Caregiving Transitions on Caregiver

Caregiving has documented negative consequences for the caregiver's physical and emotional health (Schultz & Sherwood, 2008). Caregiving-related stress in a chronically ill spouse results in a 63% higher mortality rate than that pertaining to their noncaregiving peers (Schulz & Beach, 1999). The impact of caregiving on health increases with intensity. Among caregivers providing higher hours of care, 22% report that their health is fair or poor (NAC & AARP, 2015). The impact on health from low income is substantial, with caregivers having $30,000 or less in annual income reporting fair or poor health compared to only 7% among those with income greater than $100,000 (NAC & AARP, 2015). Stress from caring for an older adult with dementia has been shown to impact the caregiver's immune system for up to 3 years after his or her caregiving ends (Kiecolt-Glaser et al., 2003) and to contribute to higher reported loneliness accompanied by higher pain, depression, and fatigue (Jaremka et al., 2014). Higher-hour caregivers who live with their care recipients report more emotional stress (52% vs. 35% for lower-hour caregivers or 34% for those who live apart). Caregivers who report high burden and/or provide care for 5 years or more say their health has suffered (NAC & AARP, 2015). Those providing substantial healthcare are more likely to experience both emotional and financial difficulty (Wolff, Spillman, Freedman, & Kasper, 2016). In addition, caring for a close relative is more emotionally stressful. Forty-five percent of spouse and 44% of parent caregivers report symptoms of emotional distress versus 35% caring for another relative or 18% for a nonrelative. In addition to mental health morbidity, family caregivers also experience physical health deterioration. Family caregivers who care for care recipients with chronic conditions suffer more emotional stress, with half or more reporting this outcome (NAC & AARP, 2015). Family caregivers experiencing extreme stress are postulated to age prematurely (Epel & Lithgow, 2014).

BACKGROUND AND STATEMENT OF PROBLEM

Definitions

Family Caregiving

Family caregiving is broadly defined and refers to a broad range of unpaid care provided in response to a health problem or disability of a chronically ill or functionally impaired older family member, partner, friend, or neighbor that exceeds the support usually provided in family relationships (Rabarison et al., 2018; Schumacher, Beck, & Marren, 2006).

Caregiving Roles

Caregiving roles can be classified into a hierarchy according to who takes on the bulk of responsibilities versus only intermittent supportive assistance. Historically, primary caregivers have been defined as those caregivers who tend to provide most of the everyday aspects of care, whereas secondary caregivers have been defined as those who help out as needed to fill the gaps (Cantor & Little, 1985; Penning, 1990; Tennstedt, McKinlay, & Sullivan, 1989). Among caregivers who live with their care recipients, spouses account for the bulk of primary caregivers, whereas adult children are more likely to be secondary caregivers. The range of the family caregiving role includes protective caregiving, like "keeping an eye on" an older adult who is currently independent but at risk, to full-time, round-the-clock care for a severely impaired family member. Healthcare providers may fail to assess the full scope of the family caregiving role if they associate family caregiving only with the performance of tasks.

Caregiver Role Transition

Caregiver role acquisition is a family role transition that occurs through situated interaction as part of a role-making process (Schumacher, 1995). This is the process of taking on the caregiving role at the beginning of caregiving or when a significant change in the caregiving context occurs. Role transitions occur when a role is added to or deleted from the role set of a person—or when the behavioral expectations for an established role change significantly. Role transitions involve changes in the behavior expectations along with the acquisition of new knowledge and skills (Geary & Schumacher, 2012; Naylor et al., 2017; Schumacher, Beidler, Beeber, & Gambino, 2006; Schumacher, Stewart, Archbold, Dodd, & Dibble, 2000). Examples of major role transitions are becoming a new parent, getting a divorce, and changing careers. The acquisition of the family caregiving role is a specific type of role transition that occurs within families in response to the changes in health of a family member who has suffered a decline in his or her self-care ability or health.

Indicators of Healthy Caregiver Role Transitions

The broad categories of indicators of healthy transitions include subjective well-being, role mastery, and well-being of relationships. These are the subjective, behavioral, and interpersonal parameters of health most likely to be associated with healthy role transitions (Schumacher, 1995). *Subjective well-being* is defined as "subjective responses to caregiving role transition" (Schumacher, 1995, p. 219). Subjective well-being includes any pattern of subjective reactions that arise from assuming the caregiver role within the boundaries of the caregiving situation. Examples of some of the more important possible threats to subjective well-being could include role strain and depression. Role mastery is associated with accomplishment of skilled role performance and comfort with the behavior required in a new health-related care situation. Examples of threats to role mastery, which indicate a vulnerability and risk of unhealthy transitions, are role insufficiency and lack of preparedness. *Well-being of relationships* refers to the quality of the relationship between the caregiver and the older adult. Examples of threats to the well-being of relationships are family conflict or a poor quality of relationship with the care receiver.

Family Caregiving Activities

Family caregiving activities include assistance with day-to-day activities, illness-related care, care management, and invisible aspects of care. Day-to-day activities include personal care activities (bathing, eating, dressing, mobility, transferring from bed to chair, and using the toilet) and instrumental activities of daily living (IADL; meal preparation, grocery shopping, making telephone calls, and money management; NAC & AARP, 2015; NASEM, 2016). Illness-related activities include managing symptoms, coping with illness behaviors, carrying out treatments, and performing medical or nursing procedures that include an array of medical technologies (NASEM, 2016; Schumacher, Beidler, et al., 2006; Schumacher et al., 2000). Care management activities include accessing resources, communicating with and navigating the healthcare and social services systems, and acting as an advocate (NASEM, 2016; Schumacher, Beidler, et al., 2006; Schumacher et al., 2000). Invisible aspects of care have been defined as protective actions the caregiver takes to ensure the older

adult's safety and well-being without his or her knowledge (Bowers, 1987; Schumacher, Beck, et al., 2006).

Caregiver Assessment

Caregiver assessment refers to an ongoing iterative process of gathering information that describes a family caregiving situation and identifies the particular issues, needs, resources, and strengths of the family caregiver.

Risk Factors for Unhealthy Caregiving Transitions

Gender

A higher percentage (68%) of female caregivers than of men (38%) provide greater than 21 hours of care per week and had higher odds of providing high-intensity care (Cohen, Cook, Sando, Brown, & Longo, 2017). Male caregivers are more likely to provide care at the lowest level, which is defined as no ADLs and devoting very few hours of care per week (Cook & Cohen, 2018; NAC & AARP, 2015; Pinquart & Sörensen, 2006a). Being female and assisting with more ADL and IADL activities are associated with experiencing burden (Riffin, Van Ness, Wolff, & Fried, 2019). A number of studies have found that female caregivers are more likely than males to suffer from burden, anxiety, depression, and other symptoms associated with emotional stress caused by caregiving (Davies, Sridhar, Newkirk, Beaudreau, & O'Hara, 2012; R. Mahoney, Regan, Katona, & Livingston, 2005; Penning & Wu, 2016; Riffin et al., 2019); lower levels of physical health and subjective well-being than caregiving men (Pinquart & Sörensen, 2006a; Riffin et al., 2019); and are at a higher risk of adverse outcomes (Schulz, Martire, & Klinger, 2005). In the pooled analysis from the Resources for Enhancing Alzheimer's Caregiver Health (REACH) trials, females had higher initial levels of burden and depression (Gitlin et al., 2003). However, Freedman, Cornman, and Carr (2014) found that there are positive aspects of spousal caregiving for older wives that offset other unpleasant aspects of the role. Female spouse caregivers responded to nursing home placement of their care recipient with decreased burden and depression compared with their male counterparts in the New York University caregiver intervention (Gaugler, Roth, Haley, & Mittelman, 2011).

Lesbian, Gay, Bisexual, Transgender, and Queer/ Questioning (LGBTQ)

Approximately 9% of caregivers self-identify as LGBTQ (NAC & AARP, 2015). Men and women are almost equally likely to be caregivers, and men report providing more hours of care than female caregivers (MetLife, 2010). Men in this group report providing more hours (41 vs. 29 hours) of care from comparison samples (MetLife, 2010). The types of care provided by the LGBTQ population are similar to those in the general population. Financial concerns, experiencing loneliness, and declining physical health are reported by much higher percentages than in the non-LGBTQ population (Fredriksen-Goldsen et al., 2011). Sadly, most LGBTQ caregivers and patients feel that their relationships with providers would be jeopardized by revealing their sexual orientation/gender (Fredriksen-Goldsen et al., 2011).

Ethnicity

One important gap in nationally represented survey data about caregiving is the lack of complete and comprehensive data about the prevalence and characteristics among diverse caregivers (NASEM, 2016). Prevalence rates of caregiving vary somewhat by ethnicity. Among the U.S. adult population older than 18 years, 16.9% of White and 20.3% of African American families provide informal care, whereas a slightly lower percentage of Asian Americans (19.7%) and a higher number of Hispanic Americans (21.0%) are engaged in caregiving for persons older than 50 years (NAC & AARP, 2015). Although non-Hispanic Whites currently make up the largest group of older adults, by 2040 it is anticipated that no racial or ethnic group will make up the majority of the population (Frey, 2014). Prior research indicates that the picture for caregiving in other ethnic groups is diverse. In another national survey, which looked only at people older than 70 years, 44% of Latinos were found to receive informal home care compared with 34% of African Americans and 25% of non-Hispanic Whites (Weiss, González, Kabeto, & Langa, 2005). Ethnic differences are also found regarding the care recipient. Among people aged older than 70 years who require care, Whites are the most likely to receive help from their spouses, Hispanics are the most likely to receive help from their adult children, and African Americans are the most likely to receive help from a nonfamily member (National Academy on an Aging Society, 2000).

Studies show that ethnic minority caregivers provide more care (Cohen et al., 2017; Cook & Cohen, 2018; Pinquart & Sörenson, 2005), higher intensity care (Cook & Cohen, 2018), and report worse physical health than White caregivers (Dilworth-Anderson, Williams, & Gibson, 2002; Pinquart & Sörenson, 2005). African American caregivers experience less stress and depression and get more rewards related to caregiving when compared with White caregivers (Cohen et al., 2017; Cook, Snellings, & Cohen, 2018; Cuellar, 2002; Dilworth-Anderson et al., 2002;

Gitlin et al., 2003; Haley et al., 2004; Pinquart & Sörenson, 2005). The use of spiritual coping strategies and informal support might explain this repeatedly noted advantage (Wilks, Spurlock, Brown, Teegen, & Geiger, 2018). Both Hispanics and African Americans report experiencing more positive aspects of caregiving (Roth, Dilworth-Anderson, Huang, Gross, & Gitlin, 2015). However, the interaction between minority status and relationship to the care receiver on caregiving responses in a study on impact of attachment and model of self indicates the possibility that interaction moderates the relation between relationship factors and caregiving responses in African American caregivers (Morse, Shaffer, Williamson, Dooley, & Schulz, 2012). Intervention trials have reported similar differential effects for African American, Hispanic or Latino, and White caregivers (Belle et al., 2006; Graham-Phillips, Roth, Huang, Dilworth-Anderson, & Gitlin, 2016; C. C. Lee, Czaja, & Schulz, 2010). Hispanic and Asian American caregivers exhibit more depression than White caregivers (Gitlin et al., 2003; Pinquart & Sörensen, 2005) and emotional drain (Anthony, John Geldhof, & Mendez-Luck, 2017). In addition, formal services are rarely used by ethnic minorities, which puts them at further risk for negative outcomes (Dilworth-Anderson et al., 2002; Pinquart & Sörensen, 2005). This may also explain why African American caregivers used less intervention services in REACH II (Graham-Phillips et al., 2016). A meta-analysis of three qualitative studies examined African American, Chinese, and Latino caregiver impressions of their clinical encounters around their care receiver's diagnosis of Alzheimer's disease (D. F. Mahoney, Cloutterbuck, Neary, & Zhan, 2005). The primary issues identified in the analysis by D. F. Mahoney, Cloutterbuck, et al. (2005) were disrespect for concerns as noted by African American caregivers, stigmatization of persons with dementia as noted by Chinese caregivers, and fear that home care would not be supported as noted by Latino caregivers. Goins et al. (2011) found among American Indian adults that greater cultural identity and engagement in traditional healing practices are associated with greater likelihood of taking on the caregiving role. Engagement with traditional culture traditions has been suggested as a possible strategy for a culture-based psychosocial intervention (Browne, Ka'opua, Jervis, Alboroto, & Trockman, 2017). These findings indicate a need for greater culturally sensitive communications from healthcare providers.

Age

Several recent studies have found that younger age caregivers compared with their older counterparts are more prone to depressive symptoms and burden from caregiving (Morse et al., 2012; Shankar, Hirschmanm, Hanlon, & Naylorm, 2014). Seventy-nine percent of millennial caregivers report that emotional distress is a major burden for them (Vega et al., 2017). In a subsequent analysis from the REACH I trials, being younger was associated with higher levels of depression for Black and White caregivers but not for Hispanic caregivers (Sörensen & Pinquart, 2005). In the 2009 California Health Interview Survey, self-identified baby boomer caregivers reported engaging in poor health behaviors owing to the demands of providing care (Hoffman, Lee, & Mendez-Luck, 2012). These findings are in contrast to past research that has indicated that spouse caregivers, who tend to be older, have more burden. This may be due to differences in the level of care provided. Older caregivers providing a higher intensity of care were more likely to experience burden (Cook et al., 2018). In REACH II subgroup follow-up analyses of minority caregivers, older African American caregivers experienced a decrease in burden with the intervention compared with younger African American caregivers (C. C. Lee et al., 2010), a finding that could be a result of the fact that older caregivers were more likely to be spouses.

Income and Educational Level

Low income is also related to being an ethnic minority and being "non-White," and the latter are risk factors for poorer health outcomes. Persons who become caregivers may be more likely to have incomes below the poverty level and to be in poorer health, independent of caregiving (Vitaliano, Zhang, & Scanlan, 2003). There continues to be a strong association between low income and providing high-intensity care (Cook & Cohen, 2018). Usually, educational level has been combined with income in most caregiving studies, so there is a lack of data on this variable. One study (Buckwalter et al., 1999) reported that caregivers who were less educated tended to report as slightly more depressed than those who were better educated. This is consistent with the findings from the REACH trial meta-analysis (Gitlin et al., 2003). In the meta-analysis completed by Schulz et al. (2005), caregivers with low incomes and low levels of education were more at risk of adverse outcomes. In one recent study, limited finances were associated with greater burden among caregivers of cognitively impaired elderly adults at the time of hospitalization (Shankar et al., 2014).

Relationship (Spouse, Nonspouse)

Past research conducted primarily among non-Hispanic White samples has shown that caregiving outcomes differ between nonspouse (who are mostly adult children)

and spouse caregivers (Morse et al., 2012; Pinquart & Sörensen, 2004; Shankar et al., 2014). In a meta-analytic comparison study of differences in spouse, adult children, and children-in-law as caregivers of older adults, spouses had more depression, greater burden, and lower well-being. Greater psychological distress among spouses was explained primarily by higher levels of providing care (Pinquart & Sörensen, 2011). Children-in-law viewed the caregiving relationship less positively and had fewer rewards from caregiving (Pinquart & Sörensen, 2011). In other reviews of the literature, authors noted that spousal caregivers have reported higher levels of depression than nonspouses (Gitlin, Corcoran, Winter, Boyce, & Hauck, 2001; Pruchno & Resch, 1989) and that spouses reported less "upset" with the care receiver's behavior than nonspouses, who showed no decrease in "upset." A prior meta-analysis of caregiving studies found that spousal caregivers benefited less from existing interventions than adult children (Sörensen, Pinquart, & Duberstein, 2002).

Quality of Caregiver–Care Receiver Relationship

Disruption in the caregiver and care receiver relationship (Croog, Burleson, Sudilovsky, & Baume, 2006; Flannery, 2002) and/or a poor quality of relationship (Archbold, Stewart, Greenlick, & Harvath, 1990, 1992; Shim, Landerman, & Davis, 2011) can make caregiving seem more difficult even if the objective caregiving situation (e.g., hours devoted to caregiving and number of tasks performed) does not seem to be too demanding. Archbold et al. (1992) reported that the deleterious effects of the lack of preparedness on caregiver strain faded after 9 months; however, a poor relationship with the care receiver remained strongly related to caregiver strain. Reporting a poorer quality of relationship with the care receiver was associated with a 23.5% prevalence of anxiety and 10% prevalence of depression in the R. Mahoney, Regan, et al. (2005) descriptive study.

Lack of Preparedness

Most caregivers are not prepared for the many responsibilities they face and receive no formal instruction in caregiving activities (Moon, 2017; NAC & AARP, 2015). New duties can include complex tasks such as administering medications, managing side effects, monitoring complex chronic conditions, and/or assuming responsibility for new tasks like handling insurance claims and doing personal care. Moorman and Macdonald (2013) found that medical complexity of the care recipients' care is an important contributor to caregiving strain. Yet, although caregivers are called on to assume these many new responsibilities, they often lack the skills needed to do so (Lutz et al., 2017; Schumacher, Beck, et al., 2006). Stewart, Archbold, Harvath, and Nkongho (1993) reported that although healthcare professionals were a caregiver's main source of information on providing physical care, the caregiver received no preparation on how to care for the patient emotionally or deal with the stresses of caregiving. Lack of preparedness can significantly increase the caregiver's perceptions of strain, especially during times of transition from hospital or inpatient rehabilitation to home (Archbold et al., 1990, 1992; Lutz et al., 2017).

Baseline Levels of Burden and Depressive Scores

In a meta-analysis of 84 caregiving studies, Pinquart and Sörensen (2003) found that caregivers have higher levels of stress and depression as well as lower levels of subjective well-being, physical health, and self-efficacy than noncaregivers. The strongest negative effects of caregiving were observed for clinician-rated depression. Differences in perceived stress and depression between caregivers and noncaregivers were larger in spouses than in adult children (Pinquart & Sörensen, 2003). Caregivers of care receivers who have dementia (Pinquart & Sörensen, 2006a) have more problems with symptom management (Butler et al., 2005; Grande, Farquhar, Barclay, & Todd, 2004) and problematic communication (Tolson, Swan, & Knussen, 2002) and have also reported increased burden, strain, and depression across studies.

Physical Health Problems

Vitaliano et al.'s (2003) quantitative review of 23 studies from North America, Europe, and Australia examined relationships of caregiving with several health outcomes. They found that caregivers are at greater risk for health problems than are noncaregivers. These studies included 1,594 caregivers of persons with dementia and 1,478 noncaregivers who were similar in age (mean: 65.6 years old) and sex ratio (65% women, 35% men). In this review, six physiological and five self-reported categories were examined that are indicators of illness risk and illness. The physiological categories included level of stress hormones, antibodies, immune counts/functioning, and cardiovascular and metabolic variables. Caregivers had a 23% higher level of stress hormones (adrenocorticotropic hormone, catecholamines, cortisol, etc.) and a 15% lower level of antibodies (Epstein–Barr virus, herpes simplex, immunoglobulin G test) than did noncaregivers. Comorbid medical illnesses are important because many caregivers are middle-aged to older adults, and they may be ill before they become caregivers. It is interesting to note that the relationship

between caregiver status and physiological risk was stronger for men than women (Vitaliano et al., 2003). High perceived strain was associated with increased mortality, which did not differ by race, gender, or type of caregiving relationship (i.e., child, spouse; Perkins et al., 2013). Zarit et al. found that caregivers who managed their own health poorly were at greater risk for increased stress-related caregiving outcomes (Zarit, Femia, Kim, & Whitlatch, 2010). A recent meta-analysis of 15 U.S. and international caregiving studies found a causal negative effect of caregiving on mental and physical health. The effect was especially pronounced among female, married, and high-intensity caregivers (Bom, Bakx, Schut, & van Doorslaer, 2018).

ASSESSMENT OF THE PROBLEM

Although systematic assessment of the patient is a routine element of clinical practice, assessment of the family caregiver is rarely carried out to determine what help the caregiver may need. In recognition of this need to better educate and support caregivers, AARP promoted the Caregiver Advise, Record, Enable (CARE) Act. The CARE Act requires hospitals to contact caregivers and ensure they receive the appropriate training on the medical and nursing tasks included in the discharge plan (Reinhard & Ryan, 2017; Reinhard, Young, Ryan, & Choula, 2019). In addition to instruction on pertinent medical tasks, effective intervention strategies for caregivers should be based on an accurate assessment of caregiver risk and strengths. According to a broad consensus of researchers and family caregiving organizations (Schumacher, Beck, et al., 2006; Stewart et al., 1993), assessing the caregiver should involve addressing the following topics. These are applicable across settings (e.g., home, hospital) but may not need to be measured in every assessment.

- Initial assessments compared to reassessments (the latter focus on what has changed over time)
- New versus continuing care situations
- An acute episode prompting a change in caregiving versus an ongoing need requiring a focus on services (Family Caregiver Alliance, 2006)

Caregiving Context

The caregiving context includes the background of the caregiver and the caregiving situation. The caregiver's relationship to the care recipient (spouse or nonspouse) is important because spouse and nonspouse caregivers have different risks and needs (Gitlin et al., 2003; Pinquart & Sörensen, 2011; Sörensen et al., 2002). The caregiver's various roles and responsibilities can either take away from or enhance his or her ability to provide care. For example, working caregivers may have to develop strategies to juggle family and work responsibilities, so we need to know what their employment status is (work/home/volunteer; Pinquart & Sörensen, 2006a). The duration of caregiving (Sörensen et al., 2002) can give the clinician clues about how new caregiving is for the caregiver or alert the clinician to the possibility of caregiver exhaustion with the role. Questions about household status, such as how many people are in the home and the existence and involvement of extended family and social support (Pinquart & Sörensen, 2006a), can give the clinician clues about how much support the caregiver has readily available. Depending on the type of impairment of the care receiver, the physical environment of the home or facility where care takes place can be very important (Vitaliano et al., 2003). Determine what the caregiver's financial status is; for example, is he or she getting by, or is the caregiver short of funds to provide for everyday necessities (Vitaliano et al., 2003). Ask about potential resources that the caregiver could choose to use and list these (Pinquart & Sörensen, 2006a). Explore the family's cultural background (Dilworth-Anderson et al., 2002; Goins et al., 2011) and look for clues on how to use this as a resource.

Caregiver's Perception of Recipient's Health and Functional Status

List activities the care receiver needs help with; include both ADL and IADL (Pinquart & Sörensen, 2003, 2006a). Determine whether the care recipient has cognitive impairment. If the answer to this question is "yes," ask whether there are any behavioral problems (Gitlin et al., 2003; Sörensen et al., 2002). The presence of mobility problems can also make caregiving more difficult. Assess this by simply asking whether the care recipient has problems with getting around (Archbold et al., 1990).

Lack of Caregiver Preparedness

Caregivers indicate lack of preparedness is a big problem for them. National surveys of caregivers show that more than 80% to 88% of caregivers would like more information about topics related to caregiving (NAC & AARP, 2015; NASEM, 2016; TransAmerica Institute, 2017). Does the caregiver have the skills, abilities, or knowledge to provide the care recipient with needed care? To assess preparedness, use questions from the Preparedness for Caregiving Scale (PCGS; see consultgerirn.org/resources). The PCGS was developed by Archbold et al. (1990). The concept of preparedness derives from role theory, in which

socialization to a role is assumed to be important for role enactment and performance. The questions prompt caregivers to rate how well prepared they think they are for caregiving in four perspectives of domain-specific preparedness: physical needs, emotional needs, resources, and stress. The clinician can interview the caregiver or ask the caregiver to complete the scale like a survey. The responses to the scale items can also be tallied and averaged for an overall score. If pressed for time, the clinician can simply ask, overall, how well prepared the caregiver thinks he or she is to care for a family member and then follow this with more specific questions if the response indicates preparedness is low. The PCGS was evaluated in a longitudinal correlational study of family caregivers (N = 103) of older patients with chronic diseases (Archbold et al., 1990, 1992). The scale has five Likert-type items with possible responses ranging from 1 (not at all prepared) to 4 (very well prepared). Overall scores are computed by averaging responses to the five items. Scores range from 1.00 to 4.00, the lowest score correlating with least preparedness. Archbold et al. (1992) reported internal reliability (Cronbach's alpha) of 0.72 at 6 weeks and 0.71 at the 9-month interview. Confirmatory factor analysis and reliability studies done with other caregiving populations support the reliability and validity of the PCGS (Petruzzo et al., 2017; Pucciarelli et al., 2014).

Quality of Family Relationships

The caregiver's perception of the quality of the relationship with the care receiver is a key predictor of the presence or absence of strain from caregiving (Archbold et al., 1990). The quality of the relationship can be assessed using the Mutuality scale (Messecar, Parker-Walsch, & Lindauer, 2011) developed by Archbold et al. (1990, 1992). *Mutuality* is defined as the caregiver's perceived quality of the relationship with the care receiver. Questions include the following: How close do you feel to him or her? and How much does he or she express feelings of appreciation for you and the things you do? An overall score can be obtained by calculating the mean across all items—or the questions can be used in an open-ended interview format in which the clinician then probes for more information and history about the relationship. This scale can also be completed via self-administration and then reviewed by the clinician with the caregiver (interview the caregiver apart from the care receiver). For this scale, there is no item that asks about the relationship overall; instead, the items explore several key features of the relationship such as conflict, shared positive past memories, felt positive regard, and positive reciprocity between the caregiver and the care receiver. The questions open the door for the clinician to probe in a gentle way the quality of the relationship. Caregivers rate how they feel about the care recipient, with possible responses ranging from 0 (not at all) to 4 (a great deal). The caregiver's mutuality score is computed by taking the average of the scores on the 15 items. Internal reliability and consistency (Cronbach's alpha) of the scale was 0.91 at both 6 weeks and 9 months from discharge from the hospital (Archbold et al., 1990).

Indicators of Problems With Quality of Care

In Cooper, Selwood, and Livingston's (2008) systematic review of the prevalence of elder abuse and neglect, they concluded that one in four vulnerable elders are at risk of abuse and that only a small percentage of these cases are detected. A study of diagnosis of elder abuse in U.S. emergency departments suggests that improved identification of this problem is needed (Evans, Hunold, Rosen, & Platts-Mills, 2017). Indicators of problems with the quality of care can include the following: evidence of an unhealthy environment, inappropriate management of finances, and demonstration of a lack of respect for the older adult. The nurse's observations can be guided by the Elder Mistreatment Assessment (Boltz, Greenberg, & Fulmer, 2019; Fulmer, 2002), which helps the nurse identify elder abuse and neglect issues (see Elder Mistreatment Assessment instrument at consultgerirn.org/resources). This assessment instrument comprised seven sections that review signs, symptoms, and subjective complaints of elder abuse, neglect, exploitation, and abandonment (Fulmer, Paveza, Abraham, & Fairchild, 2000; Fulmer, Street, & Carr, 1984; Fulmer & Wetle, 1986). There is no "score," but the older adult should be referred to social services if there is evidence of mistreatment; a complaint by the older adult; or if there is high risk or probable abuse, neglect, exploitation, or abandonment of the older adult. Please also refer to Chapter 13, Nutrition in the Older Adult.

Caregiver's Physical and Mental Health Status

The caregiver's perception of his or her own health (Pinquart & Sörensen, 2006a, 2007) is one of the most reliable indicators of a physical health problem. Depression or other emotional distress (e.g., anxiety) can be assessed using the Center for Epidemiological Studies—Depression Scale Revised (CESD-R; see cesd-r.com/about-cesdr; Eaton, Muntaner, Smith, Tien, & Ybarra, 2004; Pinquart & Sörensen, 2006a, 2007; Sörensen et al., 2002). The CESD-R was initially designed as a screen for the community dwelling at risk for developing major depressive symptomatology. It has been used widely in intervention studies

with family caregivers, where it has been self-administered. In 2004, the tool was revised; however, the revised scale has been scored so that the same range of values still applies. The CESD-R website contains all the information needed to use the tool, which is in the public domain. For each of the 20 items, participants rate frequency of occurrence during the past week on a 4-point scale from 0 (not at all or less than 1 day) to 3 (nearly every day for 2 weeks). In order to have the same range as the original, the values for the top two responses (5–7 days and nearly every day) give the same value of 3. Scores range from 0 to 60, with a higher score indicating the presence of a greater number and frequency of depressive symptoms. A score of 16 or higher has been identified as discriminatory between groups with clinically relevant and nonrelevant depressive symptoms (Fulmer et al., 2000; Radloff, 1977).

Burden or strain can be assessed using the Modified Caregiver Strain Index (MCSI; see consultgerirn.org/resources, Family Caregiving; Onega, 2018). Preexisting burden or strain places caregivers at greater risk for poor outcomes, such as depression and poor health, and may prevent them from benefiting from interventions (Onega, 2018; Perkins et al., 2013; Schulz & Beach, 1999; Vitaliano et al., 2003). The Modified CSI is a tool that can be used to quickly identify families with potential caregiving concerns. It is a 13-question tool that measures strain related to care provision. There is at least one item for each of the following major domains: financial, physical, psychological, and social and personal. Positive responses to seven or more items on the index indicate a greater level of strain. Internal consistency reliability is high (Cronbach's alpha = 0.86), and construct validity is supported by correlations with the physical and emotional health of the caregiver and with subjective views of the caregiving situation. A positive screen (seven or more items positive) on the MCSI indicates a need for more in-depth assessment to facilitate appropriate intervention.

Rewards of Caregiving

Although early family caregiving research focused almost exclusively on negative outcomes of caregiving, clearly, there are many positive aspects of providing care. Spouses can be drawn closer together by caregiving, which can be an expression of love. Caregivers caring for a parent with Parkinson's or Alzheimer's who had positive experiences in caregiving reported fewer feelings of being overwhelmed or distressed by their situations (Habermann, Hines, & Davis, 2013). Child caregivers can feel a sense of accomplishment from helping their adult parents. The important contribution to caregiver well-being that rewards of caregiving can make led to the development of a new measure of this important concept. An 11-item scale called the Positive Aspects of Caregiving (PAC) was developed during a national Alzheimer's interventions trial (Tarlow et al., 2004). In a national sample of caregivers, both Hispanics and African American caregivers reported experiencing more positive rewards from caregiving, indicating rewards are perceived or experienced quite differently by caregivers from different backgrounds or distinct demographic subgroups (Roth et al., 2015). Caregivers should be encouraged to explore and list their perceived benefits of caregiving (Archbold et al., 1995). These can include the satisfaction of helping a family member, developing new skills and competencies, and/or improved family relationships.

Self-Care Activities for the Caregiver

Self-care activities can include things like setting aside time to exercise, having time for oneself, and obtaining respite. Even if the caregiver does not use this strategy, ask him or her to think about strategies that would work for him or her. Caregivers need to be reminded that self-care is not a luxury but a necessity. At a minimum, caregivers need to learn how to put themselves first, manage stress, socialize, and get help.

INTERVENTIONS AND CARE STRATEGIES

Definitions

Psychoeducational Interventions

Psychoeducational interventions involve a structured program geared toward providing information about the care receiver's disease process and about resources and services, as well as training caregivers to respond effectively to disease-related problems, such as memory and behavior problems in patients with dementia or depression and anger in patients with cancer. Use of lectures, group discussions, and written materials is always led by a trained leader. Support may be part of a psychoeducational group, but it is secondary to the educational content. Use of technology such as phones, Internet, video contact, and interactive voice recognition to support caregivers as they take on new caregiving responsibilities is included in this category.

Supportive Interventions

This category subsumes both professionally led and peer-led unstructured support groups focused on building rapport among participants and creating a space in which to discuss problems, successes, and feelings regarding caregiving.

Respite or Adult Day Care

Respite care is given either in-home or as site-specific supervision, assistance with ADL, or skilled nursing care designed to give the caregiver time off.

Psychotherapy

This type of intervention involves a therapeutic relationship between the caregiver and a trained professional. Most psychotherapeutic interventions with caregivers follow a cognitive behavioral approach.

Interventions to Improve Care Receiver Competence

These interventions include memory clinics for patients with dementia and activity therapy programs designed to improve affect and everyday competence.

Multicomponent Interventions

Interventions in this group included various combinations of educational interventions, support, psychotherapy, and respite in Sörensen et al.'s (2002) and Pinquart and Sörensen's (2006a) meta-analyses. Individual studies carried out after the 2002 meta-analysis include nursing management and interprofessional care interventions and REACH II.

Overview

Past reviews of caregiver interventions, such as support groups, individual counseling, and education, confirm that there is no single, easily implemented, and consistently effective method for eliminating the stresses and/or strain of being a caregiver (Knight, Lutzky, & Macofsky-Urban, 1993; Toseland & Rossiter, 1989). In 2002, Sörensen and colleagues performed a meta-analysis on the effects of a second generation of 78 caregiver intervention studies. The most consistent significant improvements in all outcome domains (burden, depression, well-being, ability and knowledge, and care receiver symptoms) assessed in the meta-analysis resulted from psychotherapy and caregiver psychoeducational interventions aimed at improving caregiver knowledge and abilities or skill building. They followed this up with a meta-analysis of 127 studies with 5,930 participants to examine what works in caregiving interventions (Pinquart & Sörensen, 2006b) and found significant effects for psychoeducational, supportive and counseling, and multicomponent interventions. Another systematic review of respite interventions demonstrated only small effects on caregivers with clear benefits for only certain subgroups (Mason et al., 2007). Multicomponent interventions, which combined features of psychotherapy and knowledge or skill building, had the largest effect on burden and, in addition, were effective in improving well-being, ability, and knowledge. Translational efforts to use some of these multicomponent documented approaches can advance proven strategies (Gitlin, Marx, Stanley, & Hodgson, 2015). Some new interventions are being tested that empower caregivers by supporting them and their care receivers through the transition from hospital to home. Family-centered Function-focused Care (Fam-FCC) promotes a family caregiver partnership to build their skills to help promote the functional recovery of older adults (Boltz, Resnick, Chippendale, & Galvin, 2014). The Fam-FFC intervention had a significant impact on caregiver preparedness and other functional outcomes for the older adult, and is now being tested in a multisite, cluster-randomized controlled trial (Boltz, Kuzmik, et al., 2018). The effects of different types of interventions on selected indicators of unhealthy caregiver transitions from the meta-analyses and studies completed since 2002 are presented in Table 14.1.

Other studies of psychotherapy and psychoeducational interventions fit the same pattern of results (Akkerman & Ostwald, 2004; Berry, Grant, Elliott, Edwards, & Fine, 2012; Bishop et al., 2014; A. Burns et al., 2005; Coon, Thompson, Steffen, Sorocco, & Gallagher-Thompson, 2003; Gitlin, Winter, Dennis, Hodgson, & Hauck, 2010; G. M. Harris, Durkin, Allen, DeCoster, & Burgio, 2011; Hébert et al., 2003; Hepburn et al., 2005; Judge, Yarry, Looman, & Bass, 2013; Lavretsky et al., 2013; Martire et al., 2010; Mittelman, Roth, Clay, & Haley, 2007; Mittelman, Roth, Coon, & Haley, 2004; Mittelman, Roth, Haley, & Zarit, 2004; Rodriguez-Sanchez et al., 2013; Zarit et al., 2011). A very recent meta-analysis explored the use of cognitive behavioral therapy (CBT) and mindfulness interventions (M. Lee et al., 2019). CBT interventions were the most promising, with the largest significant effect, and mindfulness interventions were moderately significant. Psychoeducational interventions had small significant effects and emotional support, and a range of other multicomponent interventions had insignificant effects. All of these interventions address key negative aspects of caregiving: being overwhelmed with the physical demands of care, feeling isolated, not having time for oneself, having difficulties with the care recipient's behavior, and dealing with one's own negative responses.

There are several characteristics across interventions that seem to have a moderating effect on caregiving outcomes. Focusing the caregiver training exclusively on the care receiver to alter his or her symptoms has almost no effect on the caregiver (Agren, Evangelista, Hjelm, & Stromberg, 2012; Flynn Longmire et al., 2014; Pinquart &

TABLE 14.1

Effects of Different Types of Interventions on Indicators of Unhealthy Caregiver Transitions

Type of Intervention	Burden or Strain	Depression, Distress, or Lack of Well-Being	Lack of Preparedness
Psychoeducation	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002).	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)
	Significant decrease in burden (Griffiths et al., 2016)	Significant decrease in depressive symptoms (Griffiths et al., 2016)	
Skill building	Decreased burden—six studies (Acton & Winter, 2002)	Decreased depression—six studies (Acton & Winter, 2002)	Increased knowledge—nine studies (Acton & Winter, 2002)
		Significant reduction in depressive symptoms (Gallagher-Thompson et al., 2003)	14% improved reaction to CR symptoms (Hébert et al., 2003)
		Decreased bother, anxiety, depression (D. F. Mahoney, Tarlow, & Jones, 2003)	Significant increase in preparedness for caregiving (Boltz et al., 2014)
		Decreased depression (Coon et al., 2003)	
		Decreased distress (Hepburn et al., 2005)	
		Improved quality of life (Bishop et al., 2014)	
		Improved depression when the caregiver reports engaging in exemplary care activities (G. M. Harris et al., 2011)	
	Improved strain (Judge et al., 2013)	Improved psychosocial outcomes (Judge et al., 2013)	
		Decreased depressive symptoms (Berry et al., 2012)	
Supportive interventions	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Preserved self-rated health (Mittelman et al., 2007)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)
Psychotherapy	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)
	Decreased objective burden	Decreased anxiety (Akkerman & Ostwald, 2004)	Some improved reaction to CR symptoms (A. Burns et al., 2005)
		Decreased depression with yogic meditation (Lavretsky et al., 2013)	
		Improved mental health (Rodriguez-Sanchez et al., 2013)	
		Decreased depression with CBT and mindfulness intervention (M. Lee et al., 2019)	

(*continued*)

TABLE 14.1

Effects of Different Types of Interventions on Indicators of Unhealthy Caregiver Transitions (*continued*)

Type of Intervention	Burden or Strain	Depression, Distress, or Lack of Well-Being	Lack of Preparedness
Respite	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	
		Decreased depression—three studies (Acton & Winter, 2002)	
	Small effect (Mason et al., 2007)	Small effect (Mason et al., 2007)	
		Stress lowered on days respite used (Zarit et al., 2011)	
Focus on CR		Significant effect (Sörensen et al., 2002)	
		COPE: functioning improved for CR but no significant CG improvement (Gitlin et al., 2010)	COPE: no significant CG improvement in confidence (Gitlin et al., 2010)
		Treating CR depression decreased burden (Martire et al., 2010)	
	No effect (Agren et al., 2012)	No effect (Agren et al., 2012)	
	No effect (Flynn Longmire et al., 2014)	Distress decreased (Flynn Longmire et al., 2014)	
		No improvement in emotional health (Sherwood et al., 2012)	
Multicomponent—added to this category	Large significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Improved distress and depression (Bass, Clark, Looman, McCarthy, & Eckert, 2003; Callahan et al., 2006)	Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)
	REACH II interventions decreased burden (Elliott, Burgio, & Decoster, 2010)	REACH II interventions decreased depression levels, improved self-rated health (Elliott et al., 2010)	
	Significant decrease in burden in TCARE (Montgomery, Kwak, Kosloski, & O'Connell Valuch, 2011)	Significant decrease in depression in TCARE (Montgomery et al., 2011)	
Nursing and interprofessional care management—includes hospital or rehabilitation at-home and primary care	Improved carer strain (Burton & Gibbon, 2005)	Less burden (Crotty, Whitehead, Miller, & Gray, 2003)	
	Decreased burden/strain—two studies (Acton & Winter, 2002)	Less strain (R. Harris, Ashton, Broad, Connolly, & Richmond, 2005)	
	REACH interventions overall decreased burden (Gitlin et al., 2003)	More strain after intervention (Wade et al., 2003)	

(*continued*)

TABLE 14.1

Effects of Different Types of Interventions on Indicators of Unhealthy Caregiver Transitions (*continued*)

Type of Intervention	Burden or Strain	Depression, Distress, or Lack of Well-Being	Lack of Preparedness
	Decreased burden (Kalra et al., 2004)	Significant decrease in depressive symptoms (Eisdorfer et al., 2003)	
	Burden and strain were responsive to intervention (Schulz et al., 2005)	Decreased depression, distress, anxiety—four studies (Acton & Winter, 2002)	
		Decreased anxiety and depression (Kalra et al., 2004)	
		Decreased depression (Mittelman, Roth, Coon, et al., 2004)	
		Decreased reaction ratings (Mittelman, Roth, Haley, et al., 2004)	
		Clinically significant decreases in depression and anxiety (Schulz et al., 2005)	
		Significant effect (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	
		Higher role rewards (Li et al., 2003)	
		Caregiver affect improved (Gitlin, Hauck, Dennis, & Winter, 2005)	
		Well-being worse in control group (R. Burns, Nichols, Martindale-Adams, Graney, & Lummus, 2003)	
Focus on physical or emotional health of CG		Decreased psychological distress (King, Baumann, O'Sullivan, Wilcox, & Castro, 2002)	
		Decreased depression and anxiety (Waelde, Thompson, & Gallagher-Thompson, 2004)	

CBT, cognitive behavioral therapy; CG, caregiver; COPE, Care of Persons With Dementia in Their Environments; CR, care receiver; REACH, Resources for Enhancing Alzheimer's Caregiver Health; TCARE, Tailored Caregiver Assessment and Referral.

Sörensen, 2006b; Sörensen et al., 2002; Sherwood et al., 2012). Agren et al.'s (2012) psychoeducation intervention had no impact on the caregiver's perceived control, health, depression, or burden. However, some new psychoeducation interventions leveraging Internet technology seem to show more promise. Tele-Savvy, an Internet-based version of the in-person, evidence-based psychoeducation Savvy Caregiver Program (SCP) for dementia caregivers, significantly reduced burden and depressive symptoms among a small sample of 22 caregivers (Griffiths, Whitney, Kovaleva, & Hepburn, 2016). This intervention is being further tested in a national clinical trial. In the Sörensen et al. (2002) meta-analysis, group interventions were less effective in improving caregiver burden than individual and mixed interventions, which is consistent with Knight et al. (1993) but inconsistent with the meta-analysis performed by Yin, Zhou, and Bashford (2002). Length of an intervention appears to be important in alleviating caregiver depression and care receiver symptoms. Caregivers do less well with shorter interventions regarding depression because they lose the supportive aspects of prolonged contact with a group or a professional before they can benefit.

Characteristics of the caregiver are also associated with intervention effectiveness. Some caregivers benefit less from interventions than others do. For example, Sörensen et al. (2002) found that spouse caregivers benefited less from interventions than did adult children. Table 14.2 presents caregiver characteristics associated with various indicators of unhealthy caregiver transitions.

TABLE 14.2

Effects of Different Types of Caregiver Characteristics on Indicators of Unhealthy Caregiver Transitions

Characteristics of Caregiving Situation	Burden	Depression or Lack of Well-Being	Lack of Preparedness
CR has dementia	Less effective (Sörensen et al., 2002)	Less effective (Sörensen et al., 2002)	Less effective (Sörensen et al., 2002)
Adult child CGs	Greater improvement (Sörensen et al., 2002)	Greater improvement (Sörensen et al., 2002)	Greater improvement (Sörensen et al., 2002)
		Nonspouses did better (Gitlin et al., 2003)	
Spouse CGs	Smaller improvement (Sörensen et al., 2002)	Smaller improvement (Sörensen et al., 2002)	Smaller improvement (Sörensen et al., 2002)
		Wives with low mastery and high anxiety benefited the most (D. F. Mahoney et al., 2003)	
		Cuban husbands improved more on depressive symptoms (Eisdorfer et al., 2003)	
	REACH II spouse CGs improved quality of life (burden) for African Americans only (Belle et al., 2006)	REACH II spouse CGs improved quality of life (depression) for African Americans only (Belle et al., 2006)	
		Wives improved more on burden and depression after CR nursing home placement (Gaugler et al., 2011)	
		Married caregiving caused poor physical and mental health (Bom et al., 2018).	
Older CGs	Greater improvement (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	No effects (Sörensen et al., 2002)	Greater improvement (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)
	Higher risk for burden (Schulz et al., 2005)	Higher risk for depression (Schulz et al., 2005)	
	Older African American CGs improved more (C. C. Lee et al., 2010; Sörensen & Pinquart, 2005)	Older African American CGs improved more (C. C. Lee et al., 2010; Sörensen et al., 2005)	
		Greater improvement in well-being (Sörensen et al., 2002)	
Female CGs	Greater improvement (Pinquart & Sörensen, 2006b; Sörensen et al., 2002)	Females benefit more (Gallagher-Thompson et al., 2003; Pinquart & Sörensen, 2006b)	Greater improvement (Sörensen et al., 2002)
	Better improvement (Gitlin et al., 2003)	Cuban daughters improved more on depressive symptoms (Eisdorfer et al., 2003)	
	Higher risk for burden (Schulz et al., 2005)	Higher risk for depression (Schulz et al., 2005)	
		Females caregiving caused poor physical and mental health (Bom et al., 2018).

TABLE 14.2

Effects of Different Types of Caregiver Characteristics on Indicators of Unhealthy Caregiver Transitions (*continued*)

Characteristics of Caregiving Situation	Burden	Depression or Lack of Well-Being	Lack of Preparedness
Ethnicity	African American CGs had lower levels of caregiver burden (Pinquart & Sörensen, 2005)	Latinos benefit as much (Eisdorfer et al., 2003)	Hispanic and Asian American CGs were more depressed; African American CGs had lower levels of depression (Pinquart & Sörensen, 2005)
	African American CGs' spiritual coping improved their resilience though did not decrease burden (Wilks et al., 2018)	Cuban husbands and daughters improved more on depressive symptoms (Eisdorfer et al., 2003)	
		Hispanics did better (Gitlin et al., 2003)	
	REACH II Hispanics and Whites decreased burden compared to African Americans though all groups improved (Elliott et al., 2010; Graham-Phillips et al., 2016)	REACH II Hispanics and Whites decreased depression compared to African Americans though all groups improved (Elliott et al., 2010; Graham-Phillips et al., 2016)	
		REACH II Hispanics and African Americans greater rewards of caregiving (Roth et al., 2015)	
Lower education	Better improvement (Gitlin et al., 2003)	Better improvement (Gitlin et al., 2003)	
	Higher risk for burden (Schulz et al., 2005)	Higher risk for depression (Schulz et al., 2005)	

CG, caregiver; CR, care receiver; REACH, Resources for Enhancing Alzheimer's Caregiver Health.

Interventions With Little Effect

Some intervention approaches have been consistently disappointing, showing either no significant effects or limited responses. In H. Lee and Cameron's (2004) update of the Cochrane Database Review, reanalysis of three trials of respite care found no significant effects of respite on any outcome variable. Interventions focused on medication management of the care receiver's dementing condition (Lingler, Martire, & Schulz, 2005) and/or targeted at managing problematic behavior (Livingston, Johnston, Katona, Paton, & Lyketsos, 2005) were similarly disappointing. A meta-analysis of habit training for the management of urinary incontinence interventions showed that not only were there no significant differences in incontinence between the intervention and control groups, but also that caregivers found the intervention labor intensive (Ostaszkiewicz, Johnston, & Roe, 2004).

In Acton and Winter's (2002) and Cook and colleagues' meta-analyses of dementia, caregiving studies; small, diverse samples; lack of intervention specificity; diversity in the length, duration, and intensity of the intervention strategies; and problematic outcome measures led to nonsignificant results for many tested interventions (Acton & Winter 2002; Cooke, McNally, Mulligan, Harrison, & Newman, 2001). They also reported that two thirds of the interventions they examined did not show any improvement in any outcome measures. Their analysis was hampered by lack of detailed description of the interventions in the studies they examined. Study limitations have also been a factor leading to disappointing results for some innovative caregiving interventions for caregivers of care receivers with other long-term, debilitating illnesses. For example, interventions designed to teach arthritis management as a couple (Martire et al., 2003) to decrease

the gap between the caregiver's expectations and the care receiver's actual functional abilities with skill-building and nurse-coached pain management all had disappointing results because of either small sample sizes or the complexity of the problems they were designed to address (Martin-Cook, Davis, Hynan, & Weiner, 2005; Schumacher et al., 2002). According to Price, Hermans, and Grimley Evans (2000), modification interventions for wandering have never been adequately tested because of the many flaws identified in the existing published research; outcome measurement has also been problematic. More distal outcomes, such as depression, perceived stress, caregiver strain, and self-efficacy less directly related to the actual intervention, are less likely to change significantly (Bourgeois, Schulz, Burgio, & Beach, 2002; Burgio, Stevens, Guy, Roth, & Haley, 2003) than outcomes that are more specific to the intervention (Hébert et al., 2003).

Caregivers caring for care receivers who have conditions that worsen substantially over time (dementia, heart failure, Parkinson's disease, and stroke) have reported either less improvement, no improvement, or increased strain after intervention (Agren et al., 2012; Forster et al., 2001; Pinquart & Sörensen, 2006b; Sörensen et al., 2002; Wright, Litaker, Laraia, & DeAndrade, 2001). Across many studies, Sörensen et al. (2002) reported that interventions with caregivers of dementia patients are less successful than for other caregivers. They also noted that if levels of caregiving are relatively high and cannot be reduced, as is the case for dementia caregivers, then burden and depression are less amenable to change as well. A multidisciplinary rehabilitation program for patients with Parkinson's disease resulted in no improvement in depression for caregivers after treatment (Trend, Kaye, Gage, Owen, & Wade, 2002). A meta-analysis of hospital-at-home care for patients with stroke reported no evidence from clinical trials to support a radical shift in the care of patients with acute stroke from hospital-based care (Langhorne et al., 2000). Individual studies that examined other psychoeducational and/or support and counseling interventions for stroke caregivers (albeit with relatively small samples) found no significant changes between the intervention and control groups (Clark, Rubenach, & Winsor, 2003; Gräsel, Biehler, Schmidt, & Schupp, 2005; Larson et al., 2005). Only an intensive, multicomponent skills-training intervention significantly decreased burden anxiety and depression for this category of caregivers (Kalra et al., 2004). A number of family-based and symptom-management interventions for patients with cancer have also found no significant intervention effects (Hudson, Aranda, & Hayman-White, 2005; Kozachik et al., 2001; Kurtz, Kurtz, Given, & Given, 2005; Northouse, Kershaw, Mood, & Schafenacker, 2005; Wells, Hepworth, Murphy, Wujcik, & Johnson, 2003), or the effects were not sustainable (Northouse et al., 2013). In several of these studies, there was a large dropout rate among the intervention participants because of the rapidly deteriorating condition of the care receivers.

Resources for Enhancing Alzheimer's Caregiver Health

The REACH project was designed to test promising interventions for enhancing family caregiving for persons with dementia and overcome several of the limitations of prior research (Schulz et al., 2003). More than 1,200 caregivers participated at six sites nationwide. The sample was more diverse than most caregiving studies because of the multisite design: participants were 56% White, 24% African American, and 19% Latino (Wisniewski et al., 2003). Six sites participated in this trial nationwide. The following six interventions were tested:

1. A 12-month, computer-mediated automated interactive voice response intervention designed to assist family caregivers managing care receivers with dementia (D. F. Mahoney et al., 2003)
2. A psychoeducational (skill-building) approach modeled after community-based support groups tailored to be sensitive to ethnic groups tested (Gallagher-Thompson et al., 2003)
3. A manual-guided care-recipient–focused behavior management skill training and caregiver-focused, problem-solving training intervention tailored to the cultural preferences of White and African American caregivers (Burgio et al., 2003)
4. A family therapy intervention designed to enhance communication between caregivers and other family members by identifying existing problems in communication and facilitating changes in interaction patterns (Eisdorfer et al., 2003)
5. Two primary care interventions delivered over a period of more than 24 months, which included patient behavior management only and patient behavior management plus caregiver stress and coping (R. Burns et al., 2003)
6. In-home occupational therapy visits designed to help families modify the environment to reduce caregiver burden (Gitlin et al., 2005)

When the results from the REACH interventions were pooled, overall interventions decreased the burden significantly compared to the control conditions (Gitlin

et al., 2003). Only the family therapy with computer technology intervention was effective in reducing depressive symptoms. Interventions were superior to control conditions on burden for women and caregivers with lower education. Interventions had greater impact on depression among Hispanics, nonspouses, and caregivers with lower education.

REACH II followed up on REACH I, but, unlike the first set of studies, which implemented a variety of interventions at six sites, REACH II implemented the same two interventions at each of five participating sites. REACH II specifically implemented a multicomponent intervention and tested new tools for assessing caregivers at risk for adverse outcomes. Intervention participants received individual risk profiles and the REACH intervention through nine in-home and three telephone sessions for more than 6 months. Caregivers receiving REACH II reported better self-rated health, sleep quality, physical health, and emotional health than for those caregivers not receiving the intervention. Findings supported using a structured, multicomponent skills-training intervention that targeted caregiver self-care behaviors as one of five target areas. Overall, REACH II improved self-reported health status and decreased burden and bother in racially and ethnically diverse caregivers of people with dementia (Elliott et al., 2010). An analysis of the findings by sociodemographic groups indicated that caregiver's age and religious coping moderated the effects of the intervention for Hispanics and Blacks. The older Hispanic and Black caregivers who received the intervention reported a decrease in caregiver burden from baseline to follow-up (C. C. Lee et al., 2010). However, subsequent exploration of the reasons why REACH II overall was less effective for African Americans than for Hispanic or White caregivers found that African Americans received less intervention contact (Graham-Phillips et al., 2016). Findings from the REACH studies support the use of multicomponent interventions tailored to specific caregiving characteristics.

Aspects of Interventions That Improve Effectiveness

A key conclusion of the REACH I and II trials and several of the meta-analyses (Elliott et al., 2010; Gitlin et al., 2003; Pinquart & Sörensen, 2006b; Schulz et al., 2005; Sörensen et al., 2002) reviewed in this chapter was that family caregiver interventions need to be multicomponent and tailored. Multicomponent interventions have the potential to include a repertoire of various strategies that target different aspects of the caregiving experience. In focus groups conducted during a caregiving clinical trial, Farran et al. (2004) identified and cataloged the information and skills caregivers reported they needed to respond to their own needs or the caregiving process. This included care receiver issues such as managing difficult behaviors, worrisome symptoms, personal care problems, and caregiver concerns such as managing competing responsibilities and stressors, finding and using resources, and handling their emotional and physical responses to care (Farran et al., 2004). *Tailored interventions* are interventions that are crafted to match a specific target population; for example, spouse caregivers of patients with Alzheimer's disease and their specific caregiving issues and concerns identified through assessment (Archbold et al., 1995; Horton-Deutsch, Farran, Choi, & Fogg, 2002). The Tailored Caregiver Assessment and Referral (TCARE) protocol is a manualized care management protocol specifically designed for care managers working with caregivers (Montgomery et al., 2011). Shifting from a traditional focus on the patient to a more family-centered approach and assessment is more helpful (Beeber & Zimmerman, 2012; Bowen, MacLehose, & Beaumont, 2011). Interventions that are individualized or tailored in combination with skill building demonstrated the best evidence of effectiveness (Gitlin et al., 2008, 2010; Pusey & Richards, 2001). Among the psychoeducation interventions, some of the most effective were predicated on a skill-building approach (Gallagher-Thompson et al., 2003; Hepburn, Tornatore, Center, & Ostwald, 2001). Collaboration or a partnership model with the caregiver is also a key component of making the tailoring process more effective (Harvath et al., 1994). Programs that work collaboratively with care receivers and their families and are more intensive and modified to the caregiver's needs are also more successful (Brodaty, Green, & Koschera, 2003). Clinicians interested in the translation of evidence-based programs into sustainable community-based programs should review reports of the ongoing challenges to be expected with such projects (Teri et al., 2012).

Nursing Care Strategies

1. *Identify content and skills needed to increase preparedness for caregiving.*
   Psychoeducational skill-building interventions include information about the care needed by the care receiver and how to provide it, as well as coaching on how to manage the caregiving role. Tasks associated with taking on the caregiving role include dealing with change, juggling competing responsibilities and stressors, providing and managing care, finding and using resources, and managing the physical and emotional responses

to care (Acton & Winter, 2002; Boltz, Resnick, et al., 2014; Farran, Loukissa, Perraud, & Paun, 2003; Farran et al., 2004; Gitlin et al., 2003; Lutz et al., 2017; Pinquart & Sörensen, 2006b; Sörensen et al., 2002).

2. *Form a partnership with the caregiver before generating strategies to address issues and concerns.*
   The goal of this partnership is blending the nurse's knowledge and expertise in healthcare with the caregiver's knowledge of the family member and the caregiving situation. Each party brings essential knowledge to the process of mutual negotiation between the family and the nurse. Together, they develop ideas to address the issues and concerns that are most salient for the caregiver and care receiver. One strategy that can be used in the hospital setting is to interview the caregiver using the Family Preferences Index developed by Li et al. (2003) to assess the family member's preferences to participate in care while the older adult is hospitalized (Boltz, Resnick, et al., 2014; Brodaty et al., 2003; Gitlin et al., 2005; Harvath et al., 1994; Nolan, 2001). A checklist to elicit and engage the perspectives of older adults and their caregivers at medical visits can be used to enhance communication (Wolff et al., 2014).
3. *Identify the caregiving issues and concerns on which the caregiver wants to work and generate strategies.*
   Multiple strategies should be generated for each caregiving issue and concern. One of the most important findings from the review of literature on caregiving is that multicomponent interventions are superior to narrow, single-approach problem-solving (Acton & Winter, 2002; Boltz, Resnick, et al., 2014; Gitlin et al., 2005; Sörensen et al., 2002). Several Level II individual studies are presented in Table 14.1.
4. *Assist the caregiver in identifying strengths in the caregiving situation.*
   Not all outcomes from caregiving are negative, and caregiving can be rewarding for some caregivers who derive pride and satisfaction from the important role they are filling. Incorporating pleasurable activities into the daily routine or incorporating something that is either fun or meaningful into some caregiving task is a way of enhancing caregiving. Even in really difficult situations, there may be some positive benefit derived such as satisfaction in meeting an important commitment and/or recognition of personal growth (Archbold et al., 1995; Roth et al., 2015).
5. *Assist the caregiver in finding and using resources.*
   Navigating the healthcare system is one of the most difficult skills caregivers have to master (Archbold et al., 1995; Boltz, Resnick, et al., 2014; Farran et al., 2004; Schumacher et al., 2002). Caregivers rarely know how to translate a need that they have into a request for help from the healthcare system. Learning how to speak to healthcare providers, how to negotiate billing, and how to request help with transportation—all of these tasks can be overwhelming. For some caregivers, the Internet and other online sources of support and information can be helpful.
6. *Help caregivers identify and manage their physical and emotional responses to caregiving.*
   We know that caregiving is sometimes associated with deterioration of the caregiver's health or significant depression (Schulz et al., 2005). Generating strategies to take care of the caregiver is just as important as the strategies for caring for the care recipient.
7. *Use an interprofessional approach when working with family caregivers.*
   Multicomponent interventions have the strongest record in terms of alleviating some of the global negative consequences of caregiving. Involving a team of other health professionals helps the nurse and family generate new ideas for strategies and brings a fresh perspective to the idea-generating process (Acton & Winter, 2002; Belle et al., 2006; Elliott et al., 2010; Farran et al., 2003, 2004; Gitlin et al., 2003; Sörensen et al., 2002). Several Level II studies are presented in Table 14.1.

CASE STUDY 14.1

Alison Walsh is the oldest of two children, and the only one who still lives in the same city as her widowed mother. She describes her relationship with her mother as very strained and without much love—only discipline. Her mother, who recently suffered a stroke and is considered marginal for staying home by her neurologist, is expecting that Alison will move in and take care of her. In fact, Alison's mother has virtually no resources for any other option. Alison's mother is being discharged today from the hospital. Alison says she would feel hard-pressed to take on all of the new care that her mother will require, including having to do baths and many, if not all, of her ADL. In addition, she feels her relationship with her mother is so poor she does not understand why she should have to be the caregiver at this time when she has her own problems. Adding to her difficulties, Alison has only one other sibling to call on for help, and he lives more

(*continued*)

CASE STUDY (*continued*)

than 2,000 miles away in another city. Her husband has health problems as well, and his care takes considerable time.

As a child caregiver, Alison is at higher risk for depression or anxiety. The goal of intervention with Alison will be to identify and address aspects of her caregiving situation amenable to modification. The possible targets for intervention will vary from one caregiver to another, and it is important that the approach be tailored. Addressing aspects of caregiving that are strong predictors of unhealthy caregiver transitions, such as a lack of preparedness, stress and strain in the relationship, and overall burden, can help the nurse tailor the caregiver interventions. In this case study, only three parameters of assessment (lack of preparedness, poor relationship quality, and need to find rewards of caregiving) will be addressed along with some suggested strategies for addressing the concerns indicated.

First, in Alison's case, caregivers may be reluctant to raise concerns about their lack of preparedness to the nurse. They may connect lack of preparedness with being embarrassed about their own lack of understanding, or they may simply not know what it is they do not know. For example, in Alison's case, she may not realize that formal resources could be tapped to provide some of the personal care that she feels unable or unwilling to perform. Exploration of her readiness to provide care will help Alison raise her concerns so that they can be fully addressed.

Second, a lack of mutuality (the positive quality of the relationship between caregiver and care recipient) is very predictive of future and sustained reported difficulty with caregiving. Alison has a difficult relationship with her mother now and a history of a poor-quality relationship from childhood. This puts her at risk for experiencing more strain from caregiving. Alison is aware that her relationship with her mother is difficult, but she may not realize how much this is adding to her strain. Alison will need to think about strategies to get support and help to deal with her feelings.

Third, although in Alison's situation there might not seem to be any rewards of caregiving, it is important to ask about these anyway. There are two very important reasons for nurses to explore positive aspects of caregiving with the caregiver; caregivers want to talk about them, and these factors will be an important indicator of the quality of care provided to the care recipient. Nurses need to encourage an increase in positive affect (i.e., feelings such as gratitude, forgiveness, and the like) while, at the same time, working on decreasing negative feelings such as depression, anxiety, and guilt.

SUMMARY

Outcomes Specific to Caregiving

The goal of the guideline is to reduce the likelihood of unhealthy transitions to the caregiving role by lowering caregiver strain, depression, and poor physical health for caregivers. Indicators of problems with this include reports of depression and/or fatigue, increased use of over-the-counter and prescription medications, increased use of health services, neglect of own health, and substance abuse. Increased focus on the caregiver system as the unit of service should increase the nurse's confidence in working with family caregivers.

Outcomes Specific to Patient

These include improvement (where possible) in patient functional status, nutrition, and hygiene. Improved symptom management for care recipients with significant chronic disease is also a desired outcome. This could include better pain management for care recipients with cancer, improved glycemic control for care recipients with diabetes, and/or diminished problematic behaviors for care recipients with dementia. The emotional well-being of the care recipient should also be an outcome of interventions to aid the caregiver. Decreased use of emergency services and increased use of formal care supports are system outcomes that might be expected.

NURSING STANDARD OF PRACTICE

Protocol 14.1: Family Caregiving

I. GOAL

To identify viable strategies to monitor and support family caregivers

II. OVERVIEW

Family caregivers provide more than 80% of the long-term care for older adults in this country. Caregiving can be difficult, time-consuming work added on top of job and other family responsibilities. If the caregiver suffers negative consequences from the caregiving role and these are not mitigated, increased morbidity and mortality may result for the caregiver. Not all outcomes from caregiving are negative; there are many caregivers who report rewards from caregiving.

III. BACKGROUND AND STATEMENT OF PROBLEM

A. Definitions

1. *Family caregiving* is broadly defined and refers to a broad range of unpaid care provided in response to illness or functional impairment to a chronically ill or functionally impaired older family member, partner, friend, or neighbor that exceeds the support usually provided in family relationships (Rabarison et al., 2018; Schumacher, Beck, et al., 2006).
2. Caregiver role transitions: *Caregiver role acquisition* is a family role transition that occurs through situated interaction as part of a role-making process (Schumacher, 1995). This is the process of taking on the caregiving role at the beginning of caregiving or when a significant change in the caregiving context occurs. Role transitions occur when a role is added to or deleted from the role set of a person or when the behavioral expectations for an established role change significantly (NAC & AARP, 2015).
3. Indicators of healthy caregiver role transitions: The broad categories of indicators of healthy transitions include subjective well-being, role mastery, and well-being of relationships. These are the subjective, behavioral, and interpersonal parameters of health most likely to be associated with healthy role transitions (Geary & Schumacher, 2012; NAC & AARP, 2015; Naylor et al., 2017).
4. Family caregiving activities include assistance with day-to-day activities, illness-related care, care management, and invisible aspects of care. Day-to-day activities include personal care activities (bathing, eating, dressing, mobility, transferring from bed to chair, and using the toilet) and IADL (meal preparation, grocery shopping, making telephone calls, and money management; NAC & AARP, 2015; NASEM, 2016). Illness-related activities include managing symptoms, coping with illness behaviors, carrying out treatments, and performing medical or nursing procedures that include an array of medical technologies (Schumacher, Beidler, et al., 2006; Schumacher et al., 2000). Care management activities include accessing resources, communicating with and navigating the healthcare and social services systems, and acting as an advocate (Schumacher et al., 2000). Invisible aspects of care are protective actions the caregiver takes to ensure the older adult's safety and well-being without the elder's knowledge (Bowers, 1987; Schumacher, Beck, et al., 2006).
5. Caregiving roles can be classified into a hierarchy according to who takes on the bulk of responsibilities versus only intermittent supportive assistance. Primary caregivers tend to provide most of the everyday aspects of care, whereas secondary caregivers help out as needed to fill the gaps (Cantor & Little, 1985; Penning, 1990; Tennstedt et al., 1989). Among caregivers who live with their care recipients, spouses account for the bulk of primary caregivers, whereas adult children are more likely to be secondary caregivers. The range of the family caregiving role includes protective caregiving, like "keeping an eye on" an older adult who is currently independent but at risk, to full-time, around-the-clock care for a severely impaired family member. Healthcare providers may fail to assess the full scope of the family caregiving role if they associate family caregiving only with the performance of tasks.
6. *Caregiver assessment* refers to an ongoing iterative process of gathering information that describes a family caregiving situation and identifies the particular issues, needs, resources, and strengths of the family caregiver.

(*continued*)

Protocol 14.1: Family Caregiving (*continued*)

B. Etiology and/or epidemiology of risk factors associated with unhealthy caregiving transitions
   1. Just being a caregiver puts an individual at increased risk of higher levels of stress and depression and lower levels of subjective well-being and physical health (Pinquart & Sörensen, 2006a, 2007; Vitaliano et al., 2003).
   2. Female caregivers on average provide more direct care and report higher levels of burden and depression (Cohen et al., 2017; Cook & Cohen, 2018; Gitlin et al., 2003; Riffin et al., 2019).
      LGBTQ caregivers report more financial concerns, loneliness, and declining physical health than non-LGBTQ caregivers and are wary of revealing their orientation/gender to their providers (Fredriksen-Goldsen et al., 2011).
   3. Ethnic minority caregivers provide more care, use less formal services, and report worse physical health than White caregivers (Cohen et al., 2017; Cook & Cohen, 2018; Cook et al., 2018; Dilworth-Anderson et al., 2002; NAC & AARP, 2015; Pinquart & Sörensen, 2006a, 2007).
   4. African American caregivers experience less stress and depression and get more rewards from caregiving than White caregivers (Cohen et al., 2017; Cook et al., 2018; Cuellar, 2002; Dilworth-Anderson et al., 2002; Gitlin et al., 2003; Haley et al., 2004; Pinquart & Sörensen, 2004), but younger or nonspouse caregivers do not respond as well to interventions (Belle et al., 2006; C. C. Lee et al., 2010).
   5. Hispanic and Asian American caregivers exhibit more depression (Gitlin et al., 2003; Pinquart & Sörensen, 2004) and emotional drain (Anthony et al., 2017), particularly among young Hispanic caregivers (C. C. Lee et al., 2010). But Hispanic and African American caregivers report more positive aspects of caregiving (Roth et al., 2015).
   6. Less-educated caregivers report more depression (Buckwalter et al., 1999; Gitlin et al., 2003).
   7. Spouse caregivers report higher levels of depression than nonspouse caregivers (Pinquart & Sörensen, 2004; Pruchno & Resch, 1989), but appear to benefit more from interventions (Elliott et al., 2010).
   8. Caregivers who have a poor-quality relationship with the care recipient report more strain (Archbold et al., 1990; Croog et al., 2006; Flannery, 2002).
   9. Caregivers who lack preparedness for the caregiving role also have increased strain (Archbold et al., 1990, 1992; Moon, 2017; NAC & AARP, 2015).
   10. Caregivers of care recipients who have dementia have more strain and burden (Pinquart & Sörensen, 2003).

IV. PARAMETERS OF ASSESSMENT

A. Caregiving context
   1. Caregiver relationship with care recipient (spouse, nonspouse; Elliott et al., 2010; Gitlin et al., 2003; NAC & AARP, 2015; Sörensen et al., 2002)
   2. Caregiver roles and responsibilities
      a. Duration of caregiving (Sörensen et al., 2002)
      b. Employment status (work/home/volunteer; Pinquart & Sörensen, 2004)
      c. Household status (number in home, etc.; Pinquart & Sörensen, 2004)
      d. Existence and involvement of extended family and social support (Pinquart & Sörensen, 2004)
   3. Physical environment (home, facility; Gitlin et al., 2010; Vitaliano et al., 2003)
   4. Financial status (Vitaliano et al., 2003)
   5. Potential resources that caregiver could choose to use—list (Pinquart & Sörensen, 2004)
   6. Family's cultural background (Browne et al., 2017; Dilworth-Anderson et al., 2002; Goins et al., 2011)

B. Caregiver's perception of health and functional status of care recipient
   1. List activities care receiver needs help with; include both ADL and IADL (Pinquart & Sörensen, 2004)
   2. Presence of cognitive impairment—if yes, any behavioral problems (Gitlin et al., 2003; Sörensen et al., 2002)
   3. Presence of mobility problems—assess with single question (Archbold et al., 1990)

C. Caregiver preparedness for caregiving
   1. Does caregiver have the skills, abilities, or knowledge to provide care recipient with needed care (see PCGS at consultgerirn.org/resources)?

(*continued*)

Protocol 14.1: Family Caregiving (*continued*)

D. Quality of family relationships
   1. The caregiver's perception of the quality of the relationship with the care receiver (see Mutuality scale; Archbold et al., 1990; Messecar et al., 2011)
E. Indicators of problems with quality of care
   1. Unhealthy environment
   2. Inappropriate management of finances
   3. Lack of respect for older adult (see EAI at www.consultgerirn.org/resources)
F. Caregiver's physical and mental health status
   1. Self-rated health: single item—asks what the caregiver's perception of his or her health is (Pinquart & Sörensen, 2006a, 2007).
   2. Health conditions and symptoms
      a. Depression or other emotional distress (e.g., anxiety; Pinquart & Sörensen, 2003, 2006a, 2007; Sörensen et al., 2002; see cesd-r.com/cesdr)
      b. Reports of burden or strain (Schulz & Beach, 1999; Vitaliano et al., 2003; see Caregiver Strain Index at www.consultgerirn.org/resources—Family Caregiving topic)
   3. Rewards of caregiving
      a. List perceived benefits of caregiving (Archbold et al., 1995)
      b. Satisfaction of helping family member
      c. Developing new skills and competencies
      d. Improved family relationships
   4. Self-care activities for caregiver
      a. Attending to own healthcare needs
      b. Getting exercise
      c. Taking time off
      d. Seeking support
      e. Getting proper rest and nutrition

V. NURSING CARE STRATEGIES

A. Identify content and skills needed to increase preparedness for caregiving (Acton & Winter, 2002; Boltz, Kuzmik, et al., 2018; Farran et al., 2003; Gitlin et al., 2003; Pusey & Richards, 2001; Schumacher, Beidler, et al., 2006; Schumacher et al., 2000; Sörensen et al., 2002).
B. Form a partnership with the caregiver before generating strategies to address issues and concerns (Boltz, Kuzmik, et al., 2018; Brodaty et al., 2003; Gitlin et al., 2003; Harvath et al., 1994).
C. Invite participation in care while in the hospital using the Family Preferences Index, a 14-item approach to exploring caregivers' personal choices for participating in the care of hospitalized older adult family members to determine preferences to provide care (Messecar, Powers, & Nagel, 2008).
D. Identify the caregiving issues and concerns on which the caregiver wants to work and generate strategies (Acton & Winter, 2002; Boltz, Kuzmik, et al., 2018; Gitlin et al., 2003; Schumacher, Beidler, et al., 2006; Sörensen et al., 2002).
E. Assist the caregiver in identifying strengths in the caregiving situation (Archbold et al., 1995).
F. Assist the caregiver in finding and using resources (Archbold et al., 1995; Boltz, Kuzmik, et al., 2018; Farran et al., 2004; Schumacher et al., 2002).
G. Help caregivers identify and manage their physical and emotional responses to caregiving (Schulz & Beach, 1999). Screen for strain using the MCSI (Onega, 2018).
H. Use an interprofessional approach when working with family caregivers (Acton & Winter, 2002; Farran et al., 2003, 2004; Gitlin et al., 2003; Sörensen et al., 2002).

(*continued*)

Protocol 14.1: Family Caregiving (*continued*)

VI. EVALUATION OF EXPECTED OUTCOMES

A. Outcomes specific to caregiving transitions
   1. Lower caregiver strain
   2. Decreased depression
   3. Improved physical health

B. Outcomes specific to patient
   1. Quality of family caregiving
   2. Care recipient's functional status, nutrition, hygiene, and symptom management
   3. Care recipient's emotional well-being
   4. Decreased occurrence of adverse events such as increased frequency of emergent care

ABBREVIATIONS

ADL	Activities of daily living
EAI	Elder Assessment Instrument
IAD	Instrumental activities of daily living
PCGS	Preparedness for Caregiving Scale

ACKNOWLEDGMENTS

The author wishes to gratefully acknowledge the assistance of Patricia Archbold and Barbara Stewart, the developers of the Caregiver Preparedness and Mutuality scales, for their assistance in providing information and access to these valuable caregiving assessment tools. This protocol also benefited from the perspective provided by Hong Li, the developer of the Family Preference Index, on the critical importance of involving family caregivers early in the hospital care process to facilitate a healthy transition into the caregiving role.

Issues Regarding Sexuality in Older Adults*

Elaine E. Steinke

15

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe an older adult's interest in sexuality.
2. Identify barriers and challenges to sexual health among older adults.
3. Discuss normal and pathological changes of aging and their influence on sexual health.
4. Identify interventions that may help older adults achieve sexual health.

OVERVIEW

Sexuality is central to being human throughout life, and the expression of basic human needs includes intimacy, emotional expression, and love (World Health Organization [WHO], 2017, p. 3). Moreover, it encompasses sex, gender roles, and sexual orientation, and influencing factors include the "interaction of biological, psychological, cognitive, social, political, cultural, ethical, legal, historical, religious, and spiritual factors" (WHO, 2017, p. 3). *Sexual health* "requires a positive, responsible approach to sexuality and sexual relationships as well as pleasurable, safe sexual experiences that are free from coercion, discrimination or violence," with sexual rights to express one's sexuality and protection from discrimination as important to this definition (WHO, 2017, p. 3). Sexual health contributes to the satisfaction of physical needs; however, sexual contact fulfills many social, emotional, and psychological components of life as well. This is evidenced by the fact that human touch and a healthy sex life may evoke feelings of joy, romance, affection, passion, and intimacy, whereas despondency and depression often result from an inability to express one's sexuality (Buttaro, Koeniger-Donohue, & Hawkins, 2014). When this occurs, *sexual dysfunction*, defined as impairment in normal sexual functioning during desire, excitation, and/or orgasmic phases of the sexual response cycle, may result (Steinke, 2017b). There are several subtypes of sexual dysfunction, including delayed ejaculation, erectile disorder, female orgasmic disorder, female sexual interest/arousal disorder, genitopelvic pain/penetration disorder, male hypoactive sexual desire disorder, premature ejaculation, and substance/medication-induced sexual dysfunction (American Psychiatric Association, 2013).

It is frequently assumed that sexual desire and the frequency of sexual encounters begin to diminish later in life. In today's youth-focused society, sexuality in the context of aging is often believed to be impossible and is not openly discussed. Older adults may feel invisible in

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

regard to sexuality, and although this might not impact personal sexual expression, it may call into question social legitimacy and social norms in regard to later life sexuality, indirectly affecting sexual expression (Gewirtz-Meydan et al., 2018). In contrast, results of a large study of adults across generational groups (N = 962) revealed that aging sexual stigma was relatively low with moderately permissive attitudes, with no significant difference by age group or generational cohort, although older men tended to have higher sexual stigma scores compared to women (Syme & Cohn, 2016). The results of this study suggest that acceptance of aging sexuality may be improving.

Negative views of sexuality in aging often occur in healthcare settings, and healthcare providers may not recognize the importance of sexual quality of life, or assess sexual function. A systematic review of older adults' experiences with healthcare providers in recognizing sexual health status revealed that while older adults viewed sexuality as important, healthcare providers appeared disinterested or lacked understanding of sexual health of older adults (Bauer, Haesler, & Fetherstonhaugh, 2016). This may result in the older adult not seeking help for sexual problems or fearing not being taken seriously, and results in missed opportunities for healthcare providers in effective management of sexual problems, education, and counseling. Despite the negative stereotypes, sexual identity and the need for intimacy do not disappear with increasing age, and older adults do not morph into celibate, asexual beings. Physical intimacy is an important individual right, including in older age. Likewise, safety and protection from sexual abuse are key issues that are often underrecognized (Buttaro et al., 2014). This presents both ethical and legal issues, and it is important for nurses to recognize the potential for sexual abuse in all older adults, particularly in those who are less able to resist such abuses because of physical incapacity, psychological vulnerability, or cognitive impairment (see Chapter 9, Assessing Cognitive Function in the Older Adult).

Recognizing that older adults have a need for physical intimacy and that many wish to remain sexually active as they age is essential in promoting sexual quality of life. In a U.S. national poll on healthy aging, current sexual activity overall was 40%, with 46% of those aged 65 to 70, 39% of those aged 71 to 75, and 25% of those aged 76 to 80 being sexually active, with men (51%) more sexually active than women (31%), and 54% of the sample stating that sex was important to their overall quality of life (Solway, Clark, Singer, Kirch, & Malani, 2018). In partnered older adults (N = 9,164), reported sexual frequency and satisfaction revealed that high sexual frequency and high satisfaction occurred in 34.5% of the sample, and low frequency and low satisfaction in 43.5%, with high frequency and low satisfaction (10.4%) and low frequency and high satisfaction (11.6%) also noted (Gillespie, 2017). In U.S. adults aged 57 to 85 (N = 1,656), sexual frequency was two to three times per month (22%), once per month or less (29.2%), and no sex in the last year (27.7%), illustrating that older adults do indeed continue to be sexually active (Stroope, McFarland, & Uecker, 2015). Being sexually active has been associated with greater life enjoyment, improved quality of life, and greater sexual well-being (Flynn & Gow, 2015; Santos-Iglesias, Byers, & Moglia, 2016; Smith et al., 2018).

BACKGROUND AND STATEMENT OF PROBLEM

Despite the persistence of sexual patterns throughout the life span, there is limited research and information to assist nurses in assessing or intervening to promote sexual health among older adults. Contributing to this disconnect is the lack of societal recognition of sexuality as a continuing human need and a factor that perpetuates lack of sexual assessment and intervention among the older population. Other factors impacting sexual health include the presence of normal and pathological aging changes; environmental barriers to sexual health; special problems of the older adult that interfere with sexual fulfillment, such as cognitive impairment; and comorbid conditions that may impair the ability to be sexually active. Although sexuality in aging has often been overlooked in general, some literature addresses sexual activity and sexual concerns across the adult life span for diagnoses such as heart disease and cancer. For example, two scientific statements from the American Heart Association are available to help nurses and other providers in sexual counseling of cardiac patients and their partners (Levine et al., 2012; Steinke et al., 2013), and the American Society of Clinical Oncology guideline provides interventions to address sexual problems in those with cancer (Carter et al., 2018). Although resources are available for selected medical conditions, the widespread adoption of sexual counseling in practice remains problematic.

Nurses' Views Toward Sexuality and Aging

Nurses' hesitancy to discuss sexuality with older adults has a significant impact on the sexual health of this population. Maes and Louis (2011) reported that only 2% of nurse practitioners (N = 500) always conducted a sexual history, and 23.4% never or seldom did so in patients aged 50 years and older, although most reported comfort and confidence in sexual history taking. A survey of advanced practice registered nurses, doctors of osteopathy, medical

doctors, and physician assistants that was conducted in one Midwestern U.S. state found that 42.78% did not routinely assess sexual health in older adults, with 45.64% reporting it difficult to proactively assess sexual health and 41.8% reported experiencing barriers in completing a sexual assessment with older adults (Harding & Manry, 2017). Lack of training was a barrier to sexual health assessment in practice. For nurse practitioners and physicians in primary care (N = 278), good to moderate knowledge (84.2%) in addressing sexual concerns was noted, although only 3% believed they had sufficient knowledge about sexuality in aging (Hughes & Wittmann, 2015). In a small Canadian study of primary care physicians, physicians were significantly more likely to discuss sexual health with older adults aged 50 to 75 years than those over age 75 for both men and women (Pascoal, Slater, & Guiang, 2017). Topics more likely to be discussed related to medical problems such as erectile dysfunction, sexually transmitted infections, grief, and performance anxiety for men, and atrophic vaginitis, bleeding, pain, and lack of interest for women. Barriers to discussing sexual health included lack of time (83%), addressing multiple comorbid conditions (61%), believing that the person was not interested in sex (47%), and lack of expertise for such discussions (42%), indicating that increasing providers' knowledge may be an important strategy (Pascoal et al., 2017). Similarly, in a qualitative study of primary care physicians, physicians refrained from asking patients about sexual function or problems, keeping the focus of the appointment on medical problems, and when sexual problems were addressed, the approach was to offer medications for sexual dysfunction, with few physicians offering any type of sexual counseling (Levkovich, Gewirtz-Meydan, Karkabi, & Ayalon, 2018).

General discomfort among nurses when discussing sexuality, lack of experience in the assessment and management of sexual dysfunction among older adults, and lack of confidence (East & Hutchinson, 2013) often prevent nurses from addressing the sexual needs of this population. A disparity exists between nurses' readiness and willingness to discuss sexual needs and concerns with clients (East & Hutchinson, 2013). Various factors influence sexual discussions, such as lack of privacy, personal attitudes, and embarrassment. Although inadequate knowledge by nurses has been reported, a study of nurses' attitudes and beliefs revealed that 92% of nurses understood the impact of diseases and treatment on sexual function, and nearly two thirds stated that they felt both comfortable with and responsible for such discussions, but the majority did not discuss sexual concerns in practice (80%) and most lacked the confidence (60%) to do so (Saunamäki, Andersson, & Engström, 2010). Moreover, the sexuality of older adults is generally excluded from sparse gerontological curricula, and sexual assessment is viewed as less important than other assessments. A study of senior nursing students revealed that knowledge, attitudes, and self-efficacy were positively associated with sexual healthcare and that those nursing students with greater sexual knowledge had more positive attitudes, leading to more confidence in providing sexual healthcare in practice (Sung, Huang, & Lin, 2015). Additionally, results support the role of nurse educators to not only provide knowledge and skills for sexual assessment and counseling, but to also help students develop appropriate attitudes toward older adult sexuality. Without education and experience in managing sensitive issues around sexuality, health professionals are often not comfortable discussing sexual issues with older adults. Healthcare providers may lessen discomfort when addressing sexual issues by increasing their knowledge on the subject, practicing effective communication strategies to increase comfort in sexual discussions, and introducing this dimension of health into routine assessment and management protocols.

Nurses' understanding of sexuality should be broadened beyond that of a relationship between just men and women. Many clients within various healthcare systems are LGBT adults, and these alternative sexual preferences require respect and consideration. Negative media portrayals and gender stereotyping are pervasive not only in regard to older adult sexuality, but particularly for those who are gay (Garrett, 2014). A study of transgender individuals and their interaction with healthcare professionals illustrated a pattern of disrespect by healthcare professionals in regard to their sexuality, based on negative attitudes and stereotypes, that can lead to discriminatory treatment (Lindroth, 2016). Therefore, nurses are in key positions as first-line care providers to focus on health promotion in those who are LGBTQ and to proactively work to reduce and eliminate healthcare disparities and barriers. Health-promotion strategies should address such areas as HIV/AIDS; safe sex; hepatitis immunization and screening; alcohol use and substance abuse; sexually transmitted infections (STI); physical abuse, anxiety, and depression; as well as wellness exams such as prostate, testicular, breast, cervical, and colon cancer (Lim, Brown, & Justin Kim, 2014). Prevention focused on heart health, physical fitness, tobacco cessation, and diet are important for all older adults (see Chapter 32, HIV Prevention and Care for the Older Adult and Chapter 33, LGBTQ Perspectives for Older Adult Care).

Older adults in the United States who live with HIV/AIDS face considerable challenges, including stereotyping, prejudice, and discrimination related to real or perceived

sexual orientation, and this contributes to anxiety, depression, and higher risk sexual behaviors (Cahill & Valadéz, 2013). Conversely, older gay men with a same-sex domestic or married partner have a more positive affect and less depression (Cahill & Valadéz, 2013). Older women with HIV face unique challenges, including physiological changes with menopause, changing social roles, and changes in self-image, as well as stigma, negative attitudes, and discrimination, not only from their families and community, but also from healthcare professionals (Narasimhan, Payne, Caldas, Beard, & Kennedy, 2016). Sexual health education is a crucial intervention. Proactive screening and assessment are critical in the older HIV population, as is effective management that includes treatment of any mental health conditions and comorbidities.

Normal and Pathological Aging Changes

The "sexual response cycle," or the organized pattern of physical response to sexual stimulation, changes with age in both women and men. After menopause, a loss of estrogen in women results in significant sexual changes. This deficiency frequently results in the thinning of the vaginal walls and decreased or delayed vaginal lubrication, which may lead to pain during intercourse (Levin, 2015). Additionally, the labia atrophies, the vagina shortens, and the cervix may descend downward into the vagina and cause further pain and discomfort. Moreover, vaginal contractions are fewer and weaker during orgasm, and after sexual intercourse is completed, women return to the prearoused stage faster than they would at an earlier age. There can be changes in sexual desire, loss of clitoral sensations, fewer orgasms, and changes in the depth of orgasm, although some women report greater sexual desire and responsiveness (Spadt & Kusturiss, 2016). The result of these physiological age-related changes in women is the potential for significant alterations in sexual health and sexual dysfunction that have traditionally received little attention from individual healthcare providers. The genitourinary syndrome of menopause is characterized by "vaginal dryness, irritation/burning/itching of the vulva or vagina; diminished lubrication, dyspareunia, or discomfort with sexual activity; postcoital bleeding; reduced arousal, orgasm, and desire; dysuria; and urinary frequency or urgency," (p. 1418), and in a study of 423 postmenopausal women with this syndrome, 70.7% had vaginal symptoms (Moral et al., 2018). The pain resulting from anatomical changes and vaginal dryness may result in the avoidance of sexual relationships in order to prevent painful intercourse. Inquiring about genitourinary changes and menopausal symptoms is an important area for assessment by nurses and physicians, in order to design effective interventions (Mitchell & Waetjen, 2018).

Men also experience decreased hormone levels, mainly a gradual decline in testosterone, which has been associated with decreased frequency and weaker orgasms, a longer refractory period between erections, less forceful and reduced amount of ejaculate, and erectile dysfunction (Syme, 2014; Yeap, Araujo, & Wittert, 2012). Men may experience fatigue, loss of muscle mass, depression, and a decline in libido. As a result of normal aging changes, older men require more direct stimulation of the penis to experience erection, which is somewhat weaker as compared to that experienced in earlier ages. Declining levels of testosterone in the aging man have more far-reaching implications, having been associated with reduced sexual activity, frailty, dyslipidemia, atherosclerosis, vascular disease, insulin resistance, metabolic syndrome, cardiovascular events, and overall mortality, although further study is needed to establish causal relationships (Hsu et al., 2017; Panach-Navarrete & Martínez-Jabaloyas, 2017; Yeap et al., 2012). Frailty in an older population has been associated with impaired sexual functioning and distress, as well as erectile dysfunction (Lee et al., 2013), illustrating the importance of evaluating sexual health and sexual activity, as well as managing comorbid conditions with the goal of improving both overall and sexual health.

Bodily changes, such as wrinkles and sagging skin, may cause both older women and men to feel insecure about initiating a sexual encounter and maintaining emotionally secure relationships. Perceptions of body image and sexual self-esteem often influence sexual interest and sexual activity, perhaps even more so for women than men (Syme, 2014). Sensory dysfunction can also lead to decline in sexual activity for some older adults (Zhong, Pinto, Wroblewski, & McClintock, 2018). In addition, attitudes, beliefs, and lack of knowledge contribute to misperceptions about sexuality, changes in sexual function, sexual risk taking, and prevention. Cultural influences on attitudes and beliefs are often grounded in Western beliefs that youth and beauty are of higher value and that sexuality in older adulthood is nonexistent, shameful, or disgusting (Merghati-Khoei, Pirak, Yazdkhasti, & Rezasoltani, 2016; Syme, 2014). In contrast, one study that examined the role of religion and sexuality found that religious influence contributed to greater satisfaction with the frequency of sexual activity, as well as physical and emotional satisfaction with sex, but with the latter finding only in men, illustrating the positive influence of religion on one's sexual life (Iveniuk, O'Muircheartaigh, & Cagney, 2016). Being physically active has been associated with higher sex drive, increased sexual activity, and less sexual dysfunction,

while poor sleep contributed to less sexual activity, sexual dissatisfaction, and more sexual dysfunction (Allen & Desille, 2017); thus, nurses can take a proactive role in promoting a healthy lifestyle, which, besides overall health benefits, can support sexual function. In addition to normal aging changes, both chronic illness and a number of medical conditions have been associated with poor sexual health and functioning in the older population. Cardiovascular disease, diabetes, chronic respiratory diseases, and cancer can impact sexual desire and sexual function (Merghati-Khoei et al., 2016). A study of 100 women with chronic illness presenting at internal medicine clinics revealed that 65% had sexual dysfunction, including painful intercourse, reluctance to engage in sex, orgasmic problems, and sexual dissatisfaction. Predictors of sexual dysfunction included older age; menopause; unemployment; and experiencing fatigue, sleep problems, and pain and weakness in extremities (Mollaoğlu, Tuncay, & Fertelli, 2013). In a large Danish study across cardiac diagnoses (N = 1,549), sexual difficulties were experienced by 55% of men and 29% of women, with greater difficulties reported by those of older ages; diagnosed with heart failure, diabetes, or hypertension; taking beta-blocker medications; or having anxiety or depression (Rundblad et al., 2017). Sexual problems with heart failure are prevalent, ranging from 60% to 87%, and many individuals with heart failure cease sexual activity, estimated at 25%; sexual problems include decreased interest in or fear of having sex, orgasmic problems, or erectile dysfunction (Jaarsma, 2017). Changes in sexual function with stroke are common, with decline in sexual activity, sexual dissatisfaction, and sexual dysfunction, including decreased libido, decreased vaginal lubrication in women, orgasmic problems, or erectile dysfunction in men (Dusenbury, Palm Johansen, Mosack, & Steinke, 2017). Diabetic women treated with insulin were more likely to report problems with vaginal lubrication and orgasm than nondiabetic women (Copeland et al., 2012). In 200 men with type 2 diabetes mellitus, 60% had erectile dysfunction, which was significantly associated with older age, fasting plasma glucose, hemoglobin A1c (HbA1c), creatinine level, and systolic blood pressure (Sharifi, Asghari, Jaberi, Salehi, & Mirzamohammadi, 2012). In addition, significant predictors of erectile dysfunction were older age and taking calcium channel blocker medications. Decreased sexual desire and satisfaction were prevalent among persons with type 2 diabetes (Pedersen et al., 2015).

Sexual dysfunction is prevalent in cancer survivors, with 41% reporting a decline in sexual function and 52% with altered body image (Averyt & Nishimoto, 2014). In colorectal cancer, rates may be higher because of the impact of surgery, radiation, and chemotherapy on sexual function. Changes in sensation, vascular scarring, decreased vaginal lubrication, urinary or fecal incontinence, erectile dysfunction, and symptoms such as fatigue or nausea may interfere with sexual function. In men with postradical prostatectomy, sexual dysfunction often includes erectile dysfunction, reduced sexual frequency, diminished sexual desire, and orgasmic difficulties; both psychoeducational and psychotherapeutic interventions have positively impacted coping and sexual function in several studies cited in this systematic review (Lassen, Gattinger, & Saxer, 2013). Additionally, proactively providing education and counseling before surgery can assist with sexual rehabilitation and coping with the loss of erectile function in the couple's relationship, and providing resources for treatment can be useful; of note, 77% of couples in a small study rejected the approach of using erectile aids, which can be helpful in maintaining sexual function and illustrating the importance of sexual assessment and counseling (Wittmann et al., 2015).

The presence of depression among older adults impacts sexual health, in that depression often causes a decline in desire and ability to perform, exacerbated by its treatment. Lee et al. (2013) found that men who were prefrail or frail had higher depression scores and more erectile dysfunction, and depression mediated almost half of the total effect related to frailty and sexual distress. In a systematic review, those with urgency urinary incontinence faced considerable challenges in maintaining sexuality and overall quality of life, impacting psychological well-being (anxiety and depression), daily activities, sexual function, and work productivity (Coyne et al., 2013). In contrast, positive psychological well-being was associated with more sexual activity and physical tenderness in community-dwelling older adults with a partner, although unpartnered adults had lower psychological well-being scores (Freak-Poli et al., 2017). The presence of anxiety, depression, and psychological well-being should be assessed among older adults and considered for the impact of these emotional and psychological factors on sexual health (see Chapter 19, Late-Life Depression and Chapter 25, Urinary Incontinence in the Older Adult).

Medications used to treat commonly occurring medical illnesses among older adults also impact sexual function. Two of the major groups of medications include antidepressants and antihypertensives. Selective serotonin reuptake inhibitors (SSRI) are commonly used to treat depression and have been linked with sexual dysfunction, although this is likely underreported (Trenque et al., 2013). A meta-analysis of data extracted from 63 studies and more than 26,000 patients treated for major depressive disorder with second-generation antidepressants revealed that

citalopram and paroxetine contributed to statistically significant higher risk of sexual dysfunction, whereas bupropion conferred lower risk of sexual dysfunction (Reichenpfader et al., 2014). In patients with antidepressant-treated anxiety or depressive disorders, impaired sexual function occurred with fluoxetine and sertraline, while better sexual function was noted with mirtazapine (Preeti, Jayaram, & Chittaranjan, 2018). Cardiac medications that contribute to sexual dysfunction include beta-blockers (exception: nebivolol), cardiac glycosides, and diuretics, with mixed results in studies related to alpha blockers, angiotensin-converting enzyme inhibitors (ACEI), and calcium channel blockers; certain drugs exert a negative effect, and others have a positive impact on sexual function in some studies (La Torre, Giupponi, Duffy, Conca, & Catanzariti, 2015; Nicolai et al., 2014). Those taking beta-blockers and thiazide diuretics appear to be at greatest risk of sexual dysfunction (Bohdana & Vrublová, 2014). Overall, angiotensin receptor blockers (ARB) and statins do not appear to contribute to sexual problems in most studies. In a study of cardiac patients and medications, first and third generation beta-blockers, class I calcium channel blockers, vasodilators, diuretics overall, and loop diuretics negatively affected sexual activity, with significant predictors of change in sexual activity with the number of medications taken, education level, and income; for each additional medication, patients were 13% less likely to be as sexually active as before, illustrating the cumulative effect of multiple medications on sexual function (Steinke, Mosack, & Hill, 2015).

Special Issues Related to Older Adults and Sexuality

Cognitively impaired older adults continue to have sexual needs and desires that may present a challenge to nurses. A review of older adults' cognitive functioning and sexual behavior indicated that those older adults engaging in sexual activity tended to have better overall cognitive function; the ability to think abstractly may be important in continuing a sexual relationship (Hartmans, Comijs, & Jonker, 2014). In community-dwelling older adults, those without cognitive impairment engaged in more sexual activity and physical tenderness (>50% for women) compared to those with cognitive impairment (Freak-Poli, Licher, Ryan, Ikram, & Tiemeier, 2018). Conversely, forgetfulness, poor decision-making, and problems with cognitive sequencing may negatively affect sexual function (Hartmans et al., 2014). In men, sexual activity was significantly associated with number sequencing and recall, while in women only recall was associated with sexual activity (Wright & Jenks, 2016). Hypersexuality appears to be rare among cognitively impaired elderly, and apathy or indifference toward sexual activity may be more prominent (Hartmans et al., 2014; see Chapter 9, Assessing Cognitive Function in the Older Adult, and Chapter 21, Dementia: Assessment and Care Strategies).

Continuing sexual needs often manifest in inappropriate sexual behavior. Sexual behaviors common to cognitively impaired older adults may include cuddling, touching of the genitals, sexual remarks, propositioning, grabbing and groping, using obscene language, masturbating without shame, aggression, and irritability. Inappropriate sexual behavior can also lead to elder abuse, and those most likely to be victims are those who are cognitively impaired, although research is limited and such behavior likely underreported (Lichtenberg, 2014). Nurses have an ethical responsibility to be cognizant of the potential for abuse, and to report and intervene promptly to maintain the safety of the older adult victim.

Masturbation is a method by which cognitively impaired men and women may become sexually fulfilled. Nurses in long-term care facilities may assist older adults to improve sexual health by providing an environment in which the older adult may masturbate in private. Accurate assessment and documentation of the ability of cognitively impaired older adults to make competent decisions regarding sexual relationships with others while in long-term care are essential. If the resident has been determined to be incapable of decision-making, then the healthcare staff must prevent the cognitively impaired resident from unsolicited sexual advances by a spouse, partner, or other residents.

Environmental settings may also influence sexuality among older adults. Normally, engaging in sexual intercourse occurs within the privacy of one's bedroom; however, for some older adults, extended care facilities are a substitute for what one called *home*. Residents of extended care facilities face obstacles regarding their sexuality such as lack of opportunity, lack of an available partner, poor health, feeling sexually undesirable, and guilt for having these sexual feelings (Lichtenberg, 2014; Steinke, 2017a). In a study of Polish nursing home residents (N = 85), mutual respect and being able to depend on one's partner were important relationship factors (Mroczek, Kurpas, Gronowska, Kotwas, & Karakiewicz, 2013). Those reporting sexual tension that occurred occasionally or once per week or less relieved sexual tension through sexual contact with long-term partners, masturbation, watching erotic videos, walking, and engaging in diversionary activities. Sexual intercourse was reported by 34% of respondents (Mroczek et al., 2013). Negative staff attitudes and beliefs regarding residents' sexual activity often interfere with the expression of sexuality in long-term care settings. Often,

only married couples receive the privacy needed for sexual activity (Mroczek et al., 2013). In a systematic review, findings revealed that nursing homes often do not have policies regarding residents' sexual activity, despite most nursing home staff believing that residents' sexual needs should be supported (Aguilar, 2017). Of note, actions taken were often punitive, such as calling the family or a staff meeting, and overlooking addressing environmental barriers such as lack of privacy and the discomfort of staff in supporting residents' sexuality (Aguilar, 2017).

Healthcare providers are in a unique position to assess and manage HIV among the older population. The shift in the focus of HIV/AIDS care is in managing this chronic condition and its related comorbidities. Negative attitudes and stereotypes often result in greater social isolation and lack of social support by family and friends, with the older adult often more reliant on formal care providers (Cahill & Valadéz, 2013). In addition, greater attention to sexual health education regarding HIV risk in the older population is needed among elders and healthcare providers. The use of simulation and standardized patients with nursing students to increase awareness of culturally competent care of the LGBT community resulted in increased confidence in assessment and providing care to patients regardless of sexual orientation and gender identity (Hickerson, Hawkins, & Hoyt-Brennan, 2018), illustrating a realistic, proactive approach to education in a safe environment for discussion of sensitive topics (see Chapter 32, HIV Prevention and Care for the Older Adult).

ASSESSMENT OF THE PROBLEM

A model to guide sexual assessment and intervention is available and has been well used among younger populations since the 1970s. The Permission, Limited Information, Specific Suggestion, Intensive Therapy (PLISSIT) model (Annon, 1976) begins by first seeking permission (P) to discuss sexuality with the older adult. Because many sexual disorders originate in feelings of anxiety or guilt, asking permission may put the client in control of the discussion and facilitate communication between the healthcare provider and the client. This permission may be gained by asking general questions such as "I would like to begin to discuss your sexual health; what concerns would you like to share with me about this area of function?" Questions to guide the sexual assessment of older adults are available on many healthcare assessment forms. The next step of the model affords an opportunity for the nurse to share limited information (LI) with the older adult. In the case of older adults, this part of the model affords healthcare providers the opportunity to dispel myths of aging and sexuality and to discuss the impact of normal and pathological aging changes, as well as medications on sexual health. The next part of the model guides the nurse to provide specific suggestions (SS) to improve sexual health. In so doing, nurses may implement several of the interventions recommended for improved sexual health, such as safe-sex practices, more effective management of acute and chronic diseases, removal or substitution of causative medications, environmental adaptations, or need for discussions with partners and families. The final part of the model calls for intensive therapy (IT) when needed for clients whose sexual dysfunction goes beyond the scope of nursing management. In these cases, referral to a sexual therapist is appropriate.

Sexual assessments will be most effective using open-ended questions such as "Can you tell me how you express your sexuality?" "What concerns you about your sexuality?" "How has your sexuality changed as you have aged?" "What changes have you noticed in your sexuality since you have been diagnosed or treated for disease?" "What thoughts have you had about ways in which you would like to enhance your sexual health?" The loss of relationships with significant, intimate partners is, unfortunately, common among older adults and often ends communication about the importance of self to the person experiencing the loss. This greatly impacts the older adult's sexual health. Asking the older adult about past and present relationships in his or her life will help to aid this assessment.

Barriers to sexual health should be assessed, including normal and pathological changes of aging, medications, and psychological problems such as depression. Moreover, lack of knowledge and understanding about sexuality, loss of partners, and family influence on sexual practice often present substantial barriers to sexual health among older adults. Nurses should assess for the presence of physiological changes through a health history, review of systems, and physical examination for the presence of normal and aging changes that impact sexual health. Older adults may view the normal changes of aging and their subsequent impact on appearance as embarrassing or indicative of illness. This may result in a negative body image and a reluctance to pursue sexual health. It is important for nurses to consider the impact of normal and pathological changes of aging on body image and assess their impact frequently.

As discussed earlier, there are a number of medical conditions that have been associated with poor sexual health and functioning, including depression, cardiac disease, diabetes, stroke, osteoporosis, cancer, and chronic obstructive pulmonary disease (Merghati-Khoei et al., 2016). Effective assessment of these illnesses using open-ended

health history questions, review of systems, physical examination, and appropriate lab testing will provide necessary information for appropriate disease management and improved sexual function.

Assessing the impact of medications among older adults, especially those commonly used to treat medical illnesses, such as antidepressants and antihypertensives, is essential. Potential medications should be identified by reviewing the client's medication bottles, and the client should be questioned about the potential impact of these medications on sexual health. If the medication is found to have an impact on sexual health, alternative medications should be considered. The older adult should also be questioned in regard to the use of alcohol because this substance also has a potential impact on sexual response.

INTERVENTIONS AND CARE STRATEGIES

Following a thorough assessment of normal and pathological aging changes, as well as environmental factors, a number of interventions may be implemented to promote the sexual health of older adults. These interventions fall into several broad categories, including (a) education regarding age-associated change in sexual function, (b) compensation for normal aging changes, (c) effective management of acute and chronic illness affecting sexual function, (d) removal of barriers associated with difficulty in fulfilling sexual needs, and (e) special interventions to promote sexual health in cognitively impaired older adults.

Client Education

The most important intervention to improve sexuality among the older population is education. It is important to remember that sexuality was likely not addressed in formal educational systems as the older adults developed and was rarely discussed informally. Older adults may possess dated values that impact sexual action, freedom, and desires and lead to both sexual frustration and conflict. Knowledge is essential to the successful fulfillment of sexuality for all people.

The incidence of HIV infection was 17% of those aged 50 years and older in the United States in 2016, although HIV diagnoses declined by 7% between 2011 and 2015 for those aged 50 and older, with older adults often diagnosed later in the disease process (Centers for Disease Control and Prevention [CDC], n.d.). In 2015, there were an estimated 298,200 people over age 55 with HIV, and 2,749 died from the disease. This underscores the significant risk of HIV transmission in the older age group and the need for effective teaching regarding safe-sex practices. Teaching about the use of condoms to prevent the transmission of sexually transmitted diseases is essential. Older adults are more likely to have AIDS at the time of diagnosis, resulting in later treatment and potentially greater immune system damage (CDC, n.d.). Thus, it is essential to provide older adults with safe-sex information provided by the CDC, and for healthcare professionals to proactively discuss safe-sex practices with older adults and to assess HIV status and well as that for other STIs (Spadt & Kusturiss, 2016; see Chapter 32, HIV Prevention and Care for the Older Adult).

Compensating for Normal Aging Changes

Assisting older adults to compensate for normal aging changes related to sexual dysfunction will greatly lessen the impact of these changes on sexual health. Among women, the discussion of anatomical changes in sexual anatomy will help them anticipate these changes in sexuality. For example, a water-based vaginal lubricant and information on techniques to enhance sexual arousal can be provided (Spadt & Kusturiss, 2016). Topical estrogen is often used to treat vaginal dryness and low libido (Clayton & Harsh, 2016). In men, delayed response and the increased length of time needed for erections and ejaculations are among normal changes of aging, which older adults may not be aware of. When older adults understand the impact of normal aging changes, they then understand the need to plan for more time and direct stimulation in order to become aroused.

One of the most important preventive measures that older adults may undertake to reduce the impact of normal aging changes on sexual health is to continue to engage in sexual activity (Gillespie, 2017). Among older men and women, sexual activity was associated with greater life enjoyment, with sexual activities including sexual intercourse and frequent kissing, petting, or fondling (Smith et al., 2018), and the frequency of sexual activity significantly predicted quality of life (Flynn & Gow, 2015) and sexual well-being, satisfaction, and interest (Santos-Iglesias et al., 2016). Planning for more time during sexual activities; being sensitive to changes in one another's bodies; the use of aids to increase stimulation and lubrication; the exploration of foreplay, masturbation, sensual touch, and different sexual positions, along with education about these common changes associated with sex and aging, may help immensely. By doing so, changes in sexual response patterns are less likely to occur. Eating healthy foods, getting adequate amounts of sleep, exercising, using stress-management techniques, and not smoking are also very important to sexual health.

Effective Management of Acute and Chronic Illness

Effective management of both acute and chronic illnesses that impair sexual health is also important. Interventions that improve sexual health are incorporated within the current interventions to treat disease. In other words, effective disease management using primary, secondary, and tertiary interventions will not only effectively treat the disease but also result in improved sexual health. Consequently, better glucose control among diabetics enhances circulation and may increase arousal and sexual response. Appropriate treatment of depression with medication and psychotherapy will enhance desire and sexual response. Although treatment of depression may help to improve libido and sexual dysfunctions, such as orgasmic disorders, medications to treat depression often impact sexual function by lowering libido and causing orgasmic disorders. Choosing antidepressants with less impact on sexual function, when possible, is an important consideration. For example, mirtazapine supported normal sexual function, while fluoxetine impaired sexual function (Preeti et al., 2018). Antidepressants more likely to contribute to sexual problems are those in the drug classes of SSRIs or serotonin norepinephrine reuptake inhibitors (SNRI), while bupropion, mirtazapine, nefazodone, and vilazodone are associated with less sexual dysfunction (Clayton, Croft, & Handiwala, 2014). When considering medication within any class of drug for those older adults who continue to be sexually active, choosing a drug with less sexual side effects or using the lowest dose of a medication with known sexual side effects may help support sexual function.

Phosphodiesterase-5 inhibitors (PDE5-I), such as sildenafil citrate, vardenafil, tadalafil, and avanafil, play a significant role in the treatment of erectile dysfunction that occurs with aging and are effective and well-tolerated treatments; each vary as to time of onset and duration of action (Marchese, 2017). Patients with diabetes may be less responsive to a PDE5-I because of decreased nitric oxide and low testosterone levels; men with cardiac disease should be evaluated for any cardiac risk before being prescribed PDE5-I (Marchese, 2017). As noted previously, a number of medications may adversely affect sexual function in the older adult. Thorough evaluation of prescribed and over-the-counter medications is important in providing optimal medication management with the least sexual side effects and in patient education.

Both older adults and nurses may be hesitant to discuss sexual problems, so it is important for nurses to be proactive and bring up the topic of sex. A few targeted questions are often all that is needed to determine interest in sexual activity, sexual concerns, and sexual problems experienced, either related to medications or to a particular chronic disease. For example, a nurse might ask: "What concerns do you have about resuming sexual activity?" "Are you satisfied with the frequency and nature of your sexual activities" "How important is it for you to engage in sexual activity with your partner?" "What sexual activities are most important to you?" "Are there sexual activities that you have been unable to engage in?" and/or "Have you noticed any change in sexual desire that has affected your ability to be sexually active?" Asking these and similar questions is an important step in guiding management of sexual problems (also see "Assessment of the Problem" section for other suggested questions). In addition, ask questions to evaluate infection risk, such as number of sexual partners in the past year; whether sexual activity includes men, women, or both; history of sexually transmitted infections; and preventive practices; and also evaluate any current or potential for sexual abuse, such as coercion or unwanted sexual touching (Granville & Pregler, 2018). Recognition of the continuing sexual needs of older adults among nurses is essential to ongoing dialogue about sexual problems.

Removal of Barriers to Sexual Health

One of the greatest barriers to sexual health among older adults lies with some nurses' persistent beliefs that older adults are not sexual beings, although there may be some improvement in attitudes toward sexuality in aging; a systematic review indicated that nursing home staff believed that residents' sexual needs should be supported, noting that nurses with more positive attitudes were older, had more work experience, and had formal and informal education on sexuality (Aguilar, 2017). In contrast, nursing home management encouraged staff to show an "anti-sexuality attitude" in managing residents' sexual behavior. Nurses should be encouraged to open lines of communication in order to effectively assess and manage the sexual health needs of aging individuals with the same consistency as other bodily systems and treat alterations in sexual health with available evidence-based strategies.

An essential intervention to promote sexual health in this population is to educate nurses and nursing students regarding the continuing sexual needs and desires persisting throughout the life span. Education regarding older adult sexuality as a continuing human need should be included in multidisciplinary education and staff development programs. Educational sessions may begin by discussing prevalent societal myths around older adult

sexuality, developing knowledge about sexuality in aging, identifying strategies to assess and manage sexual concerns, and including role-playing opportunities to increase self-efficacy in discussing and assessing older adults' sexuality (Sung et al., 2015). Nurses should be encouraged to discuss their own feelings about sexuality and its role in the life of older adults. Moreover, the development and implementation of policies and procedures to manage sexual issues of older adult clients is important throughout environments of care (Aguilar, 2017).

Environmental adaptations to ensure privacy and safety among long-term care and community-dwelling residents are essential. Arrangements for privacy must be made so the dignity of older adults is protected during sexual activity (Wallace, 2012). For example, nurses may assist in finding other activities for the resident's roommate so that privacy may be obtained or in securing a common room that may be used by the older adults for private visits. Call lights or telephones should be kept within reach during sexual activity, and adaptive equipment, such as positioning devices or trapezes, may need to be obtained. Interventions, such as providing rooms for privacy and offering consultations for residents regarding evaluation and treatment of their sexual problems, are a few of the many ways this may be accomplished (Steinke, 2017a).

Families are an integral part of the interdisciplinary team. However, for older couples, especially those in relationships with new partners, it is often difficult for families to understand that their older relative may have a sexual relationship with anyone other than the person they are accustomed to the individual being with. A family meeting, with a counselor if needed, is appropriate in order to help the family understand and accept the older adult's decisions about the relationship. Open communication between the resident, long-term care staff, and the family is essential (Yelland & Stanfield, 2018). The ability to give consent, the cognitive status of the resident, and the safety of sexual activity is inherent in this discussion.

Special Interventions to Promote the Sexual Health of Cognitively Impaired Older Adults

Cognitively impaired older adults continue to have sexual needs and desires but may lack the capacity to make appropriate decisions regarding sexual relationships. Accurate, regular assessment and documentation of the ability to make informed decisions regarding sexual relationships must be conducted by the interdisciplinary team (Lichtenberg, 2014; Yelland & Stanfield, 2018). If the older adult is not capable of making competent decisions, participation in sexual relationships may be considered abusive with the potential for sexual exploitation, particularly if the older adult is unable to communicate comfort level with the relationship or unable to say no to unwanted sexual advances (Lichtenberg, 2014). On the other end of the spectrum, nurses should not attempt to prevent sexual relationships and may play an important role in promoting sexual health among older adults who are cognitively competent to make decisions regarding sexual relationships. In these cases, nurses should implement all necessary interventions to promote the sexual health of older adult clients.

Inappropriate sexual behavior, such as public masturbation, disrobing, or making sexually explicit remarks to other patients or healthcare professionals, may be a warning sign of unmet sexual needs among older adults. In these situations, a full sexual assessment should be conducted using clear communication and limit setting. Following this, a plan should be developed to manage this behavior while providing the utmost respect and preserving the dignity of the client. Providing an environment in which the older adult may pursue his or her sexuality in private may be a simple solution to a difficult problem (Steinke, 2017a; Yelland & Stanfield, 2018). Allowing the resident to view pornographic material or engage in masturbation can be appropriate outlets for sexual expression (Yelland & Stanfield, 2018). For residents with cognitive dysfunction, interventions include redirecting behavior, reorientation, adapting the environment, seating the resident making sexual advances in a different area during social gatherings, pants without zippers for male residents who tend to expose or fondle themselves in public, education and explanation that such behavior is inappropriate, counseling, and using same-sex caregivers (Benbow & Beeston, 2012). Medication management might be considered, and it includes antidepressants, antipsychotics, anticholinesterases, and anticonvulsants after first evaluating the benefit versus risk (see Chapter 24, Reducing Adverse Drug Events in the Older Adult). In addition, supportive management in an institutional setting is crucial. Having established policies regarding sexual behavior for those who are cognitively intact as well as those who are cognitively impaired, an environment that facilitates open discussion, and education and support of staff are clearly important strategies (Lichtenberg, 2014; see Chapter 9, Assessing Cognitive Function in the Older Adult, and Chapter 21, Dementia: Assessment and Care Strategies).

CASE STUDY 15.1

Mrs. Jones is a highly functioning 79-year-old widow, recently admitted to a nursing home with mild cognitive impairment (MCI). She began a friendship with Mr. Carl, who is cognitively intact and wheelchair bound. Mr. Carl is married to a woman who resides outside the facility. The nursing staff has noticed more and more intimate touches among the two residents and is concerned about Mrs. Jones's competency to make the decision to participate in this increasingly intimate relationship. Moreover, general concern about the sexual relationship within a long-term care setting prevails among the nursing staff.

The first step in this situation is to conduct a full assessment to determine Mrs. Jones's capacity to participate in this intimate relationship. The right to her autonomy is complicated by the presence of MCI and must be explored further. The question remains: Does Mrs. Jones have the decisional capacity to participate in an intimate relationship?

The actual and projected outcomes of the intimate relationship would require assessment to determine what nursing actions are required regarding this relationship. If an assessment of Mrs. Jones finds that she is incapable of understanding the consequences of her relationship with Mr. Carl, then she must be protected from unsolicited sexual advances by a spouse, partner, or other residents. However, if the assessment leads nurses to believe that Mrs. Jones and Mr. Carl understand the risks and consequences of their relationship, then the right to autonomy prevails.

Discussion

If clinicians determine that the older adults have the decisional capacity to consent to a sexual relationship, then a comprehensive health history, review of systems, and physical examination to determine normal and pathological changes of aging that may play a role in this sexual relationship must be conducted. Appropriate lab work for the potential presence of sexually transmitted diseases should be included. A care plan focusing on the need to promote sexual health for this couple should be developed. Teaching regarding normal and pathological aging changes and the impact of these changes, as well as medications, on sexual function should be conducted. Normal changes of aging must be compensated for, and diseases affecting sexual response should be treated with medications that will not impact sexual health. Safety from the transmission of sexually transmitted diseases and privacy should be provided for the residents, ensuring that their dignity is respected at all times.

SUMMARY

One of the most prevalent societal myths of aging is that older adults are no longer interested in sex. It is commonly believed that older adults no longer have any interest or desire to participate in sexual relationships. Because sexuality is considered mainly a young person's activity, often associated with reproduction, society does not usually associate older adults with sex. In the youth-oriented society of today, many consider sexuality among older adults to be distasteful and prefer to assume that sexuality among the older population does not exist. However, despite popular belief, sexuality continues to be important, even in the lives of older adults.

Although the sexual health of older adults has been largely ignored in the past decades, evolving images of older adults as healthy and vibrant members of society may result in a decrease in the prevalence of myths of this population as nonsexual beings. Changes in the societal image of older adults as asexual celibate beings will greatly enhance the removal of barriers to sexual health in the older population. Improved assessment and management of normal and pathological changes of aging and appropriate environmental adaptations and management of special issues of sexuality and aging will also result in improved sexual health in the older population. Oral erectile agents also play a substantial role in enhanced sexual health among older adults.

The fulfillment of sexual needs may be just as satisfying for older adults as it is for younger people. However, several normal and pathological changes of aging complicate sexuality among older adults. Environmental changes may create further barriers to sexual expression among older adults. Despite the many barriers to achieving sexual health among an aging population, nurses are in a critical position to understand sexual needs and capabilities in later life and assist older adults in developing compensatory strategies for improving sexual health in order to have the best possible sexual life. If these strategies and interventions are undertaken, increased awareness and acceptance of older adults' sexuality will ultimately take place, and the concept of sex in old age will no longer be such a shocking topic.

NURSING STANDARD OF PRACTICE

Protocol 15.1: Sexuality in the Older Adult

I. GOAL

To enhance the sexual health of older adults

II. OVERVIEW

Although it is generally believed that sexual desires decrease with age, researchers have identified that sexual desires, thoughts, and actions continue throughout all decades of life. Human touch and healthy sex lives evoke feelings of joy, romance, affection, passion, and intimacy, whereas despondency and depression often result from an inability to express one's sexuality. Healthcare providers play an important role in assessing and managing normal and pathological aging changes in order to improve the sexual health of older adults.

III. BACKGROUND AND STATEMENT OF THE PROBLEM

A. Definitions
   1. *Sexuality* is a central aspect of being human throughout life that encompasses intimacy, emotional expression, gender identities and roles, and sexual orientation, and is influenced by biological, psychological, cognitive, and other factors (WHO, 2017).
   2. *Sexual health* is a state of physical, emotional, mental, and social well-being related to sexuality, with a positive, responsible approach to sexuality and sexual relationships (WHO, 2017).
   3. *Sexual dysfunction* is an impairment in normal sexual functioning (Steinke, 2017b).

B. Etiology and/or epidemiology
   1. Many older adults continue to be sexually active, resulting in greater life enjoyment, quality of life, and sexual well-being (Flynn & Gow, 2015; Santos-Iglesias et al., 2016; Smith et al., 2018).
   2. Despite the continuing sexual needs of older adults, many barriers prevent sexual health among older adults.
   3. Healthcare providers often lack knowledge and comfort in discussing sexual issues with older adults (Bauer et al., 2016; Hughes & Wittmann, 2015; Maes & Louis, 2011).
   4. Older adults may be LGBT; alternative sexual preferences must be respected, and protective strategies discussed (Lim et al., 2014; See Chapter 33, LGBTQ Perspectives for Older Adult Care).
   5. The older population is more susceptible to many disabling medical conditions. A number of chronic conditions are associated with poor sexual health and functioning, including depression, cardiac disease, stroke and aphasia, chronic respiratory disease, cancer, and diabetes, that make sexuality difficult.
   6. Medications used among older adults, especially those commonly used to treat medical illnesses, also impact sexuality such as cardiac medications and antidepressants (Nicolai et al., 2014; Reichenpfader et al., 2014; Trenque et al., 2013).
   7. Normal aging changes, such as a higher frequency of vaginal dryness in women and erectile dysfunction in men, make sexual health difficult to achieve (Hsu et al., 2017; Levin, 2015; Spadt & Kusturiss, 2016; Syme, 2014; Yeap et al., 2012).
   8. Environmental barriers also present barriers to sexual health among older adults (Aguilar, 2017; Lichtenberg, 2014; Mroczek et al., 2013).

IV. ASSESSMENT

A. The PLISSIT model (Annon, 1976) begins by first seeking permission (P) to discuss sexuality with the older adult. The next step of the model affords an opportunity for the nurse to share limited information (LI) with the older adult. Specific suggestions (SS) and interventions to improve health are then provided. Referral to intensive therapy (IT) may be needed for those with more complex sexual problems.

(*continued*)

Protocol 15.1: Sexuality in the Older Adult (*continued*)

B. Ask open-ended questions such as "Can you tell me how you express your sexuality?" or "What concerns you about your sexuality?" and "How has your sexuality changed as you have aged?"
C. Assess for presence of physiological changes through a health history, review of systems, and physical examination for the presence of normal and aging changes that impact sexual health.
D. Review medications among older adults, especially those commonly used to treat medical illnesses that also impact sexuality such as antidepressants and antihypertensives.
E. Assess medical conditions that have been associated with poor sexual health and functioning, including depression, cardiac disease, stroke, chronic respiratory disease, cancer, and diabetes.

V. NURSING CARE STRATEGIES

A. Communication and education
   1. Discuss normal age-related physiological changes.
   2. Address how the effects of medications and medical conditions may affect one's sexual function.
   3. Facilitate communication with older adults and their families regarding sexual health as desired, including the following:
      a. Encourage family meetings with open discussion of issues if desired.
      b. Teach about safe-sex practices.
      c. Discuss use of condoms to prevent transmission of STIs and HIV (CDC, n.d.; Spadt & Kusturiss, 2016; see Chapter 32, HIV Prevention and Care for the Older Adult).
B. Health management
   1. Perform a thorough patient assessment.
   2. Conduct a health history, review of systems, and physical examination.
   3. Effectively manage chronic illness.
   4. Improve glucose monitoring and control among diabetics.
   5. Ensure appropriate treatment of depression and screening for depression (see Chapter 19, Late-Life Depression).
   6. Discontinue and substitute medications that may result in sexual dysfunction, or try lower doses or a different drug class (e.g., ARB instead of ACEI; antidepressants such as mirtazapine or bupropion).
   7. Accurately assess and document older adults' ability to make informed decisions (see Chapter 7, Healthcare Decision-Making).
   8. Participation in sexual relationships may be considered abusive if the older adult is not capable of making decisions or sexual activity is not consensual (Lichtenberg, 2014).
C. Sexual enhancement
   1. Compensate for normal changes of aging, including engaging in regular sexual activity, being sensitive to changes in one another's bodies, and the use of aids to increase stimulation and lubrication (Gillespie, 2017; Smith et al., 2018).
      a. Females
         i. Use of artificial water-based lubricants (Spadt & Kusturiss, 2016)
         ii. Use of topical estrogen (Clayton & Harsh, 2016)
      b. Males
         i. Recognizing the possibility for more time and direct stimulation for arousal caused by aging changes; use of oral erectile agents for erectile dysfunction (Marchese, 2017)
   2. Environmental adaptations
      a. Ensure privacy and safety among long-term care and community-dwelling residents (Steinke, 2017a; Wallace, 2012; Yelland & Stanfield, 2018).

(*continued*)

Protocol 15.1: Sexuality in the Older Adult (*continued*)

VI. EXPECTED OUTCOMES

A. Patients will:
   1. Report high quality of life as measured by a standardized quality-of-life assessment.
   2. Be provided with privacy, dignity, and respect surrounding their sexuality.
   3. Receive communication and education regarding sexual health as desired.
   4. Be able to pursue sexual health free of pathological and problematic sexual behaviors.

B. Nurses will:
   1. Include sexual health questions in their routine history and physical.
   2. Frequently reassess patients for changes in sexual health.

C. Institutions will:
   1. Include sexual health questions on intake and reassessment measures.
   2. Provide education on the ongoing sexual needs of older adults and appropriate interventions to manage these needs with dignity and respect.
   3. Provide a supportive environment that facilitates sexual discussions among staff and clients.
   4. Provide needed privacy for individuals to maintain intimacy and sexual health (e.g., in long-term care).

VII. FOLLOW-UP MONITORING OF CONDITION

Sexual outcomes are difficult to directly assess and measure. However, with the demonstrated link between sexual health and quality of life, quality-of-life measures, such as the Medical Outcomes Study SF-36 Health Survey (RAND Health Care, n.d.), may be used to determine the effectiveness of interventions to promote sexual health. Elder Mistreatment Detection*

Billy A. Caceres, Neelima Kurup, and Terry Fulmer

16

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Educate nurses and other healthcare professionals about elder mistreatment (EM).
2. Identify risk factors that make older adults vulnerable to mistreatment.
3. Discuss the deleterious effects EM may have on older adults' overall health status.
4. Provide a framework for identifying, reporting, and managing cases of EM.

OVERVIEW

Elder mistreatment (EM) is the debilitating and potentially fatal outcome of actions including neglect, abuse, exploitation, and abandonment of older adults. The World Health Organization (WHO) has defined elder mistreatment (EM) as "a single, or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person" (n.d.). In 2014, the U.S. Department of Justice consulted 750 stakeholders to enhance public and private response to EM (Connolly, Brandl, & Breckman, 2014). Through that work, experts are increasingly recognizing the human, social, and economic impact of EM. The prevalence of EM will grow with the aging of the population, and society needs to be aware of and ready to prevent EM. By 2030, the population of Americans aged 65 and over is projected at 73 million, comprising 21% of the U.S. population. In the year 2030, all baby boomers will be older than 65, and by 2035, older adults are projected to outnumber children for the first time in history (Vespa, Medina, & Armstrong, 2018). This has serious implications for older persons, who need care and support for their well-being. This dramatic increase in the older adult population will be reflected in rates of EM. Technological advances of the past century have increased the life span, and with that, the number of chronic diseases an older person is likely to have, therefore requiring greater caregiving needs in their activities of daily living (ADL) and management of care (Centers for Disease Control and Prevention, 2018).

The impact of EM takes a physical, emotional, and fiscal toll on the victims. The National Center on Elder Abuse (NCEA) estimates the direct medical costs associated with violent injuries to older adults at over $5 billion. The annual financial loss by victims of elder financial exploitation has been estimated at nearly $3 billion in 2009, a 12% increase from 2008 (Roberto & Teaster, 2011). EM

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

researchers agree that as the population continues to age, cases of EM will reach epidemic levels (National Research Council, 2003). Most nurses have likely provided care for an older adult suffering from EM without knowing it. Therefore, it is imperative for nurses to become better educated about EM and its complexities.

Nurses in the inpatient setting play an important role in recognizing EM. By virtue of the size of the nursing workforce, which is the largest of any of the health professions, nurses are in a unique and optimal position to assess, identify, and intervene in cases of EM. Educating nurses to recognize signs and symptoms of EM can help prepare them to identify and provide appropriate resources and support for these patients (Bryant & Benson, 2015). The identification of EM should be a regular part of any geriatric assessment, and nursing curricula should include the requisite content to ensure that all graduates have adequate knowledge and skills to assess and detect mistreatment. Many have suggested that mandatory EM training be a prerequisite for relicensure. EM is often multifactorial, so it is important to recognize it as the interplay among characteristics of the abused, the perpetrator, and environmental factors (Killick & Taylor, 2009). Nurses may have difficulty in correctly assessing EM owing to the overlay of symptoms from chronic illness that can create both false negative and false positive findings in older adults (Lachs & Pillemer, 2015). Further, cases of EM may be challenging for nurses because they may be complicated by denial on the part of the perpetrator and the older adult, refusal of services by the victim, and fears that an accusation of EM may actually worsen the situation. Significant ethical dilemmas may arise because nurses may struggle between their obligation to ensure the older person's well-being and their uncertainty in diagnosing EM (Daly, Schmeidel Klein, & Jogerst, 2012). The development and use of EM protocols that are grounded in evidence-based research is crucial to ensure that EM cases are properly handled by nurses and other healthcare professionals.

BACKGROUND AND STATEMENT OF PROBLEM

A 2017 systematic review estimated that 15.7% of older adults are subjected to some form of EM. The authors note that research to date has been conducted primarily in higher income countries and suggest the need for evidence from low- and middle-income countries (Yon, Mikton, Gassoumis, & Wilber, 2017). The National Elder Abuse Incidence Study, conducted over 20 years ago, is still referenced and estimates that there are more than 500,000 new cases of EM annually (Tatara et al., 1998). Another national study in the United States estimated the prevalence of EM within a 1-year period to be approximately 11% (Acierno et al., 2010). Currently, 44 states and the District of Columbia have legally required mandated reporting, and nurses, as mandatory reporters, have an obligation to report suspected cases of EM to appropriate state agencies; all reports made in good faith are confidential.

In the United States, there is substantial variability related to how cases of EM are reported and managed. There can be varying methods of investigation and intervention, state by state (Jogerst et al., 2003). In a systematic review, one third of healthcare professionals believe they detected a case of EM; however, only about 50% of that group actually reported the case (Cooper, Selwood, & Livingston, 2009). Similarly, another study found that despite 68% of emergency medical services staff indicating they felt they had encountered a case of EM in the past year, only 27% actually made a report (Jones, Walker, & Krohmer, 1995). Healthcare professionals believe that they will not face penalties for noncompliance in reporting, and those that observe their peers not participating in reporting EM are less likely to report themselves (DeLiema, Navarro, Enguidanos, & Wilber, 2015). This, coupled with a lack of awareness of EM among older adults (Naughton, Drennan, & Lafferty, 2014), creates barriers to determining the scope of EM and may have serious detrimental effects for victims of EM. The implementation of an interdisciplinary approach, leveraging the unique perspectives of first responders, triage providers, nurses, physicians, social workers, and case managers, can be a solution to the challenges of identifying and reporting EM (Rosen, Hargarten, Flomenbaum, & Platts-Mills, 2016). Patients visiting the emergency department give providers another important opportunity to identify EM (Rosen et al., 2016). Paramedics or first responders are also important allies in the detection of EM. They have a unique opportunity to observe the older person's home and determine if there are reasons to suspect EM.

Types of EM

Six types of mistreatment are generally included under the umbrella term of EM. Table 16.1 describes each form of EM and offers examples of each.

EM is the outcome of the actions of abuse, neglect, exploitation, or abandonment, and can be further classified as intentional or unintentional. For example, intentional neglect is a conscious disregard for caretaking duties that are inherent for the well-being of an older adult. Unintentional neglect might occur when caregivers lack the knowledge and resources to provide quality care; for example, a caregiver unfamiliar with an older adult's medication

TABLE 16.1

Forms of Elder Mistreatment

Type of EM	Definition	Examples
Physical abuse	The use of physical force that may result in bodily injury, physical pain, or impairment	Hitting, beating, pushing, shoving, shaking, slapping, kicking, burning, inappropriate use of drugs, and physical restraints
Sexual abuse	Any form of sexual activity or contact without consent, including with those unable to provide consent	Unwanted touching, rape, sodomy, coerced nudity, and sexually explicit photographing
Emotional/ psychological abuse	The infliction of anguish, pain, or distress through verbal or nonverbal acts	Verbal assaults, insults, threats, intimidation, humiliation, harassment, and enforced social isolation
Financial abuse/ exploitation	The illegal or improper use of an elder's funds, property, or assets	Cashing a person's checks without authorization or permission; forging a signature; misusing or stealing money or possessions; coercing or deceiving a person into signing any document; and the improper use of conservatorship, guardianship, or power of attorney
Caregiver neglect	The refusal or failure to fulfill any part of a person's obligations or duties to an older adult, including social stimulation	Refusal or failure to provide life's necessities such as food, water, clothing, shelter, personal hygiene, medicine, comfort, and personal safety
Self-neglect	The behavior of an elderly person that threatens his or her own health or safety; disregard of one's personal well-being and home environment	Refusal or failure to provide oneself with adequate food, water, clothing, shelter, personal hygiene, medication (when indicated), and safety precautions

EM, elder mistreatment.

may be unaware of its importance (Rosen, Stern, Elman, & Mulcare, 2018).

Neglect, whether intentional or unintentional, is recognized as the most common form of EM. It is common to see that older adults with greater functional impairments endure more severe neglect as they have a greater number of care needs (Burnes, Pillemer, & Lachs, 2016). The NAMRS Report (Aurelien et al., 2018) indicates that the highest type of EM reported was attributed to self-neglect, followed by neglect, at approximately 60% and 16%, respectively.

It is being debated to whether self-neglect should be included as a type of EM. Some associate self-neglect as a form of self-determination and consider any attempt to coerce older adults into unwanted actions as another form of abuse. Having made this point, self-neglect has been associated with several disturbing outcomes on the older person's physical and psychological well-being as well as higher mortality rates and increased utilization of healthcare services (Dong, 2017). In cases of neglect by a caregiver, older adults identified family members as the most likely perpetrators. Shockingly, neglect was seen as a "quasi-acceptable" form of abuse, whereas physical and emotional/psychological EM was viewed as extreme and harsh. Much more research is needed on neglect by caregivers.

Theories of EM

Theories for why EM occurs inform the assessment and detection of EM. The concepts of risk and vulnerability are extremely relevant to EM. A study conducted with patients recruited through emergency departments in two major cities used a risk-and-vulnerability framework (Fulmer et al., 2005). The purpose of this study was to identify factors within the older adult–caregiver relationship that may put them at risk for neglect. The theoretical framework used in this study was the risk-and-vulnerability model, which posits that neglect is caused by the interaction of factors both external and internal to the older person. The risk and vulnerability model was adapted to EM by Frost and Willette (1994) and provides an appropriate lens through which to examine EM (Frost & Willette, 1994; Fulmer et al., 2005). *Vulnerability* is determined by characteristics within the older adult such as poor health status, impaired cognition, and history of EM that may make him or her

more likely to be a victim of EM (Frost & Willette, 1994). *Risks* refer to factors in the environment that may predispose an older adult to EM and may include characteristics of caregivers such as health and functional status, as well as a lack of resources and social isolation (Fulmer et al., 2005). It is the interaction between risk and vulnerability that can predispose some older adults to EM (Killick & Taylor, 2009). The risk and vulnerability model and other models have been adapted from the health and social sciences literature in an effort to generate plausible theories of EM. However, there has been no clear consensus on one theory that explains EM (Fulmer, Guadagno, Bitondo Dyer, & Connolly, 2004). Other examples of theories include the following:

1. *Situational theory*: This theory was first used to explain causes of child abuse. The situational theory promotes the idea that stressful family conditions contribute to mistreatment. Thus, EM may be viewed as a consequence of caregiver strain resulting from the overwhelming tasks of caring for a vulnerable or frail older adult (Straus, 1971).
2. *Psychopathology of the abuser*: This posits that mistreatment stems from a perpetrator's own battle with psychological illness such as substance use, depression, and other mental disorders (Gelles & Straus, 1979).
3. *Social exchange theory*: This theory speculates that the long-established dependencies present in the victim–perpetrator relationship are responses developed within the family that then continue into adulthood (Gelles, 1983).
4. *Social learning theory*: Developed by Bandura (1978), this theory attributes mistreatment to learned behavior on the part of the perpetrator or victim from either his or her family life or the environment.
5. *Political economy theory*: This theory focuses on how older adults are often disenfranchised in society as their prior responsibilities and even their self-care are shifted onto others (Walker, 1981).

The development of interventions and strategies that cross multiple theoretical frameworks is likely to be the most clinically appropriate strategy (National Research Council, 2003).

Dementia and EM

Older adults with dementia are particularly vulnerable to EM. Chances of developing dementia increase exponentially with age, doubling approximately every 5 years past the age of 65 (Fang & Yan, 2018). The World Alzheimer Report (Prince et al., 2015) documents that the number of older adults with dementia will double to 74.7 million by 2030 and triple to 131.5 million by 2050 across all nations. Because of the cognitive deficits associated with dementia, it is difficult to screen for EM in this population. The older adult with dementia may not be able to provide a reliable history, and signs of EM may be masked or mimicked by disease (Fulmer et al., 2005). Those providing care for older adults with dementia are at particular risk for caregiver strain and burnout. High levels of caregiver burnout may be reflected by high levels of emotional exhaustion, depersonalization, and a sense of lack of personal achievement, leading to poor outcomes (Yan, 2014).

Caregiving for a person with dementia poses several challenges: increased need for supervision and personal care, managing behavioral disturbances, personality changes, and the loss of ability to communicate with loved ones effectively (Jennings et al., 2015). A study was conducted to characterize the unmet needs of caregivers managing patients with dementia-related problems. It was reported that 32% of caregivers were confident in their ability to manage dementia-related problems, 19% were aware of community services that help provide care, only 28% reported support from the provider, while 38% reported a high level of caregiver strain, and 15% presented with moderate to severe depressive symptoms (Jennings et al., 2015). The provision of effective education, helpful tools, and supporting resources to caregivers leads to lower caregiver strain and a higher quality of patient care.

Objective assessment alone cannot capture all cases of EM as many go unreported, and, thus, policies are needed that combine objective measures and interviews with both the older adult and the caregiver together and separately (Cooper, Selwood, & Livingston, 2008). Some caregivers may be forthcoming with admission of EM, and many may ask for help in developing coping strategies and plans of care to provide better care for care recipients (Wiglesworth et al., 2010).

EM in Racial/Ethnic Minorities

Research suggests that racial/ethnic differences might exist in the prevalence of EM; however, these differences are poorly understood (Laumann, Leitsch, & Waite, 2008). The U.S. Census Bureau estimates that, by 2050, racial/ethnic minorities will account for nearly 42% of all older adults (U.S. Census Bureau, 2018). Racial and ethnic minorities face persistent health disparities and inequitable healthcare primarily because of social and economic constraints, language barriers, and differing cultural norms (U.S. Department of Health and Human Services, n.d.). Studies have found especially high rates of EM in Latino

older adults (DeLiema, Gassoumis, Homeier, & Wilber, 2012). Risk factors for EM identified in one sample of Latino older adults included younger age, higher education level, and prior history of abuse, whereas years living in the United States were associated with a higher risk of caregiver neglect (DeLiema et al., 2012). Latino older adults also have a higher likelihood of emotional abuse compared to Caucasians (Burnes et al., 2016). Several studies indicate that EM may be higher in African Americans (Beach, Schulz, Castle, & Rosen, 2010; Dong, Simon, & Evans, 2013). EM seems to be a problem among Asian older adults as well. The most common forms of EM experienced by Chinese and Korean older adults were caregiver neglect and emotional/psychological EM (Dong, Chang, Wong, Wong, & Simon, 2011; Lee, Kaplan, & Perez-Stable, 2014). There are further evidences that suggest that Chinese older adults have limited knowledge of community resources for EM (Dong et al., 2011).

Some racial/ethnic groups are reluctant to share EM experiences with outsiders because it is not the norm to involve strangers in family affairs. Also, immigrant families that are undocumented are unwilling to report, fearing authorities that could compromise their family's welfare (DeLiema et al., 2015). There is a need for more research on the prevalence of EM and on culturally appropriate strategies for addressing EM among racial/ethnic minority older adults.

ASSESSMENT OF THE PROBLEM

Nearly 30 years ago, the American Medical Association (AMA, 1992) released a set of guidelines and recommendations on the assessment and management of EM. The guidelines have been updated but they are not systematically used to detect and care for EM victims. Even then, the AMA urged providers to screen all older adults for EM (AMA, 1992). Today, many, but not all, hospitals include EM screening as part of the admission process for all patients older than 65 years. Assessment of EM presents providers with several challenges: Victims may conceal or be unable to clearly articulate the events, chronic illness in older people creates both false negative and positive findings during evaluation, cultural and language barriers exist, and some cases may take long periods of time for conclusive determination of EM (Lachs & Pillemer, 2015). Reportings of EM remain low because healthcare professionals lack training, education, experience, and adequate guidelines for accurate assessment and management of EM (Hoover & Polson, 2014). Concern exists that increasing education on assessment of EM will lead to higher rates of false positive cases and, therefore, cause undue disruption in the system. However, one systematic review of 32 studies revealed healthcare professionals were more inclined to report detected cases of EM than those who had little or no education (Cooper et al., 2008).

The complexity and variation within most cases of EM make it difficult to describe the profile of a perpetrator or victim. The literature consistently shows that victims of EM may be less likely to meet their own care needs because of cognitive and physical deficits (Cannell, Manini, Spence-Almaguer, Maldonado-Molina, & Andresen, 2014; Dong, Simon, & Evans, 2012; Dong et al., 2013). This may help explain the higher mortality rates in cases of EM (Schofield, Powers, & Loxton, 2013). A link between childhood abuse or abuse in young adulthood has been associated with physical and sexual EM later in life. Individuals who were sexually abused before the age of 60 were 294% more likely to be victims of physical and sexual abuse in late life (Brozowski & Hall, 2010). Recent findings suggest that victims of EM report poor overall health (Cannell et al., 2014; Cisler, Amstadter, Begle, Hernandez, & Acierno, 2010).

Older adults may not self-report EM for several reasons, including embarrassment (Kosberg, 2014), worry that they might incur further harm by the perpetrator (Pickering & Rempusheski, 2014), fear of being placed in a nursing home (Jackson & Hafemeister, 2014), and not believing that they would receive help after exposing the abuse (DeLiema et al., 2015). Community members' reluctance to recognize and report EM, particularly when they perceive the options for intervention to be lacking, also contributes to the underreporting of EM (Roberto, Teaster, McPherson, Mancini, & Savla, 2015). Overall, perpetrators are more likely to be family members, male, living with the victim, have mental or physical health issues, have a history of substance abuse, socially isolated, unemployed or having financial problems, and under major stress (Lachs & Pillemer, 2015).

While assessing for EM, older adults should be seen separately from their caregivers in order to avoid fear of speaking out and disclosing caregiver abuse (Hoover & Polson, 2014). Special attention should be paid to both physical and psychological signs of EM. Discrepancies between severity of signs and symptoms and the description of how they occurred should be carefully noted. Researchers have documented that physically abused older adults are more likely to have significantly larger bruises and falsely identify the cause of their injuries. The characteristics of bruising in victims of EM have been studied, and bruises that occur as a result of physical elder mistreatment were found to be larger and on the face, lateral right arm, or posterior torso (including back, chest, lumbar, and

gluteal regions) (Wiglesworth et al., 2009). Other possible indicators of physical abuse include unexplained fractures, bruises, cuts, welts, and burns that require further exploration (Mosqueda & Olsen, 2015).

Signs and symptoms of EM may vary depending on the type of abuse. Table 16.2 provides strategies for assessment of each type of EM. Victims of sexual abuse are more likely female, and healthcare providers must observe for bruising on the breasts and/or genitalia, vaginal or anal bleeding, and torn or stained underclothing (Carney, 2015). Ageist attitudes among healthcare professionals may limit the cases of sexual abuse that are identified because older adults are rarely thought of as the usual victims of sexual abuse (Vierthaler, 2008). One estimate of sexual

TABLE 16.2

Assessment of Elder Mistreatment

Type of Mistreatment	Questions Used to Assess Type of EM	Physical Assessment and Signs and Symptoms
Physical abuse	Has anyone ever tried to hurt you in any way?Have you had any recent injuries? Are you afraid of anyone? Has anyone ever touched you or tried to touch you without permission? Have you ever been tied down? In case of suspected evidence of physical abuse (i.e., black eye), ask: ■ How did that get there? ■ When did it occur? ■ Did someone do this to you? ■ Are there other areas on your body like this? ■ Has this ever occurred before?	Assess for: Bruises (more commonly bilaterally to suggest grabbing), black eyes, welts, lacerations, rope marks, fractures, untreated injuries, bleeding, broken eyeglasses, use of physical restraints, sudden change in behavior Note whether a caregiver refuses an assessment of the older adult alone. Review any laboratory tests. Note any low- or high-serum prescribed drug levels. Note any reports of being physically mistreated in any way.
Emotional/ psychological abuse	Are you afraid of anyone? Has anyone ever yelled at you or threatened you? Has anyone been insulting you and using degrading language? Do you live in a household where there is stress and/or frustration? Does anyone care for you or provide regular assistance to you? Are you cared for by anyone who abuses drugs or alcohol? Are you cared for by anyone who was abused as a child?	Assess cognition, mood, affect, and behavior. Assess for: Agitation, unusual behavior, level of responsiveness, and willingness to communicate. Delirium Dementia Depression Note any reports of being verbally or emotionally mistreated.
Sexual abuse	Are you afraid of anyone? Has anyone ever touched you or tried to touch you without permission? Have you ever been tied down? Has anyone ever made you do things you did not want to do? Do you live in a household where there is stress and/or frustration? Does anyone care for you or provide regular assistance to you? Are you cared for by anyone who abuses drugs or alcohol? Are you cared for by anyone who was abused as a child?	Assess for: Bruises around breasts or genital area; sexually transmitted diseases; vaginal and/or anal bleeding or discharge; torn, stained, or bloody clothing/undergarments Note any reports of being sexually assaulted or raped.

(*continued*)

TABLE 16.2

Assessment of Elder Mistreatment (*continued*)

Type of Mistreatment	Questions Used to Assess Type of EM	Physical Assessment and Signs and Symptoms
Financial abuse/ exploitation	Who pays your bills? Do you ever go to the bank with him or her? Does this person have access to your account(s)? Does this person have power of attorney? Have you ever signed documents you did not understand? Are any of your family members exhibiting a great interest in your assets? Has anyone ever taken anything that was yours without asking? Has anyone ever talked with you before about this?	Assess for: Changes in money handling or banking practice, unexplained withdrawals or transfers from patient's bank accounts, unauthorized withdrawals using the patient's bank card, addition of names on bank accounts/cards, sudden changes to any financial document/will, unpaid bills, forging of the patient's signature, appearance of previously uninvolved family members Note any reports of financial exploitation.
Caregiver neglect	Are you alone a lot? Has anyone ever failed you when you needed help? Has anyone ever made you do things you did not want to do? Do you live in a household where there is stress and/or frustration? Does anyone care for you or provide regular assistance to you? Are you cared for by anyone who abuses drugs or alcohol? Are you cared for by anyone who was abused as a child?	Assess for: Dehydration, malnutrition, untreated pressure ulcers, poor hygiene, inappropriate or inadequate clothing, unaddressed health problems, nonadherence to medication regimen, unsafe and/or unclean living conditions, animal/insect infestation, presence of lice and/or fecal/urine smell, and soiled bedding Note any reports of feeling mistreated.
Self-neglect	How often do you bathe? Have you ever refused to take prescribed medications? Have you ever failed to provide yourself with adequate food, water, or clothing?	Assess for: Dehydration, malnutrition, poor personal hygiene, unsafe living conditions, animal/insect infestation, fecal/urine smell, inappropriate clothing, nonadherence to medication regimen

EM, elder mistreatment.

Source: Fulmer, T., & Greenberg, S. (n.d.). *Elder mistreatment & abuse*. Retrieved from https://consultgeri.org/geriatric-topics/elder-mistreatment-and-abuse

abuse in older adults notes a .9% prevalence (Cannell et al., 2014).

The aforementioned categories of EM present with physical manifestation, while victims of neglect and financial abuse have subtle manifestation such as failure to keep appointments or fill prescriptions, weight loss, and frequent visits to the emergency department for diseases that should be controlled that make detection hard but are relevant to clinicians (Lachs & Pillemer, 2015).

Since the 1970s, a number of screening instruments have been developed to detect EM. Some are more suitable for the inpatient setting where disrobing for physical assessment would be expected. Screens used in the outpatient setting or home are necessarily different. The Elder Assessment Instrument (EAI) developed by Fulmer et al. (2004) is a 41-item screening instrument that requires training on administration but has been shown to be effective in busy inpatient settings (Perel-Levin & World Health Organization, 2008). The most recent version of the EAI-R is considered more appropriate for inpatient and outpatient clinics because it relies on both objective and subjective assessment by the clinician. This assessment includes a survey of general appearance, assessment for dehydration, physical and psychological markers, or pressure ulcers in addition to subjective information reported by the older adult.

The Hwalek–Sengstock Elder Abuse Screening Test (HS-EAST) is a 15-item instrument that relies on self-report from older adults and is documented as appropriate for detecting physical abuse, vulnerability, and high-risk situations. Some instruments focus on the caregiver, but an advantage of HS-EAST is the focus on the older adult's history. It is regarded as appropriate for use in the hospital

setting and can be easily administered by nurses (Fulmer et al., 2004; Perel-Levin & World Health Organization, 2008). If a positive screen is noted, a detailed physical assessment and medical history should be completed to substantiate possible EM. Referral to experts in trauma or geriatrics should take place for the most comprehensive assessment.

In addition to these screening instruments for EM, there are other reliable and valid instruments that can aid nurses in identifying older adults at risk for EM. Physical and cognitive impairments contribute to vulnerability of abuse among older adults (Roberto, 2016). The Katz Index of Independence in ADL and/or the Lawton Instrumental Activities of Daily Living (IADL) scale may help in identifying older adults with functional deficits (Dong et al., 2012). Similarly, with higher rates of depression in victims of EM, the Geriatric Depression Scale (GDS) may be a useful instrument for nurses to use in the inpatient setting (Greenberg, 2019). The GDS is an easy-to-administer 15-item screening instrument that is effective at distinguishing depressed older adults (Greenberg, 2019). Perpetrators of EM often report higher levels of caregiver strain. The Modified Caregiver Strain Index (MCSI) is a reliable and self-administered instrument that can assist in assessing caregivers that may benefit from interventions to alleviate stress involved with caregiving demands (Onega, 2013).

The process of identifying cases of self-neglect is oftentimes more challenging than other types of EM. Assessing self-neglect is complicated but can be improved with proper identification and intervention, especially in emergency departments as victims get evaluated by multiple providers (Rosen et al., 2018). Most instruments require in-depth assessments of home life and rely on objective findings. Nevertheless, data suggest that detection of self-neglect in the inpatient setting is, unfortunately, made easier because by the time these cases reach the hospital, they are often very severe (Mosqueda et al., 2008). Utilization of Emergency Medical Services (EMS) helps with the identification of neglect. EMS providers are typically first in the patient's home and may have critical information about the home environment and interpersonal dynamics between the patient and his or her caregiver, can observe for hazards like hoarding, inappropriate temperature setting, vermin fenestration, or utilities that are not working. They can also check the refrigerator for food, identify expired or unmarked medication, and detect evidence of drug or alcohol abuse. This is possible because 911 calls are unplanned and give perpetrators little time to clean up (Rosen et al., 2018). Some signs of self-neglect may include evidence of poor nutrition; dehydration; changes in weight; poor hygiene and appearance such as soiled clothing, uncombed hair, debris in teeth; poor adherence to medical treatments such as unfilled prescriptions; refusing to perform dressing changes; poor glucose monitoring; and so forth (Cohen, Halevi-Levin, Gagin, & Friedman, 2006; Naik, Teal, Pavlik, Dyer, & McCullough, 2008; Turner, Hochschild, Burnett, Zulfiqar, & Dyer, 2012). Objective measures as well as questioning of the older adult about health patterns and activities of self-care are also important factors in detecting self-neglect because they can provide important information about the older adult's attitudes and opinions.

INTERVENTIONS AND CARE STRATEGIES

Victims of EM often interact with health systems, and it is therefore vital to have appropriate screening processes and care plans in place (Dong, 2015). Nurses should work with a multidisciplinary team (MDT) to generate appropriate interventions on a case-by-case basis (Pickens & Dyer, 2016). Institutions should develop clear guidelines for practitioners to follow when cases of EM are identified (De Donder et al., 2011; Sandmoe & Kirkevold, 2011). Referral to appropriate community organizations is vital to ensure safe discharges for suspected victims of EM. MDTs work most effectively when they have a clear sense of their respective responsibilities and contributions to the work. Various providers from differing disciplines can provide innovative insights to managing cases of EM.

Education of the public is essential to ensure communities have an awareness and sense of resources if they see or fear EM. Adult protective service (APS) workers are especially skilled at helping those who lack the cognitive capacity to consent to interventions, and in developing a plan for safe discharge and care. Emergency contact information should be provided to all older persons at risk for EM along with community resources. Services should be offered not only to victims of EM but also to their suspected perpetrators. MDTs provide individualized care plans, caregiver counseling and education, formal links to community support organizations, and guidance on advance planning (Jennings et al., 2015). Helping caregivers gain a better understanding of proper care techniques may help alleviate cases of EM.

In order to address gaps in identification and response to EM, The John A. Hartford Foundation, in partnership with The Gordon and Betty Moore Foundation, funded a planning grant in 2016 to establish a National Collaboratory to Address Elder Mistreatment. This group, comprised of national experts in EM from the University of Southern California School of Medicine, the Massachusetts Executive Office of Elder Affairs, the University of Texas, and Weill-Cornell College of Medicine, along with Education Development Center, serving as the

collaboratory convener, designed and prototyped an integrated Elder Mistreatment Care Model focused on the emergency department.

A prototype model was developed consisting of four core elements:

1. Emergency Department Assessment Profile
2. Staff training modules
3. Brief screening and response tools
4. Road map for leveraging community resources to support referral and follow-up

Each core element was designed with significant input and feedback from national experts and clinical sites with a clear focus on feasibility of implementation in settings with fewer resources.

In 2018, The John A. Hartford Foundation approved Phase II, which aims to:

1. Prepare materials and finalize sites for care model implementation
2. Test the feasibility of the model at six sites, including rural and low-resource hospital emergency departments
3. Position the model for a next phase focused on national dissemination

In order to address the significant unmet needs of older adults experiencing EM, this proposal builds on a successful planning grant and increasing national interest. The program aims to implement, and viably test, the prototype EM model focused on the emergency department and prepare for national dissemination.

Because hospital stays are usually brief, long-term interventions occur mostly in community settings. A systematic review revealed that community-based interventions tend to concentrate on the situational theory of EM by focusing on education, counseling, and social support for perpetrators of EM to help them cope with the stress of caregiving (Ploeg, Fear, Hutchison, MacMillan, & Bolan, 2009). However, even these community-based interventions have shown mixed results in terms of effectiveness in addressing the risk of EM recurrence; depression and self-esteem in older adults; and levels of caregiver strain, stress, and depression in caregivers (Ploeg et al., 2009). In a study of EM referral cases, only 84% of older adults with suspected EM were offered services (Clancy, McDaid, O'neill, & O'brien, 2011). The most common services offered were additional monitoring, home support, and counseling. Older adults were generally willing to accept additional services, with 75% of those suspected of being victims of EM agreeing to further intervention (Clancy et al., 2011). This suggests that older adults may be open to additional support in cases of suspected EM. However, older adults might continue to experience EM even after the close of an APS investigation (Jackson & Hafemeister, 2013). This may be because of continued contact with the perpetrator or because the perpetrator received no legal consequences following investigation. Similarly, a social worker–lawyer intervention for EM victims found that EM was more likely to continue in the case of female victims, married victims, and those who lived with the perpetrator (Rizzo, Burnes, & Chalfy, 2015). Repeat cases of EM can be limited by placing the victims in a safe harbor or a shelter to avoid proximity with their perpetrators when they are willing. In 2012, The Weinberg Center launched the SPRiNG (Shelter Partners: Regional. National. Global.) Alliance to create shelters that are flexible and adaptable to existing community-based resources, particularly assisted living facilities and skilled nursing facilities (The Weinberg Center for Elder Justice, 2019). For victims of EM, these shelters can provide a way for abuse to cease and the process of healing to begin.

In the inpatient setting, patients are assumed to have the autonomy to refuse medical treatments and participate in the management of their own care as long as they are deemed to be able to provide informed consent. However, what can be done if the older adult is refusing to perform activities considered essential for his or her health and well-being? The answer, at the moment, is very little. If the older adult has the cognitive capacity to make decisions about his or her own self-care, healthcare professionals must respect the autonomy of the older person and not resort to infantilization or coercive services.

It is difficult to evaluate the success of interventions implemented in inpatient settings. The nature of discharges reduces the ability of hospital staff to follow up on cases of EM. Not all suspected victims of EM will return to the same acute care institution for repeat visits, and confidentiality issues can restrict information sharing among healthcare professionals.

CASE STUDY 16.1

Mr. Campo is an 83-year-old male admitted to a medical unit for change in mental status. His 79-year-old wife is at his bedside. On admission assessment, the nurse notices Mr. Campo is confused, weak, and pale. He is also underweight with a body mass index (BMI) of 16.4 kg/m^2. When asked about the change in his cognitive status, Mrs. Campo reports that Mr. Campo

(*continued*)

CASE STUDY 16.1 (*continued*)

was diagnosed with early Alzheimer's dementia and gastric cancer last year. He has become more confused in the past 2 days. Mrs. Campo states she would have brought her husband to the emergency department sooner but that their son, José, said she should not worry about it because of his dementia.

His vital signs are as follows: blood pressure of 93/52 mmHg, heart rate of 115 beats per minute, respiratory rate of 23 breaths per minute, and a temperature of 100.8°F. He is unable to verbalize a pain score; however, he does not appear to be in pain at this moment.

On performing an EM assessment, the nurse gathers the following information from Mrs. Campo: Her husband has lost a total of 25 pounds in recent months and has been refusing to eat for the past week. Mrs. Campo's mobility is limited because of multiple sclerosis and their neighbor who used to accompany them to medical visits has moved away. Their son, José, had to move in with them a year ago after he lost his job. Mr. Campo and his son have never had a good relationship and often argue about their living arrangement. This has the entire family very depressed. Mrs. Campo also reveals that José is frequently inebriated but denies having a drinking problem. Moreover, José refuses to take Mr. Campo to see his primary care provider, stating that these health changes are "just because he's so old."

Mr. Campo is now on intravenous hydration and is being followed by a dietitian. His vital signs and mental status have improved. Further testing reveals that Mr. Campo has an esophageal tumor, which may be the cause of his anorexia.

Discussion

This may be considered a case of neglect and/or psychological/emotional abuse. José knows that Mr. Campo's health has deteriorated, yet he refuses to seek proper medical attention for his father. He also argues with his father often and may be abusing alcohol. From Mrs. Campo's report, there is no evidence of other forms of EM; however, the case should be investigated further. Although the nurse has yet to meet José, there are a number of signs to indicate that neglect or psychological/emotional abuse may be occurring in this home. As a mandated reporter, the nurse should report this case if he or she suspects any form of EM is present.

A number of risk factors are present in this family to alert the nurse to possible EM. For example, Mr. Campo has cognitive deficits because of dementia and is frail because of his cancer diagnosis. In addition, his wife has functional deficits because of her multiple sclerosis. Also, she reports feeling depressed by her current situation and lacks a strong support system.

The nurse should discuss the case with Mr. Campo's medical team as well as his social worker. The dietitian could provide the family with information about Mr. Campo's nutritional needs. The nurse should collaborate with the family and interdisciplinary team to identify community services for this family.

SUMMARY

With a rapidly aging population, cases of EM will become more prevalent. Nurses are in a powerful position to take leadership roles in the creation of EM MDTs and the resultant screening and care planning approaches necessary for the well-being of the older adult. As the largest healthcare profession, nursing can use their multiple roles and clinical settings to develop an understanding and appreciation for the complexities of detecting and addressing cases of EM. The recognition of markers of EM is an important step in guaranteeing that older adults receive high-quality care. The different manifestations and types of EM are a challenge but with a fulsome appreciation of the evidence and concerted effort, the best strategies for nursing intervention can be developed into appropriate clinical practice guidelines for consistent assessment and management of EM. The strategies in this chapter serve as a framework to help nurses navigate this complex clinical syndrome.

As advocates, nurses should ensure that their institutions have guidelines in place for managing suspected cases of EM.

NURSING STANDARD OF PRACTICE

Protocol 16.1: Detection of Elder Mistreatment

I. GOAL

Determine best practices in identifying and responding to cases of EM.

II. OVERVIEW

With the projected increase in the population of older adults worldwide and the rise in medical and technological advances, it is anticipated that older adults will continue to live longer. Therefore, it is expected that cases of EM, although currently underreported, will rise. As patient advocates and providers of care, nurses serve an important function in the screening and treatment of cases of EM. However, current data show that nurses and other healthcare professionals do not report all cases of EM they encounter because of lack of knowledge either about manifestations of EM or about how reporting and investigation by state agencies function.

III. BACKGROUND/STATEMENT OF PROBLEM

A. Definitions

1. *Elder mistreatment*: "Intentional actions that cause harm or create serious risk of harm (whether harm is intended) to a vulnerable elder by a caregiver or other person who is in a trust relationship to the elder," or "failure by a caregiver to satisfy the elder's basic needs or to protect himself or herself from harm" (NRC, 2003, p. 1). There are conflicting casual theories of EM.
2. *Physical abuse:* "The use of physical force that may result in bodily injury, physical pain, or impairment" (NCEA, 2008).
3. *Sexual abuse:* Any form of sexual activity or contact without consent, including with those unable to provide consent (NCEA, 2008).
4. *Emotional/psychological abuse*: "The infliction of anguish, pain, or distress through verbal or nonverbal acts" (NCEA, 2008).
5. *Financial abuse/exploitation:* "The illegal or improper use of an elder's funds, property, or assets" (Naik et al., 2008).
6. *Caregiver neglect:* "The refusal or failure to fulfill any part of a person's obligations or duties to an" older adult, including social stimulation (NCEA, 2008).
7. *Self-neglect:* The behavior of an older adult that threatens his or her own health or safety. Disregard of one's personal well-being and home environment (NCEA, 2008).
8. *Risk-vulnerability model:* This model posits that neglect is caused by the interaction of factors within the older adult and his or her environment. The risk and vulnerability model adapted to EM by Frost and Willette (1994) provides a good lens through which to examine EM. *Vulnerability* is determined by characteristics within the older adult that increase his or her risk of being abused by caregivers, such as poor health status, impaired cognition, and history of abuse. *Risks* refer to factors in the environment that may predispose an older adult to EM and may include characteristics of caregivers, such as health and functional status, as well as a lack of resources and social isolation (Fulmer et al., 2005).
9. *Situational theory:* This theory was first used to explain causes of child abuse. The situational theory promotes the idea that stressful family conditions contribute to mistreatment. Thus, EM may be viewed as a consequence of caregiver strain because of the overwhelming tasks of caring for a vulnerable or frail older adult (Straus, 1971).
10. *Psychopathology of the abuser:* This posits that mistreatment stems from a perpetrator's own battle with psychological illness, such as substance use, depression, and other mental disorders (Gelles & Straus, 1979).

(*continued*)

Protocol 16.1: Detection of Elder Mistreatment (*continued*)

11. *Social exchange theory:* This theory speculates that the long-established dependencies present in the victim–perpetrator relationship are responses developed within the family that then continue into adulthood (Gelles, 1983).
12. *Social learning theory:* This was developed by Bandura (1978), and this theory attributes mistreatment to learned behavior on the part of the perpetrator or victim from either family life or the environment.
13. *Political economy theory:* This theory focuses on how older adults are often disenfranchised in society as their prior responsibilities and even their self-care are shifted onto others (Walker, 1981).

B. Characteristics of victims
   1. Decreased ability to complete ADL and more physically frail (Dyer et al., 2000; Frost & Willette, 1994; Peisah et al., 2009)
   2. Cognitive deficits such as dementia (Dong et al., 2012; Fulmer et al., 2005; Gorbien & Eisenstein, 2005; Naik et al., 2008)
   3. History of trauma earlier in life (Brozowski & Hall, 2010; DeLiema et al., 2012; Draper et al., 2008; Fulmer et al., 2005)
   4. Depression and other mental disorders, as well as an increased sense of hopelessness (Dong et al., 2012; Dyer et al., 2000; Fulmer et al., 2005; Johannesen & LoGiudice, 2013)
   5. Social isolation and lack of support systems (Acierno et al., 2010; Cannell et al., 2014; Draper et al., 2008; Dyer et al., 2000; Peisah et al., 2009)
   6. History of substance abuse (Dyer et al., 2000; Peisah et al., 2009)

C. Characteristics of perpetrators
   1. Most commonly, family members
   2. Long history of conflict with the victim (Krienert, Walsh, & Turner, 2009)
   3. Lived with victim for an extended time (Rizzo et al., 2015; Wiglesworth et al., 2010)
   4. Higher rates of caregiver strain (Strasser, Smith, Weaver, Zheng, & Cao, 2013; Wiglesworth et al., 2010)
   5. History of mental illness and substance abuse (Jackson & Hafemeister, 2013; Wiglesworth et al., 2010)
   6. Depression and other mental disorders (Giurani & Hasan, 2000; Johannesen & LoGiudice, 2013; Wiglesworth et al., 2010)
   7. Social isolation and lack of support systems (Wiglesworth et al., 2010)

D. Etiology and/or epidemiology
   1. Data from the National Research Council (2003) suggest that more than two million older adults suffer from at least one form of EM annually.
   2. The National Elder Abuse Incidence Study estimates that more than half a million new cases of EM occurred in 1996 (NCEA, 1998).
   3. Even though 44 states and the District of Columbia have legally required mandated reporting, EM is severely underreported. There is a lack in uniformity across the United States on how cases of EM are handled (NCEA, 1998).
   4. NCEA (1998) estimates that only 16% of cases of abuse are actually reported.
   5. The National Council on Elder Abuse revealed that neglect accounts for approximately half of all cases of EM reported to APS. About 39.3% of these cases were classified as self-neglect, and 21.6% were attributed to caregiver neglect, including both intentional and unintentional (NRC, 2003).
   6. More than 70% of cases received by APS are attributed to cases of self-neglect with those older than 80 years thought to represent more than half of these cases (Burnes, Rizzo, Gorroochurn, Pollack, & Lachs, 2016).

IV. PARAMETERS OF ASSESSMENT

A. See Table 16.2.

(*continued*)

Protocol 16.1: Detection of Elder Mistreatment (*continued*)

V. NURSING CARE STRATEGIES

A. Detailed screening is important to assess for risk factors for EM using a combination of physical assessment, subjective information, and data gathered from screening instruments (Perel-Levin & World Health Organization, 2008).
B. Strive to develop a trusting relationship with the older adult as well as the caregiver. Set aside time to meet with each individually (Perel-Levin & World Health Organization, 2008).
C. Use of interdisciplinary teams with a diversity of experience, knowledge, and skills can lead to improvements in the detection and management of cases of EM. Early intervention by interdisciplinary teams can help lower the risk for worsening abuse and further deficits in health status (Jayawardena & Liao, 2006; Rizzo et al., 2015; Wiglesworth et al., 2010).
D. Institutions should develop guidelines for responding to cases of EM (De Donder, De Witte, Brosens, Dierckx, & Verté, 2015; Perel-Levin & World Health Organization, 2008; Sandmoe & Kirkevold, 2011; Wiglesworth et al., 2010).
E. Institutions should implement culturally appropriate strategies for identifying and addressing EM in racial/ethnic minority older adults (Horsford, Parra-Cardona, Schiamberg, & Post, 2011).
F. Educate victims about patterns of EM such that EM tends to worsen in severity over time (Phillips, 2008).
G. Provide older adults with emergency contact numbers and community resources (Lachs & Pillemer, 1995).
H. Refer to appropriate regulatory agencies.

VI. EVALUATION AND EXPECTED OUTCOMES

A. Reduction of harm through referrals, use of interdisciplinary interventions, and/or relocation to a safer situation and environment (Jackson & Hafemeister, 2013; Rizzo et al., 2015).
B. Victims of EM verbalize an understanding of how to access appropriate services.
C. Caregivers use services, such as respite care or treatment, for mental illness or substance use.
D. If possible, evaluate progress in relationships between the caregiver and the older adult through screening instruments such as the Modified CSI and GDS among other tools freely available at consultgerirn.org.
E. Institutional establishment of clear and evidence-based guidelines for management of EM cases.

VII. FOLLOW-UP MONITORING OF CONDITION

A. Follow-up monitoring in the acute care setting is limited compared to the follow-up that may be performed in the community or long-term care settings.

VII. RELEVANT PRACTICE GUIDELINES

A. American Medical Association (AMA). (1992). *Diagnostic and treatment guidelines on elder abuse and neglect*. Chicago, IL: Author.

Advance Care Planning*

17

Joanne Roman Jones
and Marie Boltz

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Distinguish instruction directives and appointment directives in terms of their strengths and weaknesses.
2. Describe assessment parameters that would ensure that older adults receive advance directive information.
3. Identify strategies to ensure good communication about advance directives among patients, families, and healthcare professionals.
4. Guide a discussion of the benefits and burdens of various treatment options to assist proxy treatment decision-making.
5. Describe measurable outcomes to be expected from implementation of this practice protocol.

OVERVIEW

One of the most important yet difficult situations healthcare professionals face is decision-making about care for those who can no longer communicate their health goals, values, and treatment preferences. Surrogate decision-making has particular relevance in the geriatric setting because the decisional capacity of older adults may be diminished, fluctuating, or lapsed. Precisely because individuals may lack the capacity to participate in discussions when decisions about treatment are required, advance care planning (ACP) has become an increasingly important priority. ACP enables individuals with decisional capacity to prospectively articulate their health goals, values, and treatment preferences so that they can be communicated and honored when the ability to make and communicate decisions has lapsed. It must be emphasized, however, that addressing ACP should not wait until one is at an advanced age or dying. Because it promotes the control of their future by responsible adults, it should be an integral part of routine healthcare for every age at every stage of health.

One indispensable ACP tool is the advance directive, a simple and effective mechanism for the clear and legally enforceable documentation of these important decisions; all capable adults are empowered to complete such a document. Although healthcare professionals agree that all decisionally capacitated individuals should be encouraged to execute advance directives, the right *not* to do so must also be respected. When patients and residents are engaged in discussion about ACP, they should be informed and reassured that neither their providers nor the facilities in which they receive treatment will condition care or

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

make assumptions about their care preferences if they do not have an advance directive.

BACKGROUND

Advance directives are legal instruments intended to secure an individual's ability to set out prospective instructions regarding healthcare. Conceived during the 1970s, they responded to the concern that patients who had lost the ability to make healthcare decisions might be subjected to medical interventions they would not have chosen, especially at the end of life. The 1990 federal Patient Self-Determination Act (PSDA) codified the right to conduct ACP by requiring all healthcare facilities that receive federal funds to offer patients or residents the opportunity to execute advance directives and assistance in doing so.

Although all 50 states and the District of Columbia have statutory and/or case law governing advance directives and all states honor them, their standards and restrictions differ (Olick, 2012; see also advance directives by state link in the Resources section). Although advance directives are useful whenever substitute decision-making is required, they are most often invoked in the geriatric and critical care settings, as disease trajectory declines and the end-of-life approaches.

TYPES OF ADVANCE DIRECTIVES

Advance directives commonly come in two varieties—instruction directives, also known as living wills, and appointment directives, also known as healthcare proxies or durable powers of attorney for healthcare. In different ways, they provide direct access to patient preferences, enabling caregivers and families to rely on the most immediate and authentic of the decision-making standards. The first advance directive was the instruction directive or living will, a written set of value-neutral instructions about specified medical, surgical, or diagnostic interventions the individual *would* or *would not* want under particular circumstances, usually at the end of life. The structure of the document typically has a trigger phrase, such as "If I am ever in an irreversible coma... " or "If I am ever terminally ill...," followed by instructions related to treatment in the specified circumstances.

Because the living will presents explicit articulation of the patient's previously expressed preferences, it is assumed to provide helpful guidance to family and caregivers about what she or he would choose in current circumstances. As became apparent, however, this type of directive is significantly limited by the fact that it is a static document that requires an individual to anticipate, often years in advance, some future medical condition(s) and determine the preferred treatment(s). Quality-of-life assessments and care preferences evolve over time, however, and it is not unusual for patients to change their minds about medical interventions that they thought they would or would never be able to tolerate.

Moreover, these documents do not always mean what they say. A living will that states, "I don't ever want to be on dialysis" probably does not mean, "I don't want three dialysis treatments if they will return me to baseline kidney function." What the individual probably means is, "I don't want to be on dialysis for the rest of my life." But living wills typically do not provide that kind of nuanced interpretation. Finally, this type of directive usually refers only to end-of-life care. The result is a set of instructions that reflect what the patient *believed* and *tried to communicate* at a *particular time* about what she *thought she would want under different circumstances* at a *later time*. Because of their significant limitations, living wills are most appropriate for someone without trusted friends or family to make surrogate decisions in the event of her or his incapacity.

The preferred advance directive is the appointment directive, also known as a healthcare proxy or a durable power of attorney for healthcare (DPOAHC). This document enables a capacitated individual to legally appoint another person to make medical decisions on her or his behalf after capacity has been lost. Depending on the type of appointment directive and the jurisdiction, the designated person may be known as a *healthcare agent, proxy, representative,* or *power of attorney (POA)*. For purposes of this discussion, the term *healthcare agent* will be used to represent any person legally appointed to make surrogate healthcare decisions. Appointment of an *alternate agent* is also recommended as a backup in the event the agent is unavailable or unable to make decisions on the patient's behalf.

The appointment directive is preferred over the instruction directive because it authorizes decision-making in the event of *temporary* or *permanent* incapacity and enables greater flexibility in responding to unanticipated or rapidly changing medical conditions. Although the agent is generally required to honor the patient's previously expressed care preferences, if those instructions do not apply to or are inconsistent with the patient's current health needs, the agent is empowered to exercise judgment and use his knowledge of the patient's health goals, values, preferences, and decision history to make choices that promote the patient's best interest. Because the agent and alternate agent have the same decisional authority as the patient once the powers are activated, he or she may make any and all care decisions the patient could make if

capable. Moreover, the authority of the agent and alternate supersedes that of anyone else (except a court-appointed guardian), including next of kin. This scope of authority presupposes a patient–agent relationship characterized by trust; familiarity with the patient's goals, values, and preferences; and the agent's willingness to exercise judgment and make often difficult decisions in the patient's interest.

As noted in Chapter 7, Healthcare Decision-Making, appointing a healthcare agent requires a lower level of capacity than that needed to make the often complex decisions the agent will make. All the individual must be able to do is understand that, at some future time, another person will be needed to make care decisions on her or his behalf and consistently designate the same person. Assessing this level of capacity can be as simple as asking, "If you couldn't make decisions about your care, who would you trust to do it?" Return in 30 minutes, ask the same question, and, if the same person is named, that is sufficient. The importance of this provision, especially in the geriatric setting, is that even patients with diminished or fluctuating capacity who are unable to make complex medical decisions may still be able to appoint an agent and an alternate to assume this responsibility.

As noted previously, one type of appointment directive is the DPOAHC, but the term POA, when applied to advance healthcare planning, can cause confusion. Powers of attorney are delegations of legal authority for specified tasks. Often, a well-meaning person will show up in the clinical setting, clutching a document, and saying, "I'm the POA, so I'm responsible for making decisions." Encourage staff to read the document. Very often, it will be a POA for banking or real estate or some other nonmedical responsibilities. Unless the document includes "healthcare decisions" or similar language, the document should be returned to the person with the explanation that the delegated powers do not include healthcare decision-making (Post & Blustein, 2015).

A key presumption of the appointment directive is that the individual and the appointed agent(s) have engaged in candid and comprehensive discussions about the individual's goals, values, and treatment preferences (Span, 2015). The literature reveals that older adults with a DPOAHC or other advance directive are less likely to die in a hospital or receive unwanted or nonbeneficial care in comparison with those without an advance directive that provides insight into treatment preferences and guidance in making decisions about care (Silveira, Kim, & Langa, 2010). Some states require the agent's signature on the advance directive as confirmation that he is aware of the appointment and has accepted the decision-making responsibilities that are entailed. In states without that requirement, however, healthcare agents may first learn of their appointment when they are called from an emergency department.

Although an instruction directive, such as a living will, typically addresses treatment decisions at the end of life, the appointment directive becomes activated anytime the individual has a *temporary* or *permanent* loss of decisional capacity, as might be associated with trauma, illness, states of diminished awareness or impaired cognition (e.g., dementia, stroke, and delirium), alcohol or other substance use or abuse, elective or emergency surgery, or any other condition that impairs decisional capacity. In these situations, a healthcare agent has the legal authority to infer or interpret the patient's treatment preferences in real time, based on current medical circumstances and likely prognosis, as well as knowledge of the patient's goals, values, and preferences. These decisions address a wide range of clinical issues and are not restricted to decisions about forgoing life-sustaining measures as death nears. In essence, the agent is able to say, "If Mama had known then what we know now about her condition and prognosis, this is what she would have decided."

In the absence of an advance directive, the care team typically turns to informal surrogates, usually family, for guidance and consent in care planning. *Family consent laws* are state-specific statutes that set out the state-approved decision-making hierarchy—the order in which persons are authorized to make decisions on behalf of a patient who lacks decisional capacity and has not appointed a healthcare agent by means of an advance directive or DPOAHC.

Variations in Advance Directives

Some states have a combined directive that provides for the appointment of a healthcare agent and an alternate agent, as well as optional instructions regarding treatment specifics. A section on organ donation ("anatomical gift") has been added to the advance directives in some states, enabling the expression of preferences about organ donation. Some states limit the authority of the appointed agent or alternate to activate these preferences, unless this person is also the identified decision-maker(s) for organ donation, a distinct statutory authority that is separate from the agent's rights and responsibilities to make decisions about the patient's treatment.

Instructional/medical directives have been suggested to address specific clinical situations and interventions. Individuals must decide prospectively which interventions they would want in the context of four scenarios: coma with virtually no chance of recovery; coma with a small chance of recovery but restored to an impaired physical

and mental state; advanced dementia and a terminal illness; and advanced dementia. Among the interventions are cardiopulmonary resuscitation (CPR), artificial nutrition and hydration (ANH), dialysis, invasive diagnostic tests, antibiotics, and blood transfusion. This type of directive shares and even exacerbates the problems with living wills by requiring individuals to anticipate hypothetical clinical conditions and make choices about interventions she or he may or may not understand. In addition, the instructional/medical directive does not address the patient's desired goals of care, willingness to allow a short-term intervention, or treatment choices associated with stage of chronic illness or exacerbation.

Five Wishes® is a hybrid directive that provides the opportunity to communicate decisions about (a) the person I want to make care decisions for me when I cannot, (b) the kind of medical treatment I do or do not want, (c) how comfortable I want to be, (d) how I want people to treat me, and (e) what I want my loved ones to know. For many people, this is an accessible and nonthreatening way to frame the issues. Five Wishes is currently recognized in 42 states and is available in 28 languages (Aging with Dignity, 2019). The "values statements" embedded in the Five Wishes document generally do not explore or express the patient's understanding of the benefits and burdens of various treatments, sometimes making it difficult to act on the patient's wishes and preferences (Lo & Steinbrook, 2004).

ADVANCE DIRECTIVES AND DECISION-MAKING

The literature reveals that quality-of-life concerns, family influence, and pragmatism inform most adults' decisions to create an advance directive (Crisp, 2007). Older adults who execute advance directives tend to believe that their physicians know their wishes and do not feel that the directive would constrain their care. Those who do not create an advance directive tend to prefer that their families make decisions for them and may not appreciate the decision-making flexibility provided by an advance directive (Beck, Brown, Boles, & Barrett, 2002). Among participants of the original Framingham Heart Study, almost 70% discussed their end-of-life care preferences and advance directives with someone, but not necessarily a physician or other healthcare provider. More than half had a healthcare proxy or living will; slightly less than half had both types of directives. Most respondents wanted a comfort care plan at the end of life, but few agreed to forgo life-sustaining treatment interventions (e.g., ventilator and feeding tube) and said they would endure a burdensome health status (e.g., intense pain, confusion, and forgetfulness) in order to prolong life (McCarthy et al., 2008).

The literature also reveals the relationship between ACP and the degree to which individuals' care preferences are known, understood, and followed. Surrogate decision-makers for hospice patients who talked with their surrogates about their end-of-life treatment wishes demonstrated greater understanding of the patients' preferences than the surrogates of patients who did not have these discussions (Engelberg, Patrick, & Curtis, 2005). Although surrogate decision-making by families demonstrated greater accuracy than primary physicians in predicting older patients' preferences for life-sustaining treatments in hypothetical scenarios, having an advance directive did not necessarily improve congruence between patients' wishes and decisions made for them by others (Coppola, Ditto, Danks, & Smucker, 2001).

Studies have revealed that surrogate decision-makers do not necessarily make treatment choices that reflect patients' preferences (Ditto et al., 2001; Mitchell, Berkowitz, Lawson, & Lipsitz, 2000). Although a small study found that communication between patients and their agents improved the accuracy of agent representations of patient preferences (Barrio-Cantalejo et al., 2009), a meta-analysis of surrogate decision-making did not find that prior discussion between patient and agent improved agent accuracy in representing patient preferences (Shalowitz, Garrett-Mayer, & Wendler, 2006). Lack of concordance between patients' stated wishes and physicians' orders, however, was not shown to be simply a denial of patient rights; rather, physicians may have been relying on additional information to guide their treatment decisions (Hardin & Yusufaly, 2004).

Advance directives and high-quality end-of-life care have been associated with patients dying in their preferred location (e.g., at home or in hospice rather than in an acute care hospital), less likelihood of being burdened with an unwanted respirator or feeding tube, fewer concerns about family/significant others being informed about what to expect, and good communication with the healthcare team (Bakitas et al., 2008; Detering, Hancock, Reade, & Silvester, 2010; Kwak & Noh, 2018; Teno, Gruneir, Schwartz, Nanda, & Wetle, 2007). Patients with advanced illness requiring end-of-life care who were randomized to an Advanced Illness Coordinated Care Program reported increased satisfaction with care and communication, completed more advance directives, and their surrogates reported fewer support problems than patients receiving standard care (Engelhardt et al., 2006). As reported in a similar study (Teno et al., 2007), no difference was found in survival rates between the experimental and control

groups. Unmet needs were reported, however, for adequate pain management and emotional support for patient and family (Teno et al., 2007).

Factors considered important by older patients with regard to their medical decision-making and ACP included their religious beliefs, dignity, physical comfort, dependency, and finances (Hawkins, Ditto, Danks, & Smucker, 2005). Few patients indicated a desire to document their specific medical treatment preferences, but they highly valued verbal communication about these matters. Spouse surrogates were less likely than child surrogates to believe that prospective documentation of treatment preferences was necessary and more likely than child surrogates to consider financial issues important. Most patients accorded their surrogate considerable leeway in decision-making. Patients indicated greater confidence in their child surrogates' understanding of their wishes than in the understanding of their spouse surrogates. An association between recent hospitalization and reduced desire to receive life-sustaining interventions (e.g., CPR, artificial nutrition, and hydration) was noted during an interview conducted just after recovery, but returned to baseline several months after hospitalization. These results challenge assumptions about the stability of treatment preferences and the temporal context during which treatment decisions are made (Ditto, Jacobson, Smucker, Danks, & Fagerlin, 2006; Hawkins et al., 2005).

Surrogate decision-making has traditionally been grounded in the notion that an individual's characteristic preferences, long-held values, and cherished convictions provide the touchstone for decisions made on her or his behalf when capacity has lapsed. ACP, in general, and advance directives, in particular, have been held to be reliable guides for surrogate decision-making because they authentically reflect the choices and principles that have given the individual's life meaning.

A thought-provoking debate within the bioethics community challenges the justification for adhering to previously articulated preferences that may not adequately meet the markedly different needs of a now-incapacitated individual. Commentators have argued that persons with advanced dementia are, in effect, different people in terms of their health status and interests, for whom care decisions should be based on their current needs and preferences rather than their prior instructions (Blustein, 1999; Dresser, 1995; Huang, Shyu, Weng, Chen, & Hsu, 2018; Post & Blustein, 2015). Ultimately, the ethical analysis would seem to rest on the imperative to preserve the dignity of the individual currently before us, as well as that of the individual she was.

Research Advance Directives

The notion of a research advance directive has been suggested because of the ethical implications of including in research studies participants with dementia who cannot provide informed consent (National Bioethics Advisory Commission, 1998). A research advance directive must be executed while the individual still has decisional capacity and must contain a detailed description and confirmation that the individual understands the purpose of research, including the concepts of risk, benefit, and burden. At the time of recruitment for a research study, the appointed surrogate decision-maker must determine whether the individual's previously articulated intention to participate in research is congruent with the proposed research.

A study involving individuals with moderate dementia and their family surrogate sought to learn whether the patients wanted to retain decision-making control of their participation in future research or allow their surrogates to make the decision at the time of recruitment. Although many but not all individuals authorized their surrogates to make future decisions about research participation, surrogates did not always want to make these decisions (Stocking et al., 2006).

Psychiatric Advance Directives

Psychiatric advance directives are written by decisionally capable individuals who want to articulate their preferences about psychiatric treatment so that these preferences may be communicated and honored during periods when decisional capacity has lapsed. Research has shown that, given the opportunity to meet with a trained facilitator, adults with psychiatric disorders demonstrated sufficient capacity to make and document treatment decisions (Elbogen et al., 2007). Psychiatric outpatients have demonstrated a desire for assistance in creating an advance directive. This population tends to be female; non-White; with limited autonomy and, a history of self-harm, arrest, and perceived pressure to take psychiatric medications (Swanson, Swartz, Ferron, Elbogen, & Van Dorn, 2006). Patients who complete a psychiatric advance directive typically exhibit good insight and reliably keep their outpatient mental health treatment appointments (Swanson et al., 2006).

Psychiatric advance directives in which patients identified their preferred psychiatric medications predicted not only that the medications were likely to be prescribed but also that medication adherence persisted over time (Wilder, Elbogen, Moser, Swanson, & Swartz, 2010). Most psychiatrists, psychologists, and

social workers agreed that psychiatric advance directives would be helpful for patients with severe mental illness who are capable of creating them. The positive attitude of these mental health professionals is also supported by their knowledge that their respective state laws do not require them to follow a directive that contains a patient's refusal of appropriate mental health treatment or a request for treatment that is not clinically indicated (Elbogen et al., 2006).

Verbal Advance Directives

Although courts tend to prefer written advance directives, oral directives are typically respected, especially in emergency situations, and can be persuasive in a judicial decision about withholding life-sustaining treatment. Some states permit patients to verbally designate a healthcare agent in discussion with their physicians, rather than executing a written directive (Lo & Steinbrook, 2004). In determining the validity of a verbal advance directive, courts seek information about whether the statement was made by a mature person who understood the underlying issues, in a deliberate rather than casual or emergency context, was consistent with characteristic values and statements exhibited in other aspects of the individual's life, including religious or philosophical convictions, and addressed the specific medical condition necessitating a decision (Lo & Steinbrook, 2004). What might seem like an offhand comment made by a patient in a practitioner's office or at the bedside should be recorded for just such an occasion, when clear and convincing evidence of the individual's wishes may be required.

A review examined studies, published between 1990 and 2018, of the knowledge or confidence of nurses and nursing students regarding advance directives or of education on advance directives in nursing curricula. Fewer than half of working nurses demonstrated knowledge, confidence, or both regarding advance directives, and nursing programs that cover advance directives at all typically devote only 1.5 hours or less to this issue (Miller, 2018). Clearly, nursing programs need more education specifically about advance directives, and more research is needed to determine what educational methods can successfully address nurses' knowledge and confidence deficits.

OTHER TYPES OF ACP

In addition to advance directives, other mechanisms enable prospective medical decision-making in specific circumstances.

Do-Not-Resuscitate Orders

Almost all diagnostic and therapeutic interventions require the informed consent of a decisionally capable patient or an authorized surrogate on behalf of a patient lacking decisional capacity. The few exceptions include emergency treatment that, if delayed, would result in significant harm or death, interventions to manage pain and other symptoms, and CPR. In the event of cardiopulmonary arrest, consent to resuscitation is presumed unless a physician enters a do-not-resuscitate (DNR) order, which is a specific order to refrain from performing CPR. Because of their life-and-death implications, most jurisdictions require DNR orders to have explicit informed consent, with few carved-out exceptions. Absent a DNR order, the patient's code status is presumed to be "full code" and, in the event of cardiopulmonary arrest, CPR must be performed.

Determining, communicating, and honoring a patient's code status often causes moral distress for caregivers, especially nurses. Care professionals are often conflicted and believe that CPR should not be instituted when it is considered medically futile, will not provide clinical benefit to the patient, or when death is inevitable and impending. Even in these situations, however, patients or surrogates often insist on CPR because of the misperception, fueled by television and film dramas, that it is always effective in restarting cardiac function. In the interest of clarity and accuracy, an increasing number of states have changed the name of the order from DNR to DNAR—do not *attempt* resuscitation.

Decisionally capable individuals or surrogates on behalf of incapacitated individuals have the right to *consent to or refuse* any proposed medical intervention. State-specific Natural Death Acts codify the right of capable patients to decline unwanted life-sustaining interventions, a right supported by the U.S. Supreme Court (*Cruzan v. Director*, 1990). Accordingly, capable patients and surrogates have the right to refuse CPR by consenting to a DNR order after they have been informed and demonstrate their understanding of the implications, including the relevant benefits, burdens, and risks. Because these are *medical orders* written by *physicians*, they are not considered advance directives, which are *patient*-generated statements of care preference.

Not uncommonly, conflict arises between and among patients, families, and care professionals regarding the necessity and appropriateness of DNR orders. For example, a physician may be unwilling to write a DNR order requested by a patient or surrogate because forgoing CPR would be considered clinically inappropriate. In this

situation, the physician is required to notify the requestor that the order will not be entered and offer to transfer the patient's care to a physician willing to write the order.

The more typical scenario is a patient who has consented to a DNR order suffering a cardiopulmonary arrest and a hysterical family member imploring the care team, "You must save my loved one!" Too often, the patient is resuscitated, and the code status is changed to full code with the reasoning, "When the patient can't make decisions, we always turn to the family." Reframing this dynamic is essential to the fundamental ethical obligation to respect patient autonomy. A medical order consented to by a capable patient is a compact between the patient and the care team. The patient's consent implicitly expresses confidence that his or her wishes will be honored, and the care team implicitly promises, "When you are at your most vulnerable and cannot advocate for yourself, we will advocate for you." Accordingly, a DNR order consented to by a family member, healthcare agent, or other surrogate on behalf of an incapacitated patient may subsequently be modified or rescinded by an authorized surrogate. A DNR order consented to by a *decisionally capable patient*, however, *may be rescinded or modified only by the patient.* The rare exception is when *a healthcare agent appointed by the patient* determines that, in the context of *current changed clinical realities, the patient would have rescinded or modified the DNR order.*

Out-of-hospital DNR orders can protect individuals at home, as well as in long-term care, rehab facilities, or other nonacute care settings from unwanted and clinically inappropriate CPR. Like in-hospital DNR orders, these are written by physicians based on clinical assessment and consented to by capable patients or surrogates. In one study, interest in and consent to DNR orders by patients on palliative home care programs were associated with sleep and incontinence problems, acceptance of their clinical condition and impending death, and their wish to die at home (Brink, Smith, & Kitson, 2008).

Artificial Nutrition and Hydration

ANH poses ethical, legal, and cultural challenges, primarily because of the traditional association between nourishing and nurturing. Before the PSDA became law, the U.S. Supreme Court ruled that capable patients have a constitutionally protected right to refuse unwanted medical treatment, a category in which the Court included ANH (*Cruzan v. Director*, 1990). Thus, ethical and legal reasoning that considers ANH the same as any other medical treatment recognizes no distinction between withholding and withdrawing life-sustaining measures, including ANH.

Powerful emotional and cultural influences persist, however, and are reflected in the varying state-specific legal evidentiary rules and procedures required to forgo or discontinue ANH. Some states hold that healthcare agents may not make decisions about forgoing ANH unless explicitly authorized to do so by the patient's advance directive. Some DPOAHC documents include a statement that the patient may check to verify that the POA is aware of the patient's wishes about ANH, without indicating the nature of those wishes. Living will statutes in some states regard ANH as a medical treatment, whereas other states consider it a comfort measure (Gillick, 2006). Given states' varying legislation, nurses need to be aware of the relevant laws of the state in which they practice and what those laws require, permit, and prohibit. They should also understand the extent to which patients and their surrogates are correctly informed about the clinical benefits and burdens of ANH at the end of life; the palliative alternatives; the cultural, religious, and language influences that may equate forgoing ANH with "starving" the patient to death; and strategies to address those concerns.

Orders for Life-Sustaining Treatment (POLST/MOLST)

An entirely different type of ACP is a consolidated set of medical orders for life-sustaining interventions. Originated in Oregon in 1995, this is a decision-making model that has been adopted by or is in development in approximately 40 states, which accounts for the variety of names (e.g., Physician or Practitioner or Pennsylvania Orders for Life-Sustaining Treatment [POLST], Medical Orders for Life-Sustaining Treatment [MOLST], Louisiana Physician Orders for Life-Sustaining Treatment [LaPOLST]; Span, 2015). In the interest of simplicity, the term *POLST* is used in this discussion to refer to all documents of this type.

Although POLST is a legal mechanism for ACP, it is fundamentally different from advance directives, and, as noted in the following, distinguishing them is crucial to their proper implementation.

- Advance directives are *statements of patient intention, not medical orders*. Thus, an advance directive that stipulates, "If I am ever in one of the following three clinical conditions, I would not want cardiopulmonary resuscitation" is not a DNR order. That instruction may be translated into a DNR order by a physician if forgoing resuscitation is deemed clinically indicated. In contrast, POLST is a consolidated set of *medical orders* that are immediately actionable.

- *Every decisionally capable person 18 years of age or older* should have an advance directive, regardless of health status. POLST is intended for a subsection of the population, *individuals who have life-limiting illnesses and, typically, are expected to live 1 year or less.*
- Advance directives become *active only when the individual is determined to have lost decisional capacity.* POLST is *active from the moment it is signed*.

POLST is a comprehensive and specific product of discussion between a practitioner and a capacitated individual or the authorized surrogate for an incapacitated individual. It begins with a statement about the goals of care, which inform decisions about medical interventions, including CPR, airway management, ANH, hospitalization, and symptom management. Precisely because of the life-limiting nature of the individual's illness(s), POLST orders respond to current rather than anticipated or hypothetical clinical circumstances. The specificity of the POLST protocol provides guidance in honoring the individual's preferences, such as wishing to die at home or in a nursing facility, rather than a hospital; wanting to be alert, even if that means incomplete pain relief; and declining intubation in the event of respiratory compromise.

The literature reveals that, for appropriate individuals, POLST enables greater specificity and accuracy in communicating end-of-life care preferences in comparison with advance directives (Bomba & Vermilyea, 2006). Nursing home residents who have completed POLST are more likely to have documented their preference for limited life-sustaining measures and are less likely to be hospitalized if they have specified comfort measures only. There is no evidence of differences in symptom assessment or management between residents who have completed POLST and those who have not (Hickman et al., 2010).

DECISIONAL CAPACITY TO ENGAGE IN ACP

A threshold consideration is assessing the decisional capacity of individuals to engage in the various types of ACP. Chapter 7, Healthcare Decision-Making, includes an in-depth discussion of decisional capacity, its assessment, and its implications for healthcare decision-making. The following section considers the role of capacity assessment in ACP.

As noted in Chapter 4, Organizational Approaches to Promote Person-Centered Care, capacity is decision specific because different decisions require different levels of capacity. To suggest that, because an individual lacks sufficient capacity to make a complex treatment decision, he lacks the capacity to make other treatment decisions risks disenfranchising and disempowering him from any participation in planning his healthcare. To promote the exercise of patient autonomy to the fullest extent while protecting patients from the harms of deficient decision-making, capacity assessment typically employs a sliding scale based on the notion of risk. The greater the risk attached to a decision, the higher the level of capacity required to honor the decision.

Chapter 7, Healthcare Decision-Making explains that decisional capacity refers to an individual's ability to (a) understand and process information about diagnosis, prognosis, and proposed treatment options; (b) weigh the benefits, burdens, and risks of the options; (c) apply a set of values; (d) arrive at a decision that is consistent over time; and (e) communicate the decision. The sliding scale assessment strategy has particular application in the setting of ACP. An individual lacking the capacity to execute a living will or an instructional/medical directive may still have sufficient capacity to create a healthcare proxy or other type of appointment directive (Mezey, Leitman, Mitty, Bottrell, & Ramsey, 2000). The former task requires the individual to envision and make decisions about complex hypothetical clinical scenarios; the latter task requires only that the individual understand that someone else will make healthcare decisions on his behalf and consistently designate the same person.

Benefit–Burden–Risk Assessment

All healthcare decision-making invokes an analysis that considers the intended and unintended consequences of a particular intervention; identifies the potential benefits, burdens, and risks; estimates the likelihood that they will occur; and weighs their importance to the patient. Based on this information, the analysis determines whether the likely benefits of the intervention will outweigh the burdens and risks. Not uncommonly, patients or surrogates are encouraged to consent to tests or treatments that are uncomfortable, burdensome, and even risky. The ethical justification is the conviction that the benefits, including clinical improvement, palliation, or improved function, will not only result but will outweigh the burdens and risks. Making the benefit–burden–risk assessment an integral part of care planning is a safeguard against performing tests and treatments because they are available rather than indicated.

Patients are not necessarily consistent in their treatment preferences, especially if the degree of burden or the chance of avoiding death is unclear. Patients exhibit varying degrees of readiness for ACP, including communication with their families, other surrogates, and physicians about their health goals and the execution of

an advance directive. Prior experience with healthcare decision-making can influence a patient's perceptions of and readiness to engage in ACP (Fried, Bullock, Iannone, & O'Leary, 2009; Fried, O'Leary, Van Ness, & Fraenkel, 2007). An appointed agent can be assisted to infer how the now-incapacitated patient would likely evaluate the benefits and burdens based on knowledge of the patient's values, preferences, and past behavior. Nurses can helpfully ask the agent, "If Mama could join this discussion, knowing what we know about her condition, prognosis, and treatment options, what would she say?" "Faced with similar situations in the past, how did she decide?" "What did she say when her brother was very ill?" Higher congruence between patient and agent regarding patients' end-of-life care preferences has been associated with a nurse-led discussion intervention: Patients in the experimental group were more knowledgeable about life-sustaining measures, less willing to receive these interventions for a new, serious medical event, and less willing to live in a state of poor health (Schwartz et al., 2002).

The rationale for forgoing (either withholding or withdrawing) a treatment is eliminating a burdensome intervention that has neither produced nor is expected to produce the desired clinical result. Under these circumstances, analysis reveals that the burdens and risks significantly outweigh any compensating benefit. As discussed in Chapter 7, Healthcare Decision-Making, surrogate decision-making standards include *substituted judgment*, used when knowledge of the patient's goals, values, preferences, and decision-making history can be used to infer her or his likely decision about current clinical conditions, and the *best interest* standard, used when making decisions for a patient whose goals, values, and preferences are unformed or unknown. In guiding the process, nurses may ask, "What does this patient have to gain or lose as a result of this intervention?" "In what ways will this patient be better or worse off as a result of having or not having this treatment?"

CULTURAL PERSPECTIVES ON ACP

The notion of ACP and written directives is not universally accepted. In some cultures, the close-knit family may consider an advance directive intrusive, irrelevant, or a refusal, if not a legal denial, of care. Many in African American and other minority populations do not view an appointment directive as relevant, nor do they regard a DNR order as a summative value statement (Cox et al., 2006). Disinterest in creating an advance directive may reflect a present-day rather than a future orientation, and unwillingness to write about, speak of, or plan for death is a pervasive cultural influence on decisions not to engage in ACP. Likewise, deference to physician authority, the family's role in protecting the patient from the burdens of life-and-death decision-making, and spiritual obligations or beliefs can exert a powerful influence on the willingness to address future healthcare.

Studies indicate different life-sustaining treatment preferences and decision-making contexts among racial and ethnic groups (Cox et al., 2006). Overall, Asian and Hispanic patients tend to prefer family-centered decision-making, in contrast to White and African American patients' preference for patient-directed decision-making (Kwak & Haley, 2005). Many studies have shown that White patients are more comfortable discussing treatment preferences, executing an advance directive, refusing certain life-sustaining treatments, and appointing healthcare agents than Black or Hispanic patients (Hopp & Duffy, 2000). Much of the reluctance of minority populations can be traced back to a regrettable history of exploitation in the clinical and research settings. Advance directive completion is more concentrated among White patients with higher education and income levels than among Black and Hispanic patients with low-income levels and less than a high school education (Mezey et al., 2000). In comparison with White patients, Latino patients are less likely to complete an advance directive or communicate their preferences, even though there are no other differences between the groups with regard to advance directive preferences (Froman & Owen, 2005).

In contrast, African American patients have been shown more likely to want life-sustaining treatments to forestall death. The literature reveals that some African American patients perceive advance directives as a legal way to deny access to treatment and care and tend to be more skeptical about the healthcare system than Mexican Americans and Euro-Americans (Perkins, Geppert, Gonzales, Cortez, & Hazuda, 2002). Among African American patients, spirituality and beliefs that conflict with palliative care goals, views of suffering, death and dying, and mistrust of the healthcare system discourage creation of advance directives (Bullock, 2006; Gerst & Burr, 2008; Johnson, Kuchibhatla, & Tulsky, 2008; Morrison, Zayas, Mulvihill, Baskan, & Meier, 1998). An intervention study using same-race peer mentors to discuss ACP with dialysis patients demonstrated a significant positive effect on Black patients but not on White patients. Positive outcomes included greater comfort in discussion, increased completion of advance directives, and enhanced feelings of well-being (Perry et al., 2005).

Cultural assimilation, as well as diversity, makes even basic assumptions about why people do and do

not create advance directives very difficult. When patients and healthcare professionals are from different ethnic backgrounds, the value systems that inform ACP and decision-making may conflict, often creating ethical and interpersonal tensions (Gao, Sun, Ko, Kwak, & Shen, 2015). Older Japanese American patients in the United States have been shown to prefer making their own decisions about forgoing life-sustaining measures, whereas older Japanese patients residing in Japan tend to defer decision-making to their physicians and families (Matsui, Braun, & Karel, 2008). Subtle themes that resonate with elder Japanese patients include feelings about being a burden to others, family obligations to support the dying person, and the overall utility of an advance directive as a means to reduce conflict without being intrusive (Bito et al., 2007). High religiosity, strong family decision-making history, and belief that the family should support the patient's wishes have been negatively correlated with advance directive creation in many cultural groups, including patients of Bosnian (Searight & Gafford, 2005), Asian Indian (Doorenbos & Nies, 2003), and Malaysian heritage (Htut, Shahrul, & Poi, 2007). Predictors of advance directive completion for multiethnic urban seniors include what investigators called "modifiable factors," such as an established relationship with a primary care physician and their doctor's willingness to initiate the ACP discussion, being knowledgeable about ACP, recognizing the family role in decision-making, and prior experience with decisions about mechanical ventilation (Morrison & Meier, 2004).

NURSES' ROLES IN ACP

All capable adult patients, regardless of their gender, religion, socioeconomic status, diagnosis, or prognosis, should be engaged in discussion about ACP and provided with information and assistance in creating advance directives. Rather than focusing on "The Conversation," these discussions should occur regularly as part of routine healthcare. Unlike interviews, they are most effective as patient-centered exchanges of information between patients and their care professionals.

Nurses have an essential role in assessing their patients' understanding of ACP and its importance at every age and stage of health. They can be crucial in reframing ACP as a way for responsible adults to control their healthcare future, rather than something reserved for the end of life. Providing accurate information about advance directives, the right to refuse as well as consent to treatment, palliative care, and hospice can counteract misinformation and apprehension about measures that permit rather than promote death. Oncology nurses tend to be more knowledgeable about advance directives than about the PSDA and the relevant laws in their respective states. They reported lacking confidence in their knowledge and ability to assist patients in creating advance directives (Jezewski et al., 2005). The ability to accurately distinguish treatment refusal and treatment withdrawal, assisted dying, and euthanasia was associated with being college educated, White, and having had prior experience as a healthcare agent for another person (Silveira, DiPiero, Gerrity, & Feudtner, 2000). They reported viewing their role as patient advocates, especially for adequate pain management at the end of life, despite knowing that it may hasten death.

Patients have reported that they complete advance directives to ease their family's financial and emotional burden and facilitate decision-making. They want to discuss ACP, including end-of-life care, but they expect their healthcare professionals to initiate these discussions. Indeed, ACP discussions between patients and their primary care physicians were found to be a statistically significant predictor of patient satisfaction with their primary medical doctors (Tierney et al., 2001). Community-dwelling older patients receiving care in a general medical clinic were more likely to create an advance directive when they had received ACP information by mail before their appointments and their physicians had received a reminder to discuss ACP. Patients in the control group, whose physicians had received only a reminder to document having asked their patients whether they had advance directives, were less likely to create directives (Heiman, Bates, Fairchild, Shaykevich, & Lehmann, 2004).

When medical residents caring for hospitalized older adults were surveyed about their attitude, skills, and knowledge regarding ACP, they were found to have incomplete, often inaccurate, understanding of patients' decision-making processes, which influenced their willingness to have ACP discussions (Gorman, Ahern, Wiseman, & Skrobik, 2005). Training in ACP not only improved the residents' knowledge of and comfort in discussing advance directives, but also positively influenced patients' interest in creating directives (Alderman, Nair, & Fox, 2008). Case managers reportedly vary in their knowledge about ACP, as well as their skills, response to family involvement and patient receptivity, and the ACP support they provide patients with (Black & Fauske, 2007). Physicians have found advance directives that address hospitalization and emergency treatment to be most useful, but they also report that these directives are not always available, especially

in emergency departments (Cohen-Mansfield & Lipson, 2008; Weinick, Wilcox, Park, Griffey, & Weissman, 2008).

A persistent myth, especially in minority populations, and one influenced by a history of abuse and denial of healthcare, is that an advance directive signals "do not treat," "withdraw life-sustaining measures," or, in some instances, "provide all interventions to keep me alive." Another pervasive belief is that, as soon as care professionals take possession of an advance directive, all its provisions, including discontinuing life-sustaining measures, will be implemented. This may explain why families will often acknowledge that the patient has an advance directive but not bring it to the care-providing facility until the end of life is near. Families, agents, and other surrogates should be helped to understand that the patient's preferences and instructions are applicable only in the indicated clinical circumstances.

Some patients erroneously believe that a lawyer is needed to execute an advance directive and that each state has only one specific advance directive document that must be used. In fact, state-approved directives may vary slightly, and individuals need only ensure that their directives are consistent with the approved model in their respective states. Absent an appointed healthcare agent or alternate, the default surrogate decision-maker is drawn from a state-approved hierarchy of family members authorized to serve as authorized healthcare surrogates. Typically, the list runs from those in closest relation to the individual to those more distantly related. This reflects the recognition in tradition and law that family plays a central role in making important decisions and the presumption that family is likely to know the individual's goals, values, and preferences. The reality in many cases is that families disagree or might be unaware of the patient's wishes. Nurses are in a position to identify potential family conflict and to act to mitigate the effects of misinformed or delayed treatment decisions.

The language of some advance directives can be confounding, especially for those with limited literacy. Randomized to a standard advance directive form (12th-grade reading level) or one that had been modified to address literacy needs (fifth-grade reading level with graphics), most English- and Spanish-speaking patients preferred the modified form, resulting in a greater number of completed advance directives in the experimental group (Sudore et al., 2007). Most community-dwelling older adults were found to understand the purposes of various treatments but understood less about potential outcomes, and vague terms, such as, *improvement* or *vegetable*, were idiosyncratically interpreted (Porensky & Carpenter, 2008).

ACP INTERVENTIONS AND STRATEGIES

One way for nurses to begin discussion about ACP when caring for older adults is to engage the patient and/or healthcare agent in discussion about the quality of life valued by the patient, the importance of preserving or prolonging life, and how the patient's illness (and, ultimately, death) will affect others emotionally, financially, and in other significant ways. Some patients might want to focus on the quality of living, whereas others, nearing the end of life, may target the quality of their dying. Some might want to talk about where and from whom they prefer to receive care, including at the end of life. Some may fear their dependence on others, whereas some may find that inevitability more tolerable. Those considering hospice may specify a preference for receiving those services at home or an inpatient facility. Patients, families, agents, and others important to the patient might need encouragement and support in expressing what they each fear most and what will be important as death approaches.

Communication About ACP

Under state laws, The Joint Commission standards, and patient bills of rights, patients have the right to have a qualified interpreter translate and transmit their discussions with their healthcare professionals. The interpreter may be the only person who recognizes subtleties in language, signaling that patients and their families may have a totally different understanding than the care team of words like *health, illness, improvement,* and *decline*; what a treatment is expected to accomplish; and how dying and death are acknowledged clinically and culturally. If ACP or advance directives are associated with end of life, they are likely to be resisted as topics of conversation. If telling or contemplating "bad news" is culturally prohibited, it may be difficult to discuss end-of-life planning. Sensitive terms and concepts are not value neutral; nuance and syntax can make all the difference. Although a translator may provide literal word-for-word translation, an interpreter communicates fact and nuance, explanation and rationale.

Families should not be responsible for communicating between or among languages. Deliberately or inadvertently, facts may be omitted, shaded, or emphasized to protect or influence patient decisions. If it is difficult to translate medical terms and concepts from English to English (i.e., medical jargon to lay language), it is infinitely harder to do it while bridging language and cultural differences. Families should be reassured that their most important job is providing support and advice, which is why The Joint Commission standards and hospital policies require trained interpreters when patients are more comfortable in another language.

CASE STUDY 17.1

Mrs. R is an 88-year-old woman, widowed for 22 years, who lived alone with little family contact before her admission to the nursing home 2 years ago. At that time, after consultation with her physician, she consented to an out-of-hospital DNR order. She had several comorbidities, including severe chronic obstructive pulmonary disease (COPD) and chronic renal failure (blood urea nitrogen [BUN] = 58); mild to moderate dementia (Mini-Mental State Exam score of 20/30); mild depression (by Geriatric Depression Scale [GDS] score); and had lost 22 pounds, putting her below her ideal body weight (IBW).

Mrs. R now requires one-person assistance with all personal care needs and bruises easily. Her prognosis is poor, and the goals of care are symptom management with a focus on comfort. She has had multiple hospitalizations for pneumonia, most recently 10 weeks ago, after which she had further weight loss and developed a grade II pressure ulcer on her right hip. She is receiving the standard meds for COPD, anxiety, sleeping problems, and appetite stimulation. Recent discussion about her quality of life by the interdisciplinary team noted that she no longer attends parties, Sabbath candle lighting, or discussion groups, all of which she used to enjoy. Beginning 6 months ago, Mrs. R has seemed unable to make decisions about her healthcare, and her decisional capacity appears to fluctuate in relation to her O_2 saturation.

Five years ago, Mrs. R executed a living will that stipulated "aggressive comfort care, including ventilatory support" in the event she experienced respiratory distress, but no documentation addresses her preferences about being hospitalized if she has another COPD exacerbation, which is to be expected given the trajectory of the disease.

Two days ago, Mrs. R began to have stertorous breathing, a nonproductive cough, and episodes of diaphoresis. She appears exhausted, her solid food intake is minimal, and she becomes very dyspneic when taking small sips of fluid. A chest x-ray was equivocal and will be repeated today. Her current vital signs are: temperature: 100.8° F, pulse oximetry: 82%; pulse and blood pressure within normal limits. The nursing home has the resources to provide oxygen, intravenous (IV) fluids, and antibiotics.

Discussion

This case is complicated by the instructions in the living will, which illustrate the weaknesses of the instruction directive. These instructions were written before Mrs. R's disease trajectory had reached a terminal state; they may not be applicable to her clinical condition or in her best interest because disease-directed measures are likely to be more burdensome than beneficial. How and by whom will the balance of benefits and burdens of hospitalization be assessed against remaining in the nursing home for palliative care? What was Mrs. R envisioning when she created her living will, and what would she decide if she could do so now?

The nursing assistants, who have been very involved in Mrs. R's care, believe that she should be hospitalized, based on their knowledge of and affection for her. The professional staff argue from prognostications about the burdens and risks of ventilatory support, especially if it becomes permanent, as well as the likely multiple skin breakdowns that will occur if she is hospitalized. The standard of substituted judgment used by surrogates is not available because the living will is silent about her goals, values, and desired quality of life, and no close or trusted person is available to provide insight into what she would decide in the current situation. The best interest standard asks what a surrogate thinks would promote Mrs. R's well-being. At this point, the benefit–burden risk assessment becomes a critical part of the discussion.

However, Mrs. R's living will does not provide the necessary information or insight to confidently make decisions on her behalf. It stipulates "aggressive comfort care," without explaining what that meant to her. It mentions "ventilatory support" in the event of respiratory distress but does not specify whether she would find it tolerable as a long-term intervention or agree to it only as a temporary measure.

Mrs. R would have been much better served had she completed an appointment directive, authorizing a healthcare agent and alternate to make these decisions in real time after consultation with her physicians. Understanding her goals, values, and preferences, her agent would have been able to address the following questions: What is the potential for improvement or return to baseline? Would intubation prolong a life she would find acceptable or merely prolong her dying? Would intubation and hospitalization be responding to

(*continued*)

CASE STUDY 17.1 (*continued*)

Mrs. R's needs or institutional anxiety? To what extent can the facility provide a quality of life with comfort and safety that might meet Mrs. R's interests at this time, even if this life quality were different from that which the staff previously enjoyed with her? In what way would hospitalization benefit Mrs. R and how might it harm her? What role might the administration of morphine play in relieving symptoms of air hunger, even though it risks shortening life? Mrs. R's agent would be authorized to make decisions that her instructions do not address or to even depart from instructions that do not apply to her current medical condition.

After discussion with an ethics consultant during an interdisciplinary meeting that included Mrs. R's family, the nursing home medical and nursing directors, the nursing assistants responsible for her care, and the director of social work who knows her well, a consensus decision was made not to hospitalize Mrs. R. The decision was guided by the clinical facts, the nursing home's ability to provide the necessary resources, Mrs. R's stated wishes for "aggressive comfort care," the likely downward trajectory of COPD, and reflection about Mrs. R's deteriorated condition after each hospitalization. Mechanical ventilation was determined likely to be more of a burden than a benefit at this point in her illness, one that would be inconsistent with a focus on comfort, which could be provided in familiar surroundings with judicious use of medication and intensive nursing care.

This case illustrates that ACP is not a static one-time event. Whether an individual's wishes and preferences are expressed in an advance directive or verbally, they must be documented and periodically reviewed whenever there is a change of clinical condition, life style, healthcare agent, goals, values, and/or preferences. The ability to reach consensus through discussion that addressed the concerns of all caring professionals while keeping the focus resident centered was key to arriving at a clinically and ethically principled, goal-driven plan of care.

SUMMARY

Discussions about ACP should occur over time, at every age and stage of health. Having such discussions shortly after hospitalization for an acute event can refocus on the goals of care and indicate where care can most effectively be provided (Happ et al., 2002). Rather than choosing specific interventions or technologies of life-sustaining treatment, nurses can help refocus the discussion with patients or residents, families, and agents on the health goals, values, and preferences; the characteristics of an acceptable quality of life, including comfort and function; and valued life activities. Among the things that nurses do better than anyone else is help individuals, their families, and other surrogates create a decision-making framework that enables care planning that most authentically and effectively meets patient/resident-centered needs and interests.

An environment conducive to meaningful ACP discussions requires appropriate time and location. An emergency admission is not an ideal time for thoughtful deliberation about these important matters. Distribution of advance directive forms without discussion, commonly done in hospital admission offices at the time of an elective admission, does not provide sufficient information or assistance in completing them, which is why nursing homes tend to wait 2 weeks before discussing advance directives with new residents. Many studies report that the most effective intervention for ACP is verbal information exchanged over several interactive sessions with healthcare professionals (Bravo, Dubois, & Wagneur, 2008; Tamayo-Velázquez et al., 2010), including the opportunity to ask questions (Jezewski, Meeker, Sessanna, & Finnell, 2007). Passive use of printed material and lack of opportunity to receive assistance in understanding directives do not promote their creation (Ramsaroop, Reid, & Adelman, 2007). Ultimately, however, the most effective way to encourage ACP is to reframe the perceptions of healthcare professionals and the lay public, disconnecting ACP from end of life and making it an integral part of routine healthcare throughout the entire therapeutic continuum.

NURSING STANDARD OF PRACTICE

Protocol 17.1: Advance Directives

I. GUIDING PRINCIPLES

1. All decisionally capable persons have the right to decide, in consultation with their healthcare providers, what will be done with their bodies.
2. All individuals are presumed to have decision-making capacity unless and until they are determined to lack this capacity.
3. All adults who can participate in a conversation, either verbally or through alternate means of communication, should be offered the opportunity to engage in ACP and document their healthcare goals and preferences.
4. Healthcare professionals can promote enhanced quality of life for older patients and residents, including care at the end of life, by encouraging ACP and the creation of advance directives.

II. BACKGROUND

A. Education about ACP and advance directives
   1. Patients clearly indicate that they want information about advance directives.
   2. Patients indicate that they want nurses and physicians to engage them in discussions about ACP and advance directives.
   3. Despite indications of interest in ACP, only 19% to 36% of Americans have completed an advance directive.
   4. Documentation of treatment preferences is insufficient unless individuals discuss their health goals and values with their healthcare providers, families, and appointed healthcare agents.

B. Advance directives
   1. Enable capable individuals to designate and legally appoint trusted persons—a healthcare agent/representative/proxy/POA and one or more alternates—who will be authorized to make healthcare decisions on behalf of the individuals during any period of temporary or permanent decisional incapacity.
   2. Ensure legal mechanisms that enable capable individuals to articulate and document their health goals and preferences regarding the kind of medical care they would or would not want in specified clinical circumstances if they lack the capacity to make or communicate their decisions.
   3. Provide guidance for healthcare professionals, families, and surrogate decision-makers about healthcare decisions that reflect an individual's goals, values, and preferences.
   4. Provide immunity from civil and criminal liability for healthcare professionals, families, and appointed healthcare agents who follow in good faith the provisions of advance directives.

C. Types of advance directives
   1. An *appointment directive* (also known as a healthcare proxy or DPOAHC) enables a decisionally capable individual to designate and legally appoint trusted persons—a healthcare agent/representative/proxy/POA and one or more alternates—who will be authorized to make healthcare decisions on behalf of the individual during any period of temporary or permanent decisional incapacity. An appointment directive enables the agent or alternate to confer with the care team in real time and respond to clinical conditions that are changing or were unanticipated by the now-incapacitated individual. Because the agent and alternate will have the same decisional authority as the individual to start, stop, or forgo treatment, the appointment directive is the preferred type of advance directive.
   2. An *instruction directive* (also known as a living will) enables a decisionally capable individual to provide instructions about medical treatment that would or would not be acceptable in specified clinical circumstances, typically at the end of life. The provisions of a living will are limited to what the individual *thought* that he or she *might want* in clinical circumstances that *have not yet occurred.*

(*continued*)

Protocol 17.1: Advance Directives (*continued*)

D. An instructional or medical directive is intended to compensate for the weaknesses of living wills by posing hypothetical medical scenarios and asking the individual to indicate specific medical interventions that would or would not be acceptable. They suffer from the same limitations as living wills.
E. Verbal advance directives are honored in some states if there is clear and consistent evidence of the capable individual's preferences for care in current specific clinical circumstances. Legal rules governing oral advance directives vary by state.

III. ASSESSMENT PARAMETERS

A. All decisionally capable adults, regardless of age or health status, should be engaged in discussion about ACP and asked whether they have created advance directives. If they have an advance directive, a copy should be requested for the medical record. If they have not created an advance directive, information and assistance should be offered.
B. Discussions about ACP and advance directives should be an integral part of routine healthcare throughout the arc of the healthcare continuum.
C. Discussions about advance directives should be conducted in the patient's preferred language to promote the exchange of information, questions, and answers.
D. Discussions should be conducted with sensitivity to the individual's health status, capacity to understand and process information, and degree of interest in participating in care planning.
E. Because capacity is decision specific rather than global, individuals who have been determined to lack the capacity to make specific decisions may still have the capacity to make less complex decisions or to designate an agent and alternate(s) to make healthcare decisions on their behalf.
F. When an advance directive has been completed:
    1. A copy of the document should be accessible in real time in the patient's current medical record.
    2. The primary care doctor should have a copy of the directive and be familiar with its provisions.
    3. The appointed healthcare agent and alternate agent(s) should have copies of the document and be familiar with its provisions.
    4. The directive should be reviewed periodically by the individual in consultation with the primary care doctor to determine whether it reflects the patient's current health status and preferences.

IV. CARE STRATEGIES

A. Nurses should assist patients/residents, appointed agents, and families in addressing ACP, including end-of-life care issues.
B. Patients should be encouraged to discuss their health goals, values, preferences, and concerns with their primary care physician, family, or other trusted surrogates.
C. In some instances, patients/residents may be more willing to discuss their health goals, values, preferences, and concerns with a nurse or clergy than a family member or other surrogate, and should be supported in doing so.
D. Patients should be assessed for their capacity to understand and process the provided information about their health status, prognosis, and treatment options.
E. Nurses must be mindful of and sensitive to the factors of race, culture, ethnicity, and religion that can influence the healthcare decision-making process. The fact that patients from non-Western cultures may not subscribe to Western notions of autonomy does not mean that these patients may not want to talk about their treatment preferences or concerns, or that they would not have conversations with their families about these matters.
F. Patients'/residents' decisions not to complete an advance directive must be respected, with the understanding that these decisions will be revisited at a later time. They should be reassured that they will not be abandoned or receive substandard care if they elect not to formulate an advance directive at this time.

(*continued*)

Protocol 17.1: Advance Directives (*continued*)

G. Nurses should be aware of the institution's mechanisms for resolving conflicts between and among the patient/resident, family members, and the appointed healthcare agent or alternate, and should assist the parties in using these resources to achieve resolution.
H. Nurses should be aware of the professional(s) responsible for managing introduction, explanation, assistance in creating, and storage of advance directives in their institution. These responsibilities may include checking with the patient/resident to ensure that a copy of the advance directive has been given to the primary healthcare provider(s), the appointed agent and alternate(s), and that the patient/resident is carrying a wallet-size card that includes advance directive and agent/alternate contact information.

V. EVALUATION OF EXPECTED OUTCOMES

To determine whether implementation of this protocol has influenced the type, as well as the number, of advance directives created, changes should be measurable and contribute to the facility's ongoing quality-improvement program. Special attention should be paid to the following:

A. Documentation in medical records of:
   1. Whether patients have been engaged in discussion about ACP and advance directives
   2. What was learned during the discussions about patients' health goals, values, preferences, and concerns
   3. Whether patients have completed advance directives
B. Presence of advance directives in patients' medical records, including
   1. Whether copies of patients' advance directives are in their medical records
   2. Whether the directives are easily accessible for reference by the care team
C. The use of trained or certified interpreters to assist staff in ACP discussions with patients whose primary language is not English
D. The number of requests by nurses for ethics committee consultation regarding questions, concerns, or conflicts related to advance directives

ABBREVIATIONS

ACP	Advance care planning
DNR	Do not resuscitate
DPOAHC	Durable power of attorney for healthcare
POA	Power of attorney

ACKNOWLEDGMENT

The authors acknowledge the contributions of Linda Farber Post and Ethel Mitty, PhD, RN, whose knowledge, wisdom, and collaboration were reflected in the previous iterations of this chapter.

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the functional trajectory of the hospitalized older adult.
2. Identify risk factors for functional decline.
3. Describe the influence of the care environment on physical function.
4. Discuss systemic interventions to optimize physical function of hospitalized older adults.

OVERVIEW

As described in Chapter 10, Assessment of Physical Function in the Older Adult, functional decline is a common complication in hospitalized older adults, even in those with good baseline function (Gill, Allore, Gahbauer, & Murphy, 2010), and frequently begins prior to hospitalization (Boltz, Chippendale, Lee, & Trotta, 2018). Loss of physical function is associated with poor long-term outcomes, including increased likelihood of being discharged from a hospital to a nursing home setting (Fortinsky, Covinsky, Palmer, & Landefeld, 1999), increased morbidity and mortality (Rozzini et al., 2005), increased rehabilitation costs, and decreased long-term functional recovery (Boyd, Xue, Guralik, & Fried, 2005; Boyd et al., 2008; Volpato et al., 2007). The immobility associated with functional decline results in infections, pressure ulcers, falls, and nonelective rehospitalizations (Gill, Allore, & Guo, 2004).

The promotion of function is a basic gerontological tenet, and functional recovery is perceived by older adults as a quality outcome of hospitalization (Boltz, Capezuti, Shabbat, & Hall, 2010). Moreover, older adults and their families have the expectation that a hospital stay and the associated bed rest will not result in functional decline but instead promote recovery and the resumption of normal roles and activities post hospitalization. Although the acute care setting, with its focus on correcting the admitting medical problem, typically prioritizes nursing tasks, such as medication administration, coordination of care, and documentation over the promotion of function as a clinical outcome, there is growing awareness of the need to attend to the functional status of the hospitalized older adult (Nolan & Thomas, 2008; Resnick, Galik, Wells, Boltz, & Holtzman, 2015). This chapter addresses the trajectory of change in physical function during the acute care stay, the factors associated with functional decline, and function-promoting

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

interventions that can potentially modify these factors. Finally, a clinical practice protocol to guide a unit-level approach to function-focused care (FFC; Protocol 18.1: Function-Focused Care Interventions) is provided.

PHYSICAL FUNCTION AS A CLINICAL MEASURE

Functional decline may result from the acute illness and can begin from preadmission and continue after discharge. In a seminal study, Covinsky et al. (2003) evaluated the changes in the performance of activities of daily living (ADL) prior to and after hospitalization of older adults with medical illness. More than one third declined in ADL function between baseline (2 weeks before admission) and discharge. This included the 23% of patients who declined between baseline and admission, and failed to recover to baseline function between admission and discharge, and the 12% of patients who did not decline between baseline and admission but declined between hospital admission and discharge. Older adults aged 85 years and older comprised the age cohort that demonstrated the most functional loss, with rates exceeding 50%.

In their examination of the functional trajectory of hospitalized older adults, Wakefield and Holman (2007) also assessed function at baseline, as well as on admission and day 4. The largest change in functional status was a decline in ADL from baseline to the time of admission; ADL did not return to baseline during the first 4 days in the hospital. The older adults whose ADL scores declined during hospitalization (regardless of the baseline status) were more likely than others to die within 3 months of discharge.

The results of these studies demonstrate that ADL status is unstable in a large percentage of older adults during an acute illness (Covinsky, Pierluissi, & Johnston, 2011). Consequently, Covinsky et al. (2003) suggest that an older adult's functional trajectory is a critical "vital sign" and an important prognostic marker and indicator to guide care delivery and transitional care. Baseline function may serve as a useful benchmark when developing discharge goals. Older adults who have sustained loss of ADL function prior to admission would, ideally, have rehabilitation as a goal of their hospital care. For those patients who have acquired ADL disability from admission to discharge, aggressive postacute rehabilitation plans could be mobilized with the goal of promoting return to baseline function.

PATIENT RISK FACTORS FOR FUNCTIONAL DECLINE

Intrinsic vulnerabilities to functional decline include prehospitalization functional status (McCusker, Kakuma, & Abrahamowicz, 2002; Zisberg et al., 2011), the presence of two or more comorbidities, and having had a hospitalization or emergency department visit in the previous 12 months (Covinsky et al., 2011; McCusker et al., 2002). Symptoms of depression both before and during hospitalization have also been associated with dependence in basic ADL at discharge and 30 and 90 days after discharge (Covinsky, Fortinsky, Palmer, Kresevic, & Landefeld, 1997). Cognitive impairment, including delirium, increases the risk of functional decline in the older adults during and after hospitalization (Boltz, Resnick, Capezuti, Shuluk, & Secic, 2012; Inouye, Schlesinger, & Lydon, 1999; McCusker et al., 2002).

The aggregate number of geriatric conditions present at hospital admission determines a patient's individual risk of functional deterioration (Buurman, van Munster, Korevaar, de Haan, & de Rooij, 2011). Polypharmacy, fall risk, use of an indwelling urinary catheter, urinary incontinence, vision impairment, and hearing loss (Buurman et al., 2012) are associated with a high risk of functional decline that persists 12 months after hospitalization. The patient's fear of falling (Boltz, Resnick, Capezuti, & Shuluk, 2014), self-efficacy, outcome expectations (McAuley et al., 2006), and views on physical activity during hospitalization (Boltz, Capezuti, & Shabbat, 2011; Brown et al., 2007) influence the level of engagement in physical activity and mobility in older adults in general and thus may influence acute care functional outcomes.

THE CARE ENVIRONMENT AND FUNCTION

A social ecological perspective assumes that the physical, social, and organizational environments contribute to patient outcomes, including functional measures (Galik, 2010). The hospital environment, with its emphasis on biomedical interventions for acute medical and surgical problems, is challenged to "fit" the complex physical, social, and psychological circumstances that predispose the hospitalized older adult to functional decline. Parke and Chappell (2010) recommend that the older adult–hospital environment fit be viewed through four dimensions: care processes, social climate, policy and procedure, and environment.

Hospital Care Processes

Hospitalization is associated with significantly greater loss of total, lean, and fat mass as well as strength in older persons. These effects appear particularly important in persons hospitalized for 8 days or more per year (Alley et al., 2010). Hospitalization itself may also pose risks for functional decline because of the deleterious effects of bed rest and restricted activity (Gill, Allore, Holford, & Guo, 2004).

Bed rest results in loss of muscle strength and lean muscle mass (Kortebein, Ferrando, Lombeida, Wolfe, & Evans, 2007), decreased aerobic capacity (Kortebein et al., 2008), diminished pulmonary ventilation, altered sensory awareness, reduced appetite and thirst, and decreased plasma volume (Creditor, 1993; Harper & Lyles, 1988; Hoenig & Rubenstein, 1999). Brown, Redden, Flood, and Allman (2009) describe bed rest and low mobility as an "underrecognized epidemic." In their study of hospitalized older veterans, they used accelerometers to measure activity level. Despite the fact that the majority were able to walk independently (78%), 83% of the measured hospital stay was spent lying in bed.

Another study (Brown, Friedkin, & Inouye, 2004) that evaluated the outcomes associated with mobility found that bed rest in older adults was ordered at some point during hospitalization in 33% of the patients. Almost 60% of the observations indicated no documented medical reason for the bed rest. Physicians' orders for bed rest were present on the date of bed rest for only 92 (52%) of the 176 observations. Low mobility (defined as having an average mobility level of bed rest or bed to chair for the entire hospitalization) was compared to high mobility (ambulation two or more times with partial or no assistance, on average). The low mobility group had a statistically significant higher rate of ADL decline, new institutionalization, and death. Similarly, Zisberg et al. (2011) found that low versus high in-hospital mobility was associated with worse functional status at discharge and at 1-month follow-up, even in older adults who were functionally stable prior to admission.

Doherty-King, Yoon, Pecanac, Brown, and Mahoney (2014) shadowed RNs for two to three 8-hour periods using handheld computer tablets to collect data on frequency and duration of mobility events (standing, transferring, walking to and from the patient bathroom, walking in the patient room, and walking in the hallway) that occurred in the nurse's presence. They found that nurses infrequently initiated mobility events for hospitalized older patients and most often engaged patients in low-level activity (standing and transferring). Other research indicated that illness severity and reason for admission did not explain low levels of mobility, measured by a step-activity monitor (Fisher et al., 2011). A recent study using accelerometry indicated that low mobility often persists; 64% of patients demonstrated no change in the first 2 weeks post discharge, and increase in ambulation frequency was positively correlated with higher Katz Activities of Daily Living Index scores, gait speed, and lower fear of falls score (King et al., 2019).

Care processes associated with immobility include physical restraints and "tethering devices," such as catheters, intravenous lines, and medication, which contribute to delirium and/or cause sedation (Boltz, Resnick, Capezuti, Shabbat, & Secic, 2011; Brown, Roth, Peel, & Allman, 2006; Resnick et al., 2016). Additionally, there is a tendency for staff to perform ADL for patients who could participate or do it for themselves, placing older adults at risk for loss of self-care ability (Boltz, Resnick, et al., 2011). This "doing for" as opposed to promoting functional independence is often associated with a lack of understanding of the patient's underlying capability (Resnick, Galik, Boltz, & Pretzer-Aboff, 2011). Interprofessional rounds support a functional approach, with the goal of preventing functional decline and discharging the older adult to the least restrictive setting. Key elements to be addressed include functional assessment (baseline, admission, current ADL status, and physical capability), alternatives to the use of potentially restrictive devices and agents, and a plan for progressive mobility and engagement in ADL (Boltz, Resnick, Chippendale, & Galvin, 2014). Additionally, protocols that support delirium prevention and abatement, and optimize nutrition, particularly regarding protein intake, while minimizing adverse effects of selected procedures (e.g., urinary catheterization) and medications (e.g., sedative–hypnotic agents) contribute to positive functional outcomes (Kleinpell, 2007).

Social Climate

Leadership commitment to rehabilitative values is essential to support a social climate conducive to the promotion of function (Boltz, Capezuti, et al., 2011; King & Bowers, 2013). Older adults have identified that respectful, encouraging communication and engagement in decision-making is important to facilitating independence (Boltz et al., 2010; Jacelon, 2004). Staff education that addresses the physiology, manifestations, and prevention of hospital-acquired deconditioning, assessment of physical capability, rehabilitative techniques, use of adaptive equipment, minimizing risk of sarcopenia, interprofessional collaboration, and communication that motivates are required to support a function-promoting philosophy (Boltz, Capezuti, et al., 2011; Gillis, MacDonald, & MacIsaac, 2008; Resnick, Galik, Boltz, et al., 2011). Nursing staff have also described the need for well-defined roles, including areas of accountability for follow-through for function-promoting activities (Boltz, Capezuti, et al., 2011; King & Bowers, 2011). Clear communication of patient needs among staff and dissemination of data (e.g., compliance with treatment plans and functional outcomes) also support these activities (Resnick et al., 2015).

Policies and Procedures

To foster function-promoting care, policies are needed that clearly define staff roles in assessing physical function and cognition and that implement identified interventions. Other supporting policies address identification and storage of sensory devices (e.g., glasses, hearing aids/amplifiers) and mobility and other assistive devices (Boltz, Capezuti, et al., 2011; Boltz, Resnick, et al., 2011). Indicative of the low priority placed on mobility promotion is the common process of restricting the patients' ability to walk to tests and procedures within the hospital.

Environment

Acute care environments directly impact patient function and physical activity. The bed is often the only accessible furniture in the room, and the height of toilets, beds, and available chairs does not always fall within the range in which transfers and function are optimized (Capezuti et al., 2008). Accessible functional seating and safe walking areas with relevant destination areas promote functional mobility. Adequate lighting, nonglare flooring, door levers, and handrails (including in the patient room) are basic requirements to promote safe mobility (Betrabet Gulwadi & Calkins, 2008; Ulrich et al., 2008). Environmental enhancements to promote orientation include large-print calendars and clocks (Kleinpell, 2007) and control of ambient noise levels, especially in critical care units (Gabo, 2003).

INTERVENTIONS TO PROMOTE PHYSICAL FUNCTION

Support for Cognition

Cognition and physical function are closely linked in older adults. The ability to engage in ADL and physical activity requires varying types and degrees of cognitive capability, including memory, executive function, visual–spatial ability, and praxis. Therefore, an appraisal of the older adult's cognition (baseline, admission, and ongoing) is an essential activity associated with promoting physical function (see Chapter 9, Assessing Cognitive Function in the Older Adult) in order to develop, implement, and evaluate a plan to promote the maximum physical functioning (Coelho, Santos-Galduroz, Gobbi, & Stella, 2009; Yu, Kolanowski, Strumpf, & Eslinger, 2006).

Interventions to prevent, detect, and manage delirium are associated with improved cognition and are thus integral components of a plan to prevent functional decline (Foreman, Wakefield, Culp, & Milisen, 2001). Liberal visiting hours and familiar items brought in from home (e.g., photos, blankets) provide meaningful sensory input, and, along with control of excessive noise and attention to sleep hygiene, enhance function-promoting interventions (Landefeld, Palmer, Kresevic, Fortinsky, & Kowal, 1995). Diversional activities, such as TV, movies, and word games, are associated with "keeping the mind active" and engagement in self-care and physical activity (Boltz et al., 2010). For patients with cognitive challenges, including dementia, activity kits that include tactile, auditory, and visual items enhance cognitive integration, perceptual processing, and neuromuscular strength as well as providing solace and an opportunity for emotional expression and relief from boredom. Activity kits can include a wide range of items such as audiotapes and nontoxic art supplies. In addition, items such as pieces of textured fabric, clothes to fold, tools, and key-and-lock boards are included for the person with more advanced dementia (McCabe, 2019; Glantz & Richman, 2007). For more information, see Chapter 20, Delirium: Prevention, Early Recognition, and Treatment.

Older adults with cognitive impairment can benefit from function-promoting interventions with demonstrated improvements in physical and cognitive function (Boltz, Chippendale, Resnick, & Galvin, 2015b). An understanding of the person's values, past experiences, and relationships supports meaningful communication to motivate them, along with the use of humor and verbal cues (Galik, Resnick, & Pretzer-Aboff, 2009). In addition, teamwork with other nursing staff, rehabilitative staff, medical providers, and families was considered a key component in facilitating self-care and physical activity (Boltz, Chippendale, Resnick, & Galvin, 2015a; Boltz, Resnick, Chippendale, et al., 2014).

Adapted communication techniques are necessary to accommodate receptive difficulties associated with cognitive impairment, including dementia. This might include the use of external amplification for someone who may not have hearing aids or may not be able to use the hearing aids as well as adapting communication techniques with the patient. The ability to participate in ADLs is often more preserved than clinicians believe, as activities such as washing the face, brushing one's teeth, and walking rely on psychomotor memory, which is preserved even in those with moderate to severe cognitive impairment. Communicating with short simple verbal requests and visual cues, and modeling the activity, can be helpful in promoting independence in ADL (e.g., assisting the person to the sink, setting the person up to brush his or her teeth, handing the person a toothbrush, and modeling the behavior; Resnick, Galik, Boltz, et al., 2011).

Physical Therapy and Exercise

Interventions such as physical therapy and individualized, targeted exercise programs as soon as possible post admission have all been tested as ways in which physical activity could be increased and deconditioning and functional decline in hospitalized older adults prevented. A single-blinded randomized controlled trial was conducted in a tertiary metropolitan hospital involving 180 acute general medical patients aged 65 years or older (Jones et al., 2006). In addition to usual physiotherapy care, the intervention group performed an exercise program for 30 minutes, twice daily, with supervision and assistance provided by an allied health assistant (AHA). In older adults with low admission ADL scores (modified Barthel Index score ≤48), there was improvement in function among individuals exposed to the exercise interventions versus those who were not. Similarly, an individually tailored exercise program to maintain functional mobility, prescribed and progressed by a physical therapist, and supervised by an AHA, provided in addition to usual physiotherapy care, was associated with reduced likelihood of referral for nursing home admissions (Nolan & Thomas, 2008). Despite the known benefit of staying engaged in function and physical activity when hospitalized, a 2007 Cochrane review (de Morton, Keating, & Jeffs, 2007) concluded that, in general, patient participation in these programs has been poor. Challenges to feasibility and implementation of these interventions include competing care demands (e.g., test schedules), illness severity, short hospital stays, a general unwillingness of patients to consent to or actively participate in exercise interventions, and a persistent belief among patients that bed rest will assure recovery (Brown, Peel, Bamman, & Allman, 2006; de Morton, Keating, Berlowitz, Jackson, & Lim, 2007; de Morton et al., 2007; Resnick, Wells, Brotemarkle, & Payne, 2014).

Functional Mobility Programs

Among the most common forms of physical activity encouraged in acute care settings are functional mobility programs. Mobility is conceptualized as a continuum progressing from bedbound to independent walking (Callen, Mahoney, Wells, Enloe, & Hughes, 2004). The benefits of interventions aimed at promoting functional mobility have recently received growing attention. A literature review conducted by Kalisch, Soohee, and Dabney (2013) identified benefits of mobility programs in four areas: (a) physical outcomes (less delirium, pain, urinary discomfort, difficulty voiding, urinary tract infection, deep vein thrombosis, fatigue, and pneumonia, as well as increased walking and ADL performance, and ventilator-free days), (b) psychological outcomes (less depression, anxiety, and symptom distress, as well as increased comfort and satisfaction), (c) social outcomes (improved quality of life and independence), and (d) organizational outcomes (decreased length of stay, mortality, and cost).

Tucker, Molsberger, and Clark (2004) demonstrated the feasibility of a "Walking for Wellness" program that consisted of a patient education program, a screening process to identify patients who would benefit from physical therapy, and daily walking assistance from cross-trained transportation staff. Walking opportunities included "walking trails" marked inside the hospital, with markers placed every 10 feet at the baseboard of the hallways providing a measure of walking distance as well as a visual incentive for patients walking in the halls. Unless otherwise indicated by the medical provider, the goal for participants was to walk in the hallways two to three times a day with trained escorts, nursing staff, family, or friends. Weitzel and Robinson (2004) developed an educational program for nursing assistants on a medical unit that emphasized promoting the functional status of hospitalized elders. Content included therapeutic communication, promotion of functional mobility, skin care, and eating/feeding problems. Discharge destination (home or nursing home) and length of stay were compared for patients before and after implementation. There was a significant reduction in the length of stay (2.4 days) and an increase in the percentage of patients discharged to the home setting.

The positive association between mobility and shorter lengths of stay was also supported in an acute care for elderly (ACE) unit, where ambulation was measured by a step monitor (Fisher et al., 2011). Patients on the ACE unit who had shorter stays tended to ambulate more on the first complete day of hospitalization and had a markedly greater increase in mobility on the second day than patients with longer lengths of stay.

To address motivational issues, Mudge, Giebel, and Cutler (2008) evaluated a functional mobility program enhanced with cognitive interventions. This research team used an individualized, graduated exercise and mobility program with an activity diary, progressive encouragement of functional independence by nursing staff and other members of the multidisciplinary team, and cognitive stimulation sessions in older adults aged 70 years and older on a medical unit. The intervention group had greater improvement in functional status than the control group, with a median modified Barthel Index improvement of 8.5 versus 3.5 points ($p = .03$). In the intervention group, there was a reduction in delirium (19.4% vs. 35.5%, $p = .04$) and a trend toward reduced falls (4.8% vs. 11.3%, $p = .19$; Mudge et al., 2008).

In patients recovering from hip surgery, functional mobility programs are enhanced with measures to prevent postoperative complications. Siu, Penrod, et al. (2006) and Siu, Boockvar, et al. (2006) found that positive processes related to mobilization (including time from admission to surgery, mobilization to and beyond the chair, use of anticoagulants and prophylactic antibiotics, pain control, physical therapy, catheter and restraint use, and active clinical issues) were associated with improved locomotion and self-care at 2 months post discharge. Patients who experienced no hospital complications and no readmissions retained benefits in locomotion at 6 months. Olson and Karlsson (2007) demonstrated that interventions focused on skin care, pain control, and progressive ambulation yielded improved functional discharge outcomes. See Chapter 40, Care of the Older Adult With Fragility Hip Fracture.

Critical Care Initiatives to Prevent Functional Decline

The geriatric imperative to support physical function has also been recognized in critical care, and studies are emerging that examine mobility promotion in the critically ill patient, including older adults. A study conducted in a respiratory intensive care unit (RICU) examined the feasibility of early mobility as well as its safety in six activity-related adverse events: fall to knees, tube removal, systolic blood pressure greater than 200 mmHg, systolic blood pressure less than 90 mmHg, oxygen desaturation less than 80%, and extubation. There were less than 1% activity-related adverse events; the majority of survivors (69%) were able to ambulate farther than 100 feet at RICU discharges (Bailey et al., 2007).

A retrospective cohort study of an interdisciplinary quality-improvement program showed positive results of an early mobility program implemented in a Trauma and Burns Intensive Care Unit. Pre- and postpatient data from the trauma registry showed a decrease in airway, pulmonary, and vascular complications (including pneumonia and deep vein thrombosis) after the early mobility program (Clark, Lowman, Griffin, Matthews, & Reiff, 2013). Another study, led by physical therapists, demonstrated, in a randomized controlled trial, that a daily exercise session using a bedside cycle ergometer in critically ill patients improved 6-minute walking distance, isometric quadriceps force, and the subjective feeling of functional well-being at hospital discharge (Burtin et al., 2009).

Nurse-led mobility protocols have increased the rate of ambulation of patients in critical care units. A multidisciplinary team developed and implemented a mobility order set with an embedded algorithm to guide nursing assessment of mobility potential. Based on the assessments, the protocol empowers the nurse to consult physical therapists or occupational therapists when appropriate. Daily ambulation status reports were reviewed each morning to determine each patient's activity level (Drolet et al., 2013). Similarly, a mobility team (critical care nurse, nursing assistant, physical therapist) in a medical intensive care unit initiated a mobility protocol for patients with acute respiratory failure. The protocol consisted of progressive mobility interventions ranging from passive range of motion for unconscious patients, to active, assistive, and active range-of-motion exercises, to functional activities such as transfer to edge of bed; safe transfers to and from bed, chair, or commode; seated balance activities; pregait standing activities (forward and lateral weight shifting, marching in place); and ambulation. As compared to usual care (passive range of motion only), protocol patients were out of bed earlier (5 vs. 11 days, $p \leq .001$), had therapy initiated more frequently in the intensive care unit (91% vs. 13%, $p \leq .001$), and had similar low complication rates. For protocol patients, the intensive care unit length of stay was 5.5 versus 6.9 days for usual care ($p = .025$), and the length of hospital stay for protocol patients was 11.2 versus 14.5 days for usual care ($p = .006$). (The intensive care unit/length of hospital stay was adjusted for body mass index, acuity, and use of a vasopressor.) There were no adverse events during an intensive care unit mobility session and no cost difference between the protocol and usual care costs (Morris et al., 2008).

Function-Focused Care: A Multimodal Intervention

FFC is a comprehensive, system-level approach that prioritizes the preservation and restoration of functional capability. It is predicated on the philosophy that physical function is as important a treatment goal as correcting the acute admitting problem and recognizes the multifactorial nature of functional decline (Resnick, Galik, & Boltz, 2013). FFC utilizes a philosophy of care in which nurses acknowledge older adults' physical and cognitive capabilities with regard to function and integrate functional and physical activities into all-care interactions. The components of FFC are as follows:

- Assessment of environment and policy/procedures that act as facilitators and barriers for patients to engage in function and physical activity
- Education of nursing staff and other members of the interprofessional team (e.g., social work, physical therapy) on rehabilitative approaches

- Education of patients and families regarding FFC
- Establishing FFC goals, including discharge goals based on capability assessments, communication with other members of the team (e.g., medicine, physical therapy), and input from patients
- Interprofessional team addresses risk factors that impact goal achievement (e.g., cognitive status, anemia, nutritional status, pain, fear of falling, fatigue, medications, and drug side effects such as somnolence) to optimize patient participation in functional and physical activity
- Mentoring and motivation provided by a nurse change agent (e.g., geriatric resource nurse) using theoretically based interventions that monitor and motivate the nursing staff to provide FFC and thereby help the nurses to motivate patients to engage in functional and physical activities

Resnick, Galik, Enders, et al. (2011) demonstrated that nurses were willing to be engaged in an FFC educational intervention on both medical–surgical and trauma units (Resnick et al., 2015) and showed improvements in knowledge and outcome expectations associated with FFC. Further, FFC interactions between patients and nurses have demonstrated a decrease in the overall loss of ADL function from baseline to discharge (Boltz et al., 2012).

Given that family caregivers play a significant role in influencing the physical activity of hospitalized older adults (Boltz, Resnick, et al., 2011), FFC has been expanded to actively engage the family caregiver in the planning, implementation, and evaluation of care aimed at promoting functional recovery. The goal of this educational empowerment model (family-centered FFC [Fam-FFC]) is to improve functional outcomes of the patient and prepare the family caregiver for discharge, without increasing caregiver strain or negatively affecting the relationship with the patient (mutuality) or the family affective response. Fam-FFC demonstrated feasibility in a pilot study of 97 patient and family caregiver (FCG) dyads. Patients exposed to Fam-FFC demonstrated improved ADL performance, walking performance, and delirium severity, and fewer 30-day hospital readmissions. FCGs who participated in Fam-FFC reported better preparedness for caregiving, less anxiety, and less depression from admission to 2 months post discharge, with no significant increases in strain or decreased mutuality (Boltz, Resnick, Chippendale, et al., 2014). A second pilot study ($N = 86$) found that patients with dementia who were exposed to Fam-FFC demonstrated improvements in ADL performance and less delirium symptoms at 2 months post discharge (Boltz et al., 2015b). FCGs who participated in Fam-FFC showed a significant increase in preparedness for caregiving and less anxiety but no significant differences in depression, strain, and mutuality.

In addition to considering baseline function and the influence of family caregivers in supporting functional recovery, experts posit that the older adults' functional goals are critical in driving the treatment plan. Additionally, there is a need to consider assessments that can measure multiple domains of functioning in older adults, including social function and cognitive function (Liebzeit, King, Bratzke, & Boltz, 2018).

CASE STUDY 18.1

TS is an 80-year-old man who was admitted from an assisted living (AL) facility to the emergency department (ED) after he was found on the floor. His workup is negative for fractures and head trauma. His admitting diagnoses include pneumonia, anemia, and dehydration. His past medical history, per his daughter's report, is remarkable for mild hypertension, treated with hydrochlorothiazide (HCTZ) and captopril, and dementia. On admission, TS was somnolent but able to respond to his name. He is receiving intravenous (IV) antibiotics and hydration. As an alternative to the use of a restraint, the IV site is "camouflaged" with dressing wrap and covered with his sweater so as not to cue him to remove it.

The admitting nurse learns from his daughter and the staff at the AL facility that TS's normal or baseline function is that he is independent in ambulation, continent (though, at times, he has trouble in wayfinding), and needs verbal cues ("prompting") to get dressed and bathe. After hydration, TS becomes more alert. He is able to respond to one-step commands and is moving all extremities, with good range of motion. The primary nurse keeps the daughter informed of his condition and the need to promote mobility and self-care. The interprofessional team makes rounds that afternoon, and, with his daughter's and TS's involvement, develops the following plan:

- Monitor confusion assessment method (CAM) and mental status when he is able to respond.
- Daughter is to bring in familiar robe, shoes, and family photo; she also plans to complete social profile, "all about me," to be shared with hospital staff.
- Glasses were labeled with his name and placed on TS.

(*continued*)

CASE STUDY 18.1 (*continued*)

- No restraints; adjustable-height low bed, in low position, then adjusted to lower leg length to promote safe transfers.
- Switch to oral antibiotics; cap IV when able to take sufficient fluids by mouth.
- Assist out of bed for meals, starting that evening.
- In the morning, attempt to ambulate to bathroom, not to be left unattended. Ambulate as tolerated in room and progress to hallway ambulation three times a day.
- Use pressure-reducing mattress.
- Assist, cue, and redirect as needed during meal; monitor for aspiration.
- Encourage self-care during bathing; cue as needed.
- Anemia workup.
- Plan to discharge back to AL at baseline level of function; estimated discharge in 48 to 72 hours.
- The staff at the AL facility will receive a full report on his condition and progress. A plan for a structured routine that includes planned walking, self-care, and involvement in his preferred activities will be developed with input from his daughter.

Discussion

The case study demonstrates decision-making that recognizes the potential of TS to return to his baseline physical function. The interprofessional team implements measures to correct his delirium and prevent avoidable complications (falls and pressure ulcers) that could negatively impact his function. The plan to promote physical activity and independence in ADL is adapted to his cognitive impairment. His daughter is engaged in his care, and the nurse leverages this support to benefit TS.

SUMMARY

Hospitalization poses many challenges to the functional health of older adults. However, functional decline is not inevitable. Interventions formerly perceived to be relevant only to the rehabilitation setting are slowly being recognized as integral to the care and treatment of the older adult in the acute setting. FFC employs nursing care practices that acknowledge the older person's capabilities and potential, while positively modifying the care environment to prevent avoidable functional decline.

NURSING STANDARD OF PRACTICE

Protocol 18.1: Function-Focused Care Interventions

I. GOAL

To help nurses collaborate with the interdisciplinary team to implement interventions that maximize the older adult's functional abilities and performance. This protocol can be used in combination with Protocol 10.1.

II. OBJECTIVE

As stated in Chapter 6, Age-Related Changes in Health: To restore or maximize physical functioning, prevent or minimize decline in ADL function, and plan for transitions of care.

III. BACKGROUND

A. Functional decline is a common complication in hospitalized older adults, even in those with good baseline function (Gill et al., 2010).

B. Loss of physical function is associated with poor long-term outcomes, including increased likelihood of being discharged to a nursing home setting (Fortinsky et al., 1999), increased mortality (Boyd et al., 2005; Rozzini et al., 2005), increased rehabilitation costs, and decreased functional recovery (Boyd et al., 2005, 2008; Volpato et al., 2007). The immobility associated with functional decline results in infections, pressure ulcers, falls, a persistent decline in function and physical activity, and nonelective rehospitalizations.

(*continued*)

Protocol 18.1: Function-Focused Care Interventions (*continued*)

C. Functional decline may result from the acute illness and can begin before admission (Fortinsky et al., 1999) and continue after discharge. Baseline function serves as a useful benchmark when developing discharge goals (Wakefield & Holman, 2007).
D. Patient risk factors for functional decline include prehospitalization functional loss; the presence of two or more comorbidities; taking five or more prescription medications; having had a hospitalization or emergency department visit in the previous 12 months; depression; impaired cognition, including delirium; pain; nutritional problems; adverse medication effects; fear of falling; low self-efficacy, outcome expectations, and attitudes toward functional independence; and views on hospitalization (Boltz, Resnick, Capezuti, Shabbat, & Secic, 2011; Brown et al., 2007; Buurman et al., 2011, 2012; Inouye et al., 1999; McAuley et al., 2006; McCusker et al., 2002).
E. Bed rest results in loss of muscle strength and lean muscle mass, decreased aerobic capacity, diminished pulmonary ventilation, altered sensory awareness, reduced appetite and thirst, and decreased plasma volume (Creditor, 1993; Harper & Lyles, 1988; Hoenig & Rubenstein, 1999; Kortebein et al., 2007, 2008). Care processes, such as curtailing mobility, imposing restraints, and tethering devices, which are associated with low mobility, lead to a higher rate of ADL decline, new institutionalization, and death (Boltz et al., 2010; Boltz, Resnick, et al., 2011; Brown et al., 2004, 2009; Zisberg et al., 2011).
F. Interprofessional rounds support promotion of function by addressing functional assessment (baseline and current), evaluate potentially restrictive devices and agents, and yield a plan for progressive mobility (Boltz, Resnick, Chippendale, et al., 2014).
G. Leadership commitment to rehabilitative values is essential to support a social climate conducive to the promotion of function (Boltz, Capezuti, et al., 2011; King & Bowers, 2013).
H. FFC educational intervention on medical–surgical units has shown improvements in knowledge and outcome expectations associated with function-promoting care (Resnick, Galik, Enders, et al., 2011; Resnick, Galik, Boltz, et al., 2011; Resnick et al., 2015).

IV. FUNCTION-FOCUSED CARE INTERVENTIONS

A. Hospital care processes (Boltz, Resnick, Chippendale, et al., 2014; Jacelon, 2004; Resnick, Galik, Enders, et al., 2011)
   1. Evaluation of leadership commitment to rehabilitative values
   2. Interprofessional rounds that address functional assessment (baseline and current), evaluate potentially restrictive devices and agents, and yield a plan for progressive mobility
   3. Well-defined roles, including areas of accountability for assessment and follow-through for function-promoting activities
   4. Method of evaluating communication of patient needs among staff
   5. Process of disseminating data (e.g., compliance with treatment plans and functional outcomes)
B. Policy and procedures to support function promotion (Boltz et al., 2010; Boltz, Capezuti, & Shabbat, 2011, 2015b; Kleinpell, 2007)
   1. Protocols that minimize adverse effects of selected procedures (e.g., urinary catheterization) and medications (e.g., sedative–hypnotic agents) contribute to positive functional outcomes
   2. Supporting policies: identification and storage of sensory devices (e.g., glasses, hearing aids/amplifiers), mobility devices, and other assistive devices
   3. Discharge policies that address the continuous plan for function promotion
C. Physical design (Betrabet Gulwadi & Calkins, 2008; Boltz, Resnick, Capezuit, & Shuluk, 2014; Boltz et al., 2015b; Capezuti et al., 2008; Ulrich et al., 2008)
   1. Toilets, beds, and chairs at appropriate height to promote safe transfers and function
   2. Functional and accessible functional furniture and safe walking areas with relevant/interesting destination areas with distance markers
   3. Adequate lighting, nonglare flooring, door levers, and handrails (including in the patient room)
   4. Large-print calendars and clocks to promote orientation

(*continued*)

Protocol 18.1: Function-Focused Care Interventions (*continued*)

5. Control of ambient noise levels
6. Policy on storage of glasses and hearing aids, access to sensory aids, hearing amplifiers and magnifiers

D. Education of nursing staff and other members of the interdisciplinary team (e.g., social work, physical therapy) regarding (Boltz et al., 2010; Boltz, Capezuti, et al., 2011; Gillis et al., 2008; Resnick, Galik, Enders, et al., 2011):
   1. The physiology, manifestations, and prevention of hospital-acquired deconditioning
   2. Assessment of physical capability
   3. Rehabilitative techniques, use of adaptive equipment
   4. Interprofessional collaboration
   5. Engagement in decision-making
   6. Communication that motivates is associated with a function-promoting philosophy.

E. Education of patients and families regarding FFC, including the benefits of FFC, the safe use of equipment, and self-advocacy (Boltz, Resnick, Chippendale, et al., 2014; Boltz et al., 2010, 2015b; Resnick et al., 2015)

F. Clinical assessment and interventions (Boltz et al., 2015b; Boltz, Capezuti, et al., 2011; Boltz, Resnick, Chippendale, et al., 2014; Nolan & Thomas, 2008; Resnick, Galik, Enders, et al., 2011; Wakefield & Holman, 2007)
   1. Assessment of physical function and capability (baseline, at admission, and daily) and cognition (at a minimum daily)
   2. Establishing functional goals based on assessments and communication with other members of the team and input from patients
   3. Social assessment: history, roles, values, living situation, methods of coping
   4. Addressing risk factors that impact goal achievement (e.g., cognitive status, anemia, nutritional status, pain, fear of falling, fatigue, medications, and drug side effects such as somnolence) by the interprofessional team optimizes patient participation in functional and physical activities
   5. Developing discharge plans that include carryover of functional interventions and addressing the unique preferences and needs of the patient

V. EXPECTED OUTCOMES

A. Patients will:
   1. Be discharged functioning at their maximum level

B. Providers can demonstrate:
   1. Competence in assessing physical function and developing an individualized plan to promote function, in collaboration with the patient and the interprofessional team
   2. Physical and social environments that enable optimal physical function for older adults
   3. Individualized discharge plans

C. Institution will experience:
   1. A reduction in incidence and prevalence of functional decline
   2. Reduction in the use of physical restraints, prolonged bed rest, and Foley catheters
   3. Decreased incidence of delirium and other adverse events (pressure ulcers and falls)
   4. An increase in prevalence of patients who leave the hospital at baseline or with improved functional status
   5. Physical environments that are safe and enabling
   6. Increased patient satisfaction
   7. Enhanced staff satisfaction and teamwork

VI. RELEVANT PRACTICE GUIDELINES

Several resources are now available to guide adoption of evidence-based nursing interventions to enhance function in older adults.

1. Agency for Healthcare Research and Quality (AHRQ). *National guideline clearinghouse*. Retrieved from http://www.guideline.gov

Late-Life Depression*

Glenise McKenzie
and Kathryn Sexson

19

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the major risk factors for late-life depression.
2. Discuss the consequences of late-life depression.
3. Identify the core competencies of a systematic nursing assessment for depression with older adults.
4. Identify nursing strategies for older adults with depression.

OVERVIEW

Contrary to popular belief, depression is not a normal part of aging. Depression in late life interferes with a person's ability to function, decreases quality of life, increases risk of morbidity and mortality (including suicide), and increases use of healthcare services (Taylor, 2014). Despite associated negative outcomes, depression in all adults, especially in adults greater than 65 years of age, continues to be underrecognized, misdiagnosed, and subsequently undertreated (Olfson, Blanco, & Marcus, 2016). Nurses in all healthcare settings are pivotal to the early recognition of depression and the facilitation of older patients' access to mental healthcare. This chapter presents an overview of unipolar late-life depression, with emphasis on age-related assessment considerations, clinical decision-making, and nursing intervention strategies. A standard-of-practice protocol for use by nurses in practice settings is presented.

BACKGROUND

Late-life depression is a term that includes older adults with a history of depressive disorders in earlier years as well as those who develop symptoms for the first time in later life. Depression may range in severity from mild symptoms (subsyndromal) to severe symptoms (major depressive episode), both of which can persist over time and both of which present negative functional outcomes in older adults (Haigh, Bogucki, Sigmon, & Blazer, 2018; Laborde-Lahoz et al., 2015). Suicidal ideation, psychotic features (especially delusions), and excessive somatic concerns (hypochondriasis) frequently accompany more severe depression in older adults when compared to younger adults with depression (Grayson & Thomas, 2013; Hegeman, de Waal, Comijis, Kok, & van de Mast, 2014). Comorbid anxiety and depression are common and have been associated with more severe symptoms, decreases in

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

memory, poorer treatment outcomes (Beattie, Pachana, & Franklin, 2010), and increased rates of suicidal ideation (Sareen et al., 2005).

While the prevalence of depression in community-dwelling older adults is lower when compared to that in middle-aged adults, depression in later life is associated with increased chronicity (rate of relapse is higher; Haigh et al., 2018). Lifetime prevalence of major depressive disorders is 13.7%, and an additional 13.8% have subsyndromal depression (symptoms negatively impact function and quality of life but do not meet criteria for major depressive disorder; Laborde-Lahoz et al., 2015). The prevalence of clinically significant depressive symptoms in adults older than 60 years of age varies depending on the clinical context; for example, it has been documented that 5% to 10% of older adults in primary care, one third of older adults post critical care hospitalization, and up to one half of older adults in their first year after placement in a nursing home are diagnosed with depression (Jackson et al., 2014; Laborde-Lahoz et al., 2015; Neufeld, Freeman, Joling, & Hirdes, 2014). Increased chronicity in late-life depression is associated with higher age, coexisting medical conditions, functional impairment, and external locus of control; Licht-Strunk et al., 2009).

MAJOR AND MINOR DEPRESSION

The *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*; American Psychiatric Association [APA], 2013) lists the criteria for the diagnosis of a major depressive disorder, the most severe form of depression. These criteria are frequently used as the standard by which older patients' depressive symptoms are assessed in clinical settings. Five criteria (or more) from a list of nine must be present nearly every day during the same 2-week period and must represent a change from previous functioning: (a) depressed, sad, or irritable mood; (b) anhedonia or diminished pleasure in usually pleasurable people or activities; (c) feelings of worthlessness, self-reproach, or excessive guilt; (d) difficulty with thinking or diminished concentration; (e) suicidal thinking or attempts; (f) fatigue and loss of energy; (g) changes in appetite and weight; (h) disturbed sleep; and (i) psychomotor agitation or retardation. For this diagnosis, at least one of the five symptoms must include either depressed mood, by the patient's subjective account or observation of others, or markedly diminished pleasure in almost all people or activities. Concurrent medical conditions are frequently present in older patients and should not preclude a diagnosis of depression; indeed, there is a high incidence of medical comorbidity. The *DSM-5* also provides criteria for persistent depressive disorder (dysthymia), which increases the risk of developing a major depression and manifests with depressive symptoms that occur on a majority of days for at least 2 years.

Major depression symptoms seem to be as common among older as among younger cohorts. A review of depressive criteria found diagnostic thresholds (number and type of symptoms) to be consistent between older adults (age 60 years and older) and middle-aged adults (age 40 years and older; Anderson, Slade, Andrews, & Sachdev, 2009). However, older adults may report somatic or physical symptoms more readily than depressed mood, and it may be difficult to distinguish somatic or physical symptoms associated with acute or chronic physical illness (Haigh et al., 2018). For instance, disturbed sleep may be associated with chronic lung disease or congestive heart failure. Diminished energy or increased lethargy may be caused by an acute metabolic disturbance or drug response. Therefore, a challenge for nurses in acute care hospitals and other clinical settings is not to overlook or disregard somatic or physical complaints while also "looking beyond" such complaints to assess the full spectrum of depressive symptoms in older patients.

Minor depression or subsyndromal depression is diagnosed in patients with clinically significant symptoms (causing impairment or distress) that do not meet *DSM-5* standard criteria for major depression or persistent depressive disorder. The *DSM-5* (APA, 2013, p. 183) classifies minor depression as an "other specified depressive disorder with insufficient symptoms" (depressed mood plus 1–3 other symptoms of major depression that are at least 2 weeks in duration). Minor depression is at least two to three times as common as major depression for older adults in the community and is most prevalent for older adults residing in long-term care settings (Meeks, Vahia, Lavretsky, Kulkarni, & Jeste, 2011). Additionally, 8% to 10% of older adults with untreated minor depression develop major depression within 1 year, and less than one third with minor depression have a remission of symptoms after 1 year (Meeks et al., 2011). Major and minor depressive symptoms are associated with serious consequences for older adults, and the majority will not improve without treatment.

DEPRESSION IN LATE LIFE IS SERIOUS

Evidence suggests that late-life depression is associated with poorer health outcomes, including higher rates of morbidity and mortality. Depression (major and minor) is associated with serious negative consequences for older adults, especially for frail older patients, such as those recovering from a severe medical illness or those in nursing homes (Mezuk, Edwards, Lohman, Choi, & Lapane, 2012). Negative

health consequences of depression for older adults include increased risk of cardiovascular disease, musculoskeletal diseases, lung diseases, cancer, lowered pain tolerance, anxiety, cognitive impairment, and increased healthcare use (Bock et al., 2016; Hegeman et al., 2014; Laborde-Lahoz et al., 2015). Depression can influence decision-making capacity and may be the cause of indirect life-threatening behavior such as refusal of food, medications, or other treatments in older patients (McDade-Montez, Christensen, Cvengros, & Lawton, 2006; Stapleton, Nielsen, Engelberg, Patrick, & Curtis, 2005). These observations suggest that accurate diagnosis and treatment of depression and related comorbidities in older patients may reduce morbidity and mortality rates in this population. It is in the clinical setting, therefore, that screening procedures and assessment protocols have the most direct impact.

Depression is a predictor of late-life suicide (Rorup, Deeg, Poppelaars, Kerkhof, & Onwuteaka-Philipsen, 2011). Suicide is the 10th leading cause of death across the age span in the United States with an age-adjusted rate in 2017 of 14 per 100,000 (Hedegaard, Curtin, & Warner, 2018). Suicide rates have increased in recent years for males and females in all age groups, inclusive of 65- to 70-year-olds (rate in 2017: 24.7 per 100,000; Hedegaard et al., 2018). Physical illness and functional impairment are associated with an increase in suicide in older adults, and it appears that this relationship is further strengthened by comorbid depression (Rorup et al., 2011). Studies have also shown that contact between suicidal older adults and their primary care provider is common, with half of older suicide victims seeking care within 1 month of committing suicide (Luoma, Martin, & Pearson, 2002).

DEPRESSION IN LATE LIFE IS MISUNDERSTOOD

Barriers to care for older adults with depression exist at many levels. In particular, some older adults refuse to seek help because of perceived stigma of mental illness (Conner et al., 2010). Others may simply accept their feelings of profound sadness without realizing that they are clinically depressed. Depressive disorders may also be missed because of overlapping anxiety disorders and/or various somatic or dementia-like symptoms or because the patient or the provider believes that depression is a "normal" response to medical illness, hospitalization, relocation to a nursing home, or other stressful life events (Haigh et al., 2018; Taylor, 2014). However, depression—major or minor—is not a necessary or normative consequence of life adversity (Haigh et al., 2018). When depression occurs after an adverse life event and negatively impacts function, it represents pathology that should be treated.

CAUSE AND RISK FACTORS

Several biological and psychosocial factors have been associated with increased risk for late-life depression. Medical comorbidity is a significant risk factor for depression in older patients and commonly co-occurs in older adults. This factor represents a major difference from depression in younger populations (Alexopoulos, Schultz, & Lebowitz, 2005). Biological contributors to depression in late life include cancer, vascular disease, general health (obesity, pain, new medical illness, insomnia, prior depression, history of suicide attempt, and poor health status), dementia (Alzheimer and vascular dementia), diabetes mellitus, Parkinson's disease, arthritis, and urological problems (Aziz & Steffens, 2013; C. Q. Huang, Dong, Lu, Yue, & Liu, 2010; Vink, Aartsen, & Schoevers, 2008; see Exhibit 19.1). Neuroanatomic correlates (volume reduction in hippocampus, orbitofrontal cortex, putamen, and thalamus) have also

been associated with late-life depression (Sexton, Mackay, & Ebmeier, 2013). The link between late-life depression and cognitive impairment is thought to be bidirectional. For example, a history of depression doubles the risk of developing dementia in late life, and cognitive symptoms of severe depression can be misinterpreted as symptoms of an early-stage dementia (Morimoto & Alexopoulous, 2013). Those with functional disabilities, especially those with new functional loss, such as stroke survivors, are also at increased risk (Mitchell et al., 2017).

Psychosocial risk factors for depression in late life include personality attributes (personality disorder, low self-efficacy), life stressors (trauma, low income, less education, poor functional status, disability), and social stressors (bereavement, loneliness, lack of a confidante, impaired social support, being a caregiver; Aziz & Steffens, 2013; Cole, 2007; Heisel, Links, Conn, van Reekum, & Flett, 2007; Pinquart & Sorensen, 2004; Vink et al., 2008). It is interesting to note that in a meta-analysis of the impact of negative life events on depression in older adults, Kraaij, Arensman, and Spinhoven (2002) found that although specific negative life events (e.g., death of significant others, illness in self or spouse, or negative relationship events) were moderately associated with increases in depression, the total number of negative life events and daily hassles had the strongest relationships with depression in older adults. This suggests that clinicians should pay close attention to the accumulation of negative life events and daily hassles when developing programs and targeting interventions to mitigate depression in older adults who are at risk for developing depression.

DEPRESSION AMONG DIVERSE POPULATIONS OF OLDER ADULTS

Beyond comorbid conditions, social influences may contribute to the complexity of diagnosis, treatment, and outcomes. For example, Cohen et al. (2006) identified a tendency of individuals of lower socioeconomic status to respond poorly to pharmacological interventions. Rates of depression among diverse populations of older adults are not well understood. The APA (2017) reports rates of depression in Blacks (24.6%) and Hispanics (19.6%), with both groups having more persistent symptoms than their White counterparts. Similarly, Kales and Mellow (2006) found lower rates of depression and higher rates of psychotic diagnoses among African American older adults. In a systematic review of studies of older Asian immigrants, Kuo, Chong, and Joseph (2008) found that the prevalence of depression among Asian Americans ranged from 18% to 20%, with significant variability among different Asian minority groups. For example, studies of Vietnamese older adults estimated depression at 50%, whereas studies of older Japanese Americans estimated depression at 3%. Depression was linked to gender, recent immigration status, English proficiency, acculturation, service barriers, and social support. Jimenez, Alegria, Chen, Chan, and Laderman (2010) found that Latinos and Afro-Caribbean older adults had higher rates of depressive disorders than their non-Latino White counterparts and that immigrant Latinos had higher rates of dysthymia than those born in the United States.

Baker and Whitfield (2006) reported that depressive symptoms were significantly associated with increased physical impairment among older Blacks. Williams et al. (2007) found that when African American and Caribbean Blacks experience a major depressive disorder, it is usually untreated, more severe, and more disabling than for non-Hispanic Whites. In addition, barriers exist in ethnically diverse populations, impacting access to treatment, including lack of insurance, economic barriers, stigma, lack of diversity among healthcare providers, dearth of culturally competent providers, language barriers, and distrust in the system (APA, 2017). Furthermore, significant disparities exist in the quality of mental health services received

by minority older adults (Pickett, Bazelais, & Bruce, 2014; Virnig et al., 2004). A study of managed care enrollees revealed that minority older adults received substantially less follow-up for mental health problems following hospitalization (Virnig et al., 2004).

Health disparities are clearly found between LGBTQ+ older adults and their heterosexual peers. The Institute for Research on Poverty (2014) found people who live in poverty to be at greater risk for mental health disorders. Nearly one third of LGBTQ+ older adults are economically disadvantaged, living below 200% of the federal poverty level, with bisexual and transgender subgroups significantly below (48.2% and 47.5%, respectively; Muraco et al., 2014) compared to approximately 26% of all adults aged 65 and older (O'Brien, Wu, & Baer, 2010). Wight, LeBlanc, Meyer, and Harig (2015) found older LGBTQ+ males who experienced "internalized gay ageism" to be associated with more depressive symptoms. Muraco and colleagues (2014) assessed effects of gender identity on depressive symptoms in transgender adults over 50 and found them to be at significantly higher risk than their nontransgender peers. Those experiencing lifetime victimization were also found to have greater depressive symptoms (Fredriksen-Goldsen et al., 2013). Those individuals who have been diagnosed with HIV have been found to be significantly more likely to develop depressive symptoms (Do et al., 2014). While the social stigma associated with sexual orientation places individuals at higher risk for depressive symptoms, increased social network size and higher levels of social support were found to lower the odds of depressive symptoms (Fredriksen-Goldsen et al., 2013).

Although misdiagnosis and subsequent inappropriate treatment can lead to poor health outcomes for diverse populations of older adults (Kales & Mellow, 2006), it is not clear that "simple" bias alone can explain the disparities in depression management that exist. For example, Beals et al. (2005) point out that differences in the social construction of depressive experiences may confound the measurement of depression in ethnic older adults. Older American Indians may be reluctant to endorse symptoms of depression because cultural norms associate these complaints with weakness (Beals et al., 2005). In a thoughtful analysis of health disparities, Cooper, Beach, Johnson, and Inui (2006) explore the complex interactions and relationships between patients and providers that frame the context in which disparities can occur. They point out that many historical, cultural, and class-related factors can influence the development of therapeutic relationships between providers and patients. Until more research clarifies the symptom pattern of late-life depression in minority populations (Sadule-Rios, 2012), it is important that clinicians be culturally sensitive and open to atypical presentations of depression that warrant closer scrutiny.

ASSESSMENT OF THE PROBLEM

Early recognition of depression is enhanced by targeting high-risk groups of older adults for assessment methods that are routine, standardized, and systematic by use of both a depression screening tool and individualized depression assessment or interview (Smith, Haedtke, & Shibley, 2015). It can be challenging to differentiate depressive symptoms from dementia symptoms because cognitive impairment is frequently a symptom of depression and significant cognitive impairment in older depressed adults has been implicated in later development of dementia. Therefore, assessment for presenting symptoms indicative of both depression and dementia requires focused attention on the historical progression of symptoms, and getting collateral information from a reliable informant (family or caregiver) and using a screening tool sensitive to change in mood symptoms in cognitively impaired individuals is recommended (Steffens, 2008).

DEPRESSION SCREENING TOOLS

In 2016, the United States Preventive Services Task Force (USPSTF) updated their recommendations to include screening for depression in all adults (Siu & USPSTF, 2016), and in 2011 the Centers for Medicare and Medicaid (CMS) included it in their value-based care initiative. Because older adults may not present with the same symptoms as younger adults (Haigh et al., 2018), it is important that screening for depression among older adults is incorporated into routine health assessments. In a recent meta-analysis (comparing 11 studies with a combined sample of 2,000 subjects), the authors reported that depressive symptoms in older adults are more likely to include agitation, somatic complaints (especially gastrointestinal symptoms), and hypochondriasis and less likely to include feelings of guilt or low sexual interest in contrast to younger adults with depression (Hegeman, Kok, Van der Mast, & Giltay, 2012). Nursing assessment of depression in older patients can be facilitated by the use of a screening tool designed to detect symptoms of depression. Several depression screening tools have been developed for use with older adults; this review focuses on two common screening tools used with cognitively intact older adults in hospital, clinic, and long-term care settings and one common tool for older adults with cognitive impairment. The Geriatric Depression Scale—Short Form (GDS-SF; Sheikh & Yesavage, 1986) takes a few minutes to complete and

was developed specifically for older adults. The GDS-SF is written in a simple yes/no format with 15 items that can be self-administered or administered by a clinician; a score of 5 or more is considered a positive screen for depression. The GDS has been shown to be valid in inpatient and outpatient settings, with an 84% sensitivity and 95% specificity (Glover & Srinivasan, 2013). Given the brevity, focus, and validity of GDS-SF, it is a good choice for either inpatient or outpatient populations (Mitchell et al., 2010).

The Patient Health Questionnaire-9 (PHQ-9) is evidence based and was originally designed for use in primary care settings (Kroenke & Spitzer, 2002). The PHQ-9 is recommended for screening cognitively intact older adults for depressive symptoms in primary care, nursing homes, and community settings and can be either self- or clinician administered (Richardson, He, Podgorski, Tu, & Conwell, 2010; Smith et al., 2015; Siu & USPSTF, 2016). The nine items of the PHQ-9 correspond with the *DSM-5* (APA, 2013) major depressive disorder criteria, and scores are based on frequency as well as number of symptoms (scores less than 5 suggest no depression; 5–9 = mild depression; 10–14 = moderate depression; and 20–27 = severe depression). Sensitivity and specificity of the PHQ-9 have both been reported to be more than 80%. The PHQ-9 has also been abbreviated to include just the first two items (PHQ-2) that ask about depressed mood and loss of pleasure (anhedonia); the PHQ-2 has similar sensitivity and specificity to the PHQ-9 (Kroenke, Spitzer, & Williams, 2003; Richardson et al., 2010). Overall, the PHQ is easy to administer, valid in cognitively intact older adults in different settings, and can also be used to monitor response to treatment (Richardson et al., 2010; Smith et al., 2015). The PHQ is not recommended for screening older adults with cognitive impairment.

The Cornell Scale for Depression in Dementia (CSDD) is an interviewer-rated scale that was developed specifically to detect symptoms of depression in older adults with dementia (Alexopoulos, Abrams, Young, & Shamoian, 1988). The CSDD contains 19 items, and a score of 12 or greater suggests depression in an individual with dementia. Screening tools are helpful in identifying depressive symptoms in older adults, but because older adults may not present with the classic symptoms of depression, they do not replace the need for a comprehensive nursing assessment.

INDIVIDUALIZED ASSESSMENT AND INTERVIEW

Central to the individualized depression assessment and interview is a focused assessment of the full spectrum of symptoms (nine) for major depression as delineated by the *DSM-5* (APA, 2013). Furthermore, patients should be asked directly and specifically if they have been having suicidal ideation—that is, thoughts that life is not worth living—or if they have been contemplating or have attempted suicide. The number of symptoms, type, duration, frequency, and patterns of depressive symptoms, as well as a change from the patient's normal mood of functioning, should be noted. Additional components of the individualized depression assessment include evidence of psychotic thinking (especially delusional thoughts), anniversary dates of previous losses or stressful events, previous coping style (specifically alcohol or other substance abuse), relationship changes, physical health changes, a history of depression or other psychiatric illness that required some form of treatment, a general loss and crises inventory, and any concurrent life stressors. Subsequent questioning of the family or caregiver is recommended to obtain further information about the older adult's verbal and nonverbal expressions of depression. However, increased screening for depression alone is not enough. For example, despite the Centers for Medicare and Medicaid's decision to reimburse for depression screening in 2011 (CMS, 2011), the rates of suicide have continued to climb, reaching 20.1 per 100,000 in those 85 and older (Drapeau & McIntosh, 2018).

DIFFERENTIATION OF MEDICAL OR IATROGENIC CAUSES OF DEPRESSION

Once depressive symptoms are recognized, medical- and drug-related causes should be explored. As part of the initial assessment of depression in the older patient, it is important to obtain and review the medical history and physical and/or neurological examinations. Key laboratory tests should also be obtained and/or reviewed and include thyroid-stimulating hormone levels, chemistry screen, complete blood count, and medication levels, if needed. An electrocardiogram, serum B12, a urinalysis, and serum folate should also be considered to assess for coexisting medical conditions. These conditions may contribute to depression or might complicate treatment of the depression (Taylor, 2014; see Exhibit 19.2). In medically ill older patients, who frequently have multiple medical diagnoses and are prescribed multiple medications, these contributing factors in the case of depression are a major imperative in nursing assessment. In collaboration with the patient's provider, efforts should be directed toward treatment, correction, or stabilization of associated metabolic or systemic conditions. When medically feasible, depressogenic medications should be eliminated, minimized, or substituted by those that are less depressogenic (Dhondt et al., 1999;

Source: Data from Celano, C.M., Freudenreich, O., Fernandez-Robles, C., Stern, S. A., Cara, M. A., & Huffman, J. C. (2011). Depressogenic effects of medications: A review. *Dialogues in Clinical Neuroscience, 13*(1), 109–125. Retrieved from https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3181967

Taylor, 2014). Even when an underlying medical condition or medication is contributing to the depression, treatment of that condition or discontinuation or substitution of the offending agent alone is often not sufficient to resolve the depression, and antidepressant medication is often needed.

INTERVENTIONS AND CARE

The goals of treating depression in older patients are to decrease depressive symptoms, reduce relapse and recurrence, improve functioning and quality of life, improve medical health, and reduce mortality and healthcare costs. Significant and equivalent improvements in depressive symptoms occur with both pharmacotherapy and psychotherapy interventions (individually or in combination) in older adult populations (Pinquart, Duberstein, & Lyness, 2006). In addition, treatment of depression improves pain and functional outcomes in older adults (Lin et al., 2003). Recurrence of depression in older adults is a serious problem and has been associated with reduced responsiveness to treatment and higher rates of cognitive and functional decline (Driscoll et al., 2005). Although antidepressants are effective in community-dwelling older adults, evidence demonstrates this efficacy is reduced when compared to the case in younger adults (Tedeschini et al., 2011). Older adults, however, tend to have higher rates of relapse following treatment (Kok & Reynolds, 2017). Therefore, continuation of treatment to prevent early relapse and longer-term maintenance treatment to prevent later occurrences is important. Even in those patients with depression who have a comorbid medical illness, treatment response can be good (Kok & Reynolds, 2017). (this also corrects the placement of the punctuation) However, the efficacy of antidepressants in people with cognitive impairment remains unclear (Kok & Reynolds, 2017). Depressed older patients who have mild cognitive impairment may be at greater risk of developing dementia if their depression goes untreated (Modrego & Ferrandez, 2004).

Regardless of the setting, older patients who exhibit the number of symptoms indicative of a major depression, specifically suicidal thoughts or psychosis, and who score *above* the established cutoff score for depression on a depression screening tool (e.g., 5 on the GDS-SF or 8–10 on the PHQ-9) should be referred for a comprehensive psychiatric evaluation. Older patients with less severe depressive symptoms without suicidal thoughts or psychosis but who also score more than the cutoff score on the depression screening tool (e.g., 5 on the GDS-SF or 8–10 on

the PHQ-9) should be referred to available psychosocial services (i.e., psychiatric liaison nurses, geropsychiatric advanced practice nurses, social workers, psychologists, a clergy member) for psychotherapy or other psychosocial therapies, as well as to determine whether medication for depression is warranted. It is also important to note that older adults at risk for depression may benefit from brief psychosocial interventions that focus on preventing the development of major depression (Lee et al., 2012), with increased social activity interventions being most effective (Forsman, Jane-Llopis, Schierenbeck, & Wahlbeck, 2009; Forsman, Nordmyr, & Wahlbeck, 2011). Findings have been mixed for prevention efforts focused specifically on minor depression (Krishna et al., 2013).

The type and severity of depressive symptoms influence the type of treatment approach. In general, more severe depression, especially with suicidal thoughts or psychosis, requires intensive psychiatric treatment, including hospitalization, medication with an antidepressant or antipsychotic drug, electroconvulsive therapy (ECT), and intensive psychosocial support (Taylor, 2014). Less severe depression without suicidal thoughts or psychosis may require treatment with psychotherapy or medication, often on an outpatient basis. Collectively, these data also suggest that patients who have depression complicated by multiple medical and psychiatric comorbidities may benefit from a referral to an interdisciplinary treatment team with specific expertise in geropsychiatry.

TREATMENT FOR LATE-LIFE DEPRESSION

The four major categories of treatment for depression in older adults are (a) lifestyle change (exercise and diet), (b) somatic therapies (e.g., pharmacotherapy, ECT, and light therapy), (c) psychosocial interventions (e.g., cognitive behavioral, psychodynamic, social engagement, and reminiscence therapy), and (d) collaborative care interventions. A compelling body of evidence supports the efficacy of these diverse treatment modalities for older adults with depression.

Lifestyle-Change Interventions

In less severe depression, lifestyle change (physical exercise and diet) may be effective and carries a lower risk of adverse effects compared to those related to pharmacological interventions. Physical exercise has been established as an effective treatment for depression in the general population, and this includes depressed older adults who are physically able to participate (Schuch et al., 2016). Reviews of physical exercise interventions have concluded that exercise programs decrease depressive symptoms and improve quality of life in older adults with major and minor depression when compared to control conditions (Catalan-Matamoros, Gomez-Conesa, Stubbs, & Vancampfort, 2016; Seong-Hi, Kuem Sun, & Chang-Bum, 2014). Tai chi and qigong are specific meditative exercise methods that may also decrease depressive symptoms and reduce stress (Rogers, Larkey, & Keller, 2009; Wang et al., 2010). Studies showing potential benefits of improved nutrition and diet supplements on depressive symptoms across the life span are building (Opie et al., 2017; Sanhueza, Ryan, & Foxcroft, 2013). For example, a vitamin D3 supplementation and improvement in depressive symptoms in older adults have been reported, but more studies are needed in order to make any solid recommendations (Farrington & Moller, 2013). Fish oil and folic acid supplementation have also shown promising results in the limited studies that included older adults (Nyer et al., 2013). Although lifestyle changes (increase in exercise and a healthy diet) are well supported and reasonable nursing recommendations, they may be inadequate in older adults with more significant depressive symptoms. Additional interventions, such as pharmacotherapy and psychotherapy, may also be necessary.

Somatic Therapy in Treatment of Late-Life Depression

Somatic therapy for remission of the symptoms of late-life depression includes pharmacotherapy, ECT, and light therapy. Pharmacotherapy or ECT is shown to be efficacious and is recommended for more severe depression. Pharmacotherapy and light therapy may also be recommended for older adults with less severe symptoms and for individuals who have not responded to nonpharmacological treatments (Kok, 2013).

Pharmacotherapy

In a meta-analysis of 80 controlled trials, antidepressants were found effective for treating depression in older adults, and all classes of antidepressants were reported to be superior to placebo (Kok, Nolen, & Heeren, 2012). Unlike younger adults, older adults may take 8 to 16 weeks of therapy to achieve a full antidepressant response (Frank, 2014; Solai, Mulsant, & Pollock, 2001). The selective serotonin-reuptake inhibitors (SSRIs) are considered the first-line pharmacotherapy for late-life depression, based on their relatively low side-effect profile and low cost (Kok, 2013; Taylor, 2014). SSRIs have been effective in treating poststroke depression (Chen, Guo, Zhan, & Patel, 2006; Hackett, Anderson, House, & Xia, 2008) and depression in persons with Alzheimer's disease (Thompson,

Herrmann, Rapoport, & Lanctôt, 2007). A systematic review of the literature found that although SSRIs are generally well tolerated in older adults, a significant minority experience serious side effects, including nausea, vomiting, dizziness, drowsiness, and increased risk of gastrointestinal bleeding, falls, and fractures (Van Damme, Declercq, Lemey, Tandt, & Petrovic, 2018). The SSRI Citalopram has a black-box warning as it may cause QTc prolongation (FDA prescribing information). Judicious use of tricyclic antidepressants (TCAs) may be an effective alternative for older adults who cannot tolerate SSRIs (Kok, 2013). Important side effects of the TCAs include anticholinergic symptoms, arrhythmia, and orthostatic hypotension. Serotonin and noradrenaline reuptake inhibitors (SNRIs) are another alternative to SSRIs when the SSRI is ineffective or contraindicated. This drug class is also effective in treating peripheral neuropathy and may be a drug of choice when trying to limit polypharmacy. In the depressed patient suffering from insomnia or anorexia, mirtazapine may be considered as it causes sedation and increased appetite (Ancoli-Israel & Ayalon, 2006; Fox, Treadway, Blaszczyk, & Sleeper, 2009).

Older patients should be closely monitored for therapeutic response to and potential side effects of antidepressant medication to assess whether dose adjustment of antidepressant medication may be warranted. Kok et al. (2012) reported that about two thirds of older adults with depression require a change or augmentation to initial treatment to achieve remission. Whenever possible, monotherapy is recommended to minimize drug side effects. Although, in general, it is advised to start antidepressant medication at low doses in older patients, it is also necessary to increase doses to ensure that older adults with persistent depressive symptoms receive adequate treatment and appropriate follow-up (Kok, 2013).

Electroconvulsive Therapy

In the case of older adults who are unable to take antidepressants for treatment of late-life depression, clinicians are increasingly looking to the use of ECT to reduce symptoms of depression and improve function. ECT involves the induction of a mild, therapeutic seizure under general anesthesia. It is an accepted treatment option for older adults with depression, especially older adults with severe depression that is resistant to pharmacotherapy or has psychotic features, severe weight loss, or anorexia (Navarro et al., 2008; Spaans et al., 2015). In fact, because of the relatively low side-effect profile, some researchers suggest that ECT should be considered a first-line treatment (Plakiotis, Barson, Vengadasalam, Haines, & O'Connor, 2013). In a systematic review of literature on maintenance of ECT, Van Shaik et al. (2010) found that long-term ECT use was not associated with long-term increases in cognitive impairment. Autobiographical memory is affected, but is improved or restored within 6 months of treatment (Verwijk et al., 2012). ECT is well tolerated in older adults, even older adults with cardiac conditions (Haigh et al., 2018).

Light Therapy

Chang, Liu, Chen, and Tsai (2018) conducted a systematic review and meta-analysis on the efficacy of light therapy on nonseasonal depression in older adults. Their findings indicate that bright white or pale blue light therapy significantly reduced the severity of geriatric depression and are similar to the findings of Wu, Sung, Lee, and Smith (2015), who examined the effect of light therapy on persons with depression in the nursing home. Based on their review, Chang and colleagues (2018) also postulate that administering therapy in the morning increases the effectiveness of treatment. Lieverse and colleagues (2011) tested the efficacy of pale blue light therapy, approximately 7,500 LUX, in decreasing depressive symptoms in older adults with major depression. This 3-week randomized trial compared bright light treatment with placebo (dim light) in 89 older adults with nonseasonal depressive disorder. The intervention was well tolerated and showed a positive treatment response (58% vs. 34%). A small pilot study in long-term care also reported significant improvement in mood when comparing bright light treatment versus placebo effects (Royer et al., 2012). This continues to be a promising area for further research and consideration when working with older adults who are depressed.

Psychosocial Approaches

The term *psychosocial* encompasses a wide array of approaches. This section provides an overview of the three major psychosocial approaches used in studies with older adult populations: (a) cognitive/behavioral, (b) psychodynamic, and (c) reminiscence or life-review therapy. Support for nonpharmacological (including psychosocial) approaches in the treatment of late-life depression has been increasing, although reviewers continue to report limitations due to methodological challenges (Apóstolo, Bobrowicz-Campos, Rodrigues, Castro, & Cardoso, 2016). Current meta-analysis has also demonstrated the utility of working closely with caregivers—whether family or staff—to introduce psychosocial interventions with resulting reduction in depression in persons with dementia

(Orgeta, Qazi, Spector, & Orrell, 2014). There is also a small but growing body of evidence related to the use of psychosocial approaches aimed at decreasing depression in older adults associated with comorbid illnesses impacting physical dysfunction (Frost, Bauernfreund, & Walters, 2018).

Cognitive/Behavioral

Cognitive and/or behavioral therapies seek to change the cognitive and/or behavioral context in which depression occurs through the use of various specific techniques such as providing new information, teaching problem-solving strategies, correcting skills deficits, modifying ineffective communication patterns, or changing the physical environment. Although specific treatment protocols vary, Cognitive Behavioral Therapy (CBT) approaches tend to be active and focused on solving specific, current day-to-day problems, rather than seeking global personality change in the client. Based on a large and growing evidence base, CBT has been shown to be effective in decreasing depression in clinically depressed older adults with major, dysthymic, and minor depression (Gould, Coulson, & Howard, 2012). Studies of computerized delivery of CBT with older adults are limited; however, there are promising findings, and older individuals may be less likely to drop out than younger individuals (Crabb et al., 2012). Psychotherapeutic interventions for older adults (without dementia) living in nursing facilities are limited; however, a recent systematic review reported positive evidence for CBT in depressed older adults living in nursing homes (Simning & Simons, 2017). Training caregivers (family or paid caregivers) to use CBT approaches (improved communication, increasing pleasant events, and problem-solving behaviors) has also been shown to decrease depression and related behaviors in older adults with dementia (Teri, McKenzie, & LaFazia, 2005). Gallagher-Thompson and Coon (2007) also identified CBT interventions as effective in decreasing depression in the older adults who are caregivers for older adult family members. Behavioral Activation (BA) therapy, delivered by nurses and aimed at increasing and sustaining functional and pleasurable experiences and environments, is a promising intervention currently under investigation (Janssen et al., 2017). Comprehensive reviews of nonpharmacological treatments reported that individual and group CBT interventions, and problem-solving therapy compared to usual treatment, significantly reduced depression for people with physical comorbidities (Frost, Bauernfreund, & Walters, 2018; Rizzo, Creed, Goldberg, Meader, & Pilling, 2011).

Psychodynamic

Psychodynamic approaches focus on establishing a therapeutic relationship as a mechanism of change as well as on examining the historical causes of current client mood and behavior. The client's psychological insight and ongoing emotional experience are considered critical for psychological progress. Evidence for the effectiveness of psychodynamic approaches with older adults has continued to build (Apóstolo et al., 2016; Renn & Areán, 2017). In a meta-analysis, a medium effect size was reported for psychotherapy in reducing symptoms of depression in older adults who reside in residential care settings (Cody & Drysdale, 2013) and a moderate to strong effect size for community-dwelling older adults with an acute depressive disorder (A. X. Huang, Delucchi, Dunn, & Nelson, 2015). A systematic review of the impact of psychotherapy on symptoms of community-dwelling older adults with minor (subthreshold) depression also found psychotherapy to be effective, safe, and cost-effective (Lee et al., 2012). Additionally, Bharucha, Dew, Miller, Borson, and Reynolds (2006) reviewed 18 studies of psychodynamic approaches ("talk therapy") with residents of long-term care settings and reported significant positive outcomes on measures of depression, hopelessness, and self-esteem. Marital and family therapy may also be beneficial in treating older adults with depression, especially older spouses engaged in caregiving (Buckwalter et al., 1999).

Reminiscence

In reminiscence therapy, older adults are encouraged to remember the past and to share their memories, either with a therapist or with peers, as a way of increasing self-esteem and social intimacy. It is often highly directive and structured, with the therapist picking each session's reminiscence topic. According to a meta-analysis that included 128 trials with older adult participants, reminiscence interventions showed moderate improvement in depression when compared to control groups, and effects were maintained at 6-month follow-up (Pinquart & Forstmeier, 2012). In two recent meta-analyses, group delivery of reminiscence showed significant improvement in depressive symptoms when compared to control interventions; however, the long-term impacts were not consistent (Elias, Neville, & Scott, 2015; Song, Shen, Xu, & Sun, 2014). Nursing interventions to encourage reminiscence include asking patients directly about their past or by linking events in history with the patient's life experience. The use of photographs, old magazines, scrapbooks, and other objects can also stimulate discussion.

Psychosocial interventions for suicide prevention in this at-risk population are generally focused on the risk

factor of depression, and some have shown promising results (Okolie, Dennis, Thomas, & John, 2017). Treatment of depression has been associated with decreased suicidal ideation in older adults (Bruce et al., 2004; Szanto, Mulsant, Houck, Dew, & Reynolds, 2003). Lapierre and colleagues (2011) reported a few studies in their review focused on improving protective factors (e.g., resilience) and noted the potential utility of increasing protective factors for reducing depression in older adults. For example, positive social relationships (Neufeld, Hirdes, Perlman, & Rabinowitz, 2015) and church attendance (Rushing, Corsentino, Hames, Sachs-Ericsson, & Steffens, 2013) may provide protection against suicidal ideation for some older adults. Van Orden and colleagues (2014) found that the desire for death and a sense that life is not worth living is not a normative finding among older adults. The evidence is limited, but does support that assessment for a desire for death is an important part of mental status assessment for older adults in order to identify those individuals who may be at risk for suicide and would benefit from closer attention to their individual risks and protective factors.

In summary, psychosocial treatments have been found effective and safe in decreasing depression and potentially decreasing suicide-related thoughts in cognitively intact older adults. There is also empirical evidence for the efficacy of cognitive behavioral-based therapies and reminiscence therapy in decreasing depression both in individuals with cognitive impairment and in their caregivers (Orgeta et al., 2014).

Collaborative Care

Collaborative depression care programs are generally comprised of scheduled patient follow-ups, intensified interprofessional communication, a formal treatment plan, and focus on multiprofessional teams that include nurses trained as care or case depression managers and have been effective in improving outcomes for older adults with depression (Dham et al., 2017; Dreizler, Koppitz, Probst, & Mahrer-Imhof, 2014; Hall & Reynolds, 2014). A meta-analysis that included 14 studies (4,440 participants) comparing nurse-delivered collaborative depression care approaches to usual care for older adults with chronic illness found a moderate impact on depression severity that remained at follow-up (Ekers et al., 2013).

Ethnic minority older adults experienced improved treatment of depression when treated by an interdisciplinary treatment team (Davis, Deen, Bryant-Bedell, Tate, & Fortney, 2011), as did low-income older adults (Areán, Gum, Tang, & Unützer, 2007). Similarly, patients with multiple comorbid medical conditions responded positively to a collaborative approach to depression management (Harpole et al., 2005). Although older adults with comorbid anxiety disorders took longer to respond to treatment, they experienced greater reductions in depression when treated by a multiprofessional team than similar patients receiving usual primary care (Hegel et al., 2005). A study of a telephone-based collaborative care depression and anxiety treatment program in patients with acute cardiac disease reported decreased depressive symptoms, increased function, and improved quality of life compared to usual care (Huffman et al., 2014), and evidence supported the cost-effectiveness of the intervention (Celano et al., 2016).

Individualized Nursing Interventions for Depression

Psychosocial and behavioral nursing interventions can be incorporated into the plan of care, based on the patient's individualized need. Timely assessment and provision of safety precautions for patients with suicidal thinking is a priority. In acute medical settings, patients may require transfer to the psychiatric service when suicidal risk is high and staffing is not adequate to provide continuous observation of the patient. In outpatient settings, continuous surveillance of the patient should be provided while an emergency psychiatric evaluation and disposition is obtained.

Promotion of nutrition, elimination, sleep/rest patterns, physical comfort, and pain control has been recommended specifically for depressed medically ill older adults (Voyer & Martin, 2003). Nursing interventions should also focus on enhancement of the older adult's physical function and activity; aerobic activity; strength training; and exercise groups (Melrose, 2018). Referral for Tai Chi, yoga, and other mindfulness-based therapies provides older adults with depression with the opportunity for enhanced symptom management of depression and anxiety (Glover & Srinivasan, 2017). Enhancement of social support is associated with improved mood and is an important function of the nurse. This may be done by identifying, mobilizing, or designating a support person, such as a family member, a confidant, friend, volunteer or other hospital resource, church member, support group, patient or peer visitor, and particularly by accessing appropriate clergy for spiritual support.

Nurses should maximize the older adult's autonomy, personal control, self-efficacy, and decision-making about clinical care, daily schedules, and personal routines (Lawton, Moss, Winter, & Hoffman, 2002). Participation in regular, predictable, and pleasant activities can result in more positive mood changes for older adults with depression (Janssen et al., 2017). For example, a pleasant-events inventory, elicited from the patient and family, can be used to incorporate and increase the quality and quantity

of pleasurable activities into the older patient's daily schedule. The addition of music therapy customized to the older adult's preference is also recommended to reduce depressive symptoms (Zhao, Bai, Bo, & Chi, 2016).

Nurses should provide emotional support and education for depressed older patients by providing empathetic, supportive listening; encouraging patients to express their feelings in a focused manner on issues such as grief or role transition; offering supportive adaptive coping strategies; identifying and reinforcing strengths and capabilities; maintaining privacy and respect; and instilling hope. In particular, it is important to increase the patient's and family's awareness that depression and related symptoms are not a normal part of aging and that they are treatable. Education should include information on the negative health outcomes of untreated depression as well as the efficacy of evidence-based treatments for older adults with depression.

CASE STUDY 19.1

Ray Stimson is an 87-year-old man with multiple medical problems. He has a history of coronary artery disease (CAD) and had triple-bypass surgery 4 years ago. He also has hypertension, type 2 diabetes, and is hard of hearing. He was admitted to the hospital for surgical repair of a hip fracture following a fall in his home. Mr. Stimson is widowed (11 months) and has two adult children who do not live locally. Before his fall, he was living independently in the community; however, his children were growing increasingly concerned about his safety. Following surgery, Mr. Stimson was irritable and resisted efforts by the nursing staff to participate in self-care activities (e.g., walking, bathing). They often found him lying stoically in bed, staring into space. The nurses also observed that he was occasionally confused and would ask about his deceased wife.

A subsequent referral to the geropsychiatric consultation liaison nurse revealed that Mr. Stimson was experiencing a great deal of postoperative pain that was not well treated on his current medication regimen. Nursing staff had charted concerns that his opioid analgesic was contributing to his mental confusion. The geropsychiatric evaluation also revealed that Mr. Stimson had been growing increasingly depressed over the past few months and was still actively grieving the loss of his wife of 62 years. As his health had failed and his independent living was threatened, he admitted he had contemplated suicide, stating, "Life is just not worth living anymore." Further assessment revealed that he did not have a specific plan in mind and admitted that he did not really think that was a solution to his problems, but that he could not see that he had many options.

The liaison nurse worked with the medical team to develop a more aggressive plan for pain management. She also arranged for a family conference to discuss discharge-planning issues. During the family conference, the liaison nurse spoke to Mr. Stimson's children about long-term planning. She explained how important it was for Mr. Stimson to participate in any placement decisions that they may be contemplating and to have a sense of control. Although his children were able to express their reservations and concerns about safety, they agreed to explore the kinds of community support services that could be activated to help support their father in his own home for as long as possible.

Mr. Stimson was able to participate in rehabilitation and gained enough strength to return to his home. Arrangements were made for follow-up with mental health services. He was started on an antidepressant and agreed to participate in the senior lunch program twice a week to increase the opportunity for socialization. Several months after his discharge, Mr. Stimson reported that he still missed his wife terribly and that he still was lonely at times. However, he had developed some friendships at the senior center and was getting out one to two times each week. His children called more often and had, for the time being, stopped sending him brochures for assisted living facilities. He acknowledged that he may need to move to a more supervised setting in the future, but for now, he was content to stay in the home where he had many pleasant memories to keep him company.

SUMMARY

Depression significantly threatens the personal integrity, health, and "experience of life" of many older adults. Depression can be addressed with prompt identification and appropriate treatment. Early recognition can be enhanced by training healthcare personnel in the use of a standardized protocol that outlines a systematic method for depression assessment adapted for older adults in various settings and with diverse comorbid conditions. Early identification of depression and successful treatment outcomes demonstrate to society that depression is a treatable condition in late life. Nurses are key healthcare team members with a responsibility to depressed older adults for early identification of at-risk individuals and related symptoms, development of collaborative plans of care, and advocacy for equitable access to mental healthcare. As Blazer (1989) stated in his seminal article, "When there is depression, hope remains" (p. 166).

NURSING STANDARD OF PRACTICE

Protocol 19.1: Late-Life Depression

I. BACKGROUND[a]

A. Depression—both major and minor depressive disorders—is highly prevalent in medically ill, functionally impaired, and institutionalized older adults.
B. Depression is not a natural part of aging or a normal reaction to acute illness hospitalization.
C. Consequences of depression include amplification of pain and disability, delayed recovery from illness and surgery, worsening of drug side effects, excess use of health services, cognitive impairment, poor nutrition, and increased suicide- and nonsuicide-related death.
D. Depression (major and minor) tends to be long lasting and recurrent. Therefore, comprehensive and timely approaches are necessary.
E. Somatic symptoms may be more prominent than depressed mood in late-life depression.
F. Mixed depression and anxiety features may be evident among many older adults.
G. Recognition of depression is hindered by the coexistence of physical illness, cognitive decline, and social and economic problems common in late life. Early recognition, intervention, and referral by nurses can reduce the negative effects of depression.

II. ASSESSMENT PARAMETERS

Identify risk factors/high-risk groups (APA, 2013; Aziz & Steffens, 2013; Melrose, 2018; Smith et al., 2015; Taylor, 2014).

A. Biological contributors
   1. Vascular disease (MI, CAD, CVA)
   2. General health (new medical illness, pain, insomnia, prior depression, history of suicide attempt, concomitant substance abuse)
   3. Dementia (vascular and Alzheimer's disease)
   4. Other chronic or disabling medical conditions (diabetes, Parkinson's disease, arthritis, low vision, COPD)
   5. Psychosocial contributors
   6. Personality attributes (personality disorder, low self-efficacy)
   7. Life stressors (trauma, low income, impaired function, disability)
   8. Social stressors (bereavement, loneliness, impaired social support, caregiving)
B. Screen all at-risk groups using a standardized depression screening tool and document score
   1. The GDS-SF is recommended for its brevity, validity, and extensive use with medically ill older adults, and inclusion of *few* somatic items that may be confounded with physical illness.
   2. The PHQ-9 and PHQ-2 are recommended for their brevity, validity with older as well as younger adults, and availability in hospital and primary care settings.
C. Perform a *focused* depression assessment on all at-risk groups and document results. Note the number of symptoms; onset; frequency/patterns; duration (especially 2 weeks); and change from normal mood, behavior, and functioning.
   1. Depressive symptoms
   2. Depressed or irritable mood, frequent crying
   3. Loss of interest or pleasure (in family, friends, hobbies, sex)
   4. Weight loss or gain (especially loss)
   5. Sleep disturbance (especially insomnia)
   6. Fatigue/loss of energy
   7. Psychomotor slowing/agitation
   8. Diminished concentration
   9. Feelings of worthlessness/guilt

(*continued*)

Protocol 19.1: Late-Life Depression (*continued*)

10. Suicidal thoughts or attempts, hopelessness
11. Psychosis (i.e., delusional/paranoid thoughts, hallucinations)
12. History of depression, current substance abuse (especially alcohol), previous coping style
13. Recent losses or crises (e.g., death of spouse, friend, pet; retirement; anniversary dates; move to another residence, nursing home); change in physical health status, relationships, roles

D. Obtain/review medical history and physical/neurological examination.
E. Assess for depressogenic medications (e.g., steroids, narcotics, sedative/hypnotics, benzodiazepines, antihypertensive, H_2 antagonists, beta-blockers, antipsychotics, immunosuppressive, cytotoxic agents).
F. Assess for related systematic and metabolic processes (e.g., infection, anemia, hypothyroidism or hyperthyroidism, hyponatremia, hypercalcemia, hypoglycemia, congestive heart failure, kidney failure).
G. Assess for cognitive dysfunction.
H. Assess level of functional disability and quality of life.

III. CARE PARAMETERS

Based on guidelines and reviews (APA, 2010; Melrose, 2018; Pinquart et al., 2006; Taylor, 2014)

A. For severe depression (GDS-SF score of 11 or greater, five to nine depressive symptoms [must include depressed mood or loss of pleasure] plus other positive responses on individualized assessment [especially suicidal thoughts or psychosis and comorbid substance abuse]), refer for psychiatric evaluation. Treatment options may include medication or cognitive behavioral, interpersonal, or brief psychodynamic psychotherapy/counseling (individual, group, family); hospitalization; or ECT.
B. For less severe depression (GDS-SF score 6 or greater, less than five depressive symptoms, plus other positive responses on individualized assessment), refer to mental health services for psychotherapy/counseling (see previous types), especially for specific issues identified in individualized assessment and to determine whether medication therapy may be warranted. Consider resources such as psychiatric liaison nurses, geropsychiatric advanced practice nurses, social workers, psychologists, and other community and institution-specific mental health services. If suicidal thoughts, psychosis, or comorbid substance abuse are present, a referral for a comprehensive psychiatric evaluation should always be made.
C. For all levels of depression, develop an *individualized* plan integrating the following nursing interventions:
    1. Institute safety precautions for suicide risk as per institutional policy (in outpatient settings, ensure continuous surveillance of the patient while obtaining an emergency psychiatric evaluation and disposition).
    2. Remove or control etiologic agents.
        a. Avoid/remove/change depressogenic medications.
        b. Correct/treat metabolic/systemic disturbances.
    3. Monitor and promote symptom management of depression and anxiety (e.g., supporting individuals to improve nutrition, elimination, sleep/rest patterns, physical comfort [especially pain control], mindfulness interventions; routine aerobic and strength exercise programs).
    4. Monitor and enhance physical function (i.e., structure regular exercise/activity; refer to physical, occupational, or recreational therapies); develop a daily activity schedule.
    5. Enhance social support and reduce isolation (i.e., identify/mobilize a support person(s) [e.g., family, confidant, friends, hospital resources, support groups]); ascertain need for spiritual support and contact appropriate clergy.
    6. Maximize autonomy/personal control/self-efficacy (e.g., include patient in active participation in making daily schedules, short-term goals).
    7. Identify and reinforce strengths and capabilities.
    8. Structure and encourage daily participation in relaxation therapies, pleasant activities (conduct a pleasant activity inventory), and music therapy.
    9. Monitor and document response to medication and other therapies; readminister depression screening tool.
    10. Provide practical assistance; assist with problem-solving.

(*continued*)

Protocol 19.1: Late-Life Depression (*continued*)

11. Provide emotional support (i.e., empathic, supportive listening, encourage expression of feelings, hope instillation), support adaptive coping, and encourage pleasant reminiscences.
12. Provide information about the physical illness and treatment(s) and about depression (i.e., that depression is common, treatable, and not the person's fault). Include attention to addressing potential fear and stigma associated with depression.
13. Educate about the importance of adherence to prescribed treatment regimen for depression (especially medication) to prevent recurrence; educate about *specific* antidepressant side effects.
14. Ensure mental health community link-up; consider collaborative care programs.

IV. EVALUATION OF EXPECTED OUTCOMES

A. Patient
   1. Patient safety will be maintained.
   2. Patients with severe depression will be evaluated by psychiatric services.
   3. Patients will report a reduction of symptoms that are indicative of depression. A reduction in the GDS score will be evident, and suicidal thoughts or psychosis will resolve.
   4. Patient's daily functioning will improve.

B. Healthcare provider
   1. Document risk assessment, interventions initiated for depression, progress of patients with depressive symptoms, and referrals.
   2. Provide support and depression-specific education to patients and their families (and other caregivers) via written and verbal information on depression and its management, including how families or carers can support the person.
   3. Conduct medication review for potential drug–drug interactions.
   4. Evaluate physiological findings necessitating adjustment (e.g., liver and renal function).

C. Institution
   1. The number of patients identified with depression will increase.
   2. The number of in-hospital suicide attempts will not increase.
   3. The number of referrals to mental health services will increase.
   4. The number of referrals to psychiatric nursing home care services will increase.
   5. Staff will receive ongoing education on depression recognition, assessment, and interventions.
   6. Develop collaborative depression care management programs.

V. FOLLOW-UP TO MONITOR CONDITION

A. Continue to track prevalence and documentation of depression in at-risk groups.
B. Show evidence of transfer of information to postdischarge mental health service delivery system.
C. Educate caregivers to continue assessment and management strategies.

ABBREVIATIONS

APA	American Psychiatric Association
CAD	Coronary artery disease
COP	Chronic obstructive pulmonary disease
CVA	Cerebrovascular accident
GDS-SF	Geriatric Depression Scale–Short Form
MI	Myocardial infarction
PHQ	Patient Health Questionnaire

[a] Somatic symptoms, also seen in many physical illnesses, are frequently associated with A and B; therefore, the full range of depressive symptoms should be assessed.

ACKNOWLEDGMENTS

This chapter is based partly on Chapter 5 of the third edition, coauthored by Dr. Lenore H. Kurlowicz, who died on September 21, 2007. The authors and coeditors acknowledge her tremendous contributions to the field of geropsychiatric nursing.

RESOURCES

Recommended Instruments for Screening for Depression

Geriatric Depression Scale–Short Form (GDS-SF)

A 15-item screening measure for depression in older adults
www.stanford.edu/~yesavage/GDS.html

Patient Health Questionnaire (PHQ-9)

A nine-item scale recommended for screening in older adults. The first two questions of the PHQ-9 are referred to as the PHQ-2 and may be used to identify the need for a more complete assessment of depressive symptoms using the PHQ-9 or GDS-SF.
www.phqscreeners.com

Delirium: Prevention, Early Recognition, and Treatment*

Cheri Blevins

20

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss risk factors of delirium in older hospitalized adults.
2. Describe the negative sequelae of delirium in older adults during hospitalization.
3. Discuss the importance of early recognition of delirium.
4. List four nonpharmacological interventions to prevent and/or treat delirium.
5. Identify long-term negative sequelae of delirium in older adults who have been hospitalized.

OVERVIEW

Delirium is a common complication in hospitalized older adults and is one of the major contributors to poor outcomes and institutionalization. The incidence and severity of delirium may be reduced by identifying risk factors, implementing nonpharmacological multicomponent interventions, and screening regularly for delirium. If delirium develops, early recognition is of utmost importance to determine and treat the underlying pathology in order to minimize negative sequelae. Although many researchers are seeking to identify effective pharmacological agents to prevent and/or treat delirium, no definitive evidence has been determined. Implementation of nonpharmacological and multicomponent bundles remain the primary intervention to prevent and/or treat delirium. Nurses play a key role in the prevention, early recognition, and treatment of this potentially devastating condition in older hospitalized adults.

BACKGROUND AND STATEMENT OF PROBLEM

Definition

Delirium is an indicator of acute brain dysfunction and is a complex neurocognitive disorder. Delirium is characterized by disturbances in consciousness and changes in cognition that develop over a short period of time (hours to days) and fluctuates. Evidence from history and physical or laboratory findings indicates a direct physiological cause from a general medical condition, an intoxicating substance, medication use, or multiple causes (American Psychiatric Association [APA], 2013). Delirious patients may exhibit hyperactive, hypoactive, or mixed motoric subtypes of delirium (Hosie, Davidson, Agar, Sanderson, & Phillips, 2013; Meagher, 2009). Two additional motoric subtypes have recently been noted: catatonic (extreme hypoactive) and excited or extreme hyperactive delirium (Maldonado, 2017; Wilson et al., 2017). Hyperactive delirium is easily

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

recognized as it is often accompanied by harmful patient behavior for patient and staff. The hypoactive subtype, with its lack of overt psychomotor activity, is also common (Hosie et al., 2013; Meagher, 2009; Pandharipande et al., 2007) and has a higher risk of mortality and other comorbid conditions, especially when superimposed on dementia (Gual et al., 2018; Yang et al., 2009).

Etiology and Epidemiology

Prevalence and Incidence

Among medical inpatients, delirium is present on hospital admission in 8% to 17% of older patients and in 40% of nursing home residents; during hospitalization, 50% of older adults develop delirium (Inouye, Westendorp, & Saczynski, 2014; Siddiqi, House, & Holmes, 2006). Among hip surgery patients, the incidence of delirium is 4% to 53%. Older adults experiencing hip fractures and preexisting cognitive impairment are extremely likely to develop delirium (25%–65%) and experience functional decline and death (Bruce, Ritchie, Blizard, Lai, & Raven, 2007; Freter, Koller, Dunbar, MacKnight, & Rockwood, 2017). Older adults admitted to medical intensive care units (ICUs) have both prevalent and incident delirium of 31% (McNicoll et al., 2003; Salluh et al., 2010). In surgical ICUs (SICUs), the prevalence of delirium on admission is only 2.6%; however, 24.4% to 28.3% develop delirium during their SICU stay (Balas et al., 2007; Chaiwat et al., 2019). Up to 81.7% of mechanically ventilated patients in medical and SICUs experience delirium (Ely et al., 2004; Pisani, Murphy, Araujo, & Van Ness, 2010), and more than half of older patients in medical ICUs still have delirium when transferred (Pisani et al., 2010). From 13.3% to 42.3% of palliative care patients have delirium on admission, 26% to 62% during hospitalization, and 58.8% to 88% when closer to death (Hosie et al., 2013). The incidence of delirium superimposed on dementia ranges from 22% to 89% (Fick, Agostini, & Inouye, 2002; Mosk et al., 2017).

Pathophysiology

The pathogenesis of delirium is an extremely complex physiological phenomenon involving interactions between neurotransmitter systems and psychoneuroimmunological pathways (American Geriatrics Society [AGS]/National Institute on Aging [NIA] Delirium Conference Writing Group, Planning Committee and Faculty, 2015). One theory postulated to be connected to the development of delirium involves five converging pathways: neuronal aging, neuroinflammation, oxidative stress, neuroendocrine dysregulation, and circadian dysregulation; additional research is needed to further explain this theory (Maldonado, 2017).

Risk Factors

The most common risk factors for the development of hospital delirium are dementia, older age, comorbid illness, severity of medical illness, infection, "high-risk" medication use, postoperative status, diminished activities of daily living, immobility, sensory impairment, urinary catheterization, urea and electrolyte imbalance, and malnutrition. Statistically significant risk factors are dementia, illness severity, urinary catheterization, low albumin level, length of hospital stay, and metabolic acidosis (Abraha et al., 2016; Ahmed, Leurent, & Sampson, 2014; Zaal, Devlin, Peelen, & Slooter, 2015). In older patients admitted for hip surgery, early cognitive impairment, such as memory impairments, incoherence, and disorientation, as well as underlying physical illness and age, are especially strong predictors of delirium (de Jonghe et al., 2007; Freter et al., 2017; Kalisvaart et al., 2006). Other possible risk factors include sleep deprivation (Weinhouse et al., 2009), elevated blood urea nitrogen (BUN)/creatinine ratio, polypharmacy, physical restraints, and anemia (Inouye et al., 1990; Inouye, Viscoli, Horwitz, Hurst, & Tinetti, 1993; O'Keeffe & Lavan, 1996).

Outcomes

The outcomes of delirium in hospitalized older adults are grave. Those who develop delirium have an increased mortality rate during hospitalization (Schubert et al., 2018) and post discharge (up to 22.7 months [Witlox et al., 2010]). These patients also experience increased hospital lengths of stay and require discharge to long-term care facilities (Shi, Presutti, Selchen, & Saposnik, 2012; Witlox et al., 2013). Other sequelae of delirium are depression, decreased functional and cognitive status, and increased geriatric syndrome complications (Anderson, Ngo, & Marcantonio, 2012; Cole, McCusker, Ciampi, & Belzile, 2008; Witlox et al., 2010, 2013). ICU patients who develop delirium have a higher mortality and complication rate, spend longer periods of time on mechanical ventilation, have increased ICU and hospital lengths of stay, and are more likely to be discharged to a long-term care facility (Ely et al., 2004; Ely, Gautam, et al., 2001; Shehabi et al., 2013; Zhang, Pan, & Ni, 2013). Thirty percent of patients surviving critical illness report depression, and 23% experience difficulty in ADLs at 12 months post discharge (Jackson et al., 2014). From 22% to 89% of older hospitalized adults with dementia also have

delirium superimposed on dementia (Fick et al., 2002), are at increased risk for developing delirium, and have worse outcomes, including a risk of death five times that for those without delirium (Ford, 2016; Morandi et al., 2014; Yang et al., 2009).

ASSESSMENT OF THE PROBLEM

Identification of risk factors is a critical first step in delirium prevention. Researchers have begun to utilize risk identification, through the electronic medical record, as a means to proactively identify those at high risk for progression to delirium in order to mitigate or eliminate those risks (Halladay, Sillner, & Rudolph, 2018; Milisen, Lemiengre, Braes, & Foreman, 2005). Recognizing delirium as a warning sign of worsening pathology is a key component of any delirium program. This can best be done by routinely assessing patients at risk for delirium with a standardized screening tool for delirium, although this is currently occurring only in 17% of hospitals (Neuman, Speck, Karlawish, Schwartz, & Shea, 2010), and nurses fail to recognize delirium 75% of the time (Rice et al., 2011).

The gold standard for diagnosing delirium is a full evaluation by a mental health expert using the criteria found in the most recent *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*; APA, 2013). However, given the rapid onset and typically fluctuating course of delirium, particularly in the hospital setting, a number of user-friendly and relatively rapid screening tools have been developed and utilized by nurses for over the past two decades.

The Confusion Assessment Method (CAM; Inouye et al., 1990) is the most widely used delirium screening instrument in hospitalized older adults, having been used in more than 5,000 original articles and translated into 13 languages (Inouye, 2015). The long CAM has 10 items and is preferred in research studies, whereas short CAM contains only the four items of the diagnostic algorithm. A version of the CAM for patients in ICUs (CAM-ICU; Ely, Inouye, et al., 2001) is recommended for use with critically ill adults (Devlin et al., 2018; Jacobi et al., 2002; Schuurmans, Deschamps, Markham, Shortridge-Baggett, & Duursma, 2003). The CAM instrument identifies the key features of delirium—acute onset and fluctuating course, inattention, disorganized thinking, and altered level of consciousness—and is supported by the best evidence (Wong, Holroyd-Leduc, Simel, & Straus, 2010). The brief CAM (bCAM) is another tool that has been used for rapid assessment for the verbal hospitalized elder utilizing the attention test of the months of year backward from December to July, with more than one error indicating inattention (Han et al., 2013; O'Regan et al., 2014). The Two-item Ultra-brief Delirium (UB-2) uses all 12 months of the year and also asks, "What is the day of the week?"; it has a sensitivity to pick up delirium of 93% and 96% in persons with dementia (Fick et al., 2018). If older adults fail either question, they are positive for delirium, and it should be followed up with another tool such as the CAM.

Other robust and usable scales include the Delirium Rating Scale (DRS), the Memorial Delirium Assessment Scale (MDAS), and the NEECHAM Confusion Scale (Adamis, Sharma, Whelan, & Macdonald, 2010; Breitbart et al., 1997; Neelon, Champagne, Carlson, & Funk, 1996; Trzepacz et al., 2001).

Another delirium scale in use is the Nursing Delirium Screening Scale (Nu-DESC; Gaudreau, Gagnon, Harel, Tremblay, & Roy, 2005). The Nu-DESC is based on the Confusion Rating Scale (CRS; Gagnon, Allard, Masse, & DeSerres, 2000), the only delirium screening scale that does not require patient participation as it evaluates the presence of confusional symptoms. The CRS can be completed in less than 2 minutes during routine nursing care and assesses four symptoms of delirium: disorientation, inappropriate behavior, inappropriate communication, and illusions or hallucinations. The CRS uses a score of 0 when there are no symptoms, 1 if there is one mild symptom, and 2 when a symptom is present and pronounced. A score of 2 or more is considered positive.

The Nu-DESC added a fifth symptom, psychomotor retardation, to account for the hypoactive variant of delirium (Gaudreau et al., 2005). When compared with blinded assessments of 59 patients with psychiatrists using the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.; *DSM-IV*; APA, 1994) criteria and research nurses using the CAM and MDAS assessments, the Nu-DESC showed 85.7% sensitivity and 86.8% specificity (De & Wand, 2015). When comparing the Nu-DESC to the CAM-ICU in ICU patients, the Nu-DESC had a sensitivity of 83% (compared to 81% for the CAM-ICU); however, the specificity of the Nu-DESC (81%) was significantly lower than that of CAM-ICU (96%; Luetz et al., 2010); so the CAM-ICU remains the preferred screening tool for delirium in critically ill patients.

Bedside nurses are in the best position to recognize delirium because they possess the skill and responsibility of ongoing patient assessment and are in key positions to recognize risk factors for delirium and the earliest cognitive changes heralding the onset of delirium. Early identification of risk factors and screening for onset of delirium are critical to implementing strategies to minimize the occurrence of this devastating pathology in hospitalized older adults. Chapter 9, Assessing Cognitive Function in the Older Adult, provides more information on screening and assessment tools.

Interventions

A Cochrane Review in 2016 found strong evidence that multicomponent interventions are noted to prevent delirium in both medical and surgical patients and moderate evidence that these interventions may decrease delirium severity (Siddiqi et al., 2016).

The focus of the AGS is to promote healthy aging through primary, secondary, and tertiary prevention under which delirium prevention and mitigation would be included (Friedman et al., 2018). It is noteworthy that virtually all of the components of these recommended nonpharmacological interventions to prevent and manage delirium are basic nursing practices that should be part of every nurse's routine care of hospitalized patients. Supporting studies (Abraha et al., 2016; AGS expert panel, 2014; Collinsworth, Priest, Campbell, Vasilevskis, & Masica, 2016; Inouye et al., 1999; Kolanowski et al., 2016; Lundstrom et al., 2005; Marcantonio, Flacker, Wright, & Resnick, 2001; Milisen et al., 2005; Rivosecchi, Kane-Gill, Svec, Campbell, & Smithburger, 2016; Rubin, Neal, Fenlon, Hassan, & Inouye, 2011; Rubin et al., 2006; Siddiqi et al., 2016; Zaubler et al., 2013) have included the following types of interventions:

1. Mobility
2. Reorientation
3. Cognitive stimulation
4. Maintenance of nutrition and hydration
5. Sleep enhancement
6. Vision and hearing adaptation
7. Nursing education
8. Geriatric consultation

CASE STUDY 20.1

Mrs. S. is a 71-year-old patient admitted, after a ground-level fall and humerus break, with a diagnosis of hyponatremia. She is a retired office worker who continues to work a waitress job for fun, lives with her fiancé, and is very active. She regularly has shopping outings with her grandchildren and enjoys driving her convertible. She recently had a bunion surgery and has mild hypertension (controlled with lisinopril 5 mg) and depression (sertraline 50 mg) since the death of her husband 9 years previously. Mrs. S. reports complete recovery from her surgery yet continues with diminished appetite, ongoing back pain despite ibuprofen daily, and dizzy spells in the day, leading to her fall. She reports wearing her contact lenses consistently and has no cognitive or executive functioning deficits. She is alert, oriented, and concerned regarding the cause of her fall, and in pain owing to the humerus break. Her admission sodium level was 122, and she also has elevated liver enzymes (ALP 300 IU/L and LDH 1,000 IU/L). Owing to the metabolic disarray, Mrs. S will not have surgery immediately to repair her bone.

What Factors Present on Admission to the Hospital Put Mrs. S at Risk for Developing Delirium?

- *Age:* Older adults are at greater risk of delirium, particularly if they have underlying dementia or depression. Physiological changes that occur with aging can affect the ability of older adults to respond to physical and physiological stress and to maintain homeostasis.
- *Metabolic disarray:* Electrolyte imbalances are direct brain insults often presenting as alterations in mental status.
- *Fall history:* Patients with a fall history may experience dizziness and potential for metabolic encephalopathy.
- *Pain:* Uncontrolled pain contributes to the development of delirium.

It is important to understand that delirium is not attributable to one particular factor but to the interplay of patient vulnerability (predisposing factors) and precipitating factors—common during hospitalization—that place the older adult at risk for delirium.

What Can You Do to Help Prevent Delirium in Mrs. S?

- Ensure adequate pain relief and assistance with positioning for comfort.
- Replace electrolytes as ordered.
- Ensure adequate sleep and rest.
- Review Mrs. S's nutritional status and collaborate with the interprofessional team to ensure adequate hydration and nutrition.
- Implement fall precautions and ensure a safe environment.

You provide care for Mrs. S on your next shift 2 days later. She has received a diagnosis of stage IV breast cancer with bone and liver metastases. She is confused and picking at the air and oriented to self only. An indwelling urinary catheter and peripheral intravenous line are

(*continued*)

CASE STUDY 20.1 (*continued*)

in place. In report, the day-shift nurse mentioned considering a physical restraint because Mrs. S was increasingly restless and impulsive. She is Nu-DESC positive, indicating that she may have delirium. The licensed independent practitioner was notified and confirmed delirium using the *DSM-5* criteria (APA, 2013).

What Are the Clinical Features of Delirium?

- *Disturbance of consciousness* characterized by reduced clarity and awareness of the environment: reduced ability to focus, sustain, and shift attention. Patients have trouble following instructions or making sense of their environment, even with cues. They may also get "stuck" on a particular concern or thought.
- *Cognitive changes:* Memory deficit, disorientation, language disturbance, and/or perceptual disturbance
- *Perceptual disturbances:* Hallucinations and delusions are common. Patients can be hyperactive and agitated or lethargic (hypoactive) and less active. The latter presentation is of particular concern because it is often not recognized by healthcare providers as delirium. The presentation may also be mixed, with the patient fluctuating from one to the other behavioral state.
- Delirium can be *characterized by* disturbances in the sleep–wake cycle and rapidly shifting emotional disturbances, with escalation of the disturbed behavior at night (sundowning).
- The clinical hallmarks of delirium are that the cited *changes occur rapidly* over several hours or days. There is a decreased attention span and a fluctuating course (waxing and waning of confusion).

It is also important to consider that delirium may occur concurrently with dementia or depression. In fact, these patients are at increased risk for developing delirium. Family and caregivers can be invaluable in helping to identify or distinguish cognitive changes in circumstances when the patient is not well known to you.

What Additional Factors May Now Be Contributing to Mrs. S's Delirium?

- *Worsening metabolic disarray:* Has her sodium corrected? Have any other electrolytes been affected by her devastating diagnosis?
- *Pain:* What is Mrs. S's pain-control regimen and status? What is the dose and frequency of the pain medication? Is the dose appropriate?
- *Hypoxemia:* Mrs. S is at risk because of limited mobility and diagnosis. What is her oxygen saturation (SpO_2)? Does she have crackles or diminished breath sounds?
- *Infection, inflammation, or other medical illness:* Could the bone break and could further complications from metastatic cancer be contributing to inflammation? An inflammatory response to a new medical problem may be the cause of the delirium. Could Mrs. S have a urinary tract infection (UTI) related to her indwelling catheter?
- *Unfamiliar surroundings:* Particularly for those with sensory deficits, unfamiliar environments can lead to misinterpretations of information, which may contribute to delirium.

What Steps Should Be Taken Now?

- *Avoid the use of restraints*, which could worsen Mrs. S's agitation and pain from her arm break.
- *Call the physician or nurse practitioner* immediately as delirium from electrolyte disturbances can be life threatening. Report your findings; request that the patient be evaluated to determine the underlying cause of the delirium. If the psychotic features of delirium worsen and the risk of harm to the patient or others is imminent, Mrs. S may also need medication to control her hyperactive symptoms to prevent further injuries.
- *Frequent reality orientation:* Frequent orientation, reassurance, and helping Mrs. S interpret her environment and circumstances should be helpful. (Monitor the patient's reaction. If the patient becomes upset or angry, you will need to modify your approach to that of more reassurance and validating the patient's experience rather than reorienting.)
- Are Mrs. S's contacts still in place? If not, ensure glasses are available. Impaired sensory input contributes significantly to delirium.
- Invite *family/significant others* to stay as much as they are able to assist with his orientation, reassurance, and sense of well-being. Monitor the effect of family visitation. If the patient has increased agitation or anxiety, then limit the visitation of the individual who seems to be triggering Mrs. S's upset.
- *Mobilize the patient*. Mobility assists with orientation and helps prevent problems associated with immobility, such as atelectasis and deep venous thrombosis.
- *Judicious use of medications* for pain, sleep, or anxiety. Drugs used to address these issues can exacerbate the delirium. Try nonpharmacological approaches for sleep and anxiety first. A regular schedule of a smaller dose or nonnarcotic pain medication almost always is better than as-needed dosing.

(*continued*)

CASE STUDY 20.1 (*continued*)

- Try to *provide for adequate sleep:* Reduce noise at night; play soft, relaxing music; offer warm milk or herbal tea, and massage; reschedule care in order not to interrupt sleep.
- Make sure the patient is well *hydrated and nourished*.
- Talk to the doctor or nurse practitioner about removing the *indwelling urinary catheter*. If strict monitoring of intake and output are not needed, remove the catheter as soon as possible. Consider use of an external female catheter. Are there additional symptoms of a UTI such as fever or pain? Consider urinalysis.
- *Address safety concerns* (e.g., increase surveillance). Mrs. S is now also at greater risk for falls and other conditions and syndromes.

SUMMARY

Delirium is a common occurrence in hospitalized older adults and contributes to poor outcomes. Thus, it is important to identify those patients at risk for delirium immediately upon admission and implement preventive measures as well as promptly recognize delirium if it develops. Nursing assessments using validated delirium screening instruments must become routine. A standard-of-practice protocol provides concise information to guide nursing care of individuals at risk for or experiencing delirium.

NURSING STANDARD OF PRACTICE

Protocol 20.1: Delirium Prevention/Management

I. GOAL

Reduce the incidence of delirium in older hospitalized adults

II. OVERVIEW

A. Delirium is a common syndrome in hospitalized older adults and is associated with increased mortality, hospital costs, and long-term cognitive and functional impairment.
B. Delirium may be prevented or diminished with the recognition of high-risk patients and the implementation of a standardized multicomponent delirium-reduction protocol.
C. Recognition of risk factors and routine screening for delirium should be part of comprehensive nursing care for older adults.

III. BACKGROUND

A. Delirium is a neurocognitive disorder that develops over a short period of time (hours to days), fluctuates in severity throughout the day, and is primarily a disturbance of attention. Delirium is a physiological consequence of another underlying disorder (APA, 2013).
B. Prevalence and incidence: In 8% to 17% of older medical patients, 31% of ICU patients, and 26% to 62% of palliative care patients, delirium is *present on admission* (Inouye et al., 2014; Siddiqi et al., 2006). Delirium *develops* in 11% to 42% of medical (Siddiqi et al., 2006), 4% to 53% of hip surgery (Bruce et al., 2007), 31% of medical ICU (McNicoll et al., 2003; Salluh et al., 2010), 24.4% to 28.3% of surgical ICU (Balas et al., 2007; Chaiwat et al., 2019), up to 81.7% of mechanically ventilated (Ely et al., 2004; Pisani et al., 2010), and 26% to 88% of palliative care patients (Hosie et al., 2013; Mosk et al., 2017).
C. Risk factors: The most common risk factors for delirium in acute hospital units are dementia, older age, comorbid illness, severity of medical illness, infection, "high-risk" medication use, postoperative status, diminished activities of daily living, immobility, sensory impairment, urinary catheterization, urea and electrolyte imbalance, metabolic acidosis, and malnutrition (Abraha et al., 2016; Ahmed et al., 2014; Zaal et al., 2015). Other possible risk factors

(*continued*)

Protocol 20.1: Delirium Prevention/Management (*continued*)

include sleep deprivation (Weinhouse et al., 2009), polypharmacy, physical restraints, and anemia (Inouye et al., 1990, 1993; O'Keeffe & Lavan, 1996).

D. Outcomes: The outcomes of delirium in hospitalized older adults are increased mortality (Schubert et al., 2018; Witlox et al., 2010), hospital length of stay, transfer to long-term care facilities (Shi et al., 2012; Witlox et al., 2013), depression, decreased functional and cognitive status, increased geriatric syndrome complications, and dementia (Anderson et al., 2012; Cole et al., 2008; Jackson et al., 2014; Witlox et al., 2010, 2013). From 22% to 89% of older hospitalized adults with dementia also have delirium superimposed on the dementia (Fick et al., 2002), are at increased risk for developing delirium, and experience worse outcomes if it occurs (Ford, 2016; Morandi et al., 2014; Yang et al., 2009).

IV. PARAMETERS OF ASSESSMENT

A. Assess for common and other risk factors (Ahmed et al., 2014; Halladay et al., 2018).
   1. Cognitive dysfunction
   2. Illness severity
   3. Comorbidities
   4. Infection
   5. Postoperative status
   6. High-risk medication use (e.g., benzodiazepines)
   7. Immobility
   8. Decreased activities of daily living
   9. Urinary catheterization
   10. Urea and electrolyte imbalance and dehydration
   11. Malnutrition
   12. Physical restraints
   13. Anemia
   14. Metabolic acidosis

B. Assess for delirium using a validated screening tool (see "Resources")
   1. Key features of delirium (CAM, CAM-ICU, bCAM)
      a. Acute onset and fluctuating course
      b. Inattention
      c. Disorganized thinking
      d. Altered level of consciousness
   2. Delirium symptoms (Nu-DESC)
      a. Disorientation
      b. Inappropriate behavior
      c. Inappropriate communication
      d. Illusions or hallucinations
      e. Psychomotor hypoactivity

V. NURSING CARE STRATEGIES

A. Eliminate or minimize risk factors
   1. Administer medications judiciously; avoid high-risk medications.
   2. Prevent and/or promptly and appropriately treat infections.
   3. Prevent and/or promptly treat dehydration and electrolyte disturbances.
   4. Provide adequate pain control.
   5. Maximize oxygen delivery (supplemental oxygen, blood, and BP support as needed).

(*continued*)

Protocol 20.1: Delirium Prevention/Management (*continued*)

6. Use sensory aids as appropriate.
7. Regulate bowel/bladder function.
8. Provide adequate nutrition.

B. Provide a therapeutic environment.
1. Foster orientation: Frequently reassure and reorient patient (unless patient becomes agitated); use easily visible calendars, clocks, caregiver identification; carefully explain all activities; communicate clearly.
2. Provide appropriate sensory stimulation: quiet room, adequate light, pursue one task at a time, use noise-reduction strategies.
3. Facilitate sleep: Offer back massage, warm milk, or herbal tea at bedtime; play relaxation music/tapes; employ noise-reduction measures; avoid awaking patient.
4. Foster familiarity: Encourage family/friends to stay at bedside, bring familiar objects from home, maintain consistency of caregivers, minimize relocations.
5. Maximize mobility: Avoid restraints and urinary catheters; ambulate or perform active ROM exercises three times daily.
6. Provide appropriate cognitive stimulation.
7. Communicate clearly, provide explanations.
8. Reassure and educate family.
9. Minimize invasive interventions.
10. Consult with a geriatric specialist.
11. Consider psychotropic medication **as a last resort** for agitation (Neufeld, Yue, Robinson, Inouye, & Needham, 2016; Patel, Baldwin, Bunting, & Laha, 2014; Zaubler et al., 2013).

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient
1. Absence of delirium
2. Cognitive status returned to baseline (before delirium)
3. Functional status returned to baseline (before delirium)
4. Discharged to same destination as prehospitalization

B. Healthcare provider
1. Regular use of delirium screening tool
2. Increased detection of delirium
3. Implementation of appropriate interventions to prevent/treat delirium from standardized protocol
4. Decreased use of physical restraints
5. Decreased use of antipsychotic medications
6. Increased satisfaction in care of hospitalized older adults

C. Institution
1. Staff education and interprofessional care planning
2. Implementation of standardized delirium screening protocol
3. Decreased overall cost
4. Decreased length of stay
5. Decreased morbidity and mortality
6. Increased referrals and consultation to earlier specified specialists
7. Improved satisfaction of patients, families, and nursing staff

VII. FOLLOW-UP MONITORING OF CONDITION

A. Decreased delirium to become a measure of quality care

(*continued*)

Protocol 20.1: Delirium Prevention/Management (*continued*)

B. Incidence of delirium to decrease
C. Patient days with delirium to decrease
D. Staff competence in recognition and treatment of delirium
E. Documentation of a variety of interventions for delirium

Dementia: Assessment and Care Strategies*

Marie Boltz

21

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Describe the spectrum of dementia syndromes.
2. Recognize the clinical features of dementia.
3. Discuss nonpharmacological and pharmacological approaches in the management of dementia.
4. Develop a nursing plan of care for an older adult with dementia.

OVERVIEW

Dementia is most commonly defined as a clinical syndrome of cognitive decline. The term *dementia* was eliminated and replaced with "major or minor neurocognitive disorder" in the latest *Diagnostic and Statistical Manual of Mental Health Disorders* (5th ed.; *DSM-5*; American Psychiatric Association, 2013). It was felt that the term *dementia* was stigmatizing and that the focus should be on decline rather than deficit. Because these changes are confusing to many healthcare professionals and the term *dementia* remains established in the literature, the terms *dementia* and *neurocognitive disorder* are used interchangeably in this chapter. In addition to disruptions in cognition, dementia is associated with a gradual decline in function and changes in mood and behavior.

There are many causes of dementia and dementia-like presentations. Differentiating these changes early in the course of illness is important because condition-specific assessment, monitoring, and management strategies can be employed. Differential diagnoses among conditions that cause cognitive impairment are confounded by the fact that these conditions may coexist and disparate neurocognitive disorders may be similarly clinically expressed.

Major goals in the clinical approach to a person presenting with cognitive impairments are identification and resolution of potentially reversible conditions (e.g., delirium, depression), recognition and control of comorbid conditions, early diagnosis and management of a neurocognitive disorder, and the provision of caregiver support. The focus of this chapter is on assessment and management of the major neurocognitive disorders.

BACKGROUND AND STATEMENT OF PROBLEM

Global estimates reflect that approximately 50 million people have dementia, which will increase to 75.6 million by 2030 and 135.5 million by 2050 (Alzheimer's Disease

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

International, 2018). It is further estimated that every 4 seconds there is a new case of dementia in the world and that once every 65 seconds, someone in the United States develops Alzheimer's disease (Alzheimer's Association, 2019). Dementia affects about 11% of individuals aged 65 years and older, and the prevalence is higher in individuals 85 years and older, at nearly 32%. More than 5.8 million individuals in the United States have the most common form of dementia, Alzheimer's disease (AD), a number that is projected to increase to approximately 14 million by 2050 (Alzheimer's Association, 2019).

This chapter discusses the most common forms of progressive dementia: AD, vascular dementia (VaD), dementia with Lewy bodies (DLB), and frontotemporal dementia (FTD). Less common, though not less significant, is progressive dementia associated with Parkinson's disease (PDD), dementias associated with HIV, and Creutzfeldt–Jacob disease.

AD, the most common form of dementia, accounts for more than 80% of all cases. A chronic neurodegenerative disease, first described by Alois Alzheimer in 1907, it is characterized by neurofibrillary plaques and "tangles" in the brain. The extracellular accumulation of amyloid beta proteins in the neuritic plaques is one of the hallmarks of AD (Takahashi, Nagao, & Gouras, 2017). The variation in the clinical presentation of the disease depends on the area of the brain that is affected. Classic features of AD include progressive loss of memory, deterioration of language and other cognitive functions, decline in the ability to perform activities of daily living (ADL), and changes in personality and behavior and judgment dysfunction (Kumfor, Halliday, & Piguet, 2017). Mild cognitive impairment (MCI) represents a transitional state between healthy aging and dementia and is characterized by cognitive impairment out of proportion to the age of the individual, yet the individual does not meet the criteria for dementia (Yanhong, Chandra, & Venkatesh, 2013). Incidence rates of MCI are 51 to 76.8 per 1,000 person-years, with a higher incidence in those with advanced age, lower education, vascular risk factors (type 2 diabetes, hypertension, obesity, dyslipidemia, smoking), cardiovascular disease outcomes (coronary artery disease, atrial fibrillation, congestive heart failure, cerebrovascular disease), and neuropsychiatric conditions (depression, anxiety, apathy; Roberts & Knopman, 2013). About 35% of MCI patients progress to AD, with an annual conversion rate of 5% to 10% (Mitchell, 2009). Cerebrospinal fluid (CSF) biomarkers' performance is the most convenient test predicting conversion, yet it remains suboptimal (Ferreira et al., 2014).

VaD, sometimes referred to as vascular cognitive impairment (VCI) and previously known as multi-infarct dementia (MID), refers to dementia resulting from cerebrovascular disease. It is the second most common cause of dementia among older adults and represents approximately 30% of all cases of dementia in the United States (Michigan Alzheimer's Disease Center, 2019). The link between AD and VaD is strong yet not entirely clear (de la Torre, 2012). The onset of VaD is usually more acute than AD, and the diagnosis of VaD is based on the association between a cerebrovascular event and the onset of clinical features of dementia, including evidence of focal deficits, gait disturbances, personality and mood changes, and impairments in executive function (Kuźma et al., 2018). As compared with AD, memory may not be impaired or is more mildly affected. Not uncommonly, AD and VaD pathology coexist, and this, often referred to as a mixed dementia, is likely to increase as the population ages (Jang et al., 2017).

DLB accounts for about one in 25 diagnosed cases of dementia (Vann Jones & O'Brien, 2014). DLB is a neurodegenerative dementia that results when Lewy bodies form in the brain. Lewy bodies are pathological aggregations of alpha-synuclein found in the cytoplasm of neurons (Morra & Donovick, 2014). Clinical features include cognitive and behavioral changes in combination with features of parkinsonism. Disorders of executive function occur early. Hallucinations, visual–spatial disturbances, and sleep disorders are prominent. Rigidity and unsteady gait are common. Many (but not all) patients with PDD develop a dementia years after the motor symptoms appear. Distinctions have been made clinically between DLB and the dementia associated with PDD based on the sequence of the appearance of symptoms over the time course. In PDD, motor symptoms precede cognitive impairment, whereas DLB begins with fluctuations in cognition. DLB and PDD may represent the same pathological process along a disease spectrum (Mayo & Bordelon, 2014).

FTD, with a prevalence of 15 per 100,000, refers to a group of progressive brain diseases whose clinical manifestations are dominated by behavioral changes and/or impairments in language (Riedl, MacKenzie, Forsti, Kurz, & Diehl-Schmid, 2014). A growing body of evidence indicates that FTD and amyotrophic lateral sclerosis (ALS) share some clinical, pathological, and molecular features as part of a common neurogenerative spectrum disorder (Gascon & Gao, 2014).

The National Alzheimer's Project Act of 2011 (NAPA) mandated a national plan to address AD and related dementias (Montine et al., 2014). NAPA, directed by the U.S. Department of Health and Human Services, is organized around the following five goals: (a) prevent and effectively treat AD by 2025; (b) enhance care quality and

efficiency; (c) expand supports for individuals with AD and their families; (d) enhance public awareness and engagement; and (e) improve data to track progress and drive improvement (Bonnel, 2013).

ASSESSMENT OF THE PROBLEM

Goals of Assessment

Early identification of cognitive impairment is the most important goal in assessment. Cognitive impairment resulting from conditions like dementia, delirium, or depression represents critically serious pathology and requires urgent assessment and tailored interventions. Yet diminished or altered cognitive functioning is often perceived by healthcare professionals as a normal consequence of aging, and opportunities for timely intervention are too often missed (Harris, 2017). Although distinctions have been made comparing the clinical features of the common cognitive impairments associated with delirium, dementia, and depression, this is difficult to do clinically because these conditions often coexist and older adults can demonstrate atypical features in any of these conditions.

The second most important assessment goal is to identify a potentially reversible primary or contributing cause of a cognitive impairment. The common causes of reversible cognitive impairment (delirium) in the older adult are covered in Chapter 20, Delirium: Prevention, Early Recognition, and Treatment.

History Taking

Complaints from the patient or observations made by others of memory loss, problems with decision-making and/or judgment, or a decline in function in an activity of daily living should alert the healthcare professional that a progressive form of dementia might exist. Collecting an accurate history is the cornerstone of the assessment process, yet this is obviously a challenge in the individual presenting with cognitive impairment. The assessment domains covered in history taking include functional, cognitive, and behavioral queries and observations. The history-taking process involves interviewing the patient, followed, perhaps, by clarifying, elaborating, and validating information with the family or others familiar with the capabilities and expressions of the patient. An informant questionnaire on cognitive decline can also provide utility, the commonly used tools being the AD8 and the Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE). The AD8 was originally validated as an informant-based interview, completed by a spouse, adult child, or friend who knew the older adult well. Recent studies validated the AD8 as a direct questionnaire for the person with potential dementia who can often rate change in performance into the later stages of dementia (Galvin, Roe, Coats, & Morris, 2007). These tools are useful for screening purposes with established reliability and validity (Galvin, Roe, Xiong, & Morris, 2006; Quinn et al., 2014). Although the accuracy is reasonable, its use alone may result in misdiagnosis or false reassurance, underscoring the need for a comprehensive evaluation.

Even when a diagnosis of dementia has been made, it is often not communicated well across care settings. The easiest way to increase recognition of dementia in hospital or home healthcare patients is to add the items "memory or thinking problems," "Alzheimer's disease," and "dementia" to the list of diseases and conditions patients and families are routinely asked about on intake forms and in intake interviews.

Functional Assessment

Dementia is characterized by deterioration in the ability to perform ADL. Because cognitive assessment can be embarrassing and/or threatening, it may be more respectful to initiate the conversation around the patient's functional domain. Asking the patient to elaborate on his or her functional abilities in ADL as well as instrumental activities of daily living (IADL) and eliciting any identified decline with specified chronology can provide some insight. The Functional Activities Questionnaire (FAQ) is an informant-based measure of functional ability and has been recognized for its ability to discriminate early dementia. An informant, typically the primary caregiver, is asked to rate the performance of the patient in 10 different activities (Pfeffer, Kurosaki, Harrah, Chance, & Filos, 1982). The Functional Assessment Staging Test (FAST) has been used to effectively discriminate among normal cognition, MCI, and dementia and has proven to be useful in measuring functional performance (Rikkert et al., 2011; Teng et al., 2010). The Alzheimer's Disease Cooperative Study (ADCS)–ADL inventory is a specific functional tool used primarily in clinical drug trials to assess and monitor patients with moderate to severe AD (Galasko et al., 1997). The patient's daily caregiver is asked to rate the older adult's usual performance on the more basic measures of function over the previous month to identify progression of functional decline. It has been recognized that individuals with a frontotemporal behavioral-variant form of dementia may have greater functional impairment than those with other forms of dementia (Lima-Silva, Bahia, Nitrini, & Yassuda, 2013). In addition to looking for potential treatments, this

rating helps to provide an explanation to the patient and family for advance care planning while the patient is still capable of decision-making.

Cognitive Assessment

The cognitive domain is assessed as part of a broader mental status evaluation, the components of which are listed in Box 21.1. Although some of the parameters of a mental status evaluation (such as memory or cognition) might be measured with a standardized tool, such as the Montreal Cognitive Assessment (MoCA) and St. Louis University Mental Status Exam (SLUMS), others require specific inquiry or direct or indirect observation by the healthcare professional and/or caregiver. The measure of mood is totally subjective and is based on self-report status. The evaluation always provides the opportunity to identify sensory impairments (vision and hearing loss), which can further impact cognition, function, and behavior. There are a variety of tools for assessing cognitive impairment, some more sensitive to mild dementia and others to moderate to severe dementia.

The gold standard of tools that measure cognition is the MMSE, which was developed over 30 years ago (Folstein, Folstein, & McHugh, 1975). The tool is no longer in the public domain, and copyright permission must be secured. Tools with comparable sensitivity and specificity for detecting dementia are the MoCA (Nasreddine et al., 2005) and SLUMS, which are available for free (Tariq, Tumosa, Chibnall, Perry, & Morley, 2006).

Instruments such as the Mini-Cog (Borson, Scanlan, Chen, & Ganguli, 2003), Memory Impairment Screen (Buschke, 1999), and General Practitioner Assessment of Cognition (Brodaty et al., 2002) have all been recognized for utility, whereas the Clock Draw test (CDT; Shulman, 2000) and newer instruments, such as the MoCA (Nasreddine et al., 2005), have greater sensitivity, address frontotemporal executive function, and have less educational and cultural bias (Ismail, Rajji, & Shulman, 2010). Unlike the more language-based tools described earlier, the CDT assesses cognition focused on executive function. A systematic review of the literature identified the CDT's usefulness in predicting future cognitive impairment (Peters & Pinto, 2008). Scoring is based on the ability to draw the face of a clock freehand, insert the hour numbers in the appropriate location, and then set the hands of the clock to the time designated by the examiner. The CDT is strongly correlated with executive function (i.e., the ability to execute complex behaviors and to solve problems) and is useful in the detection of mild dementia (Peters & Pinto, 2008). It also correlates moderately with driving performance; as the CDT score drops, the number of driving errors increases (Freund, Gravenstein, Ferris, Burke, & Shaheen, 2005; Freund, Gravenstein, Ferris, & Shaheen, 2002).

A clinically useful tool that combines the CDT with measures of cognition (three-word recall) is the Mini-Cognitive (Mini-Cog; Borson, Scanlan, Brush, Vitaliano, & Dokmak, 2000). The Mini-Cog detected cognitive impairment in a community sample of predominantly ethnic minority better than primary care physician assessment (84% vs. 41%), particularly in milder stages of the disease (Borson, Scanlan, Watanabe, Tu, & Lessig, 2005).

A systematic review of the Mini-Cog for screening for dementia in primary care demonstrated that it was brief; easy to administer; clinically acceptable and effective; and minimally affected by education, gender, and ethnicity (Milne, Culverwell, Guss, Tuppen, & Whelton, 2008) with psychometric properties similar to the MMSE (Brodaty, Low, Gibson, & Burns, 2006). See Chapter 9, Assessing Cognitive Function in the Older Adult, for more information on cognitive assessment.

BOX 21.1

Components of Mental Status Evaluation

State of consciousness: quality or state of awareness
General appearance and behavior: appropriately groomed and interactive
Orientation: person, place, time
Attention and concentration: ability to attend and concentrate
Memory: ability to register, recall, retain
Judgment and insight: ability to make appropriate decisions
Executive control functions: ability to abstract, plan, sequence, and use feedback to guide performance
Visual–spatial function: ability to mentally manipulate a figure
Speech and language: ability to communicate ideas and receive and express a message
Thought content: presence of delusions, hallucinations
Mood and affect: how individual feels most days and at a given moment and the appropriateness of behavior demonstrated

Behavioral Assessment

The vast majority of persons living with dementia exhibit behavioral and psychological symptoms of dementia (BPSD), which are distressing perceptions, thought content and mood, and behaviors such as aggression and

apathy (Kales, Gitlin, & Lyketsos; Detroit Expert Panel on Assessment Management of Neuropsychiatric Symptoms of Dementia, 2014). BPSD result in declines in function, including some that are precipitous, risk of physical abuse, poor quality of life, caregiver burden, and they account for more than one third of all dementia-related costs (R. D. Adelman, Tmanova, Delgado, Dion, & Lachs, 2014; Herrmann et al., 2006; Toot, Swinson, Devine, Challis, & Orrell, 2017).

Regular assessment and monitoring can help identify the triggers of BPSD and early manifestations of the behavior. Timely interventions can help maintain functionality and safety, and the de-escalation of the behavior can help decrease the level of distress experienced by both the patient and the caregiver. Asking the patient about levels of restlessness, anxiety, and irritability is important, as at times these emotional/behavioral states occur even earlier than cognitive changes.

The Neuropsychiatric Inventory (NPI; Cummings, Mega, Rosenberg-Thompson, Carusi, & Gornbein, 1994) measures frequency and severity of psychiatric symptoms and behavioral manifestations in individuals with dementia. The NPI takes about 10 minutes to administer, during which the caregiver is asked screening and probing questions related to the presence and degree of behaviors such as agitation, anxiety, irritability, apathy, and disinhibition. The NPI also includes a measure of caregiver stress. It has established validity and reliability, although it does not discriminate between disorder types (Lai, 2014).

Depression is a common neuropsychiatric manifestation in persons living with dementia (Petersen et al., 2017). Thus, it is important to conduct an adjunctive assessment of depression. The Geriatric Depression Scale—Short Form (GDS-SF; Sheikh & Yesavage, 1986) and Patient Health Questionnaire-9 (PHQ-9; Siu & United States Preventive Services Task Force, 2016) are valid and reliable screening instruments but are not recommended for screening in adults with cognitive impairment. The Cornell Scale for Depression in Dementia (CSDD) is an interviewer-rated scale that was developed specifically to detect symptoms of depression in older adults with dementia (Alexopoulos, Abrams, Young, & Shamoian, 1988). Screening instruments along with appropriate depression-management strategies are discussed in detail in Chapter 19, Late-Life Depression.

Physical Examination and Diagnostics

Once the functional, cognitive, and behavioral domains in progressive dementia have been established through history taking of the patient and the caregiver, a thorough review of systems is undertaken, followed by the physical examination. The history-taking process narrows the differential diagnosis of reversible and irreversible causes of dementia. A thorough neurological and cardiovascular examination will help to specify the etiology of a single type or combined dementia, which will direct the need for laboratory and imaging tests. Cardiovascular findings, such as hypertension, arrhythmias, and extra heart sounds or murmurs, along with focal neurological findings, such as weakness and sensory deficit, may favor a diagnosis of VaD, pathological reflexes, gait disorders, and abnormal cerebellar findings that may be indicative of AD, and parkinsonian signs that might indicate dementia associated with either Lewy bodies or PDD (Kane, Ouslander, Abrass, & Resnick, 2013).

There are no specific laboratory tests for the diagnosis of progressive dementia other than those that can primarily indicate a potentially reversible or contributing cause. The American Academy of Neurology (AAN) recommends two specific laboratory tests (thyroid function and B12) in the initial evaluation of suspected dementia (Knopman et al., 2001). The AAN similarly recommends that all patients with suspected dementia have an MRI study or noncontrast CT as part of the initial workup.

Referral of the patient to a neuropsychologist or memory clinic for more extensive neuropsychological testing is often indicated in order to provide more specific diagnostic information associated with neurodegenerative disease states and areas of brain dysfunction. This kind of assessment can identify subtle cognitive impairments in higher functioning individuals, distinguish MCI from dementia, and provide direction and support for care providers and the family (Zweig, 2016).

Caregiver Assessment

Eighty percent of the care provided to persons living with dementia, both care delivery (hands-on care) and care management, is provided by informal caregivers (family and friends; Alzheimer's Association, 2019). Approximately 15.5 million caregivers provide an estimated 17.7 billion hours of unpaid care, and higher numbers prevail among African American and Hispanic as compared to White and Asian-American caregivers. The majority of caregivers are women (66%) with an average age of 42; 64% are currently employed, are students, or are homemakers. Twenty-one percent of female caregivers are aged 65 and over. Men who provide caregiving tend to be spouses (Alzheimer's Association, 2019).

Caregivers have described the rewards of caregiving: reciprocity, learning and personal growth, emotional

closeness to the care receiver, and the opportunity to enact their values (McGillick & Murphy-White, 2016). However, caregiving often takes a physical, emotional, and psychological financial toll. Stress is often related to one or more of the following: employment complications, less family time, disrupted family and social relationships, less time for leisure, and less self-care (Campbell, Rowe, & Marsiske, 2011). A review of the physiological consequences of caregiving describes multiple studies that have examined the effect of the caregiving experience on physical consequences of caregiving. Being a dementia caregiver was associated with poorer function in specific domains of cognitive function (processing speed, attention, and concentration) as well as overall functioning. Also, immune function in caregivers has been shown to be worse, particularly with the immune markers of TNF-α and C-reactive protein both consistently elevated, indicating immune dysfunction (Fonareva & Oken, 2014). Researchers have also found evidence of two pathophysiological mechanisms of vascular inflammation and altered clotting profiles in caregivers (Rowe, Farias, & Boltz, 2016).

The proposed mechanisms of caregiving-associated physiological and psychological change include emotional demands of caregiving, poor sleep, sustained vigilance, and interference with caregivers' health-promoting behaviors (Covinsky et al., 2001; Simpson & Carter, 2013; Zanetti et al., 1998). The most prominent psychological change is depression, with a number of risk factors for higher levels of depression already identified. These include the caregiver having lower educational levels, lower income, being a spouse caregiver, being female, and being Caucasian (compared with being African American; Rowe et al., 2016). Predictors of high levels of depressive symptoms include poorer self-rated health, smaller social networks, and use of dysfunctional (emotion-focused) coping. Care recipient characteristics that are associated with caregiver depression include poorer cognitive function, higher dependence in ADL, and behavioral manifestations of distress in the patient (Piercy et al., 2013).

Hospitalization of the person with dementia increases the stress of caregivers. Family caregivers have described care-related worries related to safety, comfort, and emotions, and the need to keep vigil (de Vries, Drury-Ruddlesden, & Gaul, 2019). They also described the importance of bedside communication tools and positive clinician relational skills to support their efforts to promote positive outcomes for the patient (Boltz, Chippendale, Resnick, & Galvin, 2015a).

Because the demands of caregiving have the potential to impact caregiver health as well as efficacy in the caregiving role, caregiver well-being warrants assessment. The Zarit Burden Interview (ZBI) can be used to identify the degree of burden experienced by the caregiver. The ZBI is a four-item screening followed by an additional 12 items; the test has good reliability and validity (Higginson, Gao, Jackson, Murray, & Harding, 2010). Administration of this tool to a community-dwelling caregiver can indicate the extent of impact caregiving has on the caregiver's health, social and emotional well-being, and finances. The Modified Caregiver Strain Index (CSI) is a 13-question tool that measures strain (financial, physical, social, psychological, and personal) related to care provision, with excellent internal consistency and reliability (Onega, 2008; B. Robinson, 1983; Thornton & Travis, 2003). Given that higher caregiver strain has been found to be associated with higher caregiver anxiety at the time of the care receiver's hospitalization, routine evaluation of caregiver strain is integral to informing the transitional planning for persons with dementia (Boltz et al., 2015a).

The Preparedness for Caregiving is an eight-item instrument that asks caregivers how well prepared they believe they are for multiple domains of caregiving: physical care and emotional support, setting up support services, dealing with the stress of caregiving. Items are rated 0 (not at all prepared) to 4 (very well prepared); the tool shows very good reliability and internal consistency (Archbold, Stewart, Greenlick, & Harvath, 1992), including in family caregivers of hospitalized persons with dementia (Boltz et al., 2015b).

PROMOTING HEALTH, FUNCTION, AND WELL-BEING IN THE PERSON LIVING WITH DEMENTIA

Nonpharmacological strategies, including those from the cognitive, behavioral, and environmental domains, in combination with staff support and education, are effective. Physical/functional, environmental, psychosocial, educational, and behavioral interventions are discussed as follows.

Physical/Functional Interventions

Maintaining the physical and functional well-being of the individual with progressive dementia facilitates independence, maintains health status, and can ease the caregiving burden. Interventions include adequate nutrition and hydration, regular exercise, maintenance of ADL by encouraging self-care, proper rest and sleep, appropriate bowel and bladder routines, proper dental hygiene and care, and current vaccinations. As comorbidities are common, regular assessment, vigilant monitoring, and careful management of acute and chronic conditions are necessary.

The Function Focused Care Intervention for the Cognitively Impaired (FFC-CI) teaches and motivates direct

care workers (DCWs) to engage residents with dementia in activities that optimize function and activity while minimizing affective and behavioral disturbances during care interactions. Staff are provided with education on communication techniques, ways to motivate, self-care promotion, and ways to integrate physical activity in daily life. Environmental and policy modifications are provided as needed. Outcomes in both assisted living and the nursing home include improvements in the amount and intensity of physical activity (by survey and actigraphy) and physical function in the treatment group, as well as fewer falls. There was no significant difference between groups with regard to agitation or apathy (Galik, Resnick, Hammersla, & Brightwater, 2014; Galik, Resnick, Lerner, Hammersla, & Gruber-Baldini, 2016).

Vehicular-driving safety might need to be examined as recent evidence indicates that individuals with dementia pose a risk in driving safety (Man-Son-Hing, Marshall, Molnar, & Wilson, 2007). There is insufficient evidence to either support or refute the benefit of neuropsychiatric testing or intervention strategies for drivers with dementia (Iverson et al., 2010). However, it is prudent to engage the family caregiver and person with dementia in monitoring of driving safety.

Environmental Interventions

A specialized ecological model of care, which facilitates interaction between the person and the environment in a more homelike atmosphere, has proven to be beneficial for individuals with dementia. This model affords greater privacy, encourages meaningful activities, and permits more choice than the traditional model of care. It also demonstrates that individuals with dementia experience less decline in ADL and more engagement with the environment, with no measurable differences found in cognitive measures, depression, or social withdrawal (Reimer, Slaughter, Donaldson, Currie, & Eliasziw, 2004). A study of residents before and after conversion to a household model found that social engagement or interactive occupation with residents was more after implementing the household model (Morgan-Brown, Newton, & Ormerod, 2013).

A systematic review reported inclusive results and suggested that more research is needed with regard to the use of bright light in fostering better sleep and reducing behavior problems in dementia (Forbes et al., 2009). The use of aromatherapy to reduce disturbed behavior, promote sleep, and stimulate motivation also shows promise but needs more study (Thorgrimsen, Spector, Wiles, & Orrell, 2003). Manipulation of the environment (alarms, circular hallways, visual, or structural barriers) to minimize wandering has not been conclusively demonstrated to be effective (Futrell & Melillo, 2002). There is a lack of robust evidence supporting nonpharmacological interventions for wandering (L. Robinson et al., 2007).

A scoping review of dementia-friendly hospital design concluded that evidence of design principle effectiveness is needed that can be applied to general medical and surgical units (Parke et al., 2017). In the United Kingdom, the Department of Health commissioned The King's Fund, an independent charity, to focus on developing more supportive design for people with dementia in hospitals. Twenty-six projects were completed in acute, community, and mental health settings. The outcomes from the program enabled the development of a set of overarching design principles for dementia-friendly design in care settings (Waller, Masterson, & Finn, 2013). An audit tool was developed to demonstrate the impact of environmental changes, for use by people with dementia, family carers, and lay people as well as staff. The tool is divided into seven criteria that focus on how the environment can promote: (a) meaningful interaction between patients, their families, and staff; (b) well-being; (c) eating and drinking, (d) mobility, (e) continence and personal hygiene; (f) orientation, and (g) calm, safety, and security (Waller, Masterson, & Evans, 2017).

Psychosocial and Educational Interventions

Mental and social engagement is important to the well-being of all older adults. Reality orientation appears to be effective in the early stages of dementia (Bates, Boote, & Beverley, 2004). The evidence suggests that cognitive therapy is more beneficial than no therapy at all, but it may be patient specific (Carrion, Aymerich, Baillés, & López-Bermejo, 2013; Woods, Aguirre, Spector, & Orrell, 2012). Although evidence is lacking regarding its efficacy, validation therapy, based on caregiver acceptance of the reality of the experience of the person with dementia, is considered therapeutic by experts (Neal & Barton Wright, 2003).

Support groups, counseling, and education for individuals with AD and their caregivers are essential (Rowe et al., 2016). Areas for caregiver education are detailed in Box 21.2. Cross-sectional data from the National Caregiver Training Project (data collected 1995–1997) indicated that the majority of caregivers did not attend support groups (73%) or use respite services (79%), nor did they participate in bereavement services. The profile of nonusers compared to users revealed that nonusers were significantly older, more depressed, and received less social support (Bergman, Haley, & Small, 2011; K. M. Robinson, Buckwalter, & Reed, 2013).

BOX 21.2

Education Content for Caregivers

Information about the disease and its progression
Strategies to maintain function and independence
Preservation of cognitive and physical vitality in dementia
Maintaining a safe and comfortable environment
Giving physical and emotional care
Communicating with the individual with dementia
Managing behavioral problems
Advance planning: healthcare and finances
Caregiver self-care tips
Building a caregiver support network

In the hospital setting, there is evidence that providing information and engaging families in assessment and planning increases family preparedness for postacute caregiving and decreases anxiety, while also improving functional outcomes for the patient (Boltz et al., 2015b). Family video messaging can provide emotional comfort to persons with dementia and has demonstrated decreased agitation in hospitalized patients with delirium superimposed on dementia (Waszynski, Milner, Staff, & Molony, 2018).

Activity Interventions

A growing body of evidence shows that individuals with dementia enjoy music, and research on its benefits is emerging (Baird & Samson, 2015; Samson, Clement, Narme, Schiaratura, & Ehrle, 2015).

The efficacy of a music intervention with caregivers was evaluated that included coaching the caregivers of persons with early dementia to either sing or listen to music regularly as a part of everyday care. Compared with usual care, both singing and listening to music improved mood, orientation, and remote episodic memory and, to a lesser extent, attention and executive function and general cognition. Singing also enhanced short-term and working memory and caregiver well-being, whereas listening to music had a positive effect on quality of life (Särkämö et al., 2014).

A critical review conducted by Särkämö (2018) reported that music listening has an enhancing effect on mood and arousal, which can temporarily improve cognitive performance in attention or memory tasks in persons with dementia. Positive effects on neuropsychiatric symptoms, such as agitation and social interaction, have been seen with more advanced (severe) dementia. Särkämö opines that limited conclusions can be drawn in regard to the clinical efficacy of music-based interventions because of the variable methodological quality of the published studies.

In addition to music, other cultural arts (poetry, storytelling, dance) have reflected positive social and behavioral changes, although there are some study design issues that limit inclusion in a systematic review (de Medeiros & Basting, 2014). Structured short-term occupational therapy interventions have demonstrated usefulness in improving apathy in patients with dementia (Ferrero-Arias et al., 2011).

Cognitively stimulating activities selected on the basis of assessments of leisure interests, physical function, and mental status have been examined in community-dwelling older adults with dementia and delirium receiving care in a postacute facility. Cognitively stimulating activities did not improve delirium but improved executive function and reduced the length of stay (Kolanowski et al., 2016).

In the home setting, occupational therapy-led activity interventions that included caregiver education and home modifications have demonstrated improvements in functional outcomes as well as less caregiver upset with memory-related behaviors, less need for assistance from others, and better affect in caregivers (Gitlin, Corcoran, Winter, Boyce, & Hauck 2001; Gitlin, Winter, Dennis, Hodgson, & Hauck, 2010; Gitlin et al., 2003).

Behavioral Interventions

Behavioral and psychosocial symptoms of dementia are common with every form of progressive dementia, particularly in the moderate stage. The three most troublesome symptoms are agitation, aggression, and wandering. Problematic behaviors that occur during meals or bathing can be particularly challenging. It is important to recognize and realize that any new behavior could be a sign of an acute illness or an environmental influence. Unrecognized pain can also cause disruptive behavior. The Progressively Lowered Stress Threshold (PLST) is a framework to optimize function, minimize disruption, and help the caregiver (M. Smith, Hall, Gerdner, & Buckwalter, 2006). The PLST model increases the positive appraisal and decreases the negative appraisal of the caregiving situation (Stolley, Reed, & Buckwalter, 2002) and helps the caregiver manage the aggressive behaviors demonstrated in AD (Cheung, Chien, & Lai, 2011; Lindsey & Buckwalter, 2009). By adapting the environment and routines, interventions are designed to help the patient with dementia use his or her functional skills and minimize potentially triggering reactions. There are six essential principles of care in the PLST:

1. Maximize safe function: Use familiar routines, limit choices, provide rest periods, reduce stimuli when stress occurs, and routinely identify and anticipate physical stressors (pain, urinary symptoms, hunger, or thirst).

2. Provide unconditional positive regard: Offer respectful conversation, simple and understandable language, and nonverbal expressions of touch.
3. Use behaviors to gauge activity and stimulation: Monitor for early signs of anxiety (pacing, facial grimacing) and intervene before behavior escalates.
4. Teach caregivers to "listen" to the behaviors: Monitor the language pattern (repetition, jargon) and behaviors (rummaging) that might be showing how the person reduces stress when needs are not being met.
5. Modify the environment: Assess the environment to assure safe mobility and promote way-finding and orientation through cues. Consider the need for increased observation, provided by a caregiver trained in activity and function-focused approaches.
6. Provide ongoing assistance to the caregiver: Assess and address the need for education and support.

The Detroit Expert Panel on the Assessment and Management of the Neuropsychiatric Symptoms of Dementia developed "DICE" as a comprehensive approach to behavioral management (Kales et al., 2014). DICE (Describe, Investigate, Create, and Evaluate) details key patient, caregiver, and environmental considerations with each step of the approach and describes behavioral and environmental interventions that should be considered. The components are described as follows.

- **D: Describe**—Asking the caregiver, and the patient if possible, to describe the Who, What, When, and Where of situations where problem behaviors occur and the physical and social context for them. Caregivers could take notes about the situations that led to behavior issues that they could share with health professionals during visits.
- **I: Investigate**—Having the health provider examine the patient's health, dementia symptoms, current medications, and sleep habits that might be combining with environmental, social, and caregiver-related factors to produce the behavior.
- **C: Create**—The patient's caregiver and health providers develop a plan to prevent and respond to behavioral issues in the patient that may include changing routine and/or activities, modifying the environment, education, and support for the caregivers.
- **E: Evaluate**—The patient's caregiver and health providers assess how well the plan is being followed, how it is working, and what might need to be changed.

Emerging evidence shows systemic approaches that support individualized interventions to prevent and manage BPSD. An interdisciplinary team and a nurse champion, ongoing staff training and mentoring, and attention to the environment and policies are associated with enhanced uptake of person-centered interventions for BPSD (Resnick et al., 2016). In the acute care setting, the use of a Personal Approach Form, completed with family input, provides information on patient's lifestyle, hobbies, and leisure activities. Findings were incorporated into an activity plan implemented by nursing assistants and resulted in decreased mild, moderate, and severe agitation, measured by the Agitated Behavior Scale (ABS; Waszynski et al., 2013).

PHARMACOLOGICAL APPROACHES TO DEMENTIA

To date, there are no disease modifying medications to treat dementia. Medication therapy can only delay, but not reverse, the disease process. Drug therapy may offer the person with dementia as well as the caregiver the opportunity of time to make important life and financial decisions that would otherwise not be feasible (Brandt & Mansour, 2016). Currently, there are two classes of medications that are used in the treatment of AD, acetylcholinesterase inhibitors (AChEIs) and *N*-methyl-*D*-Aspartate (NMDA) receptor agonist.

AChEIs are the mainstay of treatment in AD. Three are currently available in the United States: donepezil hydrochloride (Aricept), rivastigmine tartrate (Exelon), and galantamine hydrobromide (Razadyne). Tacrine hydrochloride (Cognex)—the oldest and less favored drug)—was taken off the market in 2013 because of its adverse effect on the liver and multiple daily dosing. A combination drug, memantine/donepezil (Namzaric), is also available. Cognitive improvements in patients with mild to moderate AD have been shown for all three of the AChEIs agents available in the United States (Tan et al., 2014). The AChEIs are safe; however, they may have gastrointestinal side effects (nausea, anorexia, and diarrhea).

Memantine (Namenda), approved for moderate to severe dementia, has a different mechanism of action than do the AChEIs. This NMDA receptor antagonist has neuroprotective effects that prevent excitatory neurotoxicity. Individuals with AD have improved cognition and behavior on this drug (McShane, Areosa Sastre, & Minakaran, 2006). Side effects of memantine, although uncommon, include diarrhea, insomnia, and agitation. In combined administration of cholinesterase inhibitors with memantine, the research is mixed. Some studies (Atri et al., 2013; Riepe et al., 2007) demonstrated increased efficacy in advanced AD as compared to cholinesterase inhibitors alone, whereas another demonstrated that the combined treatment had no benefit (Howard et al., 2012). There

is insufficient evidence at this time that pharmacological therapy for dementia can delay nursing home placement.

Pharmacological Management of Behaviors Associated With Dementia

Neuropsychiatric symptoms (BPSD), including agitation and resistiveness to care, are often overwhelming for caregivers and result in institutionalization and increased healthcare utilization (Alzheimer's Association, Public Policy Office, 2013). Various psychopharmacological medications are used to treat these symptoms, such as antidepressants, antipsychotics, anticonvulsants, anxiolytics, and cholinesterase inhibitors. There are limited studies of these medications in persons with dementia, and most of their use is off-label and not FDA approved (Brandt & Mansour, 2016).

On March 29, 2012, the Centers for Medicare and Medicaid Services (CMS) launched a national initiative aimed at improving behavioral health and minimizing the use of medications such as antipsychotics to manage behaviors in persons with dementia. There is a growing imperative to conduct a comprehensive biopsychosocial assessment to better understand the origins of the behaviors and unmet needs rather than applying a quick fix that may increase the risk of falls, functional decline, and other complications. Nonpharmacological interventions should be implemented before drug therapy to address neuropsychiatric symptoms. When medications are deemed necessary, they need to be administered in the context of a comprehensive assessment, for a specific medical or psychiatric condition, in the lowest dose possible for the shortest amount of time and evaluated for continued need, response, and side effects. A Cochrane Review (Lonergan, Luxenberg, & Colford, 2002) validated the useful role of haldol in managing aggression but did not find evidence for its role in managing agitation for patients with dementia. The side effects of conventional antipsychotics are considerable and include extrapyramidal symptoms, tardive dyskinesia, sedation, orthostatic hypotension, and falls.

Although not FDA approved, the atypical antipsychotics are often prescribed for use in patients with dementia. Evidence indicates that they may benefit people with dementia, but the risks of adverse events (cardiovascular, extrapyramidal symptoms) may outweigh the benefit, especially with long-term treatment (Maher et al., 2011). Agents available on the market include risperidone, olanzapine, quetiapine, ziprasidone, aripiprazole, and paliperidone. There are little to no published data on the efficacy and safety of the last three drugs listed.

Benzodiazepines (lorazepam, oxazepam, alprazolam) are sometimes used to manage agitation and aggression; however, the risk–benefit ratio is often unsatisfactory. Although the benzodiazepines may be useful in rapidly sedating the agitated patient with dementia, the potential for falls and worsening of cognition limit long-term use. Again, nonpharmacological interventions to treat behavioral manifestations of distress are preferred (Brandt & Mansour, 2016). Pharmacological interventions, if utilized, should always be accompanied by nonpharmacological interventions that promote a sense of well-being in persons with dementia.

Although antidepressants (Seitz et al., 2011) and anticonvulsants are sometimes used to treat agitation in dementia, there is insufficient evidence to support their use. An international Delphi consensus process showed a clear preference for an escalating approach to the management of BPSD in AD, beginning with the identification of underlying causes. For BPSD overall and for agitation, caregiver training, environmental adaptations, person-centered care, and tailored activities were identified as first-line approaches prior to any pharmacological approaches. If pharmacological strategies were needed, citalopram and analgesia were prioritized ahead of antipsychotics. In contrast, for psychosis, pharmacological options, and, in particular, risperidone, were prioritized following the assessment of underlying causes (Kales, Lyketsos, Miller, & Ballard, 2019).

Supplemental Drugs

Anti-inflammatory drugs and estrogen; herbals, such as gingko; and vitamins, such as B12, folate, and vitamin E—although sometimes touted and commonly used—have no proven efficacy for dementia; however, some isolated studies have demonstrated a benefit. Dementia associated with VaD requires appropriate control of hypertension, hyperlipidemia, and aspirin therapy. Parkinsonism (rigidity), seen with DLB, may benefit from dopaminergic therapy. Selective antidepressants and amphetamines may be effective in reducing the behavioral symptoms in FTD (Nardell & Tanjo, 2014).

ADVANCE PLANNING AND END-OF-LIFE CARE INTERVENTIONS

Advance planning and providing directives for care are important in guiding the types of interventions used at the end of life and can decrease the caregiver stress in proxy decision-making. Advance directives in cases of dementia have been a debated subject, for, although advance directives are considered valid, they are marginally effective. As many as 90% of Americans with dementia will be institutionalized before death (G. E. Smith, Kokmen, & O'Brien, 2000), making this environment, in particular,

an important focus for end-of-life (EOL) care. There is a lack of research published on EOL care in the nursing home, and most of it is descriptive (Oliver, Porack, & Zewig, 2004). The end stage of AD may last for several years, and frequently distressing signs and symptoms occur at this time. Nursing home patients and their families want physicians more involved in EOL care, to acknowledge the presence of the patient and caregiver, and provide guidance (Fosse, Schaufel, Reiths, & Malterud, 2014). See Chapter 17, Advance Care Planning for a fuller discussion.

Dementia itself or associated conditions can cause physical symptoms, such as poor nutrition, urinary incontinence, skin breakdown, pain, infection, shortness of breath, fatigue, difficulty in swallowing, choking, and gurgling, in addition to the behavioral symptoms mentioned earlier. There is no acceptable standard treatment for the consequences of advanced dementia, and where guidelines do exist there is minimal palliative care content. Aggressive treatments, such as antibiotics, tube feedings, psychotropic drugs, and physical restraints to address problematic behaviors, appear to be prevalent, although there is no substantial evidence that this approach is effective in end-stage dementia and that prognosis and life expectancy are improved by these strategies (Evers, Purohit, Perl, Khan, & Marin, 2002; L. Smith & Ferguson, 2017). Measuring quality of care at the end of life for those with dementia poses significant challenges because of the limitations in subjective reporting and therefore relies on the caregiver's analysis of cues to monitor the patient's condition and experience (Volicer, Hurley, & Blasi, 2001). In spite of the clear recognition that significant improvements in EOL care for those with dementia is needed (Scherder et al., 2005), there is a lack of systematic evidence on how to approach palliative care for this population (Sampson, Ritchie, Lai, Raven, & Blanchard, 2005). However, attention to the physical and emotional comfort of the patient and support of the family's need for education, inclusion, and bereavement is considered best practice (Trotta, Boltz, Happ, & Strumpf, 2018).

CASE STUDY 21.1

Mrs. P is an 85-year-old Caucasian woman brought into the primary care clinic by her daughter for a geriatric consultation. She has a 4-year history of decline in cognitive impairment that began with memory loss and impaired judgment, which appears to be worsening; she is now experiencing some behavioral problems. Mrs. P is high school educated, widowed for 10 years, and is a retired short-order cook. She currently lives with her daughter, son-in-law (both work full time), and grandson.

Her primary care physician completed a dementia workup when the symptoms appeared 4 years ago and started her on donepezil, which was discontinued within a few days because of gastrointestinal side effects. The daughter reports she is allergic to it. Mrs. P recently had paranoid ideation, in which she accused her 15-year-old grandson of listening in on her phone conversations and taking some money from her purse. Her daughter reports that Mrs. P has always had "a short fuse" and now gets agitated easily. "She called me a moron and even took a swing at me the other day when I told her she smelled bad and needed to take a shower."

Mrs. P performs her own personal hygiene, although she needs reminders and cueing at times; she is continent. She does not perform any IADL (e.g., cooking, shopping), and it was unclear whether she was truly no longer capable of performing these functions or no longer had the opportunity or desire to do them. Mrs. P reports no desire to eat and had a weight loss resulting in a change in at least three clothing sizes that has occurred slowly over the past few years. She reports that she has always been overweight and is proud of this accomplishment. The daughter says she has tried to get her to eat by serving food that she likes, but she just "plays with the food," pushing it around on her plate, and has been seen sneaking it to the dog while at the table. When asked about her mood, she becomes tearful and says, "I feel lonely; no one cares about me anymore." Mrs. P says she hates to be alone and that the family "just come and goes—they never talk with me." She used to take an evening walk in the neighborhood, but now that she lives with her daughter, she is unfamiliar with and fearful of her surroundings. Her MoCA score is 20/30, with deficits in memory, calculation, and ability to copy the cube. She scores 10/15 on the GDS.

Past medical history includes thyroidectomy, left cataract extraction, cholecystectomy, and hysterectomy for benign disease. Her daughter thinks that Mrs. P may have been on antihypertensives in the past. The only medication Mrs. P takes at present is for her thyroid, but neither she nor her daughter know the name of the drug.

On physical examination Mrs. P is afebrile; blood pressure is 132/70, and she is about 10 pounds below her ideal body weight. Mrs. P is alert, cooperative, and smiles at intervals during the examination and has hearing loss bilaterally with clear canals; no thyromegaly. Cardiovascular examination reveals no murmur, edema, or discolorations of the extremities. Pulses

(*continued*)

CASE STUDY 21.1 (*continued*)

are strong throughout. There are no focal neurological symptoms. Gait is slow but steady. She has full range of motion, but her muscle tone and strength are diminished in both upper and lower extremities.

A diagnosis of depression and progressive dementia of the Alzheimer's type is made, and she is started on the combination of donepezil and memantine, both to be titrated slowly. Additional information from Mrs. P's primary care physician will be consulted about potential lab work and diagnostic studies, including thyroid function. The need for a nutritional and hearing evaluation will be explored. Antidepressant therapy may be considered at a later date.

Health teaching and additional resource information is provided to the family, including a structured daily routine and activities.

Discussion

Depression is not uncommon in those with a progressive dementia. Severe anxiety, agitation, and aggression can occur; tearfulness and decreased appetite with weight loss may also be present. Using the PLST model, the nurse focuses on teaching the daughter to recognize triggers and prodromal signs of increasing anxiety and intervene appropriately when anxiety and agitation occur. Strategies are emphasized in each of the PLST principles of care: maximize safe function, provide unconditional regard, use behaviors to gauge activity and stimulation, "listen" to the behaviors, and modify the environment. Less confrontational language and behaviors are emphasized in approaches and interactions with Mrs. P. The daughter is also provided with specific contact information for the geriatrician's office as well as the local and national resources available through the Alzheimer's Association and the Alzheimer's Disease Education and Referral Center (ADEAR). Instructions include dietary strategies to increase nutritional density and an exploration of ways to increase social engagement and exercise while assuring safety. If available in the area, Meals on Wheels, Friendly Visitors, and Home Safety Assessment might be of benefit. Specific medication instructions with particular emphasis on how to use the titration packet are provided, with the recommendation to coadminister with food to reduce the likelihood of gastrointestinal side effects. It was explained that what Mrs. P experienced earlier was likely medication intolerance, not an allergy, and that administering with food should help. The nurse plans a follow-up phone call for the next day and schedules a follow-up medical and health teaching appointment in 1 month to evaluate the effectiveness of the plan of care. The patient and family are instructed to call or return if new or changed behaviors or physical symptoms develop. Caregiving has its burdens and rewards and impacts the entire family. At the next visit, the nurse plans to have the daughter, son-in-law, and grandson present to get their perspective and engage them in discussion on the development of a family-centered plan of care, including advance care planning.

Also, the family is educated about the advisability of preparing an emergency bag, packed ahead of time, ready in the event of hospitalization. Items to include are the following:

- Health insurance cards, lists of current medical conditions, medicines being taken, and allergies
- Healthcare providers' names and phone numbers
- Copies of healthcare advance directives
- Personal information sheet
- Comforting objects or music player with earphones
- A pad of paper and pen
- A small amount of cash
- A note on the outside of the emergency bag to remind you to take your cell phone and charger with you
- A change of clothing, toiletries, and personal medications for the caregiver
- Pain medicine, such as ibuprofen, acetaminophen, or aspirin, for the caregiver (National Institute on Aging, 2017)

SUMMARY

It is important that healthcare professionals identify cognitive impairments in older adults early and differentiate a progressive from a reversible etiology, such as delirium. Comprehensive assessment, monitoring, and pharmacological and nonpharmacological management of physical, functional, cognitive, and behavioral problems are important both in the initial identification and in the ongoing care of the individual with progressive dementia. Education and support of the family and professional caregiver are essential. It is difficult to identify clearly what constitutes quality of life for the individual with progressive dementia, what interventions enhance this quality, and how this is accomplished; thus, it is important to assess individual preferences. It is imperative that geriatric nurses evaluate practice and generate new knowledge to assure best practice in the care of individuals with progressive dementia and their caregivers.

NURSING STANDARD OF PRACTICE

Protocol 21.1: Dementia: Recognition and Care Strategies

I. GOALS

A. Early recognition of dementing illness
B. Appropriate management strategies in care of individuals with dementia and their families

II. OVERVIEW

The rapid growth of the aging population is associated with an increase in the prevalence of progressive dementias. It is imperative that a differential diagnosis be ascertained early in the course of cognitive impairment and that the patient is closely monitored for coexisting morbidities. Nurses have a central role in assessment and management of individuals with progressive dementia.

III. BACKGROUND

A. Definitions/distinctions
    1. Dementia (also referred to as a major neurocognitive disorder) is a clinical syndrome of disruptions in cognition.
    2. In addition to disruptions in cognition, dementias are commonly associated with changes in function, mood, and behavior.
    3. The most common forms of progressive dementia are AD, VaD, DLB, and FTD; the pathophysiology for each is poorly understood.
    4. Differential diagnosis of dementing conditions is complicated by the fact that concurrent disease states (i.e., comorbidities) often coexist.
B. Prevalence
    1. Dementia affects about 11% of individuals aged 65 years and older.
    2. More than 5.8 million individuals in the United States have AD, with the number projected at about 14 million cases by 2050.
    3. Global prevalence of dementia is about 50 million, and is projected to reach 135.5 million by 2050.
C. Risk factors
    1. Advanced age
    2. MCI
    3. Cardiovascular disease
    4. Genetics: family history of dementia, PDD, cardiovascular disease, stroke, presence of ApoE4 allele on chromosome 19
    5. Environment: head injury, alcohol abuse

IV. PARAMETERS OF ASSESSMENT

No formal recommendations for cognitive screening are indicated in asymptomatic individuals. Clinicians are advised to be alert for cognitive and functional decline in older adults to detect dementia and dementia-like presentation in early stages. Assessment domains include cognitive, functional, behavioral, physical, caregiver, and environment.

A. Cognitive parameters
    1. Orientation: person, place, time
    2. Memory: ability to register, retain, recall information
    3. Attention: ability to attend and concentrate on stimuli
    4. Thinking: ability to organize and communicate ideas
    5. Language: ability to receive and express a message

(*continued*)

Protocol 21.1: Dementia: Recognition and Care Strategies (*continued*)

6. Praxis: ability to direct and coordinate movements
7. Executive function: ability to abstract, plan, sequence, and use feedback to guide performance

B. Mental status screening tools
1. SLUMS and MoCA are commonly used tools.
2. CDT is a useful measure of cognitive function that correlates with executive control functions.
3. Mini-Cog combines the CDT with the three-word recall.

When the diagnosis remains unclear, the patient may be referred for more extensive screening and neuropsychological testing, which might provide more direction and support for the patient and the caregivers.

C. Functional assessment
1. Tests that assess functional limitations, such as the FAQ and the FAST, can detect dementia. They are also useful in monitoring the progression of functional decline.
2. The severity of disease progression in dementia can be demonstrated by performance decline in ADL and IADL tasks and is closely correlated with mental status scores.

D. Behavioral assessment
1. Assess and monitor for behavioral changes, in particular the presence of agitation, aggression, anxiety, disinhibitions, delusions, and hallucinations.
2. Evaluate for depression because it commonly coexists in individuals with dementia. The GDS is a good screening tool.

E. Physical assessment
1. A comprehensive physical examination with a focus on the neurological and cardiovascular system is indicated in individuals with dementia to identify the potential cause and/or the existence of a reversible form of cognitive impairment.
2. A thorough evaluation of all prescribed, over-the-counter, homeopathic, herbal, and nutritional products taken is done to determine the potential impact on cognitive status.
3. Laboratory tests are valuable in differentiating irreversible from reversible forms of dementia. Two laboratory tests specifically recommended in the initial evaluation are thyroid function and B12. Structural neuroimaging with noncontrast CT or MRI scans is appropriate in the routine initial evaluation of patients with dementia.

F. Caregiver/environment
1. The caregiver of the patient with dementia often has as many needs as the patient with dementia, so a detailed assessment of the caregiver and the caregiving environment is essential.
   a. Elicit the caregiver perspective of patient function and the level of support provided.
   b. Evaluate the impact that the patient's cognitive impairment and problem behaviors have on the caregiver (mastery, satisfaction, and burden). Two useful tools include the ZBI and the CSI tools.
   c. Evaluate the caregiver experience and patient/caregiver relationship.

V. NURSING CARE STRATEGIES

A. The PLST framework provides a framework for the nursing care of individuals with dementia.
1. Monitor the effectiveness and potential side effects of medications given to improve cognitive function or delay cognitive decline.
2. Provide appropriate cognitive-enhancement techniques and social engagement.
3. Assure adequate rest, sleep, fluid, nutrition, elimination, pain control, and comfort measures.
4. Avoid the use of physical and pharmacological restraints.
5. Maximize functional capacity: Maintain mobility and encourage independence as long as possible, provide graded assistance as needed with ADL and IADL, provide scheduled toileting and prompted voiding to reduce urinary incontinence, encourage an exercise routine that expends energy and promotes fatigue at bedtime, and establish bedtime routine and rituals.

(*continued*)

Protocol 21.1: Dementia: Recognition and Care Strategies (*continued*)

6. Address behavioral issues: Identify environmental triggers, medical conditions, caregiver/patient conflict that may be causing the behavior; define the target symptom (i.e., agitation, aggression, wandering) and pharmacological (psychotropics) and nonpharmacological (manage affect, limit stimuli, respect space, distract, redirect) approaches; provide reassurance; and refer to appropriate mental healthcare professionals as indicated.
7. Assure a therapeutic and safe environment: Provide an environment that is modestly stimulating, avoiding overstimulation, which can cause agitation and increase confusion, and understimulation, which can cause sensory deprivation and withdrawal. Eliminate any environmental hazards and modify the environment to enhance safety. Provide environmental cues or sensory aids that facilitate cognition, and maintain consistency in caregivers and approaches. Psychosocial interventions and cultural arts therapy in dementia may prove beneficial.
8. Encourage and support advance care planning: Explain the trajectory of progressive dementia, treatment options, and advance directives.
9. Provide appropriate EOL care in the terminal phase: provide comfort measures, including adequate pain management; weigh the benefits/risks of the use of aggressive treatment (tube feeding, antibiotic therapy).
10. Provide caregiver education and support: Respect family systems/dynamics and avoid making judgments; encourage open dialogue, emphasize the patient's residual strengths; provide access to experienced professionals; and teach caregivers the skills of caregiving.
11. Integrate community resources into the plan of care to meet the needs for patient and caregiver information; identify and facilitate both formal (i.e., Alzheimer's Association, respite care, specialized long-term care) and informal (i.e., churches, neighbors, extended family/friends) support systems.

VI. EVALUATION/EXPECTED OUTCOMES

A. Patient outcomes: The patient remains independent and functional in the environment of choice for as long as possible, the comorbid conditions the patient may experience are well managed, and the distressing symptoms that may occur at EOL are minimized or controlled adequately.
B. Caregiver outcomes (lay and professional): Caregivers demonstrate effective caregiving skills; verbalize satisfaction with caregiving; report minimal caregiver burden; and are familiar with, have access to, and use available resources.
C. Institutional outcomes: The institution reflects a safe and enabling environment for delivering care to individuals with progressive dementia; the quality improvement plan addresses high-risk problem-prone areas for individuals with dementia such as falls and the use of restraints.

VII. FOLLOW-UP TO MONITOR CONDITION

A. Follow-up appointments are regularly scheduled; frequency depends on the patient's physical, mental, and emotional status and caregiver needs.
B. Determine the continued efficacy of pharmacological/nonpharmacological approaches to the care plan, and modify as appropriate.
C. Identify and treat any underlying or contributing conditions.
D. Community resources for education and support are accessed and used by the patient and/or caregivers.

Pain Management in the Older Adult*

22

Ann L. Horgas, Joanne Laframboise-Otto, Karen Aul, and Saunjoo L. Yoon

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss the importance of effective pain management for older adults.
2. Describe the best methods of assessing pain, including among elders with dementia.
3. Discuss pharmacological and nonpharmacological strategies for managing pain.
4. State at least two key points to include in education for patients and families.

OVERVIEW

Pain is a common experience among older adults. Across all care settings and most specialty areas, nurses regularly interact with older adults. By the year 2030, it is projected that there will be 72.1 million adults 65 years of age or older, representing 19% of the U.S. population. Individuals aged 85 and older are the fastest growing segment of the population (Federal Interagency Forum on Aging-Related Statistics [Federal Interagency], 2016).

Aging increases the risk of pain due to high rates of chronic and acute health conditions. Almost half of adults aged 65 and older have four or more chronic health conditions (Altman & Frist, 2015). In 2010, 13.6 million adults over age 65 were hospitalized in acute care settings, and an additional 298.4 million older adults sought care at an ambulatory care clinic at least once (Federal Interagency, 2016). Pain is typically associated with some of these medical visits. Further, more than 19 million surgeries were performed on older adults, including 5.2 million musculoskeletal surgeries (e.g., knee and hip arthroplasty surgeries; Federal Interagency, 2016). Therefore, older adults are at risk for pain associated with chronic diseases as well as postsurgical and procedural pain.

Effective pain management relies on systematic and comprehensive assessment as well as multidimensional pain treatment. In this chapter, we provide an overview of pain, including the epidemiology of pain, definitions and types of pain, causes and consequences of pain, and barriers to pain management in older adults. We also provide an overview of pain assessment strategies, including self-report and objective pain measurement, the latter of which is relevant to pain assessment for older adults with dementia. This overview is followed by a discussion of pharmacological and nonpharmacological pain management strategies for use with older adults.

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

Epidemiology of Pain in Older Adults

The high prevalence of pain among older adults in the United States is well documented (Institute of Medicine [IOM], 2011; Morrissey, Viola, & Shi, 2014). In a nationwide survey of 7,601 older adults, approximately 50% of respondents reported experiencing bothersome pain in the preceding month (Patel, Guralnik, Danise, & Turk, 2013). The Centers for Disease Control and Prevention (Dahlhamer et al., 2018) estimated that over 60% of older adults in the United States experience chronic pain. Such estimates are higher in long-term care settings where older adults have multiple medical conditions. It is estimated that as many as 83% to 93% of nursing home residents experience pain on a regular basis (Abdulla et al., 2013).

Definitions, Causes, and Types of Pain

The International Association of the Study of Pain (IASP) defines *pain* as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey, 1994, p. S74). Pain is also described as a complex, multidimensional, subjective experience with sensory, cognitive, and emotional dimensions (Melzack & Casey, 1968). In clinical practice, McCaffery's parsimonious definition of pain is often cited: "Pain is whatever the experiencing person says it is, existing whenever he says it does" (1968, p. 95). These definitions highlight the subjective nature of pain.

Several types of pain can affect older adults. *Acute pain* is typically associated with surgery, fractures, acute illness, or trauma. *Persistent pain* (often referred to as chronic pain) typically continues past the usual healing time, often beyond 3 to 6 months. *Persistent* pain is most frequently associated with chronic diseases common among older adults, including degenerative joint disease, cardiovascular disease, diabetes mellitus, osteoporosis, cancer, and peripheral neuropathies.

Pain is also characterized by the type of pain stimulus. *Nociceptive pain* is caused by actual or threatened damage to organs, skin, muscle, and bones (e.g., nonnervous system tissue). This type of pain is caused by activation of nociceptors (sensory receptors throughout the body) that process painful stimuli. Osteoarthritis pain is one of the most common types of nociceptive pain in older adults (Savvas & Gibson, 2016). *Neuropathic pain* is caused by damage or disease to the somatosensory nervous system. Subtypes of neuropathic pain include central and peripheral pain. Disease or damage to the central somatosensory nervous system causes *central neuropathic pain*. Conditions such as Parkinson's disease, poststroke myelopathies, spinal cord injuries, spinal stenosis, multiple sclerosis, and fibromyalgia are common causes of this type of pain. *Peripheral neuropathic pain* is caused by conditions such as postherpetic neuralgia, metabolic disorders (e.g., diabetic neuropathy, alcohol abuse), nerve compression or entrapment, phantom limb pain, and trigeminal neuralgia (Guerriero, Bolier, Van Cleave, & Reid, 2016). Neuropathic pain is characterized by tingling or stabbing sensations and is often associated with abnormal sensations (dysesthesia) or pain from typically nonpainful stimuli (allodynia). Owing to the prevalence of acute and chronic health conditions in this population, older adults may experience multiple types of pain. For example, patients may experience persistent pain (e.g., osteoarthritis) with acute pain (e.g., cancer, cardiac, illness-related, or postsurgical pain). Further, patients may experience both nociceptive and neuropathic pain, which require different treatment measures. Healthcare providers should assess for all types of pain that may negatively impact mobility, recovery, rehabilitation, and quality of life.

Consequence of Pain for Older Adults

Over the past several decades, much attention has been devoted to the issue of pain in older adults in the research and clinical literature (Horgas, 2017a). Nonetheless, there is empirical evidence that pain among older adults continues to be undertreated (Morrissey, Horgas, Miller, & Wiener, 2019). In older adults, untreated or ineffectively treated moderate to severe persistent pain has major implications for overall health, functioning, and quality of life (Horgas, 2017a). Pain has been associated with depression, social withdrawal, sleep disturbances, impaired mobility, decreased activity engagement, and increased healthcare use (American Geriatrics Society [AGS] Panel on the Pharmacological Management of Persistent Pain in Older Persons, 2009). Other conditions that can be exacerbated by pain include falls, cognitive decline, deconditioning, malnutrition, gait disturbances, and slowed rehabilitation (AGS, 2009).

In the hospital setting, older adults suffering from acute pain are at increased risk for complications such as thromboembolism, pneumonia, and functional decline. In addition, there is growing evidence that inadequate management of severe, acute, postoperative pain leads to the development of persistent postsurgical pain (Johansen, Romundstad, Nielsen, Schirmer, & Stubhaug, 2012; Macrae, 2008). Surgeries associated with increased risk of persistent postsurgical pain include lower extremity amputation, breast surgery, thoracotomy, inguinal hernia repair, coronary artery bypass surgery, and cholecystectomy, all of

which are common surgeries among older adults (Kehlet, Jensen, & Woolf, 2006).

Pain is burdensome for caregivers who must manage pain for older adults at home (Reinhard, Levine, & Samis, 2012). Overall, unrelieved pain reduces the quality of life for older adults and contributes to increased healthcare resource utilization and costs (IOM, 2011; Morrissey et al., 2014). Thus, it is not surprising that the IOM (2011) declared chronic pain a major public health problem in the United States.

Barriers to Pain Management in Older Adults

Pasero and McCaffery (2011) provided a comprehensive chapter on biases, misconceptions, and misunderstandings that hampered the healthcare provider's assessment and treatment of patients who reported pain. These issues apply to patients across the life span and led the authors to conclude the following:

> A veritable mountain of literature published during the past three decades attests to the undertreatment of pain. Much of this literature is consistent with the hypothesis that human beings, including health care providers in all societies, have strong tendencies or motivations to deny or discount pain, especially severe pain, and to avoid relieving the pain. Certainly, we should struggle to identify and correct personal tendencies that lean to inadequate pain management, but this may not be a battle that can be won. Perhaps it is best to assume that there are far too many biases to overcome and that the best strategy is to establish policies and procedures that protect patients and ourselves from being victims of these influences. (p. 48)

Among older adults, there are a number of barriers that impede pain assessment and management and contribute to inadequate pain management. These barriers fall into three domains: individual-based, provider-based, and system-based factors. *Individual-based factors* include the following: (a) belief that pain is a normal part of aging, (b) concern about being labeled a hypochondriac or complainer, (c) fear of the meaning of pain in relation to disease progression or prognosis, (d) fear of opioid addiction and analgesics, (e) worry about healthcare costs, and (f) belief that pain is not important to healthcare providers (AGS, 2009). Cognitive impairment is also an important barrier because dementia reduces an older adult's ability to remember and report pain (Horgas, 2017a; Horgas, Elliott, & Marsiske, 2009).

Provider-based factors refer to knowledge deficits among healthcare providers in effective pain management. Because there is no objective measure for pain, providers must rely on patient self-report to assess pain. Healthcare providers tend to underestimate patient reports of pain, a finding that is well documented for cognitively impaired older adults (Horgas, 2017a). Older adults with dementia are undertreated for pain when compared with cognitively intact older adults (Horgas et al., 2009; Horgas & Tsai, 1998; Lukas, Barber, Johnson, & Gibson, 2013; Morrison et al., 2003). This finding may reflect providers' difficulty in detecting pain in individuals who cannot verbally express it and a lack of knowledge regarding adequate pain assessment and use of management strategies with this population.

System-based factors include policies and regulations about prescription practices and prescriptive authority. Providers face strict regulations on how opioids can be prescribed and who can prescribe them. The U.S. federal government recently issued new regulations on prescribing in an effort to combat the current opioid epidemic and, in the process, may have limited access to pain medications for older adults who need them (Guerriero & Reid, 2017). Also, prescription costs, insurance coverage, access to providers, and access to pain medications are important system-based factors. While not an exhaustive list, these barriers highlight some of the challenges that both healthcare providers and older adults face when managing pain.

ASSESSMENT OF PAIN

In clinical settings, pain is often assessed using two straightforward questions: (a) "Are you having any pain?" and (b) "On a scale of 0 to10, how much pain are you having now?" Answers to these basic questions provide information about the presence of pain and its intensity. However, pain is a multidimensional phenomenon, and a more comprehensive pain assessment approach is needed to gain a full understanding of the patient's pain experience. It is important to note that an objective biological marker or laboratory test for pain does not exist, and thus pain assessment must rely on the patient's self-report. In individuals who cannot verbalize pain, such as those with dementia or communication disorders, pain assessment must include observational measures of pain. These approaches to pain assessment will be discussed in the following sections.

Self-Reported Pain

A patient's self-report is considered the gold standard for pain assessment (AGS, 2009). The first principle of pain assessment is to *ask* about the presence of pain at regular and frequent intervals (Horgas, 2017a). It is important to

allow older adults sufficient time to process the questions and formulate answers, especially when working with cognitively impaired older adults. It is also important to explore different words that patients may use synonymously with pain, such as discomfort or aching. Use open-ended questions, such as "Tell me about your pain, aches, soreness, or discomfort," when eliciting information about pain from older adults (Herr, 2011).

Self-reported pain intensity is measured in various ways. Some commonly used tools include the Numerical Rating Scale (NRS), the Verbal Descriptor Scale (VDS), and the Faces Pain Scale (FPS; Herr, 2011). The NRS is widely used in hospital settings. Patients are asked to rate the intensity of their pain on a 0 to 10 scale. The NRS requires the ability to discriminate differences in pain intensity and may be difficult for some older adults to comprehend. In one study, adults over age 81 had a significantly higher failure rate in completing the NRS (11.1% failure rate) compared to those in the 61 to 70 (5.5% failure rate) or 71 to 80 (7.8% failure rate) age groups (Wood, Nicholas, Blyth, Asghari, & Gibson, 2010).

The VDS is recommended for use with older adults (Herr, 2011), but is more commonly used in research than in clinical settings. This tool measures pain intensity by asking individuals to select a word that best describes their present pain (e.g., no pain to worst pain imaginable). The VDS is considered a reliable and valid measure of pain intensity and is reported to be the easiest to complete and most preferred by older adults (Herr, 2011; Herr, Bjoro, & Decker, 2006).

The Faces Pain Scale (FPS) is commonly used to assess pain in acute care settings. Initially developed to assess pain intensity in children, the FPS is often recommended to measure pain in hospitalized, cognitively impaired older adults, although there is not strong empirical evidence to support this approach. The FPS and the FPS–Revised (FPS-R) consists of cartoon-like faces exhibiting pain expressions, ranging from the least pain to the most pain possible (Herr et al., 2006). Patients are asked to select the facial expression that represents the level of pain they are experiencing at present. See the "Resources" section for information on accessing these pain measurement tools.

In addition to these simple pain assessment tools, several multidimensional measures have been developed to assess overall pain and pain associated with cancer or osteoarthritis. These measures are generally broader in scope, assessing pain intensity and contributing and relieving factors of pain, as well as the impact of pain on daily functioning (e.g., sleep, movement, relationships). The McGill Pain Questionnaire is one of the most widely used multidimensional tools. This tool measures pain affect and evaluation (based on 78 word descriptors), pain location (using a body map), and pain intensity (based on the Present Pain Intensity subscale, a single question rating subjective pain on a 6-point scale; Melzack, 1975). The Brief Pain Inventory (BPI) is a commonly used multidimensional measure, originally designed for cancer pain but widely used as a general pain measure (Cleeland & Ryan, 1994). A three-item version of the BPI, called the PEG Scale, is available for quick assessment of pain interference with activities (Guerriero et al., 2016; Krebs et al., 2009). This tool measures average *P*ain intensity, pain interference with *E*njoyment, and pain interference with *G*eneral activities over the past week. Questions are scored on a 0 to 10 scale (0 indicating no interference and 10 indicating complete interference; Guerriero et al., 2016). The Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) is often used to measure pain associated with osteoarthritis (Bellamy, Buchanan, Goldsmith, Campbell, & Stitt, 1988). The reader is referred to the "Resources" section for more information on these measurement tools.

Observed Pain Indicators

Comprehensive pain assessment requires focusing on objective indicators of pain. Cognitive impairment, such as that associated with Alzheimer's disease and related disorders, compromises an older adult's ability to self-report pain. Patients with dementia, broadly defined, and those with aphasia or other neurological disorders cannot provide verbal self-reports of pain. Thus, other assessment approaches must be used to identify the presence of pain (Herr, Bursch, Ersek, Miller, & Swafford, 2010).

The American Society for Pain Management Nursing issued a consensus statement about assessing pain in nonverbal patients and recommended a hierarchical pain assessment approach (Herr, Coyne, et al., 2006). The four steps in the recommended process are: (a) attempt to obtain a self-report of pain; (b) look for an underlying cause of pain, such as surgery or a procedure; (c) observe for pain behaviors; and (d) seek input from family and caregivers (Herr, Coyne, et al., 2006). If any of these steps are positive, the nurse should assume that pain is present, and a trial of analgesics or nonpharmacological pain treatment should be initiated. Pain behaviors should be observed before and after the treatment trial in order to evaluate if the strategies were effective or need modification.

Observational techniques for pain assessment focus on behavioral or nonverbal indicators of pain (Hadjistavropoulos et al., 2007; Herr, 2011; Herr, Coyne, et al., 2006; Horgas et al., 2009). Behaviors such as

guarded movement, bracing, rubbing the affected area, grimacing, painful noises or words, and restlessness are often considered pain behaviors (AGS, 2009; Horgas et al., 2009). In the acute care setting, vital signs are often considered physiological indicators of acute pain. However, elevated vital signs are not considered a reliable indicator of pain, but rather should initiate pain assessment (Pasero & McCaffery, 2011). In addition, older adults with dementia often express pain through behavioral changes. For example, changes in interpersonal interactions (e.g., aggression, agitation, resisting care), activity patterns (e.g., wandering), and mental status (e.g., confusion, crying) may signal the presence of pain (Ahn & Horgas, 2013; Husebo, Achterberg, & Flo, 2016).

Approximately 20 different observational measurement tools have been developed to assess behavioral indicators of pain (see comprehensive reviews by Herr, Bjoro et al., 2006 and Taylor, Harris, Epps, & Herr, 2005). These tools differ in their content, comprehensiveness, scoring, and psychometric characteristics (e.g., reliability and validity). There is not one behavioral measure of pain that can be universally applied in all settings or with nonverbal individuals. However, an expert panel developed a consensus statement focused on pain behavior assessment tools for use in nursing homes (Herr, 2010). Two measures were recommended for use: the Pain Assessment in Advanced Dementia (PAINAD) Scale (Warden, Hurley, & Volicer, 2003) and the Pain Assessment Checklist for Seniors With Severe Dementia-II (PACSLAC-II; S. Chan, Hadjistavropoulos, Williams, & Lints-Martindale, 2014; Fuchs-Lacelle & Hadjistavropoulos, 2004).

Although most observational measures have undergone some psychometric testing, most lack evidence to support sensitivity to change over time. This undermines the ability to detect treatment effects, a fundamental aspect of effective pain management. One notable exception is the MOBID-2 (Mobilization-Observation-Behavior-Intensity-Dementia-2 Pain Scale; Husebo, Ostelo, & Strand, 2014). The MOBID-2 has undergone extensive, rigorous testing in several clinical trials and has demonstrated reliability and sensitivity to treatment effects with patients (Husebo, Ballard, Sandvik, Nilsen, & Aarsland, 2011; Husebo, Strand, Moe-Nilssen, Husebo, & Ljunggren, 2010).

In summary, a comprehensive review of these measures, as well as other similar tools, is available on the City of Hope website (see the "Resources" section). In addition, the Hartford Institute for Geriatric Nursing provides online resources for pain assessment in older adults with dementia that include information on the PAINAD tool and an instructional video on how to use it (see the "Resources" section for link). Several caveats about observational tools must be noted: (a) the presence of these behaviors is suggestive of pain but not always a reliable indicator of pain, and (b) the presence of pain behaviors does not provide information about the intensity of pain (Pasero & McCaffery, 2011). As such, pain behavior tools should be used as one component of a comprehensive pain assessment with older adults.

Pain Assessment Resources

Several excellent clinical guidelines and consensus statements are available to guide healthcare providers when conducting comprehensive pain assessment and measurement. The American Pain Society issued an interdisciplinary expert consensus statement on assessment of pain in older adults (Hadjistavropoulos et al., 2007). This excellent resource includes a comprehensive overview of pain measurement tools and recommendations for pain assessment approaches, including the assessment of psychological, emotional, and functional aspects of pain. More recently, Booker and Herr (2015) developed a focused pain assessment protocol for older adults and provided guidelines for selecting pain assessment tools. Also, see review articles on pain assessment and measurement in older adults with and without dementia (Horgas, 2017a, 2017b; Horgas & Glover, 2017, 2018). In addition, there are several excellent websites focused on pain assessment in older adults, most notably The Geriatric Pain website (www.geriatricpain.org). In addition, the Hartford Institute for Geriatric Nursing provides online resources for pain assessment in older adults with dementia (https://consultgeri.org/try-this/dementia/issue-d2) that include tools and instructional videos (Horgas & Miller, 2008).

SUMMARY

Systematic and thorough assessment is a critical first step in appropriately managing pain in older adults. Self-reported pain should be assessed in all patients, and observed pain indicators should be assessed in individuals who are unable to verbally express pain. The use of a standardized pain assessment tool and approach is important in measuring pain. It enables healthcare providers to document their assessment, measure changes in pain, evaluate treatment effectiveness, and communicate with other healthcare providers, the patient, and the family. Information from family and caregivers should also be obtained to supplement and contextualize information from pain self-reports and observed pain indicators.

INTERVENTIONS AND CARE STRATEGIES

The primary goal of pain management in older adults is to maximize function and quality of life by minimizing pain to the extent possible (Horgas, Grall, & Yoon, 2016). Pain relief is one of the most common goals of older adults (Makris, Abrams, Gurland, & Reid, 2014). However, balancing treatment for multiple comorbidities with treatment for pain can be challenging (Fine, 2012; Patel et al., 2013; Schere et al., 2016). Polypharmacy is common among older adults (Ersoy & Engin, 2018). Thus, a multimodal approach to the management of pain, including pharmacological and nonpharmacological therapies, is recommended (Hochberg et al., 2012; Makris et al., 2014; Schneiderhan, Clauw, & Schwenk, 2017). These two approaches to pain management are presented in the following sections.

Pharmacological Pain Treatment

Analgesic medications are an integral component of pain management in older adults (Horgas et al., 2016). The plan to use pharmacotherapy for the treatment of pain is a mutual decision among the healthcare provider, the patient, and caregiver, with the goals of optimizing pain relief as well as improving quality of life and patient functioning (Horgas et al., 2016). Guidelines from the AGS recommend the establishment of realistic pain goals with the acknowledgment that complete resolution of pain in the older adult may not be achievable (AGS, 2009; Guerriero et al., 2016; Makris et al., 2014). Pain pharmacotherapy in the older adult is a process of trial and error that aims to balance drug effectiveness with management of its adverse effects, considering age-related changes in drug absorption, distribution, metabolism, and excretion (Kaye, Baluch, & Scott, 2010). Comorbidities increase the use of multiple drugs (polypharmacy) and the risk of drug-to-drug interactions (Horgas et al., 2016). In patients with dementia, pharmacological pain management is considered a priority because altered cognitive functioning limits their ability to engage in nonpharmacological pain relief strategies (Corbett et al., 2014; Horgas, 2017b).

Choice of analgesic drugs for older adults depends on the type, severity, and duration of pain. In 2008, the World Health Organization (WHO) established guidelines for the treatment of cancer pain (Pergolizzi et al., 2008). Although focused on cancer-related pain, the WHO ladder has been used as a guide by healthcare providers in decision-making regarding analgesic use with a variety of patient populations. Using a three-step approach, drug choices are made from three categories based on pain severity: mild, moderate, or severe. Drug choices include nonopioids, opioids, and adjuvant agents. Combinations of these drugs may be prescribed for patients such that two or more drugs can treat varied underlying pain mechanisms and different types of pain. This practice would allow for smaller doses of analgesics to be used and would, in turn, minimize adverse effects (Pergolizzi et al., 2008). Types of analgesic drugs commonly prescribed are as follows.

Nonopioid Drugs

Nonopioid drugs (e.g., acetaminophen, ibuprofen, or naproxen) are recommended to treat mild to moderate pain. Acetaminophen is considered the first drug of choice for the treatment of persistent pain (AGS, 2009) and for mild to moderate pain in older adults (Galicia-Castillo & Weiner, 2019; Makris et al., 2014). The U.S. Food and Drug Administration (FDA) has recommended that the total daily dose of acetaminophen not exceed 3 g/d, and 2 g/d in frail patients, those over 80 years of age, and those who use alcohol on a regular basis (FDA, 2011; Galicia-Castillo & Weiner, 2019). Hepatoxicity is a risk for individuals with reduced hepatic function or history of alcohol abuse; therefore, the maximum daily dose should be reduced to 50% to 75% in this population (Galicia-Castillo & Weiner, 2019). The importance of monitoring acetaminophen intake to prevent the cumulative effects of this drug requires watching for "hidden" dosages in combination drugs such as opioid + nonopioid, and in over-the-counter (OTC) medications, and should be monitored closely by healthcare providers. Patients and caregivers should be educated about this risk and how to avoid it. In 2011, the FDA required drug manufacturers to limit the strength of acetaminophen in combination products to 325 mg per tablet, capsule, or dosing unit to lower the potential for acetaminophen-induced hepatotoxicity (Galicia-Castillo & Weiner, 2019).

Nonsteroidal anti-inflammatory drugs (NSAIDs) are more effective than acetaminophen for patients with inflammatory pain, such as the pain associated with rheumatological diseases. In general, NSAIDs should be used only for brief periods, typically 1 to 2 weeks, during episodes of increased nociceptive pain (Gloth, 2011). There are two types of NSAIDs: nonselective (e.g., ibuprofen or naproxen) and cyclooxygenase-2 (COX-2) selective inhibitors (e.g., celecoxib). The COX-2 drugs were introduced in the pharmaceutical market with the goal of reducing the gastrointestinal (GI) side effects associated with nonselective NSAIDs. However, the GI effects resulting from COX-2 drugs were found to be similar to those of nonselect

NSAIDs. In 2004, two of the initial COX-2 drugs (rofecoxib and valdecoxib) were withdrawn from the market because of their association with increased risks for adverse cardiovascular events, including myocardial infarction and stroke (Galicia-Castillo & Weiner, 2019). The AGS Beers Criteria® Update Expert Panel (2019) recommend that all NSAIDs, including nonselective and COX-2 drugs, be used with caution in older adults, especially in those with underlying cardiovascular diseases (e.g., myocardial infarction, heart failure, or stroke), renal disease, or history of gastropathy. The drug naproxen is an exception because it is considered a reasonable choice for patients at risk for cardiovascular disease (Galicia-Castillo & Weiner, 2019). The concomitant use of gastroprotective agents such as proton-pump inhibitor drugs (e.g., prilosec or protonix) and H2 receptor antagonist drugs (e.g., famotidine or ranitidine) is recommended to decrease the risk of GI adverse effects in elderly patients (Galicia-Castillo & Weiner, 2019). The FDA recently released warnings about the drug ibuprofen, another commonly used NSAID, citing increased incidence of cardiovascular events (including myocardial infarction) and recommending that maximum dosing not exceed 3,200 mg/d. In the general population, OTC doses of NSAIDs have a good safety profile. However, risks for adverse effects are significantly higher in the older adult, especially those with chronic kidney disease, gastropathy, and cardiovascular disease such as heart failure (AGS Beers Criteria, 2019).

Opioid Drugs

When pain persists, increases, or has significant pain-related functional impairment, opioid drugs can be used in older adults (AGS, 2009; Makris et al., 2014). Opioid drugs (e.g., oxycodone, morphine, hydromorphone, or fentanyl) are effective for treating moderate to severe pain from multiple causes. According to the AGS Panel on the Pharmacological Management of Persistent Pain in Older Persons (2009), opioid analgesics can be used safely and effectively in older adults if they are properly selected and monitored by the healthcare provider. Patients with persistent uncontrolled pain requiring opioid therapy should receive around-the-clock scheduled dosing to ensure steady drug levels of the opioid (Pasero & McCaffery, 2011). The use of extended-release opioids can reduce the need for frequent dosing and provide better pain relief, which is especially helpful with older adults (Galicia-Castillo & Weiner, 2019; Kaye et al., 2010).

In light of the current opioid epidemic in the United States, opioid use has been the focus of much attention. Healthcare providers are making more conscientious decisions when prescribing opioid analgesics for the control of pain. Prescribing decisions and practices are now being more closely scrutinized by federal agencies such as the FDA. The CDC has published new recommendations for prescribing opioids for noncancer pain, which providers are encouraged to follow (Dowell, Haegerich, & Chou, 2016). The Centers for Medicare and Medicaid Services (CMS) has published position statements on drug diversion putting forth recommendations for actions at the federal and state levels that impact providers and patients. Although young to mid-age adults are affected most by problems such as opioid dependence, drug diversion, and mortality associated with opioid overdosing, these problems also impact older adults who are prescribed opioids for pain control (Dowell et al., 2016).

Healthcare providers should prescribe opioids based on clearly defined therapeutic goals. Prescribing should occur based on serial attempts to reach these goals, with the lowest opioid analgesic dose chosen on the basis of its efficacy and minimal adverse effects (AGS, 2009; Galaria-Castillo & Weiner, 2019). Potential adverse effects such as respiratory depression, a rare but serious side effect, can be mitigated by slow dose escalation and careful monitoring for signs of hypoxia (Galaria-Castillo & Weiner, 2019). Potential adverse effects such as constipation, a common side effect and a problem especially for older adults, can be managed by the concurrent use of stool softeners (Galaria-Castillo & Weiner, 2019).

Some older adults are reluctant to use opioids because of fear of addiction, severity of adverse effects, and death associated with drug overdose (Galaria-Castillo & Weiner, 2019). These concerns have been heightened by the opioid epidemic. However, careful prescribing and close monitoring of older adults receiving opioids for pain relief can decrease the likelihood of these problems. Patient and caregiver education about appropriate use of opioid analgesics, safety precautions (e.g., driving, falls), safe storage to prevent diversion, and risks of obtaining opioid prescriptions from multiple providers is imperative (Horgas, 2017a).

In summary, opioid use for pain relief with older adults has been shown to be efficacious for short-term use, but little is known about the efficacy of long-term use (Reid, Eccleston, & Pillemer, 2015). Further, because of the lack of high-quality evidence, little is known about the prevalence of opioid misuse in older adults (Maree, Marcum, Saghafu, Weiner, & Karp, 2016). These are areas in need of further study to provide an evidence base for opioid pain management practices with older adults.

Adjuvant Drugs

Adjuvant drugs are agents administered in conjunction with analgesics to relieve pain. These drugs provide relief from pain beyond their intended use and include, for example, antidepressants and antiepileptics. When administered with nonopioids and opioids to achieve pain control, these drugs work by providing additive analgesic effects or by enhancing the patient's response to analgesics (Horgas, 2017b). Adjuvant drugs are specifically recommended for patients with neuropathic pain (AGS, 2009). Tricyclic antidepressants (TCAs; e.g., nortriptyline and desipramine) have demonstrated dual effects on both pain and depression. However, the AGS guidelines (2009) recommend that TCAs should be avoided in older patients because of their anticholinergic effects, including confusion, dry mouth, constipation, and orthostatic hypotension (AGS Beers Criteria, 2019; Galicia-Castillo & Weiner, 2019). Selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine uptake inhibitors (SNRIs) are safer classes of antidepressant drugs to use in older adults because they are effective in the treatment of neuropathic pain and have better adverse effect profiles than TCAs (Reisner, 2011). Anticonvulsants (e.g., pregabalin and gabapentin) can be used as adjuvants for treating pain associated with trigeminal neuralgia and postherpetic neuralgia. These drugs have fewer adverse effects than TCAs but must be titrated slowly, and older patients should be closely monitored for adverse effects such as dizziness, somnolence, fatigue, and weight changes (AGS, 2009; Reisner, 2011). Local anesthetics such as lidocaine as a patch, gel, or cream can be used as an additional treatment of postherpetic neuralgia pain (Horgas, 2017b). A major benefit of using these routes is avoidance of systemic adverse effects (Galicia-Castillo & Weiner, 2019).

Special Considerations for Administering Analgesics in Older Adults

Older adults require close monitoring when taking analgesic medication, especially when beginning a new drug or changing the dosage of a drug. It is important to observe for therapeutic effects and adverse effects and then determine the need to titrate dosages or change drug therapy (Makris et al., 2014). Adverse effects are drug and dose specific and can include neurological changes (e.g., dizziness, confusion, or sedation), cardiorespiratory changes (e.g., hypotension or respiratory depression), and GI changes (e.g., bleeding or constipation; Makris et al., 2014). It is important to assess for these changes and take prompt medical action.

Recommendations for beginning pharmacotherapy for pain include starting at low doses and gradually titrating upward while monitoring for and managing adverse effects. The medical adage "start low and go slow" for prescribing medications for geriatric patients applies to analgesics as well, particularly when administering opioids to opioid-naïve older adults. Healthcare providers need to titrate analgesic doses upward to achieve the desired therapeutic effects using short-acting analgesics first, then consider using longer-acting analgesics for long-lasting pain relief once analgesic drug tolerability has been established (Fine, 2012). For most older adults with mild to moderate pain or for those taking drugs for persistent pain, analgesics taken "around the clock" rather than "pro re nata" (prn) are recommended. Using analgesic drugs with a short half-life and the fewest side effects is also recommended (Pasero & McCaffery, 2011). Overall, adopting a preventive approach to pain management whenever possible is recommended with the elderly. By treating pain before it occurs, often less dosage of analgesia is required to relieve pain and, in turn, fewer adverse effects are experienced (Pasero & McCaffery, 2011).

The least invasive method of drug delivery should be used with older adults. The oral route is the most convenient and is recommended with older adults whenever possible, provided swallowing is intact (Pasero & McCaffery, 2011). When more rapid onset of drug action is needed or when the patient cannot take oral medications, intravenous, subcutaneous, and intramuscular routes for administration can be used. Drugs administered via these routes typically have a shorter duration of action and require administration skills (Fine, 2012). Generally, the intramuscular route should be avoided in the older adult because of the potential for tissue injury, unpredictable drug absorption, and injection discomfort (Pasero & McCaffery, 2011). Transdermal, rectal, and oral transmucosal routes should be considered with older adults (Galicia-Castillo & Weiner, 2019).

Drugs to Avoid in Older Adults—Beers Criteria (2019)

It is important to recognize the dangers associated with potentially inappropriate medications (PIMs) for the treatment of pain in older adults. The AGS Beer's Criteria (2019) is a well-known and widely used resource for identifying medications that have an unfavorable balance of risk and benefits. There are several analgesic agents considered PIMs on the Beers List. In general, the AGS Beers Criteria recommend avoiding opioids except in

cases of severe acute pain (e.g., recent fractures or joint replacement surgery) owing to the association with falls or fractures (AGS Beers Criteria, 2019). Meperidine has a toxic metabolite (normeperidine) with a long half-life that causes neuro-excitation and seizures, and its use should be avoided with older adults (AGS Beers Criteria, 2019). Tramadol was recently added to the AGS Beers Criteria (2019) owing to the risk of the syndrome of inappropriate antidiuretic hormone (SIADH) and hyponatremia associated with its use.

Nonselective NSAIDs, as a class of drugs, are considered PIMs because of their increased risk for GI bleeding. These drugs include ibuprofen and naproxen. Indomethacin is more likely than any other NSAID to have adverse effects on central nervous system (CNS) functioning and has the most adverse effects. Thus, the use of indomethacin should be avoided in older adults (AGS Beers Criteria, 2019). Both NSAIDs and selective COX-2 inhibitors should be avoided in older adults with symptomatic heart failure (AGS Beers Criteria, 2019).

Several classes of adjuvant drugs are on the Beers List and should be avoided with older adults. Skeletal muscle relaxants prescribed to treat muscle spasms and back pain should be avoided in older adults because of their CNS adverse effects, anticholinergic effects, sedation, and fall/fracture risk (AGS Beers Criteria, 2019). Antidepressants, alone or in combination, are associated with anticholinergic effects, sedation, and hypotension, placing older adults at risk for falls (AGS Beers Criteria, 2019). Finally, drugs used to treat the adverse effects of analgesics and adjuvant drugs, including sedatives, antihistamines, and antiemetics, can contribute to anticholinergic effects, hypotension, and falls (AGS Beers Criteria, 2019).

Nonpharmacological Treatment for Pain

Nonpharmacological pain treatment is an essential component of effective and patient-centered pain management (CDC, 2016; Joint Commission, 2017). Given the high rates of chronic conditions and polypharmacy previously cited, consideration should be given to relieve pain without adding further pharmacological agents when possible. There is evidence to support the use of nonpharmacological pain treatment for common chronic pain conditions, such as exercise for low back pain and osteoarthritis (CDC, 2016). In a systematic review of 105 U.S.-based randomized controlled trials conducted over the past 50 years, several nonpharmacological therapies to treat pain were identified and found to be effective (Nahin, Boineau, Khalsa, Stussman, & Weber, 2016). In particular, complementary health approaches such as yoga, tai chi, and acupuncture improved pain management (Nahin et al., 2016). Over 30% of adults use some form of complementary therapy, according to the report by the National Center for Complementary and Integrative Health (NCCIH, 2018). The most commonly reported nonpharmacological strategies included exercise, nutritional supplements, ointments, massage, relaxation (e.g., breathing, meditation, imagery, music), activity modification, massage, and heat or cold application (NCCIH, 2018). The use of transcutaneous electrical nerve stimulation (TENS), chiropractic practices, vitamins, herbal remedies, magnets, and acupuncture was less prevalent in older adults (NCCIH, 2018; Stewart et al., 2012). Nonpharmacological therapies that were recommended for chronic pain management included acupuncture, mindfulness meditation, massage, TENS, cognitive behavioral therapy (CBT), and supplements such as glucosamine and topical capsaicin cream (Abdulla et al., 2013; Zhang et al., 2008). Many of these nonpharmacological therapies are safe and effective in reducing pain and improving function (Makris et al., 2014). Older adult patients should be encouraged to use multimodal approaches, including nonpharmacological treatment, for more effective pain management (Makris et al., 2014).

Types of Nonpharmacological Treatment

Pain is a physical and emotional experience (Merskey, 1994). Thus, emotional responses to and correlates of pain such as anxiety and depression are common (Abdulla et al., 2013; Denise et al., 2014). Multimodal approaches are increasingly encouraged to address both the physical and the emotional components of pain (Abdulla et al., 2013; Keefe, Porter, Somers, Shelby, & Wren, 2013; Makris et al., 2014). Nonpharmacological pain treatment strategies such as acupuncture, acupressure, massage, mindfulness meditation, and yoga may be beneficial to manage pain both physically and emotionally. Physical pain relief modalities include, but are not limited to, TENS, use of heat and cold, massage, physical activity, acupuncture, acupressure, and exercise. Emotional pain relief modalities include guided imagery, mindfulness meditation, CBT, biofeedback, tai chi, and yoga (Abdulla et al., 2013; Makris et al., 2014). Various types of dietary supplements are also commonly used nonpharmacological pain treatments among older adults. Many of these nonpharmacological strategies have been empirically evaluated for their effectiveness in pain management for older adults and reviewed for level of evidence ratings (Makris et al., 2014). A brief explanation of some commonly used nonpharmacological pain treatments follows.

Acupuncture Acupuncture is recommended primarily as a complementary therapy. It is considered a safe effective treatment according to a meta-analysis (Vickers et al., 2012), evidence-based guidelines (Abdulla et al., 2013; Makris et al., 2014; Park & Hughes, 2012), and leading professional organizations such as the Osteoarthritis Research Society International (OARSI; Zhang et al., 2008) as well as the AGS (2009). Although a randomized clinical trial conducted in Australia (Hinman et al., 2014) did not support acupuncture as an effective treatment for chronic knee pain, a more recent meta-analysis of 39 clinical trials concluded that acupuncture needling therapy was superior to sham acupuncture and that no-acupuncture controls for relieving chronic musculoskeletal pain had a persistent effect (Vickers et al., 2018). Thus, recent Clinical Practice Guidelines from the American College of Physicians (ACP) recommend acupuncture as an effective treatment to manage chronic back pain based on a systematic review (Tick et al., 2018). Among the clinical trials reviewed, however, the frequency and duration of acupuncture treatment varied from three times per week for 2 weeks to once a week for 26 weeks. Thus, more research is needed to define the optimal treatment dosage and timing.

Acupressure Acupressure involves applying physical pressure by hands, fingers, or elbows on different pressure points and is based on the same principles as acupuncture. One type of acupressure that has shown improvement in pain outcomes is auricular acupressure (AA)—pressure applied to the ear. E. You, Kim, Harris, and D'Alonza (2019) highlighted the fact that acupressure can be safely self-administered, which is a significant advantage from a self-management perspective. Like acupuncture studies, there is considerable variability in the dosage and timing of acupressure treatments. One study reported that AA applied daily for 7 days was effective to manage chronic low back pain (Yeh, Chien, Chiang, & Huang, 2012). Another study used acupressure once per day for 5 days a week over an 8-week period and demonstrated significantly improved pain relief compared to the usual care in older adults with knee osteoarthritis (Li, Harris, Tsodikov, Struble, & Murphy, 2017). Similarly, acupressure applied for 15 minutes 4 times per week for 12 weeks indicated reduced pain intensity among community-dwelling frail older adults (C. W. C. Chan et al., 2017). These studies support the effectiveness of acupressure to relieve chronic pain, despite differences in dosage, frequency, and duration of acupressure treatment. Thus, further study is needed to define the parameters of optimal acupressure treatment for pain relief.

Massage Massage is considered an effective adjunctive therapy for pain without serious adverse events (Abdulla et al., 2013; AGS, 2009; Makris et al., 2014; Zhang et al., 2008). Clinical Practice Guidelines from the ACP recommend massage therapy as an effective treatment to manage chronic back pain (Tick et al., 2018). Massage therapy may be beneficial when combined with aromatherapy. A study by Arslan, Kutlutürkan, and Korkmaz (2019) found aromatherapy massage helped to reduce chronic pain from osteoarthritis. Another type of healing touch, therapeutic touch, involves the use of hands to promote energy healing. There is some evidence to support its use to relieve pain. For example, a pilot study by Mueller, Palli, and Schumacher (2019) suggested using therapeutic touch as a noninvasive intervention because it was beneficial to adult neurological patients with chronic back pain.

Mindfulness Meditation

Mindfulness-based interventions appear to be effective in managing musculoskeletal pain (Lopes, Vannucchi, Demarzo, Cunha, & Nunes, 2019) and chronic back pain (Cherkin et al., 2016), demonstrating clinically meaningful improvement in pain after use. In one clinical trial, it was found that 8 weeks of a meditation program was as effective as an educational program in reducing chronic low back pain (Morone, Rollman, Moore, Qin, & Weiner, 2009). Relaxation, as a mind–body therapy, was also effective for managing chronic headaches and musculoskeletal pain in adults (Gonzalez et al., 2019), and for treating persistent pain of older adults living in long-term care facilities (Shropshire, Stapleton, Dyck, Kim, & Mallory, 2018).

Transcutaneous Electrical Nerve Stimulation (TENS)

The effectiveness of TENS for managing back pain has been well studied. A recent meta-analysis of TENS as an intervention found short-term improvement of functional disability but not symptoms of chronic back pain (Wu et al., 2018). In contrast, older adults demonstrated similar changes in experimental pain responses when compared to middle and younger adults (Simon, Riley, Fillingim, Bishop, & George, 2015). Older adults may need higher doses of TENS to have comparable effects for pain relief as do young adults (Simon et al., 2015) or this intervention may be used in combination with acupuncture (Abdulla et al., 2013; Park & Hughes, 2012). To obtain pain relief with TENS, adequate intensity and dosing should be established and applied (DeSantana, Walsh, Vance, Rakel, & Sluka, 2008).

Tai Chi

Tai chi is a movement-based exercise regimen that has demonstrated effectiveness in managing pain, improving physical functioning, and lowering fall risk (Huang, Feng, Li, & Lv, 2017; Makris et al., 2014). Systematic reviews and meta-analyses provide evidence that tai chi is safe for older adults (Abdulla et al., 2013; Kang, Lee, Posadzki, & Ernst, 2011). A recent randomized controlled trial to manage chronic multisite pain with tai chi intervention demonstrated decreased pain severity and pain interference compared to light physical exercise (T. You et al., 2018). Despite many trials of tai chi, the effectiveness of this intervention for chronic pain in older adults is still inconclusive because of methodological issues among studies (Hall, Maher, Latimer, & Ferreira, 2009). Therefore, tai chi is not widely supported to relieve pain.

Cognitive Behavioral Treatment Cognitive behavioral treatment (CBT) includes cognitive and behavioral coping skills training, cognitive restructuring, acceptance, and behavioral activation (Niknejad et al., 2018). CBT has also contributed to significant improvement in chronic pain and self-efficacy (Niknejad et al., 2018), and improved pain treatment and mobility among older adults with osteoarthritis (Baird, Murawski, & Wu, 2010). CBT is recommended for pain relief when delivered by a professional therapist (Abdulla et al., 2013; AGS, 2009) in a group-based setting (Niknejad et al., 2018). CBT requires multiple sessions (Green, Hadjistavropoulos, Hadjistavropoulos, Martin, & Sharpe, 2009; Niknejad et al., 2018). While the period and number of CBT interventions varied between studies, the mean number of sessions was 8.4 (min-max: 6–14) times and mean duration 9.4 (min-max: 4–35) weeks (Niknejad et al., 2018). A CBT intervention once a week for 10 weeks improved maladapative pain behavior, increased relaxation, and improved coping (Green et al., 2009) among participants.

Although these nonpharmacological therapies are not an exhaustive list of regimens, they demonstrated evidence to support their use in older adults. Each of these modalities has demonstrated mixed results, largely because of individual patient preferences and methodological differences in how the studies were conducted. Thus, there is no conclusive evidence that these modalities will relieve pain in older adults. Acupuncture seems to have the most consistently effective results for pain management. Nonpharmacological modalities should be considered on an individualized basis, depending on patient preference and response, physical function, psychological functioning, and acceptability and used as an adjunct to pharmacological treatment.

In summary, nonpharmacological treatments are widely used measures to help manage and relieve pain. These approaches are challenging to study because it is difficult to (a) find a convincing placebo and (b) establish optimal dose, frequency, and duration of such interventions. In addition, studies have inconsistent findings because of differences in designs, inconsistent measures, and mixed intervention durations. Further, it has not been determined which specific type of nonpharmacological treatment works best for specific types of chronic pain. Despite the lack of strong evidence and rigorous support for these nondrug approaches, they are of interest to patients, clinicians and researchers. Thus, healthcare providers should consider all possible combinations and options for managing pain and discuss these approaches with their older adult patients to identify the best options for each individual patient. More detail about these nonpharmacological treatments for pain can be found in the clinical guidelines referenced throughout this chapter. In addition, Shoji and colleagues provide a comprehensive review of behavioral interventions to treat pain and related symptoms among older adults from a palliative care perspective (Shoji, Glover, & Horgas, 2018).

Special Considerations for Using Nonpharmacological Treatment for Older Adults

Individuals vary widely in their preferences for and ability to use nonpharmacological treatments to manage pain. Spiritual and/or religious coping strategies, for example, should be consistent with the individual's values and beliefs. Other strategies, such as guided imagery, biofeedback, or relaxation, may not be feasible for cognitively impaired older adults. Tai chi or exercise should be customized based on functional ability and mental status of the older adult. Therefore, it is important for healthcare providers to consider a broad array of nonpharmacological treatments for pain and to tailor selections to the individual patient. It is also important to gain patient and family input about the use of home and folk remedies because use of herbals or home remedies is often not disclosed to healthcare providers and may result in negative drug–herb interactions (Yoon & Horne, 2001; Yoon, Horne, & Adams, 2004; Yoon & Schaffer, 2006).

IMPROVING PAIN MANAGEMENT IN HEALTHCARE SETTINGS

Nurses have a crucial role in assessing and managing pain. The promotion of comfort and relief of pain is fundamental to nursing practice, and, as integral members of

interdisciplinary healthcare teams, nurses must work collaboratively to assess and treat pain effectively. Given the prevalence of pain in older adults and the burgeoning aging population seeking care in our healthcare systems, this role is vitally important. In addition, nurses have a primary responsibility to teach the patient and family about pain and how to manage it, both pharmacologically and nonpharmacologically. As such, nurses must be knowledgeable about pain management, in general, and about managing pain in older adults, specifically. Moreover, nurses are responsible for basing their practice on the best evidence available, and helping to bridge the gap among evidence, recommendations, and clinical practice.

High-quality pain management requires strong institutional commitment and leadership that supports team-based quality-improvement processes (Dirks, 2010; Gordon et al., 2005). The American Pain Society recommendations for improving the quality of pain management in healthcare settings emphasizes a multilevel systems approach that ensures prompt pain assessment and effective pain treatment, including reassessing and adjusting treatment plans. Patients and families should be involved in developing and altering pain management plans. Documentation, identification of quality indicators, and measurement of pain management and process outcomes are required components of quality pain management initiatives. This interdisciplinary, comprehensive approach requires input from all parties in the healthcare setting with the unified goal of high-quality pain management for all patients across all settings.

CASE STUDY 22.1

Mrs. B is a 93-year-old woman living with her daughter in the community. She has been diagnosed with anxiety disorder, hypertension, and diabetes, and has a severe hearing problem. Recently, Mrs. B fell in her bathroom and broke her right leg, which resulted in admission to the hospital. Before the fall, she typically walked around the neighborhood daily with her daughter. She now stays in her hospital bed with bruising, swelling, and pain in her right lower extremity. Her daughter has stayed with Mrs. B at the bedside and is worried about her anxiety and pain. Mrs. B is ordered oxycodone hydrochloride 5 to 10 mg every 6 hours orally or morphine sulfate 1 mg intravenously every 4 hours for pain as needed.

The nurse conducted an assessment of vital signs and completed a thorough pain assessment and mental status assessment, starting with self-report questions and asking the daughter for observations about her mother's response. The nurse explained the analgesic choices, including the types, routes, dosages, and potential side effects, to the patient and her daughter. When the nurse asked Mrs. B and her daughter about their perspective of pain medications and their acceptable level of pain (pain goal), both expressed fear of taking opioid medications. After further discussions with the nurse, Mrs. B and her daughter agreed to oxycodone 5 mg (instead of 10 mg) to manage Mrs. B's pain. They expressed that this was an informed decision—that Mrs. B's anxiety about pain medication was relieved, and that they felt relieved to be part of the pain treatment decision. Follow-up pain evaluation revealed that 5 mg of oxycodone did not relieve Mrs. B's pain. Mrs. B. was repositioned, ice was applied, and gentle music turned on. Afterward, Mrs. B rested comfortably. Her daughter was relieved to see her mother resting comfortably and felt more knowledgeable about her mother's pain experience and how to manage it.

SUMMARY

Pain is a significant problem for older adults, and has the potential to negatively impact independence, functioning, and quality of life. In the acute care setting, pain can negatively affect healing. In order for pain to be effectively managed, it must first be carefully and systematically assessed. Pain assessment in older adults should start with self-reported pain. It should also incorporate assessment of nonverbal pain behaviors and family input about usual pain responses and patterns, particularly in patients unable to verbally communicate their pain. The use of established pain assessment measurement tools is recommended. Pain treatment in older adults should be tailored to the type and severity of pain, with medications that can be safely used in older adults, or combined with nonpharmacological treatment for heightened effectiveness. Older adults, their families, and their healthcare providers should be knowledgeable about pain and how to manage it. Thus, education is an important part of the process and should not be overlooked. Healthcare settings must emphasize the importance of effective pain management and empower their staff through resources, education, committed leadership, and organizational policies to provide high-quality pain management to older adults. Pain management is a crucial nursing role that can improve the healthcare experience and quality of life for the older adults.

NURSING STANDARD OF PRACTICE

Protocol 22.1: Pain Management in Older Adults

I. GOAL

All older adults will either be pain free or their pain will be controlled to a level that is acceptable to the patient and allows the person to maintain the highest level of functioning possible.

II. OVERVIEW

Pain, a common, subjective experience for many older adults, is associated with a number of acute (e.g., surgery, trauma) and chronic (e.g., osteoarthritis) conditions. Despite its prevalence, evidence suggests that pain is often poorly assessed and poorly managed, especially in older adults. Cognitive impairment related to dementia and related disorders represents a particular challenge to pain management because older adults with these conditions may be unable to verbalize their pain. Nurses, an integral part of the interdisciplinary care team, need to understand the barriers to pain management to provide optimal care and to educate patients and families about managing pain.

III. BACKGROUND

A. Definitions
   1. *Pain:* Pain is defined as "an unpleasant sensory and emotional experience" (Merskey, 1994, pS74) and also as "whatever the experiencing person says it is, existing whenever he says it does" (McCaffery, 1968, p. 95). These definitions highlight the multidimensional and highly subjective nature of pain. Pain is usually characterized according to the duration of pain (e.g., acute vs. persistent) and the cause of pain (e.g., nociceptive vs. neuropathic). These definitions have implications for pain management strategies.
   2. *Acute pain:* Defines pain that results from injury, surgery, or trauma. It may be associated with autonomic activity such as tachycardia and diaphoresis. Acute pain is usually time limited and subsides with healing.
   3. *Persistent pain:* Defines pain that lasts for a prolonged period (usually more than 3–6 months) and is associated with chronic disease or injury (e.g., osteoarthritis; AGS, 2009). Persistent pain is not always time dependent, however, and can be characterized as pain that lasts longer than the anticipated healing time. Autonomic activity is usually absent, but persistent pain is often associated with functional loss, mood disruptions, behavior changes, and reduced quality of life.
   4. *Nociceptive pain:* This refers to pain caused by stimulation of specific peripheral or visceral pain receptors. This type of pain results from disease processes (e.g., osteoarthritis), soft-tissue injuries (e.g., falls), and medical treatment (e.g., surgery, venipuncture, and other procedures). It is usually localized and responsive to treatment.
   5. *Neuropathic pain:* Refers to pain caused by damage to the peripheral nervous system or CNS. This type of pain is associated with diabetic neuropathies, postherpetic and trigeminal neuralgias, stroke, and chemotherapy treatment for cancer. It is usually more diffuse and less responsive to analgesic medications.

B. Epidemiology
   1. Approximately 50% of community-dwelling older adults and 85% of nursing home residents experience persistent pain.
   2. The Centers for Disease Control and Prevention estimated that over 60% of older adults in the United States experience chronic pain (Dahlhamer et al., 2018).
   3. More than 19 million surgeries were performed on older adults in 2010, including 5.2 million musculoskeletal surgeries (including knee and hip replacements; Federal Interagency, 2016). Thus, older adults are at risk for pain associated with chronic diseases as well as postsurgical and procedural pain.

C. Etiology
   1. Older adults have chronic medical conditions that are typically associated with persistent or chronic pain, such as osteoarthritis and peripheral vascular disease.
   2. Older adults often have multiple medical conditions, both chronic and/or acute, and may suffer from multiple types and sources of pain.

(*continued*)

Protocol 22.1: Pain Management in Older Adults (*continued*)

D. Significance
   1. Untreated or ineffectively treated moderate to severe persistent pain has major implications for older adults' health, functioning, and quality of life (Horgas, 2017a).
      a. Pain is associated with depression, social withdrawal, sleep disturbances, impaired mobility, decreased activity engagement, and increased healthcare use (AGS, 2009).
      b. Other geriatric conditions that can be exacerbated by pain include falls, cognitive decline, deconditioning, malnutrition, gate disturbances, and slowed rehabilitation (AGS, 2009).
      c. Unrelieved pain reduces quality of life for older adults and contributes to increased healthcare resource utilization and costs (IOM, 2011; Morrissey et al., 2014). The IOM (2011) declared chronic pain a public health problem in the United States.
   2. Nurses play a key role in pain management. The promotion of comfort and relief of pain is fundamental to nursing practice. Nurses need to be knowledgeable about pain in late life in order to provide optimal care, to educate patients and families, and to work effectively in interdisciplinary healthcare teams.

IV. ASSESSMENT PARAMETERS

A. Assumptions
   1. Most hospitalized older patients suffer from both acute and persistent pain.
   2. Older adults with cognitive impairment experience pain but are often unable to verbalize it.
   3. Both patients and healthcare providers have personal beliefs, prior experiences, insufficient knowledge, and mistaken beliefs about pain and pain management that (a) influence the pain management process and (b) must be acknowledged before optimal pain relief can be achieved.
   4. Pain assessment must be regular, systematic, and documented in order to accurately evaluate treatment effectiveness.
   5. Self-report is the gold standard for pain assessment.
   6. Effective pain management requires an individualized approach.

B. Strategies for pain assessment
   1. Initial, quick pain assessment (Herr, Bjoro, et al., 2006)
      a. Assess older adults who present with acute pain of moderate to severe intensity or who appear to be in distress.
      b. Assess pain location, intensity, duration, quality, and onset.
      c. Assess vital signs. If changes in vital signs are absent, do not assume that pain is absent (Herr, Coyne, et al., 2006).
   2. Comprehensive pain assessment (AGS, 2009; Herr, Coyne, et al., 2006; Pasero & McCaffery, 2011)
      a. Review medical history, physical examination, and laboratory and diagnostic tests in order to understand sequence of events contributing to pain.
      b. Assess cognitive status (e.g., dementia, delirium), mental state (e.g., anxiety, agitation, depression), and functional status. If there is evidence of cognitive impairment, do not assume that the patient cannot provide a self-report of pain. Be prepared to augment self-report with observational measures and proxy report using the hierarchical approach.
      c. Assess present pain, including intensity, character, frequency, pattern, location, duration, and precipitating and relieving factors.
      d. Assess pain history, including prior injuries, illnesses, and surgeries; pain experiences; and pain interference with daily activities.
      e. Review medications, including current and previously used prescription drugs, OTC drugs, and complementary therapies (including home remedies). Determine what pain control methods have previously been effective for the patient. Assess patient's attitudes and beliefs about pain and the use of analgesics, adjuvant drugs, and nonpharmacological treatments. Assess history of medication or alcohol abuse.

(*continued*)

Protocol 22.1: Pain Management in Older Adults (*continued*)

f. Assess self-reported pain using a standardized measurement tool. Choose from published measurement tools, and recall that older adults may have difficulty using 10-point NRSs. Vertical verbal descriptor scales or faces scales may be more useful with older adults. Use the same tool consistently.
g. Assess pain regularly and frequently, at least every 4 hours. Monitor pain intensity after giving medications to evaluate effectiveness.
h. Observe for nonverbal and behavioral signs of pain, such as facial grimacing, withdrawal, guarding, rubbing, limping, shifting of position, aggression, agitation, depression, vocalizations, and crying. Also watch for changes in behavior from the patient's usual patterns.
i. Gather information from family members about the patient's pain experiences. Ask about the patient's verbal and nonverbal/behavioral expressions of pain, particularly in older adults with dementia.
j. When pain is suspected but assessment instruments or observation is ambiguous, institute a clinical trial of pain treatment (i.e., in persons with dementia). If symptoms persist, assume that pain is unrelieved and treat accordingly.

V. NURSING CARE STRATEGIES

A. General approach
1. Pain management requires an individualized approach.
2. Older adults with pain require comprehensive, individualized plans that incorporate personal goals, specify treatments, and address strategies to minimize the pain and its consequences on functioning, sleep, mood, and behavior.

B. Pain prevention
1. Develop a written pain treatment plan on admission to the hospital or before surgery or treatments. Help the patient to set realistic pain treatment goals, and document the goals and plan.
2. Assess pain regularly and frequently to facilitate appropriate treatment.
3. Anticipate and aggressively treat for pain before, during, and after painful diagnostic and/or therapeutic treatments. Administer analgesics 30 minutes before activities.
4. Educate patients, families, and other clinicians to use analgesic medications prophylactically before and after painful procedures.
5. Educate patients and families about pain medications; their side effects; adverse effects; and issues of addiction, dependence, and tolerance.
6. Educate patients to take medications for pain on a regular basis and to avoid allowing pain to escalate.
7. Educate patients, families, and other clinicians to use nonpharmacological strategies to manage pain, such as relaxation, massage, and the use of heat and cold.

C. Treatment guidelines
1. Pharmacological (Horgas, 2017a; Pasero & McCaffery, 2011)
a. Administer pain drugs on a regular basis to maintain therapeutic levels. Use medications as needed for breakthrough pain.
b. Document treatment plan to maintain consistency across shifts and with other care providers.
c. For postoperative pain, choose the least invasive route. Intravenous analgesics are the first choice after major surgery. Avoid intramuscular injections. Transition from parenteral medications to oral analgesics when the patient has oral intake.
d. Choose the correct type of analgesic. Use opioids for treating moderate to severe pain and nonopioids for mild to moderate pain. Select the analgesic based on thorough medical history, comorbidities, other medications, and history of drug reactions.

(*continued*)

Protocol 22.1: Pain Management in Older Adults (*continued*)

e. Among nonopioid medications, acetaminophen is the preferred drug for treating mild to moderate pain. Guidelines recommend not exceeding 3 g/d (maximum 2 g/d in frail elders). The maximum dose should be reduced to 50% to 75% in adults with reduced hepatic function or history of alcohol abuse. Monitor for excess acetaminophen intake from combination drugs (e.g., opioid + nonopioid) or OTC medications that include acetaminophen. Educate patients and families about this risk and drugs to avoid.
f. The other major class of nonopioid medications, NSAIDs, should be used with caution in older adults. Monitor for GI bleeding and consider giving with a proton-pump inhibitor to reduce gastric irritation. Also monitor for bleeding, nephrotoxicity, and delirium.
g. Older adults are at increased risk for adverse drug reactions because of age- and disease-related changes in pharmacokinetics and pharmacodynamics. Monitor medication effects closely to avoid overmedication or undermedication and to detect adverse effects. Assess hepatic and renal functioning.

2. Nonpharmacological (Horgas, 2017b; Pasero & McCaffery, 2011)
   a. Investigate older patients' attitudes and beliefs about, preference for, and experience with nonpharmacological pain treatment strategies.
   b. Tailor nonpharmacological techniques to the individual.
   c. Cognitive behavioral strategies focus on changing the person's perception of pain (e.g., relaxation therapy, education, distraction) and may not be appropriate for cognitively impaired persons.
   d. Physical pain relief strategies focus on promoting comfort and altering physiological responses to pain (e.g., heat, cold, TENS units) and are generally safe and effective.

D. Follow-up assessment
   1. Monitor treatment effects within 1 hour of administration, and at least every 4 hours.
   2. Evaluate patient for pain relief and side effects of treatment.
   3. Document patient's response to treatment effects.
   4. Document treatment regimen in patient care plan to facilitate consistent implementation.

VI. EXPECTED OUTCOMES

A. Patient will
   1. Be either pain free or pain will be at a level that the patient judges as acceptable.
   2. Maintain highest level of self-care, functional ability, and activity level possible.
   3. Experience no iatrogenic complications, such as falls, GI upset/bleeding, or altered cognitive status.

B. Nurse will
   1. Demonstrate evidence of ongoing and comprehensive pain assessment.
   2. Document evidence of prompt and effective pain management interventions.
   3. Document systematic evaluation of treatment effectiveness.
   4. Demonstrate knowledge of pain management in older patients, including assessment strategies, pain medications, nonpharmacological interventions, and patient/family education.

C. Institution/Facilities will (Dirks, 2010; Gordon et al., 2005)
   1. Maintain strong institutional commitment and leadership to improve pain management. Evidence of institutional commitment includes:
      a. Providing adequate resources (including compensation for staff education and time; necessary materials)
      b. Clear communication of how better pain management is congruent with organizational goals
      c. Establishment of policies and standard operating procedures for the organization
      d. Requiring clear accountability for outcomes
   2. Establish an internal pain team of committed and knowledgeable staff who can lead quality-improvement efforts to improve pain management practices.
   3. Require evidence of documentation of pain assessment, intervention, and evaluation of treatment effectiveness. This includes adding pain assessment and reassessment questions to flow sheets and electronic forms.

(*continued*)

Protocol 22.1: Pain Management in Older Adults (*continued*)

4. Provide evidence of using a multispecialty approach to pain management. This includes referral to specialists for specific therapies (e.g., psychiatry, psychology, physical therapy, interdisciplinary pain treatment specialists; clinical pathways and decision support tools will be developed to improve referrals and multispecialty consultation).
5. Provide evidence of pain management resources for staff (e.g., educational opportunities, print materials, access to Web-based guidelines and information).

Assessing, Managing, and Preventing Falls in Acute Care*

23

Deanna Gray-Miceli
and Patricia A. Quigley

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Perform a fall-focused health history and physical, functional, and mobility assessment as part of the nursing assessment of the older adult who has fallen.
2. Evaluate the older adult who is unsafe and at risk for falls and/or fall-related injury, as well as corresponding nursing interventions to minimize risks for injury among fall-prone hospitalized older adults.
3. Design nursing plans of care aimed at reducing serious injuries among older adults prone to falls based on the suspected fall type and fall risks.
4. Use findings from a comprehensive post-fall assessment (PFA) to develop an individualized plan of nursing care for the secondary prevention of recurrent falls.
5. Mobilize institutional resources to provide a collaborative interprofessional falls or safety team.
6. Use the latest evidence-based innovations in practice to champion a nurse-led fall-prevention intervention to prevent recurrent falls.
7. Use commonsense approaches and practice standards to manage persons at risk for falls or who have fallen.

OVERVIEW

Population-level data provided by the Centers for Disease Control and Prevention provide evidence of the magnitude and burden of harm among certain age groups, such as those 65 and older, due to falls and fall-related injury (Centers for Disease Control and Prevention [CDC], National Centers for Injury Prevention and Control [NCIPC], 2019). Evidence shows falls and resulting injuries in older adults are a major public health problem not only because of their magnitude and consequences, but also because of their degree of preventability.

Keeping patients safe and free from falls during hospitalization is an expectation of care supported by practicing healthcare professionals and providers, healthcare organizations, state and federal government, accreditation agencies, and key stakeholders in promoting the health and safety of the public, especially for persons cared for in health care facilities (Institute of Medicine [IOM], 2003; The Joint Commission-Sentinel Event Alert 55, 2015a and 2015b). Specific aims to keep patients safe in healthcare facilities by preventing falls are focused to: (a) reduce fall-related injury and fatality from falls; (b) champion

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

an interprofessional fall-prevention program to prevent patient falls and fall-related injuries; and (c) promote improvements in patient safety by reducing preventable falls through system-wide solutions whenever possible (The Joint Commission, 2015). To accomplish these aims requires providers to use two sets of lenses, one focused on the retrospective question "Why did the fall occur in the first place?", which can best be answered through a comprehensive post-fall assessment (PFA), and the other on the prospective questions "Who is at risk to fall and/or at risk for fall-related injuries?" and "How can their fall be prevented and injuries averted?" In either approach, person-, unit-, or organization-level factors are implicated.

Use of a guiding conceptual framework can help nurses to navigate best practice approaches to prevent falls and fall-related injuries, whether they occur from person-, unit-, or organization-level factors within health care facilities. One framework, the epidemiological injury framework, is based on identified personal risk factors and levels of prevention (primary, secondary, and tertiary; Katz, Wild, Elmore, & Lucan, 2013, p. 4). This framework allows nurses to identify best practice interventions according to the presence or absence of personal risk factors, disease states, and goals of care (Katz et al., 2013). The CDC's public health model has been used to address unintentional injuries and traumatic brain injury (TBI). This four stage model guides TBI prevention moving from surveillance to identification of risk and protective factors for TBI to development and testing of evidence-based interventions to bringing effective interventions to scale from widespread adoption (Baldwin, Breiding, & Sleet, 2016). The Haddon Matrix is another useful model which identified the pre-event, the event, and the post-event states in context of influencing factors among the person (host), agent, physical and social environment (Barnett et al., 2005). Another useful guiding framework, and focus of this chapter, centers on application of the nursing metaparadigm, which considers the person experiencing the fall, the person's environment, his or her health (including risk factors), and the nursing response.

The nursing response to the falling patient requires the use of the highest level of evidence-based interventions, as well as the use of best practice standards should empiric research evidence be lacking. Use of best practice standards of care is evidenced by what a nurse in a similar situation would do to assess or intervene to prevent a fall. It relies on nursing judgment, and commonsense approaches or practice standards to manage persons at risk for falling or who have fallen. Promoting patient safety calls for an understanding and dovetailing of multiple frameworks and practice approaches, particularly when research-based evidence is lacking. For instance, knowing the situational context, such as when and where the fall occurred, is as important as knowing the person's behavior at the time of the fall that may have precipitated the fall. For these reasons, eliciting the person's recollection of his or her fall, through appropriate history taking, helps to identify individual-level or personal risk factors as well as explain (from the patient's perspective), the circumstances of the fall.

Recognizing the unique circumstances of each and every person's fall becomes an important consideration for nursing care of that individual. The first critical step in the nursing process to keep patients safe and free from falls and injury is implementation of a nursing assessment. The nursing assessment serves as the gatekeeper for effective communication to healthcare providers and team, plans of care, tailored interventions, and evaluation of the effectiveness of those interventions. The nursing assessment includes an assessment of the person's concerns, clinical condition, the person's surrounding environment, his or her health and function, and current nursing care strategies.

Health Systems Improvement for Fall Prevention

The occurrence of patient falls is associated with a multitude of individual-level, unit-level, or organizational level factors such as those occurring from human factor ergonomics and/or system issues. For example, a patient fall can occur because proper protocols were not in place, that is, errors of omission in the care plan occurred and/or staffing and skill mix were inadequate. Health systems improvement for fall prevention thus includes a comprehensive evaluation of all known factors and risks across these three levels (person, unit, and organizational level) based on the most current evidence.

One aim for health systems improvement for fall prevention is active involvement of all stakeholders who seek to uphold the triple aim of better patient-care experiences and use of cost-effective interventions so that falls are reduced (Institute for Healthcare Improvement [IHI], n.d.). Among others, one health systems level improvement is fall-prevention programs. Across *all* patient settings, evidence exists that fall-prevention programs are effective. The RAND report cites, from a meta-analysis of 20 randomized clinical trials (among all patient settings, but mostly long-term care), that fall-prevention programs reduced either the number of older adults who fell or the monthly rate of falling (Shekelle et al., 2004). Effective fall-prevention programs in acute care hospitals are championed by nurses using one or more approaches in

collaboration with interprofessional teams. Program evaluation should extend beyond traditional fall rates to causes of fall, types of fall, sources of injury, and severity of injury. These data inform organizational efficiency and effectiveness of fall and fall injury programs at the patient, unit, and population level. Fall management must differentiate and segment vulnerable patients to protect from injury when a fall is experienced (Oliver, Healy, & Haines, 2010; Zubkoff et al., 2018). Assessing risk of injury provides the data for nurses to provide specific interventions to reduce injury (e.g., hip protectors, floor mats, and helmets) based on using existing tools. Strong evidence exists to support the benefit of multifactorial fall-prevention programs for injurious falls in acute care. System-level interventions with emerging evidence of effectiveness result from the work of innovation: nurse champions, safety huddles, teach-back strategies, post-fall huddles (PFHs), and interventions to reduce fall-related trauma.

To be most effective, action needs to be taken by both leaders and frontline staff, to be championed by all members of the interprofessional team, including support workers, and tailored to the preferences and needs of individual patients (Degelau et al., 2012; Ganz et al., 2013; Oliver et al., 2010; Shekelle et al., 2013; Spoelstra, Given, & Given, 2012).

This chapter begins with: (a) the scope and magnitude of the problem of falls and outcomes related to injuries, such as fatal injuries, traumatic brain injury, and hip fracture; (b) an organizational practical approach to comprehensive nursing assessment of the falling patient that seeks to identify the patient's recollection of the fall, the person's understanding of the fall, the stability of the patient, associated symptoms of the person's fall, emotional responses, and presence of injury; (c) individual patient level and environmental risk factors for falling. Throughout the chapter, we have identified some commonsense practice standards for nurses to implement to mitigate the risk of falls and fall-related injury.

BACKGROUND AND STATEMENT OF PROBLEM

Scope, Magnitude, and Outcomes of Falls and Fall-Related Injuries

Many of the adverse healthcare outcomes resulting from falls, such as injury and/or functional decline, typically strike those patients older than 85 years *and* can be prevented. The most serious outcome is a *fatality*. The National Center for Injury Prevention and Control (NCIPC) ranks fatal falls as the leading cause of unintentional injury–fatality among older adults aged 65 to 85+ years between 1999 and 2010 (CDC, 2015c). The fatal fall incidence increases with age—those older than 85 years are the most vulnerable.

Falls with injury populate our healthcare delivery system at alarming rates, resulting in more than 3 million injuries treated in EDs annually, 800,000 hospitalizations, and more than 27,000 deaths annually (Centers for Disease Control and Prevention, Web-Based Injury Statistics, 2016). Every 11 seconds an older adult is seen in the ED for a fall, and every 19 minutes an older adult dies from a fall (National Council on Aging, 2018). In a recent examination of fall death rates in the United States, an increase in 30% has been reported from 2007 to 2016 (CDC, NCIPC, 2019). Reported hospital inpatient falls vary according to the type of study conducted, that is, multisite or single-site study, the type of unit (medical–surgical, telemetry, rehabilitation, or other), skill mix, and total number of nursing hours per patient day. The rate of falls in acute care hospitals, drawn from single-site studies, is estimated to range from 1.3 to 8.9 per 1,000 bed days, translating into significantly more than 1,000 falls per year in a large facility (Oliver et al., 2010). The rate of falls, drawn from multisite studies, however, increases to three to five falls per 1,000 bed days (Oliver et al., 2010). In terms of unit type, recent evidence from a longitudinal study using National Database of Nursing Quality Indicators (NDNQI) data found the mean fall rates for most unit types are stable or are decreasing, whereas those for surgical units increased over time (He, Dunton, & Staggs, 2012). Changes in practice are cited as potential key drivers behind the increased rate of falls post surgery. As early ambulation is encouraged, more patients on these units are out of bed. Fall rates have also been associated with registered nurse skill mix and total nursing hours per patient day. In He et al.'s study, lower fall rates were significantly associated ($p < .001$) with higher registered nurse skill mix and total number of nursing hours per patient day.

Serious injuries resulting from falls range from minor to severe types of injuries, such as hip fractures and traumatic brain injury (TBI), among others. And although we would like to believe that seemingly "minor" strikes to the head, spine, or limbs produce minor injury, evidence shows this is simply not true. We now know that ground-level falls from a standing position among adults older than 70 years cause more severe injuries and that those afflicted are less likely to survive compared with adults younger than 70 years (Spoelstra et al., 2012). In fact, those 70 years and older are three times as likely to die from these low-level, ground falls compared with adults younger than age 70 years. Evidence suggests that seemingly minor strikes to the head can result in tears in cranial

blood vessels and subdural mater (Strub, 2002). Given these findings, significant changes in clinical practice approaches are urgently needed for early identification of serious complications related to head trauma in older adults who appear to have "minimal head trauma, no obvious signs of head injury or concussion." New evidence supports a ramping up of the classic markers of head injury toward greater vigilance in recognition of other critical signs and symptoms of head trauma. Ergo, it is just not enough to assess older adults for risk of falls, but one must assess for risk of injury. Conventional practice has always drilled into practitioners the need to assess for hip-fracture injury or spinal fracture injury. Stepped up changes are warranted for heightened surveillance by healthcare professionals for all types of injury outcomes, most importantly, TBI as well as hip fracture. A brief overview of the evidence related to TBI and hip-fracture incidence is presented.

Traumatic Brain Injury

About 1.7 million people sustain TBI annually (CDC, 2015a). Of all external causes implicated in TBI, such as assault, being struck, and motor vehicle accident, falls account for 35%. The CDC reports falls as the leading cause of TBI for adults aged 75 years and older (CDC, 2015a). Of all the TBI-related ED visits in the United States during 2006 to 2010, the 65-years-and-older age group accounted for 81.8% of the TBI-related ED visits (CDC, 2015c). This age group also has the highest rates of TBI-related hospitalization and death. Because of limitations in study design, baseline health status, and inability to grade injury severity across studies, we have much less evidence of who, among the 75+-year-old cohort, carries the greater risk for TBI. Is it the patient with type 2 diabetes, Parkinson's disease, or those patients on anticoagulation medication? One study that relied on a 15-state CDC TBI surveillance system found an increased incidence of depression, dementia, and Parkinson's disease in patients with fall-related TBI (Coronado, Thomas, Sattin, & Johnson, 2005).

The issue of increased comorbidity has been suggested as a likely contributing factor for the higher incidence of TBI in persons 65 years and older, owing to increased use of aspirin and anticoagulation in management of these chronic conditions (Thompson, McCormick, & Kagan, 2006).

Groups at risk for the development of TBI include men, who are twice as likely to sustain a TBI, adults aged 75 years or older, and African Americans who have the highest death rate from TBI (CDC, NCIPC, 1999). Older adult residents who experienced head injuries from a fall were more likely to live in assisted living (47.9%; $p <$ .04) and to be walking at the time of their fall (69.0% vs. 36.1%) compared with older adult fallers without a head injury (Gray-Miceli, Ratcliffe, & Thomasson, 2013). The link between ambulation and head injury when fall occurs from a standing position has clinical relevance across all settings of care.

Physiological changes in the brain matter itself, seen with aging, have also been suggested as contributing factors to the increased risk of TBI in older adults. It has been suggested that dura mater becomes more adherent to the skull with age (Thompson et al., 2006), giving way to the development of tears even with minor strikes or blows to the head. The field of cellular neuroscience has also isolated changes of the microglia, rendering them weaker against protection of the brain after an ischemic or traumatic insult (Lourbopoulos, Erturk, & Hellal, 2015). Although it is unknown, age-related changes among older adults' brain tissue and supporting structures may underlie accumulating evidence, which has shown that elderly patients with TBI have worse mortality and functional outcome than nonelderly patients who presented with head injury despite lower injury severity (Susman et al., 2002). Noted neurosurgical experts report that when the head hits a stationary object, such as when the patient hits his or her head on the floor, "lesions are produced in the white matter of the brain from these shearing forces … resulting in strain and stretching of axons and vessels." This damage is in addition to any bleeding or clot formation (Strub, 2002, p. 2).

Hip Fracture

The news headline, well known to older Americans, reads: "Death or Immobility Often Follows Hip Fractures in Nursing Homes." This common adverse outcome of a fall is realized not just in nursing homes, but also among those living independently in the community. The CDC estimates that more than 95% of hip fractures are caused by falling, often sideways, on the hip (CDC, 2015b). Annually, at least 258,000 hospital admissions for hip fracture among those 65 years and older occur nationwide (CDC, 2015b).

Women, especially White women, carry the greatest risk of hip fracture compared with men (Hall, DeFrances, Williams, Golosinskiy, & Schwartzman, 2010), African American women, or Asian women (Ellis & Trent, 2001). An underlying diagnosis of osteoporosis increases risk of fall-related hip fracture (National Osteoporosis Foundation, 2013). There are 54 million people with osteoporosis and/or low bone mass (43.4 million with low bone mass and 10.2 million with osteoporosis; National Osteoporosis Foundation, 2013). Classic risk factors for osteoporosis,

pertinent to hospitalized patients, include immobility, insufficient calcium or vitamin D supplementation, and lack of weight-bearing exercises owing to the acute treatment of other diseases.

The U.S. Preventive Health Task Force recommends screening for osteoporosis with bone measurement testing to prevent osteoporotic fractures in women aged 65 years and older and in younger women at risk for osteoporosis (U.S. Preventive Services Task Force, 2018). Health-promotion activities, including regular screening for osteoporosis, begin with a complete health history. Once detected, osteoporosis is treatable by medications that build bone and supplementation of calcium and vitamin D, coupled with regular walking and exercise. Although it would seem advantageous to recommend the use of hip pads to protect the hip bone from injury during a sideways fall, there is insufficient evidence to recommend hip protectors routinely for all persons at risk for a fall.

Falls with injury remain a major prioritized patient safety focus when considering that, in 2010, older adults who were aged 65+ years accounted for approximately 45% of the inpatient population. The repeat-fall age group is 75 years and older and comprised 28% of the inpatient population (CDC, 2015b).

Older adults in acute care hospitals are a vulnerable population at risk for falls and falls with injury, be it from age-related factors, disease-related factors, medications, functional declines or disabilities, or for all of these reasons taken together. Therefore, the nurse's antenna for suspicion for injury should be raised so that assessment for these serious types of injuries predominate our post-fall and fall risk analyses.

NURSING ASSESSMENT OF THE FALLING PATIENT

Falling is recognized as a geriatric syndrome, a complex and multidimensional phenomenon among older adults (Inouye, Studenski, Tinetti, & Kuchel, 2007). Additionally, because the older adult's perception of his or her fall is influenced by his or her experiences, situational contexts, and beliefs about falling, what the person chooses to disclose to the nurse about the fall is highly subjective. Thus, use of an organizational, practice-based approach to a comprehensive post-fall nursing assessment of the falling patient allows for consistent gathering of key information needed to determine possible underlying fall etiologies (Gray-Miceli, Johnson, & Strumpf, 2005). The organizational approach presented in this chapter is based on evidence-based national guidelines for fall prevention among older adults (Panel on Prevention of Falls in Older Persons, American Geriatrics Society [AGS], & British Geriatrics Society [BGS], 2011) by providing the clinician with a discrete set of fall-focused historical questions and physical assessment parameters to assist in the search for identifying various underlying causal event factors associated with falls. This approach begins with eliciting the persons' experience and perception of their fall and recreates the situational context of the fall and key symptoms associated with the fall, which help nurses to answer the question "Why did this fall occur in the first place?", among other important steps outlined in other published works (Gray-Miceli et al., 2005). Nurses should strive to increase their understanding of the patients' perceptions about their fall, whenever feasible. Lim et al. (2018) acknowledged that efforts to reduce falls are limited by insufficient understanding of patients' views about falls and preventive initiatives dictated by healthcare providers. After interviewing 100 medically stable cognitively intact patients one day after the fall, themes revealed that patients were apathetic toward falls, described self-blame behaviors, admitted to risk-taking behavior, were reluctant to impose on busy nurses, and more. These results compel nurses to change conversations with patients and use evidence-based and theoretically derived assessment strategies that incorporate the patient's voice.

This practice approach has been used by registered nurses with long-term care older residents post fall and found feasible, acceptable, and comprehensive (Gray-Miceli, Ratcliffe, & Johnson, 2010). More recently, practicing registered nurses have found this practice-based approach very useful and of benefit to older adults (Gray-Miceli, 2018).

Value of the Post-Fall Assessment

Determination of why the fall occurred is of vital importance. The value of the PFA, if performed properly and comprehensively using appropriately empirically tested tools, is that underlying fall etiologies can be discerned so that appropriate plans of care can be instituted. To simply perform a fall risk assessment or perform a PFA and document the findings without linking the risk or actual fall cause to a strategy is *useless*. Once the likely type of fall is determined using a comprehensive post-fall evaluation tool, the nurse can put into motion an appropriate plan of care.

Empirical research directed at determining the various types of falls occurring among older adults using a comprehensive PFA tool as the basis for determination has resulted in a broader classification scheme consisting of eight fall types observed among older adults in long-term care, including falls caused by acute illness, chronic diseases, medications, behavior, unknown, environment,

misjudgment, or poor patient safety awareness (Gray-Miceli et al., 2010). Fall risk screening tools identify the likelihood of an anticipated physiological fall with known intrinsic and extrinsic fall risk factors. These screening tools provide the first level of assessment data as the basis for comprehensive assessment. Only through comprehensive PFA can multifactorial, complex fall, and injury risk factors be defined (Quigley, Neily, Watson, Wright, & Strobel, 2007). Fall risk assessment and PFA are two very different and distinct approaches for fall prevention. Fall risk assessment tools offer limited types of inquiry, typically streamlined and focusing on five or six areas of inquiry, which are not a substitution or replacement for a comprehensive post-fall inquiry or assessment. It is vital for the nurse to be aware that critical information is missing in streamlined fall risk assessment tools, as they do not replace a comprehensive PFA and analysis of likely fall type.

Therefore, the purpose of the PFA is to identify the clinical status of the older adult, verify and treat injuries, and identify underlying causes of the fall whenever possible. Components of the PFA are typically routinely performed by professional nurses in all patient settings, although this evaluation may be skeletal or limited according to the completeness of questions and examination included in the tool used. Few empirically published tools for PFA exist, and previous research has shown that fall risk determination, using short forms asking five to eight questions about risk, often replaced (inappropriately) PFA in institutionalized settings (Gray-Miceli, Strumpf, Reinhard, Zanna, & Fritz, 2004; Ray et al., 1997; Rubenstein, Robbins, Josephson, Schulman, & Osterweil, 1990).

Evidence shows that comprehensive PFA tools are useful and available to assist professional registered nurses in performing a PFA, especially in institutionalized settings (Gray-Miceli, Strumpf, Johnson, Draganescu, & Ratcliffe, 2006). In institutional settings where teams are unavailable, comprehensive PFA should be carried out by professional nurses and findings conveyed and discussed through consultation with specialty-trained providers.

The PFA is a comprehensive yet fall-focused history and physical examination of the present problem (falling), coupled with a functional assessment, review of past medical problems, and medications. Clinical fall-prevention guidelines are very clear about all of the necessary components for inclusion of patients who have fallen, which include fall history; fall circumstance; medical problems; medication review; mobility assessment; vision assessment; neurological examination, including mental status; and cardiovascular assessment. In addition to this information, data are collected about the patient's physical status. Performing a comprehensive PFA allows the clinician to identify intrinsic risks and recent causes of a fall such as orthostatic hypotension and/or bradyarrhythmia or tachyarrhythmia associated with dizziness (Gray-Miceli et al., 2006). There are various stages of a PFA, ranging from the immediate period following the fall (within 24 hours) to the interim period and then the longitudinal period, where adverse outcomes such as pain from an injurious fall can occur. In the hospital setting, certain components of a PFA can be elicited immediately following a patient fall, with the decision to ask certain questions immediately, depending on the medical stability of the patient and nursing judgment.

Prior to conducting this seven-step PFA, it is important for the nurse to recognize his or her own bias about how, when, where, and why falls occur among older adults. Each interviewer brings to the interview/assessment his or her own set of values, beliefs, perceptions, experiences, and attitudes about falls and their prevention. Setting any bias aside, so active and reflective listening can occur, is essential to eliciting a comprehensive PFA. The seven-step approach presented in this chapter also fosters opportunities for teach-back education and development of tailored individualized care plans for the prevention of recurrent falls.

Setting the Stage for the Interview

It is advisable for the nurse to take notes and also have a blank sheet of paper to jot down important findings and impressions for use in teach-backs with the older patient. For each of the seven steps of the nursing assessment, identify the aim in each step, as indicated in Box 23.1.

Prior to conducting the interview, and as part of the setup, the nurse will need to ascertain if the patient is capable of providing the needed information. Typically, the nurse who has developed a relationship with the patient knows the patient the best. In other instances, the person will need to be evaluated for cognitive impairment. Nurses should also use additional sources of information gathered from family caregivers or eyewitness accounts to help validate the person's recollection of events. In cases where cognitive impairment exists, the patient might recount a fall from long ago and think that it was his or her most recent fall. It is helpful, therefore, to label the fall along with a time frame, for instance, as the fall that happened over Thanksgiving or the fall that occurred this morning while shaving. If the fall is associated with an activity, the patient is likely to recall the activity and exact events leading up to the fall.

BOX 23.1

Components of a "Stepwise Approach to a Comprehensive Post-Fall Assessment" for Older Adults in the Acute Care Setting

Step 1: Elicit a fall-focused history ("What and Why").
Step 2: Recreate the situational context ("When and Where, Stability and Behavior").
Step 3: Review past medical history, associated symptoms, and high-risk medications.
Step 4: Perform a fall-focused physical, functional, and mobility assessment.
Step 5: Detect environmental hazards and eliminate.
Step 6: Synthesize Steps 1 to 5 to identify the likely type of fall and construct a case synopsis for communication with the interprofessional team.
Step 7: Inform, educate, and empower older patients.

A stepwise approach to a comprehensive post fall assessment. *Annals of Long-Term Care: Clinical Care and Aging, 13*(12), 16–24. doi:10.7282/T3PG1TNZ; Gray-Miceli, D. (2014). *5 easy steps to prevent falls: The comprehensive guide for nurses to keeping patients of all ages safe*. Silver Spring, MD: American Nurses Association.

BOX 23.2

Critical Observations Made During the Immediate Post-Fall Assessment

Expressions or verbalizations of pain (facial grimacing, crying, screaming, agitation)
Changes in behavior or function, which may indicate pain
Swelling of an extremity (wrist, arm, leg) or head (hematoma, skull pain)
Unstable vital signs
Discolored cyanotic skin
Skin temperature (cold, clammy, diaphoretic)
Skin lacerations, contusions
LOC, no response to stimuli or significant change in LOC
Changed range of motion of extremities
Evidence of neck, head, or spinal cord injury
Abnormal or erratic neurological responses, such as absent pupil response, fixed or dilated pupils, seizures, or abnormal changes in posture

LOC, loss of consciousness.

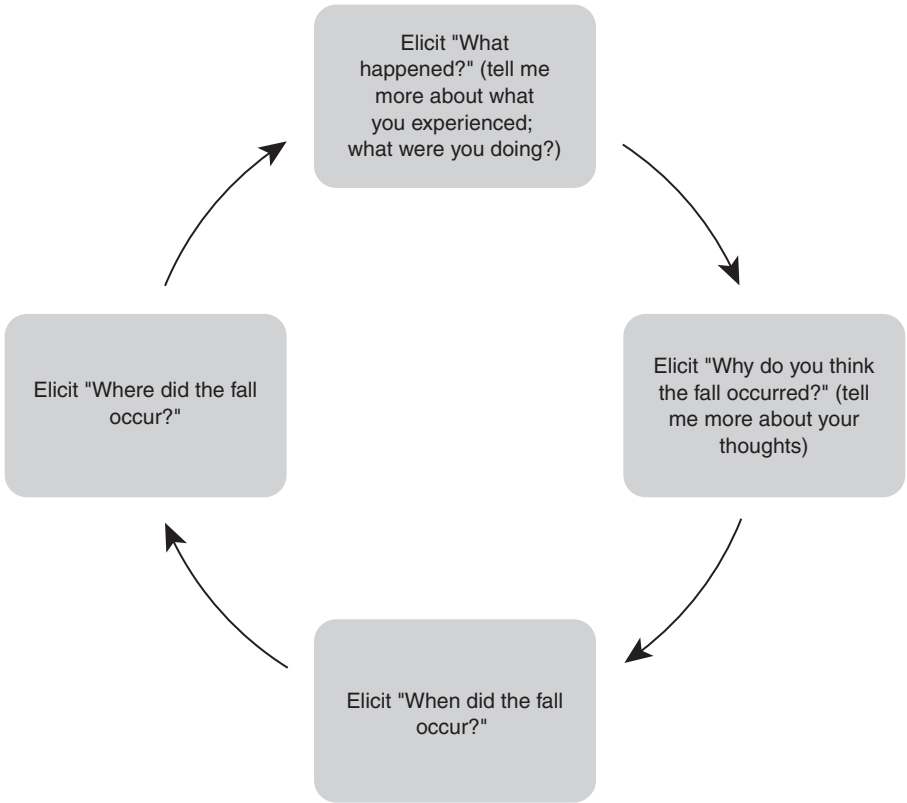
The length of the interview and nursing assessment will vary from patient to patient and will depend on many factors. Whenever possible, it is best to do the five-step assessment in one block of time. However, issues such as patient fatigue, pain, and level of alertness are all important factors that can interrupt a comprehensive PFA. Ideally, the patient should be interviewed in a private, quiet area which is comfortable for him or her and provides a tabletop for the nurse to use to take notes. The interview should allow 45 minutes to complete all elements of the assessment, realizing that additional time will need to be reserved to provide the patient with teach-back education.

Before proceeding with the interview to discuss the fall with the older adult, it is vital for the nurse to establish if the older patient is physically injured and/or physiologically stable to proceed with the interview. For more details, refer to the section "Assess and Diagnose the Older Adult Patient's Risk of Serious Injury: Fractures." Nurses must therefore review critical observation made of the patient during the immediate PFA (Box 23.2). Once the nurse determines the patient is physiologically stable, she/he should proceed with the modified seven-step approach "A Stepwise Approach to a Comprehensive Post-Fall Assessment" (Gray-Miceli et al., 2005) adapted for use by nurses in the acute care setting. Refer to Box 23.1.

Steps 1 and 2 focus on obtaining the four W's of the fall: "What, Why, When, and Where?" (Gray-Miceli, 2014). See Figure 23.1.



Step 1: Eliciting the Older Adult's Experience and Perception of The Fall

The overall aim of Step 1 is to elicit the person's thoughts, feelings, experiences, and perceptions of the most recent fall. Starting the conversation by saying, "Today, I would like to speak to you about the fall that occurred this morning" provides context and helps the patient to focus on the most recent fall, and not one that might have occurred last week or 1 year ago. All falls are important to discuss, but it is best to focus on one fall at a time, realizing there may be patterns or similarities among falls and that stories can become intertwined. Here is where labeling the fall that occurred, for instance, "this morning's fall," helps avoid confusion among the older adult and the interviewer.

In Step 1, the focus is to obtain the "What and the Why?" of the fall. The "what" is actually *what* the patient recalls happened and is typically linked to an activity, but does not have to be. The "why" of the fall helps the nurse to understand the patient's thoughts and perceptions about *why* the fall occurred: faulty equipment? An arthritic knee? Or the person has no idea. All responses are important to note. The best means for eliciting the "What and Why of the fall" is to state: "Tell me about your most recent fall to

FIGURE 23.1

The four W's of the fall discussed in Steps 1 and 2.

Source: Gray-Miceli, D. (2014). *5 easy steps to prevent falls: The comprehensive guide for nurses to keeping patients of all ages safe*. Silver Spring, MD: American Nurses Association. Retrieved from http://www.nursesbooks.org/Homepage/Hot-off-the-Press/5-Easy-Steps-To-Prevent-Falls.aspx.

the ground, everything you can recall and how you were feeling." The emotional response to a fall is highly subjective and can range from "it was nothing" to "it made me angry, fearful of aging, afraid to walk, anxious, sad and blue, to disgust or embarrassment" (Gray-Miceli, 2001). Nurses must ask about not only the physical injury post fall, that is, "Did you injure yourself?" but also about the emotional impact of the fall. Emotional responses experienced by older adults such as fear of falling, helplessness, and anger/frustration can impact older adults' mobility and activities of daily living (Gray-Miceli, 2001) and are thus vital to include in the assessment, because these responses can influence health behaviors (Gray-Miceli & Ratcliffe, 2015).

Step 2: Recreate the Situational Context of the Fall

The aim of Step 2 is to determine the "When and Where" of the fall in relation to time and space and the physiological stability of the patient. Noting any particular behavior is important as this becomes an important aspect of the situational context that may help to inform the clinician about the fall circumstance. The months of the year, days of the week, and time of day speak to when the fall occurred, but it is the "Where" the fall occurred that ties the fall not only to an activity, but also to the person's body in space or position at the time of the fall (sitting, standing, turning, running, and/or rolling over). Recreating a visual image of the fall by the examiner can help point to possible underlying causative factors contributing to the fall. When the examiner shares this image with the patient, the patient has the opportunity to clarify important events associated with the fall. One way to create a visual image is for the examiner to concentrate on the setting, location, time of day, and what the person was doing moments before the fall and then to summarize that image by repeating it back to the patient. For instance, state, "As I understand it, you pushed yourself up out of bed

to a standing position, then became dizzy, the room spun around, you had nothing to hold onto, so you grabbed the covers from the bed to help brace your fall, you woke up on the floor, feeling stunned and had a racing heart, but because of the covers you did not sustain any injury." Then the nurse examiner asks for verification from the patient. If correctly envisioned, the examiner can illustrate a picture and make notes to review with the patient regarding his or her position, timing, factors associated with the fall, and how to avoid future falls from occurring for the same reason.

Situational Context and Fall

Also embedded within the situation context is the patient's behavior during the activity that was associated with the fall. For example, "Was the person in a hurry and rushing? Did he or she forget how to use the assistive device? Did he or she feel dizzy and thought it would pass?" When assessing the patient's risk of falls and risk of injury, it is imperative that the nurse consider the situational context as well as the medical stability of the patient (behavior, level of alertness, and cognition). So, although it may appear that the alert and oriented older patient with lower extremity weakness who is resting in a low-rise bed surrounded by floor mats is at low risk for an injurious bed fall, his or her risk of injury increases as he or she walks, because of the lower extremity weakness. As the patient is out of bed and walking, with weakened limbs, risk of ambulatory falls occurs.

Thinking about the next fall you are trying to prevent, whether it is a bed fall, an ambulatory fall, or a fall during transitioning from bed to chair, will further help in identifying fall risk and source of trauma for injury. With the older adult patient lying in bed or sitting on the chair, try to identify those situations that place the older adult at greater risk for falling or injury. Various situational circumstances of falls identified in the literature and commonly encountered in clinical practice include the following:

- Patient rolls off the mattress or slips off the edge of the bed; that is, a **bed fall**.
- Patient slides from the chair, or falls getting into or out of the chair; that is, a **chair fall**.
- Patient falls while walking; that is, **an ambulatory fall**.
- Patient falls getting on/off the toilet or when getting up to stand from a seated position; that is, **a fall during transfer**.
- Patient found on the floor or lower level; an unwitnessed fall.

A risk-versus-benefit analysis should always be part of fall management decision-making for patient safety and prevention of injury (Quigley & Goff, 2011), especially when patients move about on the hospital unit as they gain independence in mobility. Therefore besides assessing the situational circumstances (where the fall occurred) nurses must assess the patients risk for falls in these circumstances (see personal risk factors).

Behavioral Factors

Older adults in the acute care setting enter hospitals for management of their conditions. They may never have encountered an illness or event that resulted in sudden changes in their bodies. When physiologically unstable or cognitively impaired, these factors pose a safety risk as physical capacity and physical independence in functioning are suddenly altered. These patients often cannot do the things they once could with ease and are admitted to an unfamiliar environment. As physical independence decreases, their autonomy and desire to do what they are accustomed to doing may remain. This creates a conflict. They wish to get up but may not fully recognize it is really not safe for them to do so. Gender, degree of frailty or injury, cultural background, baseline personality, and prior hospitalization experience are all likely to influence how the patient is coping with this sudden illness. Assessment should include whether older adults perceive these changes as stressors; and, if so, do they believe they do not require help? Nurses caring for elderly patients must remember that they have many years of experience in coping, or not, with their chronic condition. How they have coped and managed from day to day is likely to influence their current reaction to the hospital experience and current behavior. Reminding the patient that he or she is ill and needs temporary help is one remedy through the use of teach-backs, but it is likely to be ignored or short lived by persons who refuse help and want to remain independent despite medical advice. Those with cognitive impairment, depending on the severity of impairment, may not have the current cognitive ability to recognize that they are overestimating their actual ability to perform.

Nurses working with any hospitalized patient should observe their behavior, noting if they seem preoccupied, anxious, fearful, cautious, or reckless. Once behaviors are identified, nurses can work with patients to identify potential hazardous situations in their teach-backs.

Step 3: Review Medical History, and Associated Symptoms, Assess Fall Risk and High-Risk Medications

The aim of Step 3 is to review the past medical history and to identify key symptoms occurring at the time of the patient fall, including use of high-risk medications implicated

in falls. As the nurse obtains information gathered in Steps 1 and 2, it is likely that symptoms will be identified and described by the patient. Some symptoms may be linked to underlying medical events and/or chronic illnesses (refer to Gray-Miceli et al., 2005 for a comprehensive list of acute and chronic illnesses associated with falls in older adults), which may be part of the patient's past medical history. Other medical events or diseases, such as syncope from sudden loss of blood volume, may be of an acute nature. When the nurse identifies a symptom occurrence, it is vital to describe its onset, timing (duration), frequency, location, and associated aggravating or alleviating factors. Determining whether it is of a short duration, as in an acute event, or a more recurring chronic symptom helps in relaying effective communication to a physician to build the overall plan of care for appropriate interventions.

Table 23.1 presents some of the key symptoms *never to miss* in the review of systems that are often associated with recurrent falls and that, if acute, require prompt referral to a physician. Reporting these symptoms immediately to the primary care provider is required for further evaluation/ treatment as they can indicate physiological instability. A comprehensive evaluation of a patient with symptomatic falls includes further diagnostic evaluation accomplished by electrocardiogram, x-rays, serum glucose, electrolytes, complete blood count, urinalysis, oxygenation levels, and other tests as dictated by various pertinent physical assessment findings.

The new onset of symptoms associated with a fall can be due to a multitude of factors such as those arising from acute or chronic illness or high-risk medication use.

TABLE 23.1

Key Symptoms by System Associated With Recurrent Falls

System Involved	Key Symptom
Cardiovascular or neurological	Blacking out (syncope)
Cardiovascular	Dizziness associated with heart rate abnormality (bradycardia, tachycardia, or arrhythmia) Dizziness or loss of balance associated with standing (orthostatic hypotension—drop in blood pressure with standing) Lightheadedness associated with head rotation (possible alteration in carotid artery blood flow)
Neurological	Seizures at the time of the fall Sudden unilateral weakness at the time of the fall (stroke) Sudden loss of unilateral vision (stroke) Loss of balance due to vertigo or Parkinson's disease
Musculoskeletal	Sudden onset of hip, leg, spine (vertebral) pain with weight bearing (possible bone fracture) Trip or slip due to misfooting
Metabolic	Extreme fatigue, exhaustion of new onset (electrolyte disturbances, blood volume abnormalities, anemia, blood glucose abnormalities)

Past Medical History of a Fall or Fracture Injury

Many studies have shown a prior fall to be the most potent predictor of another fall among older adults (Degelau et al., 2012; Gates, Smith, Fisher, Lamb, & Phil, 2008; Oliver, Daly, Martin, & McMurdo, 2004). Therefore, careful fall-history screening is vital as a health-promotion measure and quality-of-care check for all newly admitted patients to the hospital or seen in the ED.

The presence of a current fracture injury, such as a hip fracture, could reoccur if care is not taken to protect such vulnerable patients. Older adult patients with a current hip fracture and/or surgical repair have muscular weakness, incisional pain, and referred limb pain with potential loss of sensation, all of which contribute to their inability to maintain balance and prevent a fall from occurring should they become off balance. While ambulating or transferring, the patient puts less weight on the surgical limb, shifting it toward the unaffected limb, which bears the brunt of the patient's body weight. If osteoporosis exists and has been untreated, it is possible that the impact of walking can cause the "good" limb to fracture. In any event, the presence of pain or use of narcotic analgesia can also alter the patient's response to "avoid slips, spills, or obstacles" in her or his path.

The standard of care calls for identification of personal (intrinsic) risks to fall. Many of these risks (but not all) are contained on fall risk scales, such as the Morse Scale (Morse, 2009) used in acute care health facilities (refer to Box 23.3). Behavioral factors such as agitation, disruptive or aggressive behavior and impulsivity can result in impaired safety judgment and falls.

High-Risk Medications Contributing to Falls and Injury Risk in Older Adults

"Culprit" drugs or medications implicated in increasing fall risk are those causing potentially dangerous side effects, including drowsiness, mental confusion, problems with balance or loss of urinary control, and postural hypotension (Fritsch & Shelton, 2019). Classifications of medications implicated in falls for older adults include psychotropic agents (benzodiazepines, sedatives/hypnotics, antidepressants,

BOX 23.3

Intrinsic Risks to Falls

Alteration in level of consciousness and/or cognitive impairment
Impaired safety judgment and/or behavioral factors (agitation, disruptive, aggressiveness or impulsivity)
Dependence in transferring or ambulation mobility (needs assistive device or human help)
Use of one-size non-skid socks
Visual impairment
Lower extremity weakness and/or gait or balance impairment
Orthostatic or postural hypotension
Neuropathy of lower extremities/feet

and neuroleptics), antiarrhythmics, digoxin, and diuretics (Fritsch & Shelton, 2019). The risk of falls alone should not automatically disqualify a person from being treated with warfarin (Garwood & Corbett, 2008).

A recent review of medications and fall risks, taking into account a series of studies, finds strong evidence for benzodiazepines, antidepressants, and antipsychotics to increase the risk of falls (Boyle, Naganathan, & Cumming, 2010; Bulat, Castle, Rutledge, & Quigley, 2008a, 2008b). Their analysis confirms that there is no evidence that very short or short half-life benzodiazepines, selective serotonin reuptake inhibitor (SSRI) antidepressants, or atypical antipsychotics are safer in terms of fall risks than earlier generations of drugs in the defined drug category. Furthermore, they conclude that antihypertensives, in particular diuretics, are associated with a modestly increased risk for falling (Bulat, Castle, Rutledge, & Quigley, 2008c).

Medications increase falls across all age groups but are heightened with older adults because of potential loss of function and life if they fall. Thus, reduction of medication use or modifying medication to reduce fall risk is essential. Constant attention to identifying risk versus benefits should be exercised by all practitioners, especially pharmacists (Fritsch & Shelton, 2019).

Step 4: Perform a Fall-Focused Physical, Functional, and Mobility Assessment

The aim of Step 4 is to identify pertinent positive and negative physical assessment findings associated with a fall that can produce functional impairment and/or mobility dysfunction. Some examples of treatable types of falls, the system effected, and the physical assessment finding are presented in Table 23.2. The physical assessment begins with assessment of vital signs and also inclusion of pain assessment. The resting vital signs often give clues as to the presence of pain or the presence of physiological instability. The assessment of arterial saturation can be helpful, because when it is abnormal, it can explain why a person may fall when he or she is fatigued and concomitantly has a low pulse oxygenation rate.

TABLE 23.2

Physical Assessment Findings Associated With Recurrent Falls

System Involved	Key Symptom
Visual system	Sudden loss of vision in one or both eyes (stroke) Blurred vision or loss of nighttime vision (cataract)
Cardiovascular	Slow heart rate (<60 bpm) Fast heart rate (>100 bpm) Drops in blood pressure with standing (orthostatic hypotension)
Neuromuscular	Gait instability Balance instability Lower extremity weakness on neurological assessment

bpm, beats per minute.

National recommendations for post-fall evaluation call for assessment of vision, gait, balance, musculoskeletal system, cardiovascular system, neurological system, the head, and footwear (Panel on Prevention of Falls in Older Persons et al., 2011). Within the assessment of the cardiovascular system it is critical to assess postural blood pressure while supine, sitting, and standing with the use of standby assistance from nurse's aides in case the patient develops sudden loss of balance. In previous work on assessment of orthostatic hypotension in nursing home residents who fell, nearly 44% experienced loss of balance, and not dizziness, even though drops in blood pressure met the diagnostic criteria of orthostatic hypotension (Gray-Miceli, Ratcliffe, Liu, Watland, & Johnson, 2012).

One modification the nurse can incorporate in his or her assessment of the frail older adult suspected to have orthostatic hypotension or who has a diagnosis of orthostatic hypotension is to assess the patient's blood pressure when supine and then assist the person to a sitting position and, while close to the person's side, retake the blood pressure. Should blood pressure drop significantly with sitting, there is no need to stand the patient to reassess his or her blood pressure.

Among other parameters assessed, neurological head assessment includes actively looking for signs of head injury; palpation of the skull looking for bulges or hematomas,

cuts, or lacerations; and assessment of the pupils for equality, roundness, reactivity to light, and accommodation.

The mental status assessment is critical to detect the presence of delirium (acute cognitive impairment) or chronic cognitive impairment due to diseases such as dementia. During conversation with the patient, the nurse is likely to observe physical assessment findings indicative of cognitive impairment—some examples include: inability to follow one- or two-stage commands; inability to recall the examiner's name within the first few minutes of the exam, despite repetitions; inability to sustain attention or immediate recall of events; and/or in addition to inability to speak or express himself or herself (aphasia), among others.

Physiological Stability of the Patient

In many situations, the nurse will find the older patient on the floor, and the standard approach to eliciting the history described earlier is not feasible because of the physiological stability of the patient, who may be injured. Thus, further dialogue and communication should take place when the patient is physiologically stable and comfortable in his/her room. However, other elements of the physical assessment must be performed immediately to ensure patient safety. Box 23.4 lists those elements that are essential to include in the immediate PFA when the older adult is found on the floor or lower level.

BOX 23.4

Immediate Post-Fall Assessment When the Older Adult Is Found on the Floor or Ground

Actions taken by professional nurses and nursing staff:

If the older adult patient is found on the floor, remain with the patient, summon additional help, and proceed to:

- Ask the older adult how he or she is feeling and whether there is pain.
- Control any bleeding (follow unit protocol) from injured site.
- Assess level of consciousness and perform neurological assessment, including pupillary checks (according to unit protocol).
- Gather and document vital signs: Note the apical pulse rate and the supine blood pressure.
- Examine for signs of external injury to the head, spine, neck, and extremities.
- Determine oxygenation status.
- Determine finger-stick glucose if hypoglycemia is suspected.
- If stable, sit the patient up with support and assess sitting blood pressure.
- Immobilize an extremity if fracture is suspected.
- Reassure the older patient.
- If stable, assist with transfer to an appropriate area for further evaluation of the historical events leading to the fall (refer to Box 23.1).
- Diagnosis and treatment.

(*continued*)

Functional Status of the Patient

Assessment of the patient's functional status includes ability to walk, transition from a chair to the bed and vice versa, and independently perform self-care through standard activities such as dressing, bathing, grooming, eating, and toileting. The functional assessment can be observed among patients as they prepare to take care of themselves when first arising in the morning or at other times during the day such as during activities of daily living. The nurse notes whether the patient can or cannot perform the activity independently or safely. These are two separate types of determinations. Experts report that in order to prevent functional decline and falls, it is vital for nurses to optimize function and physical activity (Resnick & Boltz, 2019). Physical activity, defined as bodily movement that expends energy, including bed mobility, transfers, and others, has a positive impact on the physical and psychosocial outcomes among older adults during hospitalization (Resnick & Boltz, 2019). Moreover, function-focused care for use in acute care is an intervention approach to increase physical activity among hospitalized patients as it prevents functional decline and falls and other adverse events (Boltz, Chippendale, Resnick, & Gakvin, 2015; Boltz, Resnick, Capezuti, Shabbat, & Secic, 2011; Resnick et al., 2016). Key activities, signs of impairment, and potential underlying factors that can lead to falls are provided in Table 23.3. One critical question to consider is whether the patient can *safely* perform the activity alone (independent) or whether he or she requires assistance because it is unsafe (i.e., dependent on another or requiring supervision).

Nursing assessment of patient safety includes, among others, evaluation of mental status, physiological status, and the ability to follow directions and to repeat those directions when asked (a complete list of factors is beyond the scope of this chapter).

TABLE 23.3

Key Activities, Signs of Impairment, and Underlying Factors That Can Lead to Falls

Observe This Activity	Signs of Impairment/ Inability to Accomplish This Activity	Possible Underlying Factors
Standing up from a high-back straight arm chair	Falls backward attempting to stand or sits down again during the attempt to stand	Drop in blood pressure Shoes not on feet, feet slide on the floor Lower extremities are weak Upper extremities are weak, and patient cannot push self to an upright position Confusion/cognitive impairment—unable to follow simple instructions
Getting out of the wheelchair or a chair	Unable to lean forward and push self up to a standing position	Upper extremity weakness Cognitive impairment Balance impairment
Walking 10 feet in a steady line	Leans to one side or path deviates to one side	Prior cerebrovascular event: Cerebellar issue Disorders causing gait apraxia, gait ataxia
Getting out of bed	Rolls onto one side and then onto the floor	Poor safety awareness/judgment/cognitive impairment Orthostatic hypotension

Mobility Assessment

An integral component of the functional assessment is the patient's ability to ambulate and to be mobile. Evidence finds persons over age 85 need more help with mobility related to walking and getting in/out of bed or chair than those between the ages of 65 and 84 years (Centers for Medicare and Medicaid Services, 2014). Both impaired function and needing more help with mobility related to walking are significant predictors of longer hospital lengths of stay and repeat hospitalizations (impaired mobility: odds ratio = 1.94, $p < .001$ and impaired function: odds ratio = 1.68, $p < .01$). Inability of older adults to perform customary roles within families and society constitutes, at the social level, a disability or handicap (Verbrugge & Jette, 1994). Therefore, nursing interventions to preserve function and maintain mobility are particularly important in any fall-prevention intervention program. Restoration of physical mobility and function leads to quality patient outcomes. By way of example, reduced muscular strength and inability to walk is a functional impairment and limitation that leads to a disability when the older adult is unable to shop or assume prior role functions (Verbrugge & Jette, 1994). In the broadest sense, impaired mobility means the person needs assistance to maintain mobility, and in the strictest sense, impaired mobility can mean the person is confined completely in movement, as when persons are confined to a wheelchair or bed. Without proper rehabilitation or restoration, persons with impaired mobility can deteriorate to a state of immobility.

The importance of safe mobility is espoused by the American Nurses Association's (ANA's) *Safe Patient Handling and Mobility: Interprofessional National Standards Across the Continuum* (ANA, 2015). The aim of the bedside mobility assessment is to identify the patient's strengths during mobility so as to prevent falls and injury from occurring during activities such as transferring, pivoting, toileting, showering or bathing, and ambulation. There are many demographic (such as over age 85), situational, and clinical factors influencing mobility in older adults (Gray-Miceli, 2017) of equal importance to recognize. Situational factors and indicators, at the person level, include statements made by patients that reveal an emotional response to their functional limitations or impairment induced post fall, which may include fear, anger/frustration, and embarrassment (Gray-Miceli, 2001). It is important to recognize these emotional responses in the plan of care and mobility evaluation because they can be reasons that explain why the person does not wish to engage in an active mobility plan.

Tailoring a mobility plan to suit older adults in the acute care hospital setting involves consideration of emotional responses that might be expressed or identified by the nurse during the course of the conversation about mobility. Some emotional responses may need to be further evaluated should they be identified as a significant factor impairing the older adults' progress. In terms of the assessment of any symptom reported along with a fall, further evaluation of its onset, duration, timing, frequency of occurrence, and aggravating or alleviating factors is indicated. If the symptom persists, then monitoring is indicated and/or referral to a specialist.

Typically, the primary care provider will be able to judge the need for additional consultation or referral to a physiatrist or psychologist. In the acute care setting, the physical therapist will be equipped to evaluate mobility and the person's concerns during periods of transition. Additional assessment tools can be used by the professional nurse to establish whether an emotional response is interfering with the older adult's mobility. For instance, fear of falling has been linked to self-efficacy (Tinetti, Richman, & Powell, 1990). Measurement tools that have been used to evaluate the older adults' degree of fear of falling as a measure of self-efficacy have been developed and shown to have reliability and validity (Greenberg, Sullivan-Marx, Sommers, Chittams, & Cacchione, 2014).

In the acute care setting, nurses can use available tools such as the Bedside Mobility Assessment Tool and also work in harmony with the licensed physical therapist to identify patient strengths and weaknesses related to mobility (Bonyton, Kelly, & Perez, 2014). It is important to note that emotional responses can influence subsequent activity restriction and mobility. Promoting the older adults' ability to ambulate and maintain function without encountering dependency or activity restriction is very important since we know periods of reduced mobility can quickly lead to immobility.

Step 5: Detect Environmental Hazards and Eliminate

Falls due to environmental hazards are potentially preventable because they encompass foreseeable events, such as spills or improper footwear, which are correctable (Connell, 1996). Common extrinsic or environmental factors, which represent preventable falls, are highlighted in Box 23.5.

BOX 23.5

Extrinsic Risks to Falls

Floor surfaces that are slippery, wet, shiny, or uneven or cracked
Equipment that is faulty, not supportive, or that collapses when used, laden with debris
Intravenous poles, stretchers, or beds that are nonsturdy or move away from the patient when used for support
Poor lighting or extraglaring "blinding" bright lights on floor surfaces or in the patient room
Bathrooms lacking grab rails, bars, or nonskid appliqués or mats
Bathrooms with sharp edges
Bathroom fixtures that are not secure in the wall or are difficult for the patient to use properly
Physical restraints
Inappropriate footwear

Equipment used to assist the patient with mobility can also be found to create an environmental hazard leading to a fall if that equipment is found to be not sturdy or rickety. Therefore, it is commonplace for nurses and care teams to evaluate the environment and to regularly assess equipment to ensure it is functioning properly and safe. National guidelines for safe patient handling have been created and serve as a reference (ANA, 2015).

Step 6: Synthesize Steps 1 to 5 to Identify the Likely Type of Fall and Construct a Case Synopsis That Envelops All Possible Underlying Causal Event Factors, Fall Risks and/or Antecedents to the Fall So As to Tailor the Plan of Care and Communicate Findings to the Interprofessional Team

This may seem like a daunting task, but it is not. The nurse gathering the historical information about the fall described in Steps 1 to 5 should have a suspicion of the multitude of underlying causal event factors including intrinsic and extrinsic risks involved in the patient fall. In previous work, we found nurses were able to identify many of the causal event factors associated with the fall and to further categorize the likely type of the fall when asked to do so among their patients residing in long-term care, who possessed on average 10 chronic illnesses and took many high-risk medications (Gray-Miceli et al., 2010). Table 23.4 provides the broadest array of fall types identified by nurses in long-term care and in acute-care hospital settings. It is important to note that many of the fall types/categories seen in long-term care (LTC) can occur among older adults as they transition from LTC to rehabilitation, subacute, or acute care. The fall types listed here are not mutually exclusive and allow for a person to have more than one type of fall. A quick comparison of fall types evidenced through research is presented in Table 23.4 to illustrate similarities in categorization schemes.

Note that in the acute care setting Morse has studied and presented a classification scheme of the three most commonly observed types of falls: (a) accidental fall (related to an unsafe environment or environmental risk factor); (b) anticipated physiological fall (related to known intrinsic and extrinsic risk factors of the individual); and (c) unanticipated physiological fall (resulting from an unexpected medical event; Morse, 2009). Risk factors vary by the type of fall, and the interventions to reduce an accidental fall are different from the interventions used to reduce risk factors associated with anticipated physiological falls.

Reasons for patient falls and injuries are tied directly to impairments in consciousness, cognition, behavior, and

TABLE 23.4

Fall Types Identified and Categorized by Nurses

Categorization of Fall Type in LTC (Gray-Miceli et al., 2010)	Categorization of Fall Type in Acute Care (Morse, 2009)
Falls likely due to:	
Fall due to symptoms of chronic illness	Anticipated physiological fall
Fall due to symptoms of acute illness	Unanticipated physiological fall
Fall due to environmental hazards	Accidental fall
Fall due to patient poor safety awareness and Fall due to poor patient judgment	Accidental fall and/or anticipated fall
Fall due to adverse effects of high-risk medication use	Anticipated and/or unanticipated physiological fall

acute and chronic types of medical conditions, in addition to the situational context of the fall. Some of these risks are caused by *intrinsic* factors, whereas others are the result of *extrinsic* factors. The standard of care calls for assessment of fall risk factors and then the development of an intervention plan addressing each of these factors. Not all fall risk factors are modifiable; those that are should be treated.

Accidental or environmental falls are potentially preventable because they encompass foreseeable events, such as spills or improper footwear, which are correctable (Connell, 1996). Review important intrinsic risks that contribute to anticipated physiological falls. Common extrinsic or environmental factors, which represent preventable falls, are highlighted in Box 23.5.

Asking and answering questions to evaluate, for instance, the occurrence of key associated factors or environmental factors is an important assessment finding. The following case synopsis illustrates the synthesis of findings from the PFA to a meaningful likely underlying causal event factor. Consider the following situation:

Situation of Mrs. Stiles (Synthesis of Steps 1–5)

Mrs. Stiles, an 85-year-old woman admitted to the hospital for sepsis due to a urinary tract infection, fell out of bed. *Subjective:* She replied, "I was in a hurry and got up from the bed quickly, walked to the bathroom because of urgency and dribbling." Further inquiry revealed, on review of systems, no chest pain, dizziness, vertigo, shortness of breath, sudden leg weakness, or other key symptoms. She takes no sedatives, hypnotics, or high-risk medications associated with falls. *Objective:* She has an IV with D5W/2 NSS at KVO rate. She is receiving Bactrim DS by mouth BID for the UTI. Vital signs: temperature: 97.1°F; heart rate 80 and regular; BP 120/80 supine, sitting, and standing. Head shows a small laceration to the posterior scalp, requiring bandages and ice for the evolving hematoma. Neurological—awake and alert, Cr nerves II–XII intact, no focal weaknesses of extremities, wearing nonskid sneakers. *Assessment:* s/p fall with head injury suspect due to urinary frequency; *Plan:* monitor urgency, institute bladder scanning every 2 hours and post void to rule out residual urine and to anticipate urinary needs; institute toileting every 2 hours or more frequently according to scans and provide toileting assistance via use of a bedpan- until the severity of head injury is determined; neurological checks as per facility protocol for head injury, discuss with pricare provider urinalysis results and need for a repeat urinalysis as well as referral to urology.

Step 7: Inform, Engage, and Use Teach-Back to Educate and Empower Patients

Patient Engagement

Evidence confirms that patient outcomes are improving when patients and caregivers are fully engaged as partners in their care (Hibbard & Greene, 2013). Interventions that tailor patient education and support to each patient's level of activation and engagement as a partner in one's fall-prevention program builds skill and confidence to prevent and manage falls. Redesigning patient education methods can be accomplished with methods such as: Teach-Back, Ask Me 3, and Falls T.I.P.S (Dykes, I-Ching, Soukup, Chang, & Lipsitz, 2012; Dykes et al., 2010).

Teach-Back

Health literacy requires that providers evaluate the degree to which individuals learn by assessing their capacity to obtain information, process, and understand basic health information and services so that they can make informed health decisions (Nielsen-Bohlman, Panzer, & Kindig, 2004). Teach-backs identify what the patient learned by a return demonstration or feedback, and, more important, what the patient had difficulty learning, so that the provider

can fill that gap through ongoing education (Boushon et al., 2012). A more detailed discussion of teach-backs and patient education geared toward the older adult patient is available for practicing nurses (Gray-Miceli, 2014).

According to the AHRQ (2019), healthcare providers are increasingly using teach-back in their practices to teach adults. Thirty percent of adults were educated via teach-back in 2015 compared to 24% in 2011. Health literacy requires that providers evaluate the degree to which individuals learn by assessing their capacity to obtain information, process, and understand basic health information and services so that they can make informed health decisions (Nielsen-Bohlman et al., 2004).

Another resource for patient engagement and education is IHI and National Patient Safety's Ask Me 3 Videos to teach clinicians the use of the National Patient Safety Foundation's (NPSF) Ask Me 3 approach to patient education and including teach-back as a method to evaluate effectiveness. One such video is from NPSF: www.youtube.com/watch?v=B3EB-icaNKQ.

The three questions of Ask Me 3 to frame education are: What is my main problem? What do I need to do? Why is it important for me to do this? Nurses are teachers. To be effective teachers, nurses must redesign approaches to patient and family/caregiver education, consider patient/resident autonomy, and apply adult principles to essential patient education strategies (Guillaume, Crawford, & Quigley, 2016).

FALLS AND INJURY RISK ASSESSMENT

The older adult's risk potential of incurring a fall that could result in injury is contingent on several "real-time" underlying factors: (a) baseline pathophysiological changes at the time of the fall, such as presence of osteoporosis/osteopenia, prior fracture, anticoagulation, hypoglycemia, or sensory neuropathy; (b) use of high-risk medications such as centrally acting medications (described in Step 3, p. 382); (c) presence of fall risk factors associated with known medical conditions such as cognitive impairment (i.e., delirium and dementia), impaired vision, or impaired proprioception; (d) environmental factors such as room or bed placement, suboptimal furniture height, or one-size nonskid socks (described in Step 5; Box 23.6); and (e) behavioral factors, such as the presence of agitation, disruptive or aggressive behavior, impulsivity, and/or impaired safety judgment (described in Box 23.2).

Summary of Baseline Pathophysiological Changes

Pathophysiological changes of the sensory system, from age or from disease, can trigger not only a fall but a fall with injury. Some of the more common age-related changes of the sensory system related to vision that predispose to falls include the presence of cataract formation or macular degeneration. With cataracts, the crystalline lens becomes yellowed and cloudy, creating a visual alteration and potential for blindness, depending on the severity of the cataract. Age-related macular degeneration, however, causes loss of central vision, which can obfuscate ability to see objects directly in front of the patient. Assessment is geared at identifying unilateral visual loss and monocular vision. Seeing at night can become troublesome; therefore, higher levels of illumination are required. Consultation with an ophthalmologist for treatment of these disorders can prevent falls and falls with injury.

The contribution of vision to risk of falling has been summarized by fall experts Lord, Smith, and Menant (2010). They substantiated by review of numerous studies the impact of visual deficits on older persons' stance and balance, increasing risk of falls. Their evidence confirms significant increases in postural sway when there are changes in or loss of vision. Another common sensory disorder affecting the peripheral nerves among older adults is peripheral neuropathy (Cuevas-Trisan, 2019; Hatton & Rome, 2019). Older adults experience sensory changes prior to motor changes. With sensory changes, older adults will have changes in step width that is wider and step length that is shorter (Richardson, 2002). With motor changes, older adults will have trouble with diminished reflexes, ankle dorsiflexion, and even foot drop. Common among persons with B12 deficiency, disorder of the microvasculature, or type 2 diabetes, sensory neuropathy is a painful disorder that leads to loss of sensation typically affecting a stocking–glove distribution, referred to as sensory neuropathy (Richardson, 2002). Feeling one's feet on the floor can be a lost sensation altogether. Referral to a podiatrist or physiatrist can be of help to find appropriate footwear and to discuss treatment options.

Age-related changes in the neurological system can also predispose individuals to falls. The reduction in the righting reflex and an overall decrease in reflexes accompanying age cause not only slow movement but also potential for balance impairment, resulting in a fall and/or injury, especially if ambulating on an uneven surface. With a slowed reflex, the ability of the older adult to reach out and stop the fall may be lost altogether. In this situation, the person can fall flat on the face, shoulder, or back, resulting in serious cranial or extremity fractures. Although not considered normal aging, "frailty" is associated with a higher case incidence of falls. Frailty is an independent risk factor for falls (Nowak & Hubbard, 2009). Frailty is defined as a geriatric syndrome that has multiple clinical markers such as weight loss, gait speed slowness, and

slowness in movement, evidenced by an increased time to perform standard tests such as the Timed Get Up and Go test. It is estimated that frailty increases with age and is highest among older adults aged 85 years and older and is more common among women.

Age-related changes in the musculoskeletal system and pain are commonly encountered among older adults who fall and incur fall-related fractures (Cuevas-Trisan, 2019). Normal aging results in some diminution of muscle mass and strength, along with osteopenia, and when untreated progresses to osteoporosis. Older adults with diseases affecting the musculoskeletal system, such as sarcopenia and osteoporosis, profile physical frailty and fracture risk, which result in progressive decline toward dependency, recurrent falls, and serious injury.

Why Do Older Adult Patients in an Acute Care Setting Fall, and Who Is at Greatest Risk?

Strong, sustained evidence supports fall prevention based on an interdisciplinary, multifactorial approach to assessment, treatment, and evaluation by the care team (Cameron et al., 2012; Degelau et al., 2012; Ganz et al., 2013; Shekelle et al., 2013; Spoelstra et al., 2012). Evidence from systematic reviews of fall risk factors in hospital inpatients supports the following risk factors to be linked to falls: a recent fall, muscle weakness, behavioral disturbance, agitation or confusion, urinary incontinence or frequency, use of "culprit" medications (especially sedative/hypnotics), postural hypotension, syncope, and age greater than 85 years (Oliver et al., 2010).

Screening a patient for fall risk is not the same as fall risk assessment. All patients require a risk screen, which prompts an in-depth assessment on admission. All tools used by nurses to screen and assess for risk should be valid and reliable, with known predictive properties for the anticipated physiological fall. From assessment, referrals to the interdisciplinary care team should occur to seek the underlying cause of the identified risk factors that contribute to the production of an injurious fall (Quigley, 2016). Whenever possible, the care team should work collectively to modify or eliminate the risk factors present. It is frequent reassessments upon change in patient status by nursing and the care team that reveal decreases and increases in fall risk. Assessment after a patient fall informs causes of falls, sources of injury, and complications. However, population-based care requires that care teams protect the most vulnerable irrespective of a score on a screening tool. In 2010, 45% of the inpatient hospital population in the United States were 65 years of age and older—among whom 19% were aged 75 to 84 and 9% were aged 85 and older. These findings should compel all organizations to implement patient safety programs based on increased vulnerability for hospital-acquired harm that result in loss of function or loss of life. For example, falls among persons aged 85 and older are the leading cause of unintentional injury death (Levant, Chari, & DeFrances, 2015).

Fall risk is formally screened through administration of fall risk tools. The Morse Fall Scale is a screening tool and should only be completed using the FACT acronym: after a *f*all, on *a*dmission of the patient, on *c*hange in patient status, and on *t*ransfer or discharge (National Center for Patient Safety [NCPS], 2014). The St. Thomas Risk Assessment Tool in Falling Elderly Inpatients (STRATIFY) tool has also been widely used, but, overall, researchers report that the use of any of the tools offers no added benefit over nursing staff's clinical judgment. Oliver et al. (2010) recommend the Morse Fall Scale and the STRATIFY tool as the two screening tools with the best predictive properties, and the Morse Fall Scale was designed specifically to predict the probability of an anticipated physiological fall. The HD (Hester Davis) Scale (Hester & Davis, 2013) for fall risk predicts the anticipated physiological falls. This scale is the newest scale that progresses from screening to assessment, aligns interventions to fall risk factors, and is validated in both paper and electronic medical records. The HD Scale generates an individualized care plan, which when implemented results in mitigation and/or elimination of fall risk factors.

Some of the more commonly encountered risks of fall and injury observed in acute care are evident on many of the widely published and available risk-analysis tools. All of the nursing fall risk tools include assessment of cognitive function.

It is very important to recognize cognitive impairment as studies confirm that early detection of acute mental status changes, especially delirium, leads to early treatment and resolution. Moreover, early recognition of cognitive impairment caused by underlying chronic dementia is equally important. Acute care studies have shown that in patients with underlying dementia before hospitalization, cognitive function typically worsens with hospitalization. Both acute delirium and chronic dementia are independent risk factors for fall (Sillner, Holle, & Rudolph, 2019), impacting impaired safety judgment. Impaired safety judgment is a nursing diagnosis that refers to the patients' inability to recognize whether their actions are safe or not. Therefore, when safety impairment exists in the acute care setting, it is incumbent on the registered nurse to protect the patient from harm. Impaired safety judgment arises from acute or chronic illnesses, medications and other factors such as pain.

BOX 23.6

Medical Conditions That Raise the Risk of Serious Injury (Fracture)/Internal Bleeding

Medical conditions
Osteopenia
Osteoporosis
Fracture history
Thrombocytopenia
Acute lymphocytic leukemia
Acute anemia or loss of blood volume
Any state of altered level of consciousness "delirium," lethargy, obtunded or comatose
Bleeding/Clotting disorder
Medications
Blood thinners
Thrombocytopenic agents

Impaired safety judgment is a very serious safety concern especially should other medical conditions co-exist for serious injury, as outlined in Box 23.6. An integral component of the nursing assessment is to remain current with patients' medical conditions that increase fall risk. If present, strategies must be integrated into the patient's individualized plan of care, which can mitigate, reduce, or eliminate these risks altogether.

Diagnosis: Cognitive Dysfunction (Dementia/Delirium)

Important characteristics of level of alertness are the patients' ability to maintain attention and concentration, follow commands, and engage in appropriate conversation. If impairment exists in level of consciousness, an assessment should be made to differentiate delirium from dementia. Cognitive impairment is a known fall risk factor, requiring clinical assessment to differentiate.

Delirium. Delirium has many synonyms, including acute confusional state, altered mental status, reversible dementia, and organic brain syndrome.

On admission, all patients older than 65 years, regardless of admitting diagnosis, should be assessed for both dementia and delirium. Assessment is usually completed with the Confusion Assessment Method (CAM; Degelau et al., 2012).

Dementia. Patients with dementia include those with a diagnosis of Alzheimer's disease, vascular dementia, Lewy-body dementia, frontotemporal lobe dementia, and those associated with other disorders. Such patients normally have slower reaction times and demonstrate impaired judgment. Individuals with dementia also possess varying degrees of alterations in visual–spatial orientation. Screening for dementia can be completed with the Mini-Cog, Mini-Mental State Exam (MMSE; Borson, Scanlan, Chen, & Ganguli, 2003; Folstein, Folstein, & McHugh, 1975), and Kokmen Short Test of Mental Status Sources (Degelau et al., 2012; see Chapter 17, Advance Care Planning). These patients are at risk for falls and injury, if injury-reduction practices are not implemented.

Additionally, any postoperative surgical patient is at high risk for both a fall and injury due to altered level of consciousness from anesthesia, centrally acting medication, and orthostasis. An important factor in determining a patient's safety within his or her environment is whether he or she can process information and execute simple one-, two-, and/or three-stage commands. The ability to execute a command is contingent on the level of consciousness, behavior, and cognition.

Traditionally, the level of consciousness is assessed and written as alert and oriented times four (person, place, time, and situation). The ability of the person to sustain attention can be gauged by observation of one's ability (or not) to execute a simple one stage versus complex three-stage command. This type of assessment is typically routine when the nurse first greets the patient and is beyond a simple assessment of whether or not the patient is awake, "alert," and oriented and can say, "Hello." All of these determinations are critical factors in the nurse's judgment of patient safety. After the first assessment, the nurse should reassess the older patient frequently because the level of consciousness can change quickly. Thus, at first glance it appears to the nurse that the patient is awake and alert, but later in the shift, the patient may typify "delirium" and appear hyper- or hypo-alert. Thus, patients require frequent monitoring of the level of consciousness.

Observation of a patient's behavior includes the patient's affect, demeanor, and ability to process stimuli in the environment. Agitated older adults are at risk for falls and injury because attention to the normal environmental cues is blunted or lost altogether. Depressed older adults may be at risk for impaired safety awareness and management because of blunted responses or apathy as well as centrally acting medications used to treat the depressants.

For each of these four factors—consciousness, affect, behavior, and cognition—nurses work with primary providers to evaluate the underlying causes and find treatable solutions wherever possible. Note that the roots of many of the disturbances of *consciousness*, *behavior*, and *affect* are some classic acute medical events such as hypotension, infection, dehydration, profound blood loss, or toxicity from medications. If no identifiable etiology exists, the standard of care requires

nurses to institute observation and safety interventions (Box 23.7). Nurse-initiated actions remain constant until the patient is stabilized or transferred to a higher level of care.

Assess and Diagnose the Older Adult Patient's Risk of Serious Injury

Fractures

Nurses must ask a few commonsense questions when determining whether an elderly patient is at risk for serious injury (Box 23.7). *Serious injury* is defined as injuries that result in loss of function and loss of life (Boushon et al., 2012). The National Quality Forum (NQF, 2007) defines *moderate harm* as the harm from falls resulting in suturing, Steri-Strips, fracture, or splinting; *major harm* as those falls that result in surgery, casting, or traction; then *death*. One of the most prevalent conditions increasing risk of serious injury in older patients, such as a fracture, is the presence of osteoporosis. For many reasons, the true incidence of osteoporosis is unknown in the older population, especially in men (Kaufman et al., 2000), who comprise a large percentage of the acute care hospital and long-term care beds. Therefore, it is entirely conceivable that the older adult will fracture an extremity or vertebrae with a fall, even though there is no documented diagnosis of osteopenia or osteoporosis. Depending on bone density and the severity of the trauma sustained during a fall, fracture risk must remain a consideration so that interventions to reduce harm can be implemented. Nurses must remember that osteopenia and osteoporosis can be present, even though they have not formally been diagnosed. Nurses must know risk factors for osteopenia and osteoporosis, because not all older adults have received a dual-energy x-ray absorptiometry (DEXA) or bone densitometry scan. Most older individuals with hip fractures have osteoporosis; yet, findings from a retrospective analysis of records of patients receiving hip-fracture surgery show that the frequency of treating these high-risk older patients for osteoporosis is less than optimal; women are offered treatment more than men (Kamel, 2003). If osteoporosis has been diagnosed, then certain protective interventions should be considered, such as the use of hip protectors (Applegarth et al., 2009; Bulat, Applegarth, et al., 2008; Shekelle et al., 2013).

As indicated for those older persons without safety judgment and who are unable to transfer and ambulate independently, the use of low-height beds and/or floor mats placed around the bedside reduce the chance of harm to the patient should they fall; alternatively, padding a hard surface will reduce the chance of injury. Treatment for osteoporosis needs to be discussed, ranging from the use of medication agents to supplemental calcium and vitamin D, although research findings show a controversial association between vitamin D and physical performance improvements in gait and balance (Annweiler, Schott, Berrut, Fantino, & Beauchet, 2009). However, a recent meta-analysis found vitamin D to be the only intervention shown to be effective in reducing falls among female stroke survivors in an institutional setting (Batchelor, Hill, Mackintosh, & Said, 2010).

Hemorrhage

Other medical comorbidities that increase the risk of serious injury include bleeding disorders and use of blood-thinning medications to prevent stroke. A risk-versus-benefit analysis should always be part of fall management

BOX 23.7

Interventions for Patients Suspected of a Serious Injury

Notify the physician or healthcare professional immediately.
Activate Rapid Response Team.
If on the floor, do not move the patient until medically evaluated.
Apply supplemental oxygen if indicated.
Assess vital signs and pulse oximetry every 15 minutes.
Prepare the patient for an x-ray of the extremity or CT scan of the head.
Pad side rails if there is altered level of consciousness among the bedridden.
Do not leave the patient alone; obtain a sitter or one-on-one assistance.
Lower the height of the bed, use tab alarms or personal alarms.
Assess and maintain airway, breathing, and circulation.
Assess and monitor pain (does it increase over time or is it unrelieved?).
Maintain an NPO status unless ordered otherwise.
For suspected injury to soft tissue, apply ice for swelling, following the RICE principle.
Prepare the patient for laboratory data; frequently, a serum blood count, type and cross match, bleeding time, and serum electrolytes are ordered.
Observe and monitor the injury site: Does the swelling increase? Is there an open fracture? Does the tissue discolor? Is there loss of circulation?
Are there any coexisting symptoms, which worsen over time, such as headache, backache, pain in the extremity, or experiences of dizziness or shortness of breath?

RICE, rest, ice, compression, elevation.

decision-making for patient safety and prevention of injury (Quigley & Goff, 2011). Those with thrombocytopenia require monitoring of neurological status post fall in an effort to early identify a patient with a looming internal bleed or developing hematoma. These clinical conditions are very serious and can be fatal if not assessed early.

Head Trauma

To detect the development of serious conditions, such as a subdural hematoma, frequent neurological checks are done for several days, depending on hospital clinical practice policies and guidelines, following head injury in older patients and those who are on blood thinners or who have coexisting medical conditions (Degelau et al., 2012; Ganz et al., 2013). In addition, vital signs and assessing behavior, affect, cognition, and level of consciousness are all part of any assessment of a patient with head injury. Changes in speech, such as slurred speech, or subtle diminution in cognitive abilities (i.e., they no longer recognize you after recalling your name) are significant findings post-fall head injury that require immediate attention. Recent evidence suggests that the major predictors of death in patients with ground-level falls were age greater than 70 years and a Glasgow Coma Scale score of less than 15 (Konstantinos et al., 2010). Older patients who have unwitnessed falls or do not recall falling despite evidence to the contrary should be monitored for head injury following the CDC guidelines for head injury (see "Resources"). TBI caused by head injuries is a condition that is preventable and, more important, readily recognizable. Subtle changes in cognition, level of consciousness, or behavior post fall indicate underlying head trauma. Box 23.6 details best practice interventions in cases in which a head injury is suspected post fall.

There is a strong clinical reason to suspect that older adults who are on anticoagulants are at higher risk for TBI, but empirical research in this age group is lacking. Still, best practice approaches to care of older adults must include a risk–benefit evaluation of medications, such as Coumadin, Plavix, and/or aspirin, among others, that place the older adult at an increased risk of bleeding following a fall. Additionally, use of helmets may be considered because they absorb trauma and reduce impact to the head (Quigley & Goff, 2011).

Post-Fall Management: Huddles and Assessment

Post-Fall Huddles

Because older adults continue to fall despite the implementation of evidence-based guidelines to prevent falls, identifying the causes of each fall is critical to preventing future falls. Within the inpatient settings, clinicians are able to act when a patient fall occurs and to quickly determine the event with the patient, using the PFH process. The purpose of the PFH is to determine the root cause of the fall and the source of injury in order to mitigate and eliminate causes of harm (Cameron et al., 2012; Ganz et al., 2013; U.S. Department of Veterans Affairs, 2014).

PFHs are conducted in all settings of care to determine the cause of the fall and intervene appropriately (Anderson, Mokracek, & Lindy, 2009; Ganz et al., 2013; The Joint Commission, 2015a, 2015b; Quigley et al., 2009). The definition of *huddle* varies from study to study, but a huddle is an immediate evaluation of each fall, by a team, preferably interprofessional, with the patient in the environment where the patient fell. Data about the root cause of the fall determine the type of fall, such as accidental, anticipated physiological, and unanticipated physiological fall. Analysis of data enables clinicians, administrators, and risk managers to profile population risk at the patient, unit, hospital, and system level. Valid and reliable data are essential to examine patterns and trends surrounding fall occurrence, program structure, and processes needed for program evaluation.

Overview of Effective Fall and Injury Prevention Programs in Hospitals

Nurse Champions

Embracing nurse champions at the point of care, the IHI's Transforming Care at the Bedside has partnered with the Veterans Integrated Service Network (VISN) 8 Patient Safety Center to focus on acute care fall and injury prevention for the past 5 years. Dedicated to building program capacity, infrastructure, and expertise, fall experts have mentored and coached nurses from across acute care settings to address vulnerable older adults who are at greatest risk for loss of function or loss of life if any type of fall occurs. This approach to nursing practice has been transformational (Boushon et al., 2012; Ganz et al., 2013).

Comfort Care and Safety Rounds

Traditionally, nursing staff complete routine and frequent comfort care and safety rounds to observe patient status, anticipate and meet patient needs, and increase patient safety. These rounds have modified to intentional or purposeful 1- to 2-hour rounding designed to increase patient satisfaction and safety. However, evidence is based on quality-improvement projects that reported issues with feasibility and staff adherence. Any associations between

intentional rounding and fall reduction were flawed because of methodological issues (LeLaurin & Shorr, 2019). Still, this intervention has been included in hospital fall-prevention toolkits (Boushon et al., 2012; Degelau et al., 2012; Ganz et al., 2013; NCPS, 2014). The IHI recommends implementing routine rounds that "combine frequent and regular toileting rounds with existing patient-care tasks, such as patient turning, environmental safety assessments, and pain assessment, and addressing all patient needs (e.g., pain, position, toileting, and environment) in one effective encounter" (Boushon et al., 2012, p. 22).

Many hospital-based fall-prevention programs include toileting rounds. The range of toileting-related falls in bathrooms was reported to be 38% to 47% (Tzeng, 2010). Evidence confirms the relationship between delirium, toileting needs, high-risk prescription medications, ambulation impairment, and an increase in the number of patient falls (Fridman, 2019). The high percentage of falls associated with toileting is alarming, considering the small amount of time patients spend toileting or in the bathroom. These statistics should compel nurses to increase efforts to assess, individualize, and hard-wire toileting schedules as part of comfort and safety rounds. The purpose of toileting rounds as well as individualized toileting plans is to prevent patients from having elimination accidents, attempting to toilet without assistance, and falling. Toileting is a fundamental element of basic care that has an important place in the prevention of patient falls.

INTERVENTIONS FOR FALL PREVENTION AND MANAGEMENT

Instituting General Safety Measures

Hospitals and their staff have a legal responsibility and due diligence to ensure freedom from environmental hazards and ensure safety for all patients, staff, and visitors. Routine environmental assessment using a checklist should include the unit, corridors, entrance, and exits, as well as patient holding areas, patient rooms, and areas where patients are transported (radiology, nuclear imaging, and operating room; Ganz et al., 2013; Shekelle et al., 2013). In each of these areas, an environmental assessment is performed focusing on floor surfaces; furniture; hallways; steps; device safety, such as stretchers, wheelchairs, and other types of chairs; presence or absence of clutter; bathrooms with appropriate grab rails; and routine assessment of equipment. Use of a checklist signed by the designated employee allows for audit review of compliance, serving as an internal benchmark of compliance.

Early Mobility for Older Patients to Prevent Falls

When nurses implement fall-prevention strategies that limit mobility, negative consequences result, such as functional decline, confusion, pressure injury, hospital-acquired infections, and institutionalization (Growdon, Shorr, & Inouye, 2017). Nurses have a responsibility to initiate early mobility, because this decreases fall and injury risks (Inouye, 2019). The HELP (Hospital Elder Life Program) has resources to guide nurses' implementation of early mobility programs (Mobility Change Package and Toolkit; Inouye, 2019). Early mobility, whenever older patients are medically stable, is a fundamental and basic aspect of care for all older adult patients to receive during their hospitalization. It is a step toward the prevention of deconditioning, reduced mobility and immobility, and other cascading problems that can result when less sedentary (for instance, orthostatic pneumonia or atelectasis). Early mobility starts with nonambulatory patients: assisted bed mobility, sit-to-stand exercises, range of motion exercises, and lower extremity exercises. Nursing staff assist the patient out of bed to walk to the bathroom whenever possible, rather than to use a bedpan or even a bedside commode that offers little opportunity for mobility. Wearing proper footwear, corrective lenses, and clearing a path that is free of clutter and spills are essential. Use of a walking aid, such as a standard cane or walker, may also be required; appropriate assistive devices can be ascertained through an occupational or physical therapist consultation (Quigley & Goff, 2011). For older adults who may have cognitive impairment and are at risk for serious injury, assistance with ambulation and their device is recommended, given findings that ambulatory fallers in assisted living had greater risk of head injury than fallers residing in skilled nursing (Gray-Miceli, Ratcliffe, & Thomasson, 2013).

Another essential approach for the older adult with comorbidities is for nurses to preemptively ask the older patient, who is transitioning with his or her assistance, from sitting to standing and then while walking, "How are you feeling?" Of concern is the detection of symptoms such as lightheadedness, vertigo with rotational movement, or muscular stiffness. These symptoms can be managed and monitored, if significant enough to prohibit mobility, once they are detected. Another concern exists for the older adult patient with orthostatic hypotension. In this instance, gradual upright incline with assistance while monitoring for symptoms of lightheadedness is important. Should an older adult experience symptoms or develop acute physiological evidence of a problem (for instance, near syncope, syncope, or changes in heart rate or blood pressure), slowly easing him or her back to a recumbent position and notifying the physician for further evaluation are warranted.

Mobility programs should be instituted which are built on the positive feedback that the patient feels about their status and progress as well as objective findings of gains in strength each day (Resnick & Boltz, 2019). Checklists can monitor progress and serve to validate to the patient his or her clinical progression. Care must be taken, however, to remind persons who are restricted from independent mobility to always wait for assistance. Recommendations are to set a similar time each day and to use consistent staff. An integral component of any mobility program is the footwear of patients. A recent study found patients who wore their own footwear significantly improved participants' balance compared to being barefoot; in fact, the greatest benefit was seen in those individuals with the poorest balance (Hatton & Rome, 2019; Horgan et al., 2009).

Specific Nursing Interventions

Personal alarms are routinely used to alert nursing staff about impending falls or changes in patient mobility status; however, they have limited effectiveness (Shorr et al., 2012). Care should be taken when deciding to use these devices, because they do not prevent a fall from occurring (Oliver et al., 2010); rather, they heighten staff's awareness by sounding an alarm, indicating a change in position has occurred. They also act as a deterrence to patient mobility, which has negative consequences to the patient. There are many commercial products available, but, generally, they are of two types: personal alarms clipped to the patient's gown or chair and bed–chair pressure sensors. Despite their widespread use, there is insufficient evidence that they reduce falls in an acute care hospital setting (Kwok, Mok, Chien, & Tam, 2006; LeLaurin & Shorr, 2019; Shorr et al., 2012). Effectiveness in the prevention of falls may best be gauged by the timeliness of the rescue (Quigley & Goff, 2011), as documented by Quigley, Votruba, and Kaminski (2019). Greater nurse surveillance capacity was significantly associated with better quality care and fewer adverse events (Kutney-Lee, Lake, & Aiken, 2009).

Patient-Engaged Virtual Surveillance

As part of general safety, some facilities designate any older adult aged 65 years and older who has been admitted as being on "safety precautions," which can include various other safety measures (presented in the following text). Surveillance is the third important component of a fall and fall injury prevention program. Frequent and/or continuous observation is critical to the safety of patients who fail the teach-back and are unable to be a full partner in one's fall-prevention program. These patients may have cognitive and immobility deficits, impulsivity, dementia, delirium, and/or lack of safety awareness. Evidence shows that sitters have limited effectiveness to prevent falls and, along with bed alarms, may provide a false sense of safety for nurses, patients, and families (Feil & Wallace, 2014; LeLaurin & Shorr, 2019) and can be intrusive and agitating. Integration of innovative video surveillance technology and continuous observation by monitor technicians that engage patients has significantly reduced falls across age groups (Quigley, Votruba, & Kaminski, 2019). This study adds evidence that continuous observation and timeliness of response are key factors in preventing falls, especially when nursing staff trust the technology (Cournan, Fusco-Gessick, & Wright, 2018).

Interventions to Reduce Trauma: Floor Mats, Hip Protectors

Interventions to protect from injury are separate and distinct from interventions to prevent falls. Injury-reduction interventions include floor mats, hip protectors, and elimination of sharp edges on furniture and room accessories; reduce fall distance; and move furniture from the bedside (Quigley, 2016). Both floor mats and use of low-rise beds have an important place in the effort to prevent the occurrence of serious injury when a bed fall occurs for vulnerable populations, patients at risk for injury, or those who have a fall injury history (Boushon et al., 2012). Biomechanical evidence confirms the protective properties of floor mats to reduce trauma (Bowers, Lloyd, Lee, Powell-Cope, & Baptiste, 2008; Crane, Certo, & Goodworth, 2012; Raymond, Catena, & Vaughan, 2011; Wright & Laing, 2012). Floor mats are placed at the bedside to protect the head and the torso and serve to cushion the impact of the fall. Floor mats are a standard of care to protect patients from injury when they fall from bed or chair (Ganz et al., 2013; Pearson & Coburn, 2011). All organizations should purchase only floor mats with beveled edges to reduce trip hazards and consider glow-in-the-dark strips for nighttime detection.

Hip protector clothing absorbs trauma and reduces hip-fracture risk and is often included in injury prevention programs (Boushon et al., 2012; Pearson & Coburn, 2011). Hip protectors retain protective properties to shield a hip from fracture (Bulat, Applegarth, et al., 2008). When pooling data from cluster randomized trials involving elderly in nursing homes, hip protectors were found to decrease risk of hip fracture (Sawka et al., 2007). In clinical practice, hip protectors are offered to patients at risk for hip fracture in the event of a lateral fall. Prudent patient safety environments would ensure that older adults at risk for hip fracture or who have already sustained hip fracture would have the same safety net offered in long-term care (LTC) to that of hospitals. In addition, many clothing options are available: pants, sweatpants, shorts,

undergarments, incontinent briefs. Floor mats and hip protectors have the greatest protective properties to reduce trauma due to falls and are feasible paired interventions to reduce trauma for vulnerable populations—those 85 years of age and older and those at risk for fracture or fracture history (Zubkoff et al., 2018).

CASE STUDY 23.1

Mrs. S is an 80-year-old White woman admitted to the step-down rehabilitation unit at the hospital following a 3-week admission for treatment of a community-acquired pneumonia. Mrs. S received intravenous antibiotics and fluids for management of the infiltrate and associated dehydration. Mrs. S's hospitalization was complicated by the development of acute confusion, which escalated following the use of IV theophylline and the use of Ventolin nebulizers. Mrs. S also developed a deep vein thrombosis of the leg, which was treated with IV heparin, and she now receives Coumadin. Mrs. S's fall risk score was significant for visual impairment because of a cataract, delirium, focal lower extremity weakness resulting from osteoarthritis, chronic obstructive lung disease, and forgetfulness with short-term memory loss. She is at risk for injury because of osteoporosis and anticoagulation.

Before this hospitalization, Mrs. S was functioning independently in her home, until her son and daughter found her on the floor, mildly confused and disoriented, complaining of dizziness. Mrs. S was transported to the emergency department for further evaluation. She was diagnosed with a right lung infiltrate via chest x-ray and moderate to severe dehydration. An IV line was started, and she was treated with antibiotics and admitted for observation. A 12-lead electrocardiogram showed a sinus bradycardia at 54 beats/minute (bpm). A CT scan of the head was not performed; rather, Mrs. S was placed on observation and admitted to a medical–surgical unit.

After the 3-week long hospitalization, Mrs. S was transferred via wheelchair to the rehabilitation unit. During the admission assessment, you note Mrs. S's fall risk increased from baseline as a result of increased confusion/disorientation, periods of restlessness, and reduced mobility. Mrs. S's vital signs are stable. You learn in the nursing report that Mrs. S needs constant supervision, or she wanders off the unit. During the physical examination, you are paged overhead and respond by going to the nursing station. When you return to examine Mrs. S, she is gone. A second overhead page is called "stat" for assistance on your unit. Mrs. S was found sitting on the floor outside of the elevator, complaining of pain in her right hip and right ankle.

The immediate PFA shows possible loss of consciousness as Mrs. S was observed unresponsive for a few seconds. There is evidence of a head injury with a laceration and hematoma to the scalp as well as right lower leg pain and swelling. Mrs. S's sitting blood pressure is 80/50 mmHg, and her pulse rate is 60 bpm—regular, but weak. Ice is applied to her scalp and her leg is immobilized. The physician is notified immediately, and a stat CT scan of the head is ordered, later confirming an acute intracranial bleed. Mrs. S is prepared for cranial surgery and then hip-fracture repair the following day.

Discussion

1. What nursing actions should have been taken to prevent the fall and serious injury?
   Mrs. S is at high risk for serious injury, as indicated by her fall risk screen score and use of the anticoagulation medication Coumadin. The standard of practice for caring for an older adult hospitalized with increased risk of falls with serious injury requires the nurse to recognize that this patient is likely to have impaired judgment and inability to follow directions because of her disorientation, relocation to a new unit, and evidence of restlessness. Because she is ambulatory, but forgetful, this creates a situation in which the patient needs constant supervision. Mrs. S should be allowed to ambulate, but only with one-on-one supervision and/or physical assistance whenever possible. The nurse failed to recognize the importance of providing constant supervision to the patient. Actions that should have been undertaken include constant supervision by support staff, such as volunteers and/or a special assignment of a nurse's aide to stay with the patient. Family would need to be notified of this decision and to enlist their support for considering a private-duty nurse's assistant. Acute confusion or delirium renders Mrs. S unsafe to make the necessary decisions or judgments about her care.

   In terms of preventing serious injury, Mrs. S could be offered a hip protector as such protection is indicated for older adults who are deemed at high risk for fracture. Osteoporotic older adults who fall are likely to fracture an extremity or incur serious injury. A low-rise bed and floor mats should be used because she is at high risk for falling from bed again. Her needs can be anticipated by regular

(*continued*)

CASE STUDY 23.1 (*continued*)

rounds and by offering the use of the toilet, which can help prevent urinary accidents and/or falls when walking toward the bathroom.

It is imperative that Mrs. S be allowed to continue to move freely and ambulate provided she is supervised and/or assisted because of her disorientation. Daily walking on the unit, in the patient's room, and whenever possible to increase mobility is essential.

2. How should the nursing assessment be focused?
Further assessment for reversible causes of delirium is warranted. As Ventolin has precipitated acute confusion, this drug should be used sparingly and possibly substituted with less "anticholinergic agents." A pharmacy consultation, as part of the interprofessional assessment, would be appropriate. Alternative respiratory interventions for increased pulmonary secretions, such as clapping, postural drainage, deep breathing, and the use of inspirometry, could be instituted.

Further assessment of Mrs. S's falls (i.e., a fall evaluation) is clinically indicated. She has had two falls recently: one at home and the other in the hospital. While the root cause of these falls is unknown, increased evaluation is critical through post-fall huddles and medical evaluation. The history of "being dazed" that occurred in both falls warrants additional workup for orthostasis. In the emergency department, the patient did not receive a CT scan of her head. The fall evaluation includes, among other tests, a 24-hour Holter monitor. A consultation with a geriatrician and/or neurologist is clinically warranted; also, patient-engaged virtual surveillance should be activated to bed exit, room elopement, and, ultimately, the fall and resulting injury. Comprehensive assessment and interdisciplinary care planning are critical to develop and implement her individualized care plan, to mitigate and eliminate fall risk, and to protect her from further injury.

The following case study illustrates a real-life patient fall that resulted in serious physical injury and trauma. The nursing assessment is vital to detect problems that require early intervention/management.

SUMMARY

Fall and serious injury prevention is a shared responsibility by all healthcare providers and professionals caring for older adult patients. National recommendations exist to guide practice and should be routinely incorporated into any fall-prevention program and practice policy. Some of the evidence-based research presented here can help clinicians make choices about which interventions may be the most efficacious or effective, bearing in mind that this choice changes with changes in the patient's condition. Therefore, selecting the most appropriate intervention will always depend on what the nursing and medical assessment determine the likely cause of the fall to be and the medical stability of the patient at that time. Among older adults with advanced years of age with complex illness and multiple comorbidities and geriatric syndromes, this determination becomes increasingly more challenging, but not impossible to make. The safety of older adults in the hospital and continuing on discharge home depends on continual assessment and reevaluation of their condition coupled with education, the use of the most effective and safest technology, and the older adults' knowledge and willingness to participate in evidence-based care.

Nursing staff and hospital organizations are fortunate to have resources of some best practice exemplars used by acute care hospitals in their efforts to reduce patient falls. Exemplars that have been reviewed by expert panels are available from the IHI and AHRQ's fall toolkits (Ganz et al., 2013; NCPS, 2014). Some best practice exemplars and compilation of evidence-based interventions are also addressed in the ANA publication *5 Easy Steps to Prevent Falls: The Comprehensive Guide for Nurses to Keeping Patients of All Ages Safe* (Gray-Miceli, 2014). Framed around a public health model for fall prevention, content includes important steps for practicing professional nurses in fall history taking, fall-focused physical examination, environmental assessment, fall-focused nursing diagnosis and targeted interventions, and patient education through teach-backs (Gray-Miceli, 2014). These resources provide best practice examples to the nursing workforce so that fall knowledge and fall and injury solutions can be implemented in practice.

Hospital organizations vary in their ability to successfully eradicate patient falls. Their success is contingent on many factors in addition to a trained, knowledgeable nursing and interprofessional team workforce. The Joint Commission has suggested that, to become a high-reliability hospital, a series of incremental changes should be undertaken. Leadership's commitment to zero falls, a fully functional culture of safety, and widespread deployment of highly effective process improvement measures are required in their process approach for high-reliability healthcare (Chassin & Loeb, 2013). Quigley and White (2013) discuss components of patient safety culture and the integration of these components with fall prevention, the role of nurses, and high reliability.

NURSING STANDARD OF PRACTICE

Protocol 23.1: Fall Prevention

I. GOALS

A. Reduce preventable falls (accidental and anticipated physiological falls) and serious injury in hospitalized older adults.
B. Mitigate and eliminate multifactorial risks and causes of falls in older adults.
C. Implement fall prevention and management consistent with best available evidence, clinical practice guidelines, and standards of care that are age specific and population based.

II. OVERVIEW

Falls among older adults are not a normal consequence of aging; rather, they are considered a geriatric syndrome most often caused by discrete multifactorial and interacting, predisposing (intrinsic and extrinsic risks), and precipitating (dizziness and syncope) causes (Gray-Miceli et al., 2005; Rubenstein & Josephson, 2006). Fall epidemiology varies according to clinical setting. In acute care, fall incidence ranges from 2.3 to 7 falls per 1,000 patient-days, depending on the unit. Nearly one third of older adults living in the community fall each year in their homes. The highest fall incidence occurs in the institutional long-term care setting (nursing home), where 50% to 75% of the 1.63 million nursing home residents experience a fall yearly. Falls rank as the eighth leading cause of unintentional injury for older Americans and were responsible for more than 16,000 deaths yearly (Oliver et al., 2010).

III. BACKGROUND/STATEMENT OF THE PROBLEM

A. Definition
   1. A *fall* is an unexpected event in which the participant comes to rest on the ground, floor, or lower level (Prevention of Falls Network Europe, 2006).
B. Fall etiology
   1. Fall *risk factors* include intrinsic risks of cognitive, vision, gait, or balance impairment, high-risk/contraindicated medications, and/or the extrinsic risks of assistive devices, inappropriate footwear, restraint, use of unsteady furniture or equipment, poor lighting, and uneven or slippery surfaces.
   2. Fall *causes* include, among others, orthostatic hypotension, arrhythmia, infection, generalized or focal muscular weakness, syncope, seizure, hypoglycemia, neuropathy, and medication.

IV. PARAMETERS OF ASSESSMENT

A. Assess and document all older adult patients for intrinsic risk factors to fall.
   1. Advancing age, especially if older than 75
   2. History of a recent fall, repeat falls, or fall-related injury (Panel on Prevention of Falls in Older Persons et al., 2011)
   3. Specific comorbidities: dementia, hip fracture, type 2 diabetes, Parkinson's disease, arthritis, and depression
   4. Functional disability: use of assistive device
   5. Alteration in level of consciousness or cognitive impairment
   6. Gait, balance, or visual impairment
   7. Use of high-risk medications (Chang et al., 2004)
   8. Urge urinary incontinence (Brown et al., 2000)
   9. Physical restraint use (Capezuti, Maislin, Strumpf, & Evans, 2002)
   10. Bare feet or inappropriate footwear
   11. Identify risks for significant injury resulting from current use of anticoagulants, such as Coumadin, Plavix, or aspirin, and/or those with osteoporosis or risks for osteoporosis (Resnick, 2003).

(*continued*)

Protocol 23.1: Fall Prevention (*continued*)

B. Assess and document patient-care environment routinely for extrinsic risk factors for fall, and institute corrective action:
   1. Floor surfaces for spills, wet areas, and unevenness
   2. Proper level of illumination and functioning of lights (night-light works)
   3. Tabletops, furniture, and beds are sturdy and in good repair
   4. Grab rails and bars are in place in the bathroom
   5. Adaptive aids work properly and are in good repair
   6. Bed rails do not collapse when used for transitioning or support
   7. Patient gowns/clothing do not cause tripping
   8. IV poles are sturdy if used during mobility, and tubing does not pose a safety hazard for tripping

C. Perform PFH and a comprehensive PFA following a patient fall to identify possible fall causes (if possible, begin the identification of possible causes within 24 hours of a fall) as determined during the immediate, interim, and longitudinal post-fall intervals. Because of known incidences of delayed complication of falls, including fractures, observe all patients for about 48 hours after an observed or suspected fall (ECRI Institute, 2006; Gray-Miceli et al., 2006; Panel on Prevention of Falls in Older Persons et al., 2011).

D. Perform a physical assessment of the patient at the time of the fall, including vital signs (which may include orthostatic blood pressure readings); neurological assessment; and evaluation for head, neck, spine, and/or extremity injuries.
   1. Once the assessment rules out any significant injury:
      a. Obtain a history of the fall by the patient or witness description and document
      b. Note the circumstances of the fall, location, activity, time of day, and any significant symptoms
      c. Review underlying illness and problems
      d. Review medications
      e. Assess functional, sensory, and psychological status
      f. Evaluate environmental conditions
      g. Review risk factors for falling (American Medical Directors Association, 2003; ECRI Institute, 2006; Panel on Prevention of Falls in Older Persons et al., 2011; Resnick, 2003).

E. In the acute care setting, an integrated multidisciplinary team (comprised of the physician, nurse, healthcare provider, risk manager, physical therapist, and other designated staff) plans care for the older adult at risk for falls or who has fallen, hinged on findings from an individualized assessment (ECRI Institute, 2006; The Joint Commission, 2007).

F. The process approach to an individualized PFA includes use of standardized measurement tools of patient risk in combination with a fall-focused history and physical examination, functional assessment, and review of medications (American Medical Directors Association, 2003; Panel on Prevention of Falls in Older Persons et al., 2011; Resnick, 2003). When plans of care are targeted to likely causes, individualized interventions are likely to be identified. If falling continues despite attempts at individualized interventions, the standard of care warrants a reexamination of the older adult and his or her fall.

V. NURSING CARE STRATEGIES

A. General safety precaution and fall-prevention measures that apply to all patients, especially older adults, include:
   1. Assess the patient-care environment routinely for extrinsic risk factors, and institute appropriate corrective action.
      a. Use standardized environmental checklists to screen; document findings.
      b. Communicate findings to risk managers, housekeeping, maintenance department, all staff, and hospital administration if needed.
      c. Reevaluate environment for safety (ECRI Institute, 2006).

(*continued*)

Protocol 23.1: Fall Prevention (*continued*)

2. Screen/assess older adult patient for multifactorial risk factors for fall on admission, following a change in condition, on transfer to a new unit, and following a fall (ECRI Institute, 2006; NCPS, 2014):
   a. Use standardized or empirically tested fall risk tools in conjunction with other assessment tools to evaluate risk of falling (Panel on Prevention of Falls in Older Persons et al., 2011; Tinetti, Williams, & Mayewski, 1986).
   b. Document findings in nursing notes, interprofessional progress notes, and the problem list.
   c. Communicate and discuss findings with interprofessional team members.
   d. In the interprofessional discussion, include review and reduction or elimination of high-risk medications associated with falling.
   e. As part of fall protocol in the facility, flag the chart or use graphic or color display of the patient's risk potential to fall.
   f. Communicate to the patient and the family caregiver the identified risk to fall, and specific interventions chosen to minimize the patient's risk.
   g. Include patient and family members in the interprofessional plan of care and discussion about fall-prevention measures.
   h. Promote early mobility and incorporate measures to increase mobility, such as daily walking, if medically stable and not otherwise contraindicated.
   i. On transfer to another unit, communicate the risk assessment and interventions chosen and their effectiveness in fall prevention.
   j. On discharge, review fall risk factors and measures to prevent falls in the home with the older patient and/or family caregiver. Provide patient literature/brochures, if available. If not readily available, refer to the Internet for appropriate websites/resources.
   k. Explore with the older patient and/or family caregiver avenues to maintain mobility and functional status; consider referral to home-based exercise or group exercises at community senior centers. If discharge is planned to a subacute or rehabilitation unit, label the older adult's mobility status at the time of discharge on the transfer, or indicate other types of physical activity in the home to strengthen lower extremities or assist with gait/balance problems.
3. Institute general safety precautions according to the facility protocol, which may include:
   a. Referral to a fall-prevention program
   b. Use of a low-rise bed that measures 14 inches from the floor
   c. Use of floor mats if patient is at risk of serious injury such as osteoporosis
   d. Easy access to call light
   e. Minimization and/or avoidance of physical restraints
   f. Initiate patient-engaged video surveillance
   g. Use proper footwear
   h. Regular toileting at set intervals and/or continence program; provide easy access to urinals and bedpans
   i. Observation during walking rounds or safety rounds
   j. Use of corrective glasses for walking
   k. Reduction of clutter in traffic areas
   l. Early mobility program (ECRI Institute, 2006)
4. Provide staff with clear, written procedures describing what to do when a patient fall occurs.

B. Identify specific patients requiring additional safety precautions and/or evaluation by a specialist or:
1. Those with impaired judgment or thinking caused by acute or chronic illness (delirium and mental illness)
2. Those with osteoporosis, at risk of fracture
3. Those with current hip fracture
4. Those with current head or brain injury (standard of care)

(*continued*)

Protocol 23.1: Fall Prevention (*continued*)

C. Review and discuss with the interprofessional team the findings from the individualized assessment, and develop a multidisciplinary plan of care to prevent falls (Chang et al., 2004).
   1. Communicate to the physician significant PFA findings (ECRI Institute, 2006).
   2. Monitor the effectiveness of the fall-prevention interventions instituted.
   3. Following a patient fall, observe for serious injury resulting from a fall, and follow facility protocols for management (standard of care).
   4. Following a patient fall, monitor vital signs, level of consciousness, neurological checks, and functional status as per facility protocol. If significant changes in patient condition occur, consider further diagnostic tests, such as plain film x-rays, and CT scan of the head/spine/extremity, and provide a neurological consultation and/or transfer to a specialty unit for further evaluation (standard of care).

VII. EVALUATED/EXPECTED OUTCOMES

A. Patients will
   1. Maintain their safety.
   2. Avoid preventable falls.
   3. Not develop serious injury from a fall if it occurs.
   4. Know their risks of falling.
   5. Be prepared on discharge to prevent falls in their homes.
   6. Continue prehospitalization level of mobility.
   7. Those who develop fall-related complications, such as injury or change in cognitive function, will be promptly assessed and treated appropriately should fall-related complications, injury, or cognitive decline occur.
   8. Be fully engaged as a partner in the fall-prevention plan of care.
B. Nursing staff will
   1. Accurately detect, refer, and manage older adults at risk of falling or who have experienced a fall
   2. Integrate into their practice comprehensive assessment and management approaches for fall prevention in the institution
   3. Gain appreciation for older adults' unique experience of falling and how it influences their daily living and functional, physical, and emotional status
   4. Educate older adult patients anticipating discharge about fall-prevention strategies
   5. Collaborate and coordinate fall prevention as members of interprofessional teams
C. Family caregivers will
   1. Benefit from added knowledge about fall prevention to become sensitized and more aware of simple strategies to prevent falls
   2. Be fully engaged in patient safety efforts
D. Healthcare organizations will
   1. Realize reduced fall and injurious fall rates
   2. Realize the benefits of fall-prevention programs that minimize liability
   3. Support budgetary lines for fall-prevention interventions directed to patients and healthcare staff

VIII. FOLLOW-UP MONITORING OF CONDITION

A. Monitor fall incidence and incidences of patient injury caused by a fall, comparing overall fall rates, rates by type of fall, and root causes of fall events, within and across units over time.
B. Compare falls, falls with injury, and percentage of falls with major injury per quarter against national benchmarks available in the National Database of Nursing Quality Indicators.
C. Incorporate continuous quality-improvement criteria into fall-prevention program.

(*continued*)

Protocol 23.1: Fall Prevention (*continued*)

D. Identify fall team members and roles of clinical and nonclinical staff (ECRI Institute, 2006).
E. Educate patient and family caregivers about fall-prevention strategies so they are prepared for discharge.

Reducing Adverse Drug Events in the Older Adult*

DeAnne Zwicker, Carolina Carvajal, and Terry Fulmer

24

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Conduct a comprehensive geriatric medication assessment and identify risks for adverse drug events (ADEs).
2. Describe five reasons older adults experience ADEs.
3. Delineate strategies to prevent common medication-related problems in older adults.
4. Define The Joint Commission safety goals on reconciling medication to reduce ADEs.

OVERVIEW

Adverse drug events (ADEs) comprise the largest single category of adverse events experienced by hospitalized patients (Brennan et al., 1991). In a community retrospective cohort study, at least 1 in 785 hospitalized patients had an ADE within a 6-month period (Cahir, Bennett, Teljeur, & Fahey, 2014). Furthermore, the occurrence of ADEs is associated with increased morbidity, mortality, and costs in care (Poudel, Acharya, Ghimire, Dhital, & Bharati, 2017). A systematic review of 16 studies that examined the effect of Computerized Physician Order Entry (CPOE) found that CPOE was associated with half as many errors as paper entry, which is a promising finding, but much is needed to be accomplished to eradicate all ADEs (Nuckols et al., 2014).

The Institute of Medicine estimates between 380,000 and 450,000 annual ADEs occurred in the United States in 2007 (Aspden, Wolcott, Bootman, & Cronenwett, 2007). Assuming 400,000 preventable ADEs each year, at an incremental hospital cost of $5,857 per ADE, $3.5 billion was spent in 2006 alone (Aspden et al., 2007). These findings were also referenced by the National Academies of Sciences, emphasizing the importance, relevance, and paucity of progress to date (National Academies of Sciences, Engineering, & Medicine, 2018). Others have found that ADEs in community hospitals cost more than $3,000 on average and increased length of stay by 3.1 days (Hug, Keohane, Seger, Yoon, & Bates, 2012).

BACKGROUND AND STATEMENT OF THE PROBLEM

Adverse Drug Events

ADEs are defined as "an injury resulting from medical intervention related to a drug" (Kohn, Corrigan, & Donaldson, 2000, p. 33). This includes medication errors, adverse drug reactions (ADRs), allergic reactions, and overdoses (for more information regarding ADE

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

terminology, see the resource "Clarifying Adverse Drug Events: A Clinician's Guide to Terminology, Documentation, and Reporting"). ADEs, compared with medication errors, are a more direct measure of patient harm. Almost 100,000 emergency hospitalizations in the United States were due to ADEs in adults 65 years of age or older, with nearly half occurring in adults 80 years of age and older (Budnitz, Lovegrove, Shehab, & Richards, 2011). This number is likely much higher, as only 50% of all ADEs are reported in U.S. hospitals, with most going unreported. ADEs also increase costs to patients, length of hospital stay, and mortality (Levinson, 2018).

Older adults are the largest consumers of prescription and over-the-counter (OTC) medications (Hamilton, Gallagher, Ryan, Byrne, & O'Mahony, 2011) and thus contribute to increased risk. A longitudinal study of a community-dwelling sample of older adults aged 62 to 85 found an increase in the use of prescription medications, dietary supplements, and concurrent use of interaction medicines by 15% in 2011 when compared to 2005 (Qato, Wilder, Schumm, Gillet, & Alexander, 2016). Furthermore, ADEs are thought to cause 10% to 30% of all hospital admissions in older adults (Thomas et al., 2013), with an increase in the number of ADE incidents occurring after discharge. Kanaan et al. (2013) found that of the identifiable ADEs during a 45-day follow-up after hospitalization, 35% of ADEs were preventable and suggests the need for quality and safety medication errors to extend beyond a singular assessment tool (Kanaan et al., 2013). Intrinsic factors such as advanced age, frailty, and polypharmacy further contribute to greater risks in adverse outcomes (Buck et al., 2009). National patient safety goals established by The Joint Commission (2019) require healthcare organizations to implement comprehensive medication reconciliation (MR) at every transition point, including admission, transfer, and discharge along the continuum of care through collaborative efforts.

Also, when a new symptom develops in a person taking multiple medications, the symptom must always be considered an ADE first, particularly in frail hospitalized patients. Providers should evaluate the relationship between the new symptom and most recent medications prescribed to identify potential cause. Inappropriate treatment of a new symptom may result in a prescribing cascade of multiple drug treatments and possibly result in an ADR (Petrovic, van der Cammen, & Onder, 2012). In a systemic review, medication review may reduce emergency department visits in older adults (Christensen & Lundh, 2016).

Adverse Drug Reactions

ADRs are preventable causes of harm to patients and, as previously mentioned, an unnecessary use of healthcare resources (Lavan & Gallagher, 2016). Predicting risk of ADRs includes changes in pharmacokinetics and pharmacodynamics, increasing burden of comorbidity, polypharmacy, inappropriate prescribing, and suboptimal monitoring (Branowicki et al., 2017). Risk tools for evaluation of ADRs are available, but none have sufficient predictive and detection value. However, hospital postdischarge interventions such as home visits and follow-up phone calls from medical team members can contribute to reduced hospital readmissions (Branowicki et al., 2017). Good clinical practices during clinic visits and hospital admissions such as detailed documentation and regular review of prescribed medications can also assist in better detection (Branowicki et al., 2017).

Caution is also recommended for newly assigned medication to patients with clear statements of therapeutic goals and recognition of the impact a particular drug can have on multiple organs (Lavan & Gallagher, 2016). Duplication, additive effects, discontinuation of therapy, skipping medication, changing dose to cause, and physiological antagonism too can contribute to ADRs (Alomar, 2014). For such reasons, prescribers and medical staff should regularly review medication efficacy and be vigilant of ADRs and their contributory factors.

ADRs often go unidentified in older adults because of their atypical presentation. Missed conventional symptoms of disease seen in younger persons such as no pain with an acute abdomen contribute to such unidentified reactions (Steinman & Holmes, 2014). These changes are often prodromal to an acute illness, especially in frail older adults. Symptoms may include a change in functional capacity, falls, vague cognitive changes, behavioral changes, appetite decrease, anorexia, or new onset incontinence (Steinman & Holmes, 2014). It is essential to take patient, family, and nonprofessional care provider reports of subtle symptoms seriously so they are not missed. Timely identification of acute illness with vague presentation enables early treatment of illness, resulting in reduced morbidity and mortality and an enhanced quality of life in older adults. Because atypical presentation makes ADRs difficult to accurately identify, nurses must be aware that ADRs may present themselves in such a manner. One strategy for improving recognition of ADRs is to identify risk factors associated with ADRs (Box 24.1). The most common risk factors include increasing age (85 years or older), multiple medical conditions, polypharmacy or multiple medications, and physical, cognitive, or functional impairment (Steinman & Holmes, 2014).

BOX 24.1

Risk Factors for Potential Adverse Drug Reactions in Older Adults

Medication-Related Factors

Class of medication
- Anticoagulants and antiplatelets
- Cardiovascular meds
- Hypoglycemics (oral and insulin)
- Benzodiazepines
- Antipsychotics
- CNS agents/sedative/hypnotics
- Psychotropics
- Anticholinergics
- NSAIDs
- TCAs
- Opioid analgesics
- Corticosteroids

Specific medication
- Warfarin
- Digoxin
- Diuretics
- Benadryl
- Lithium salts
- Chlorpropamide
- Theophylline
- Beta blockers
- ACEI/ARBS
- ASA

Patient characteristics
- Polypharmacy
- Dementia/Memory problems
- Multiple chronic medical problems (>4–6)
- Reduced homeostatic mechanisms
- Reduced lean body mass
- Renal insufficiency (CrCl <50 mL/min)
- Recent hospitalization
- Advanced age (85 years of age)
- Frailty
- Multiple prescribers
- Regular use of alcohol (~1 fl oz/d)
- Geriatric syndromes
- Prior ADR
- Nonadherence
- Alcohol misuse/abuse

Provider factors
- Prescribing potentially inappropriate medications
- Individual clinical information for prescribing
- Inadequate monitoring of adherence
- Adding medication for nonspecific indication
- Regular medication review
- Monitoring: new medication, lab parameters, follow-up visit
- Identifying functional changes—self-administration ability

ACEI, angiotensin converting enzyme inhibitors inhibitors; ADR, adverse drug reaction; ARBS, angiotensin-receptor blockers; ASA, acetylsalicylic acid; COX, cyclooxygenase; CrCl, creatinine clearance; NSAIDs, nonsteroidal anti-inflammatory drugs; TCAs, tricyclic antidepressants.

High-Risk Medications

Several high-risk drug classes have been consistently associated with ADEs in hospitalized patients. Anticoagulants, antihyperglycemic agents, sedatives, narcotics, antibiotics, antipsychotics, and chemotherapeutics are the leading drug classes associated with ADEs. A common feature among these drugs are narrow therapeutic windows that require close monitoring and dose adjustments that contribute to potential errors in timing calculations (Evans, Lloyd, Stoddard, Nebeker, & Samore, 2005). Older adults experience medication-related events for five major reasons:

1. *Alterations in pharmacokinetics:* a reduced ability to metabolize, distribute, and absorb drug along with *pharmacodynamics*; physiological effects, that is, what the drug does in binding at the receptors (Rochon, 2019).

2. *Polypharmacy:* referred to as the use of five or more medications on a daily basis (Fulton & Riley Allen, 2005) and experience of an ADE while taking multiple medications at a single time (Qato et al., 2016).
3. *Therapeutic failures:* under- or overdosage of therapeutics. Failure in accomplishing treatment goals as a result of inappropriate drug therapy and in no relation to the natural progression of disease (Fillit, Rockwood, & Young, 2016).
4. *Iatrogenic causes:* illness due to medication as a result of ADRs, inappropriate prescribing, medication errors, and use of medication for treatment of symptoms that are not disease dependent or specific, such as self-medication or prescribing cascades (Rochon, 2019).
5. *Medication adherence:* taking medication as assigned by a doctor and/or pharmacist professional. Additionally, medical adherence is further defined as a two-way form of communication in which a patient and medical provider assume active roles in fulfilling the set therapeutic regimen (Lo, Chau, Woo, Thompson, & Choi, 2016).

Older adults often combine OTC medications with prescription medications or herbal remedies yet do not report their use to healthcare providers. Likewise, providers often do not inquire about OTC medications or herbal remedies. Underreporting may lead to ADEs, including unrecognized adverse drug–disease or drug–drug interactions (Lopez-Gonzalez, Herdeiro, & Figueiras, 2009; see Table 24.1 and Table 24.2). Patient safety in medication management is a major focus in older adults; however, current information on use of prescription medications, OTC medications, and dietary supplements is still limited (Qato et al., 2008). It is important to differentiate an ADR from an ADE (see Figure 24.1).

TABLE 24.1

Common Drug–Drug Interactions

Drug 1	Drug 2	Interaction	Effects
Warfarin (Coumadin)	Diltiazem	Inhibits drug	↑ Anticoagulation
Warfarin	Verapamil	Metabolism	Potential bleeding
Warfarin	Metronidazole	Metabolism	Potential bleeding
Warfarin	NSAID	NSAID ↓ prostaglandins. Increases GI erosion. ↓ Platelet aggregation	GI bleeding
Warfarin	ASA	Same as NSAID	GI bleeding
Warfarin	Sulfa drugs	Unknown	↑ Warfarin effects
Warfarin	Acetaminophen-opiate combination Fluconazole Cipro Biaxin	↑ INR	Bleeding
Digoxin	Amiodorone	↓ Renal/nonrenal clearance of digoxin	Digoxin toxicity
Digoxin	Clarithromycin	↓ Renal clearance of digoxin	Digoxin toxicity
Digoxin	Verapamil	↓ Impulse conduction and muscle contraction	Potential bradycardia or heart block
Levothyroxine	Calcium carbonate	L-thyroxine (T_4) absorbs calcium carbonate	ACE inhibitors absorption of L-thyroxine (T_4)
Glyburide	Co-trimoxazole	Potentiates effect of sulfonylureas	Hypoglycemia

(*continued*)

TABLE 24.1

Common Drug–Drug Interactions (*continued*)

Drug 1	Drug 2	Interaction	Effects
ACE inhibitors	Potassium-sparing diuretics	Unknown	Life-threatening hyperkalemia
Diuretics	NSAIDs	ACE inhibitors renal perfusion	Renal impairment
Phenytoin (Dilantin)	Cimetidine Erythromycin Fluconazole	Not specified	Increases levels of phenytoin within 1 week
Theophylline	Quinolones	↓ Liver metabolism of theophylline	Theophylline toxicity
Acetylcholinesterase inhibitor, e.g., Aricept, Exelon	Anticholinergics	↓ Ability to augment acetylcholine level	Therapy less effective

ACE, angiotensin converting enzyme; ASA, aspirin; CNS, central nervous system; GI, gastrointestinal; INR, international normalised ratio; NSAID, nonsteroidal anti-inflammatory drug; SSRI, selective serotonin reuptake inhibitor.

Sources: Data from Ament, P. W., Bertolino, J. G., & Liszewski, J. L. (2000). Clinically significant drug interactions. *American Family Physician, 61*(6), 1745–1754. TABLE 24.2

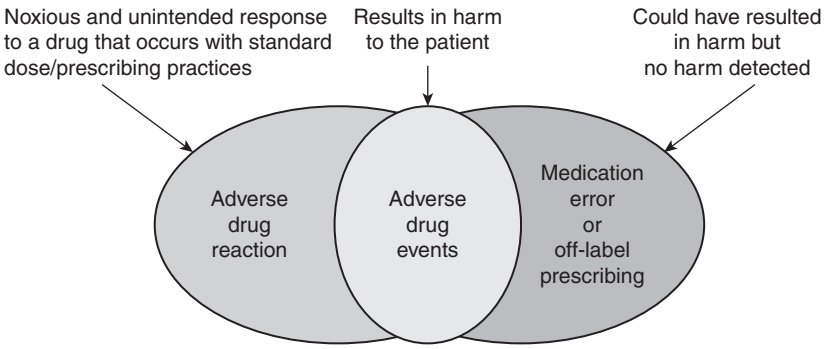
Potentially Harmful Drug–Drug Interactions



Drug Agent at Risk	Potentially Harmful Drug Interaction With (Example)
Angiotensin-converting enzyme (ACE) inhibitors (e.g., lisinopril)	Potassium-sparing diuretics (spironolactone)
ACE inhibitors (e.g., lisinopril) or angiotensin receptor blockers (losartan [Cozaar])	Sulfamethoxazole/trimethoprim (Septra DS or Bactrim)
Benzodiazepines (Ativan or Xanax) Zolpidem (Ambien)	Many interacting medications—not all inclusive: alcohol, CNS agents, antifungals (Ketoconazole), SSRIs (Paxil or Prozac), anticonvulsants, beta agonists, macrolides, h2 receptor agonists (cimetidine)
Calcium channel blocker Amlopidine (Norvasc)	Macrolide antibiotics Azithromycin (Zithromax); erythromycin
Digoxin	Macrolide antibiotic Azithromycin (Zithromax), erythromycin
Lithium	Loop diuretics or ACE inhibitors (Lasix or lisinopril, respectively)
Phenytoin (Dilantin)	Sulfamethoxazole/trimethoprim (Septra DS or Bactrim)
Sulfonyureas (glipizide, glyburide)	Antimicrobial agents (antibiotics)
Theophylline	Ciprofloxacin (Cipro)
Warfarin (Coumadin)	Antimicrobials (antibiotics) or NSAIDs (nonsteroidal anti-inflammatory drugs) (Aleve or ibuprofen)

CNS, central nervous system; SSRI, selective serotonin reuptake inhibitor.

Medication Adherence

Medication adherence is "the process by which patients take their medication as prescribed" (Vrijens et al., 2012, p. 691). Specifically, adherence is composed of *initiation*—time when a patient takes his or her first dose of prescribed medication; *implementation*—extent to which actual dosing corresponds to the prescribed dosing regimen; and *discontinuation*—when the patient stops taking medication for any reason (Vrijens et al., 2012).

A systematic review performed on persons with diabetes showed adherence rates varying from 31% to 87%. Age is not a risk factor for medication nonadherence; however, chronic illness and taking multiple medications does increase risk (Phillips, Christenfeld, & Glynn, 1998). Medication adherence to high-risk older adults may be considered as the most likely to have difficulty, especially when considering multiple conditions, greater costs, and increase in medications prescribed.

Medication Errors

The National Coordinating Council for Medication Error Reporting and Prevention (n.d.-a) defines *medication errors* "as any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of a health care professional, patient, or consumer" (para. 2). A large percentage of errors are caused by incorrect medication administration and dose. Errors in time interval and incorrect medication assignment, along with negligence and prescribing errors, are also contributors. Emphasis and priority have been placed in healthcare policy reforms on improving the safety profile of healthcare delivery systems to reduce prescription errors (Aspden et al., 2007). Prescription errors commonly occur at hospital admission followed by other transitions in levels of care.

ASSESSMENT TOOLS AND INNOVATIVE STRATEGIES

Age-Friendly Health Systems

The Institute for Healthcare Improvement (IHI) has, in partnership with the John A. Hartford Foundation in New York City, taken on the bold challenge of creating age-friendly health systems in 20% of American health systems by 2020. This work, characterized as a social movement, aims to accelerate the quality and safety of care for older adults across the care continuum (Fulmer & Berman, 2016; Fulmer, Mate, & Berman, 2018). In creating a conceptual model, a team of experts have arrived at a patient model, referred to as the 4Ms. It is comprised of the following four areas: what *m*atters to the patient, *m*entation, *m*obility, and *m*edications. Together, they constitute the critical elements to be addressed when taking care of older adults. If any of the four Ms are not addressed appropriately, each and all are likely to have a cascading effect in a detrimental direction. Medication problems, for example, are likely to create problems within all areas of this model. By using the very best evidence from geriatric assessment literature, the friendly-age health systems initiative ensures approaches to care improvement are evidence based and reliably implemented.

Tools for Medication Assessment in Older Adults

Geriatric assessment tools are used to evaluate an older adult's ability to self-administer medications, including:

- Physical and cognitive functional capacity
- Review of the patient's medication list for potentially inappropriate medications (PIMs) that are indicated but underutilized
- MR/Evaluation for potential drug–drug or drug–disease interactions that assist in renal function assessments
- Encouraging the Brown Bag Method to augment reconciliation

Each of these methods should be patient/family-centered and include collaboration with interdisciplinary team members.

Beers Criteria

The Beers Criteria, also known as the Beers List, is a medication list compiled by the American Geriatrics Society of medications to generally avoid or use with caution in adults 65 years of age and older in view of potential harmful side effects and drug-to-drug interactions. The list comprises avoidance and adjustments of medications for older adults with kidney dysfunction and other specific health conditions outside of hospice and palliative care settings. Overall, the Beers Criteria is a tool that provides an essential starting point for discussion among medical providers, caregivers, and older adults (American Geriatrics Society, 2019).

STOPP and START

The **STOPP** criteria are intended to identify potentially inappropriate prescriptions (PIPs vs. PIMs) by physiological systems and include several more medications than the Beers Criteria (Hamilton et al., 2011). The prevalence of inappropriate medications in hospitalized older adults using this criterion was determined to be between 35% and 77% (Gallagher & O'Mahony, 2008; Hamilton et al., 2011).

The **START** criteria identify potential prescription omissions of medications that should be prescribed in hospitalized adults. According to the **START** criteria, 41.9% to 66% of hospitalized older adults experienced either undertreatment or omission of an appropriate medication (Lang et al., 2012). Overall, the **START** criteria are a vital tool in alerting doctors to the right treatment and recommend important medications for specific chronic conditions often omitted. The tool is intended to be used simultaneously with **STOPP** Criteria (Gallagher, O'Connor, & O'Mahony, 2011).

In a randomized controlled trial, the **STOPP** and **START** criteria were employed to identify PIPs and potentially omitted prescriptions (POPs) as determined by a pharmacist who made recommendations based on the criteria. Researchers reported a significant decrease in PIPs and POPs in the intervention group but not in the control group at the 6- to 12-month follow-up (Frankenthal, Lerman, Kalendaryev, & Lerman, 2014). The intervention group also showed a decline in falls and indicates how pharmacist–physician collaboration in using the **STOPP** and **START** criteria in older adults may aid in decreasing ADEs.

Recent updates to the START and STOP criteria include expansion and update for the purpose of minimizing inappropriate prescriptions and adding new evidence-based criteria in view of expanding therapeutics. They are as follows:

- New **STOPP** categories in antiplatelet/anticoagulants, drugs that affect/are affected by renal function, increase in anticholinergic burden, minimizing inappropriate prescribing. Overall, these new categories and updates assist in identifying PIMs and are more extensive than the Beers Criteria in identifying a greater number of older adults needing hospitalization because of ADEs (O'Mahony et al., 2015).
- New **START** categories in urogenital and analgesics and vaccines (O'Mahony et al., 2015).

Cockroft–Gault Formula

The Cockroft–Gault Formula is useful for estimating/predicting creatinine clearance based on age, weight, and serum creatinine levels (Terrell, Heard, & Miller, 2006). A creatinine clearance of less than 50 mL/min places older adults at risk for ADEs, and virtually all people over 70 have a creatinine clearance of less than 50. It is important to note this formula may estimate far higher creatinine levels in older adults than actual glomerular filtration rates, particularly those of lower weight (see Exhibit 24.1).

Brown Bag Method

The Brown Bag Method is used to assess all medications an older adult has at home, including prescriptions from all providers, and includes OTC medications and herbal remedies. All medications at home are placed in a bag and brought to the hospital/other care settings and

EXHIBIT 24.1

Cockroft–Gault Formula for Estimation of Creatinine Clearance (CrCl)

Formula for men:

$$\text{CrCl in milliliters per minute}^{a} = \frac{(140 - \text{age in years})(\text{weight in kilograms})}{72(\text{serum creatinine in milligrams per deciliter})}$$

Formula for women: Use formula for men and multiply by 0.85

[a] A creatinine clearance of less than 50 mL/min places older adults at risk of ADEs, and virtually all people older than 70 years have a creatinine clearance of less than 50.

ADEs, adverse drug events.

should be used in conjunction with a complete medication history (Nathan, Goodyer, Lovejoy, & Rashid, 1999). Implementation of the Brown Bag Method should follow a cohesive and action plan method for its effectiveness, since its use is usually varied. In a study of a small medical private practice and urban medical practice, MR was improved when action plans in regard to how to remind and tell patients what to bring before their appointments along with methods in praise and tracking progress were clearly defined (Weiss et al., 2016). Although the researchers suggest limitations due to a small sample, the significant improvements suggest action plans in larger settings could assist in improving MR (Weiss et al., 2016).

Drug Regimen Unassisted Grading Scale (DRUGS) Tool

This is a standardized method of assessing the ability of older adults managing their own medicine. It is comprised of four progressive tasks: identification, access, dosage, and timing. These progressive tasks are to be conducted for each individual medication (Edelberg, Shallenberger, & Wei, 1999).

INNOVATIVE ASSESSMENT STRATEGIES

Changes With Aging in Pharmacotherapy

Nurses and the interdisciplinary team must first be aware of aging changes in pharmacokinetics and pharmacodynamics when assessing medications in older adults (Steinman & Holmes, 2014). New research is directed at pharmacogenetics and pharmacogenomics with application to ADRs. Inter-individual variations of these genes may account for the differences observed in drug efficacy and appearance. The following describes aging changes:

- *Pharmacokinetics:* The time course of absorption, distribution across compartments, metabolism, and excretion of drugs in the body. As the body ages, the metabolism and excretion of many drugs decline, and physiological changes require dosage adjustment for some drugs. The vast majority of drugs are cleared either through liver or renal clearance (Steinman & Holmes, 2014).
- *Changes in drug absorption* (e.g., increased gastric pH and decreased gastrointestinal motility).
- *Drug distribution:* Includes decreased cardiac output, reduced total body water, decreased serum albumin (which is more likely to be related to malnutrition or acute illness than aging), and increased body fat. Changes in tissue or plasma binding can change the apparent volume of distribution determined from plasma concentration measurements. Older adults have a relative decrease in skeletal muscle mass and tend to have a smaller volume of distribution (Vd) such as Vd of digoxin, which binds to muscle proteins.
- *Reduced total body water:* Creates a potential for higher serum drug levels owing to low volume of distribution and occurs with water-soluble drugs (hydrophilic) such as alcohol or lithium. Decreased serum albumin results in higher unbound drug levels with protein-bound drugs such as warfarin, phenytoin, digoxin, and theophylline. Drugs that distribute in fat (e.g., diazepam) may thus have a larger volume of distribution. These lipophilic drugs (e.g., long-acting benzodiazepines [BZDs]) are stored in the body fat and slowly leech out, resulting in increased half-life, with the drug staying around longer (Salvi et al., 2012; Steinman & Holmes, 2014).

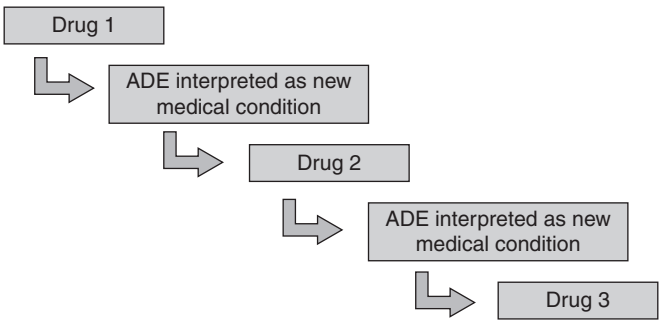
Strategies to Improve Medication Adherence in Older Adults

Although medication adherence has been well studied, there are few data on what specific interventions work to improve medication adherence (for more information, see the resource "Interventions to Improve Medication Adherence: A Review"). Various strategies can be used to assist in overcoming barriers to medication adherence. One of them requires healthcare providers to change how they think about and discuss medication use with patients. Posing open-ended questions such as "How many doses of your medication have you missed over the past week?" as opposed to closed-ended questions such as "Have you missed any doses of medication?" allows patients an opportunity to voice a concern. Using more open-ended questions and a nonjudgmental tone of voice can improve communication and allow for more information to be exchanged.

Identification of ADEs

ADRs in older adults often go unidentified because of their atypical presentation in older adults. Missed conventional symptoms of disease seen in younger persons (Steinman & Holmes, 2014), such as no pain with an acute abdomen, contribute to unidentified reactions. These changes are often a prodrome (symptom(s) indicative of an approaching disease) of an acute illness, especially in frail older adults. Symptoms may include a change in functional capacity, falls, vague cognitive changes, behavioral changes, appetite decrease, anorexia, or new onset incontinence (Steinman & Holmes, 2014). It is essential to take patients, family, and nonprofessional care provider reports of subtle symptoms seriously so they are not missed. Timely identification of acute illness with vague presentation enables early treatment of illness, resulting in reduced morbidity and mortality and an enhanced quality of life in older adults. Atypical presentation makes ADRs difficult to accurately identify; thus, nurses must be aware that ADRs may present atypically. One strategy for improving recognition of ADRs is to identify risk factors associated with ADRs. The most common risk factors include increasing age (age 85 years or older), multiple medical conditions, polypharmacy or multiple medications, and physical, cognitive, or functional impairment (Steinman & Holmes, 2014).

When a new symptom develops in a person taking multiple medications, the symptom must always be considered an ADE first, particularly in the frail hospitalized patient. Providers should evaluate the relationship between the new symptom and the most recent medication given to identify the potential cause. Inappropriate treatment of a new symptom may result in a prescribing cascade of multiple drug treatment and possibly an ADR (Petrovic et al., 2012; see Figure 24.2).



Also, in a systematic review, medication review reduced emergency department visits in older adults. Although more research is needed in the efficacy of medication review, the authors suggest medication review should be a part of regular geriatric care (Christensen & Lundh, 2016) and can assist in better identifying an ADE.

Over-the-Counter (OTC) Medications

Older adults are the largest consumers of OTC medications and dietary supplements which may lead to adverse drug-to-drug or drug–disease interaction

FIGURE 24.2

Prescribing cascade.

ADE, adverse drug event.

Source: Reproduced from Rochon, P. A., & Gurwitz, J. H. (1997). Optimising drug treatment for elderly people: The prescribing cascade. *BMJ*, *315*(7115), 1096–1099. doi:10.1136/bmj.315.7115.1096, with permission from BMJ Publishing Group Ltd.

and impaired cognition due to anticholinergic effects (Tachjian, Maria, & Jahangir, 2010). In a systemic review, herbal–drug interactions were found in St. John's wort, ginkgo, garlic, ginseng, and kava and suggests the need for further research on herbal–drug interactions (Izzo & Ernst, 2009). Furthermore, OTC medications with anticholinergic effects can cause impaired cognition and an adverse event, suggesting the need for increased communication and education among older adults and their medical team to reduce a potential adverse event (Holden et al., 2019).

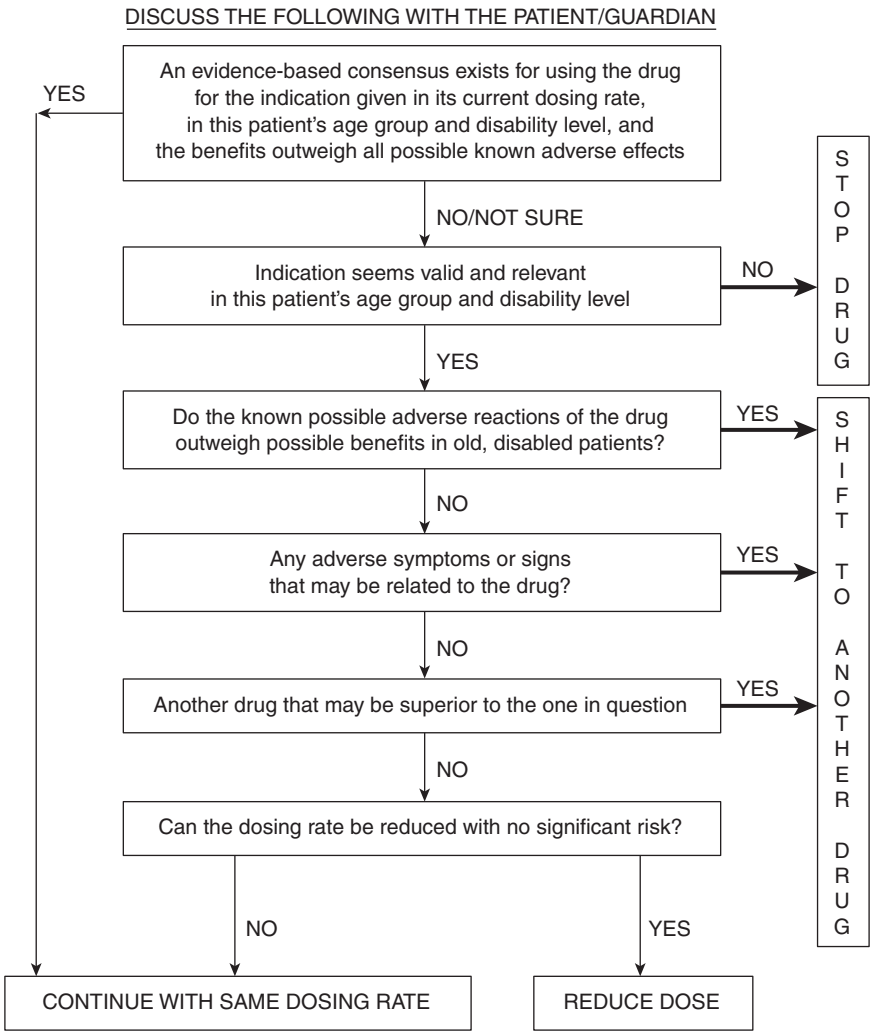
In the United States, community-dwelling older adults take about as many OTC drugs as prescription drugs. In a study of 6,887 patients, self-medication represented about 4% of ADRs, with the remainder of ADRs found in prescribed OTCs (Schmiedl et al., 2014). The study also found women aged 70 to 79 and men aged 60 to 69 experienced an ADE related to self-medication. Of self-prescribed OTC medications, nonsteroidal anti-inflammatory drugs (NSAIDs) and acetylsalicylic acid (ASAs) were the most frequent ADRs causing GI complaints (Schmiedl et al., 2014).

The National Institute on Drug Abuse (NIDA) estimates that 19% of older adults misuse the combination of alcohol and medication (National Institute on Drug Abuse, 2014). Combination of these drugs with alcohol can worsen age-related renal insufficiencies, resulting in chronic salicylate intoxication due to its water solubility. Cold remedies, including those with alcohol, are significant sources of drug potentiation in aging adults. A history of alcohol consumption and OTC ingestion is important to determine drug interactions (National Institute on Drug Abuse, 2014).

Low-dose aspirin and NSAIDs are the most commonly linked OTCs to hospital admissions (Schmiedl et al., 2014). In a study evaluating concomitant use of prescriptions, OTCs and herbal remedies were found to have major interactions in the use of nonprescription therapies in more than half of a sample size of 1,000 older adults (Qato et al., 2008). Within these interactions, almost half involved the use of anticoagulants such as warfarin or antiplatelet agents such as aspirin, with common effects in men rather than women across all age groups. Drug-to-drug interactions increased with age due to nonprescription medications (Qato et al., 2008). Finally, although the FDA has been evaluating OTC ingredients and encouraging active labelling, it is yet to be seen if the FDA will be more specific on safety issues that relate to older adults. Healthcare providers need to specifically ask patients what OTC and herbal remedies they are taking and their frequency.

De-Prescribing

Falls, orthostatic hypotension, delirium, renal failure, and gastrointestinal and intracranial bleeding are the most common clinical problems in ADRs. Increased ADR risk is associated with age-related changes in pharmacokinetics and pharmacodynamics, increasing the burden of comorbidity, polypharmacy, inappropriate prescribing, and suboptimal monitoring of drugs. Prescribers and clinicians should regularly review medication efficacy and be vigilant for ADRs and their contributory risk factors. De-prescribing should occur at an individual level when drugs are no longer efficacious or beneficial or when safer alternatives exist. Inappropriate prescribing and unnecessary polypharmacy should be minimized. Comprehensive geriatric assessment (CGA) and the use of explicit prescribing criteria can be useful in this regard. The Garfinkel algorithm has been suggested as one such evidence-based approach to this end (Garfinkel, 2018; see Figure 24.3).



Many studies have revealed common high-risk medications in older adults. Four medications or medication classes were implicated alone or in combination in 67% of hospitalizations: warfarin (33.3%), insulin (13.9%), oral antiplatelet agents (13.3%), and oral hypoglycemic agents (10.7%; Budnitz et al., 2011). Although warfarin is deemed high risk, it is often underprescribed due to provider fear of bleeding; however, older patients often gain a greater absolute reduction in risk of stroke (Steinman, Handler, Gurwitz, Schiff, & Covinsky, 2011). Purposeful monitoring and special attention given to these medications can significantly reduce the risk of serious adverse effects.

Digoxin should also be closely monitored as one-third of all emergency department visits are digoxin-related ADEs (Salvi et al., 2012; Steinman & Hanlon, 2010). According to a systematic review, monitoring of high-risk medications is more likely to reduce ADEs (versus prescribing interventions) as providers can anticipate and address abnormal results immediately. Thus, proactive and appropriate monitoring is more likely than interventions to reduce ADEs. Other medications to monitor are BZDs, which are an independent risk factor for falls (Rochon, 2019). Prescription of OTC NSAIDs given with cardiac-dose ASA account for 30% of upper GI bleeding-related admissions.

According to the American Geriatric Society, it is now recommended that treatment with proton pump inhibitors (PPIs) be reserved for frequent symptoms or erosive esophagitis, with treatment being administered once a week for 8 weeks with morning meals. Maintenance therapy should be provided for long-term Barrett esophagitis

FIGURE 24.3

Improving drug therapy in elderly patients: The Garfinkel Algorithm.

Source: Garfinkel, D, Zur-Gil, S, & Ben-Israel, J. (2007). The war against polypharmacy: A new cost-effective geriatric-palliative approach for improving drug therapy in disabled elderly people. *Israel Medical Association Journal, 9*(6), 430–434. Retrieved from https://www.ima.org.il/MedicineIMAJ/viewarticle.aspx?year=2007&month=06&page=430

or erosive esophagitis. De-prescribing PPIs is now suggested for those who don't really need treatment, because long-term use may result in bone loss and/or fractures, pneumonia, and vitamin B deficiency.

Prevention of ADEs

It is prudent that healthcare team members are aware of the risk factors for ADEs in older adults and of which medications put older adults at high risk for adverse events. In a prospective observational study, Kongkaew et al. (2013) reported patient age, length of time since starting a new drug, total number of prescription drugs, and hospitalization were significantly associated with ADEs. The most common preventable ADEs were antiplatelet drugs, anticoagulants, diuretics (loop and thiazide diuretics), angiotensin-converting enzyme (ACE) inhibitors, and antiepileptic drugs (Kongkaew et al., 2013). Knowing and recognizing

these drug classes as being at high risk for ADEs support the importance of regular international normalized ratio (INR) monitoring and ongoing evaluation for anticoagulants or chemistry panels for diuretics to monitor electrolytes or potential orthostatic hypotension, particularly in frail older adults. In initiating ACE inhibitors, serum potassium and increasing creatinine levels need to be monitored closely. It is important for nurses to recognize that hypotension and/or hyponatremia can occur when a patient is dehydrated or volume depleted. Patients taking potassium-sparing diuretics may experience hypokalemia, even in the presence of loop diuretics. These high-risk drugs should be on the radar for potential ADEs for all providers (Kongkaew et al., 2013).

Comprehensive Geriatric Assessment

An accurate medication history must be obtained from each patient along with medication history validation. Ascertaining the amount and types of medication typically consumed, including OTC medications and herbal remedies, should be examined, along with estimation of how long each has been taken. The following medication history recommendations by FitzGerald (2009) are suggested to be used in conjunction with MR methods such as the Brown Bag Method:

- Currently prescribed drugs, doses, route of administration, frequency taken, and duration of treatment
- OTC drugs and herbal remedies
- Drugs taken in the recent past
- Previous drug hypersensitivity reaction and the nature (rash or anaphylaxis)
- Adherence to therapy (are you taking your medication regularly? How many pills did you miss this week/month?)
- Obtain up-to-date list from primary provider or pharmacy
- Check with pharmacy regarding prior ADRs and last order dates for each medication
- Inspect drugs and their container for name, dosage, and number of meds taken since dispensation

Also, a CGA is a more global and individualized assessment that ensures a specific plan for a patient (Petrovic et al., 2012). It should be conducted for each individual patient and repeated with any change in status as new symptoms develop. In a study of 746 patients receiving a CGA on admission, IADL dependency, malnutrition, acute kidney injury, and presence of pressure ulcers were found to be independent factors with in-hospital death (Avelino-Silva et al., 2014). However, it should be noted, of the 30 instruments developed to evaluate medication management ability, to date, research has not shown sufficient validity and reliability (Avelino-Silva et al., 2014). However, researchers report the DRUGS Tool and Medication Management Instrument for Deficiencies in older adults are the most promising (Brandt, Gruber-Baldini, & Orwig, 2006).

Questionnaires can assist in assessing potential adverse events and medication adherence. The Brief Medication Questionnaire is a self-report tool that identifies persons at risk for nonadherence (Svarstad, Chewning, Sleath, & Claesson, 1999) and has been validated in a wide range of disease states (Rogers et al., 2009). Likewise, The Morisky Medication Adherence Questionnaire was developed to identify adherence to antihypertensive medications and has good concurrent and predictive validity in low-income and minority patients as it determines patient willingness and ability to take oral medications (Morisky, Ang, Krousel-Wood, & Ward, 2008). A thorough medication review should be performed and include patient adherence variations with attention to OTC drugs and herbal remedies. The review should include a previous history of ADRs as this is a harbinger for future ADRs (Steinman et al., 2011).

Performing a systematic review of interventions using electronic reminders for patients to take medications yielded significant effects on patient adherence in seven of the eight studies reviewed (Vervloet et al., 2012). Of these, seven showed short-term effects in under 6 months of follow-up. Adherence was improved using short message service (SMS) reminders, including four studies using an electronic recording device and one pager reminder (Vervloet et al., 2012).

Medication Reconciliation

MR is the process by which the most accurate patient medication list possible is obtained and compared to physician medication orders throughout the continuum of healthcare services (IHI, 2011) The IHI recommends including the drug name, dose, frequency, and administration route. It should include OTC medications, herbal remedies, vaccinations, supplements, and vitamins. Unintentional medication discrepancies at the time of transitions occur commonly at the time of admission, during intrahospital transfer, and at discharge. About one-third of these discrepancies have the potential to cause patient discomfort or clinical deterioration. MR reduced discrepancies with a decrease in potential ADEs (Mueller, Sponsler, Kripalani, & Schnipper, 2012).

The process of MR has three steps:

- Verification—renewing the patient's medication history and developing an accurate list of medications

- Clarification—ensuring medication(s) and doses are appropriate along with an up-to-date medication list when medication(s) is ordered
- Reconciliation—identifying any discrepancies between medication orders and those on the patient's medication list along with appropriate changes to medication orders; and documenting any changes and communicating an updated medication list to the patient's next provider within or outside the hospital (Mueller et al., 2012).

Patients should also be provided with a written medication information list along with MR at the time of hospital discharge (Mueller et al., 2012). Finally, pharmacists are also optimal team members who can complete MR in the community setting or after discharge as a follow-up of discharge medications. In a systematic review and meta-analysis, the pharmacist's readmission rates reported in five and six cohorts demonstrated reduction in clinically relevant discrepancies in two studies (McNab et al., 2018). Of the 14 studies, no significant readmission rate was reported (McNab et al., 2018).

CASE STUDY 24.1

Medication Reconciliation

Mrs. J is an 80-year-old woman who has lived alone her entire life with regular visits from her daughter. She is admitted to an inpatient geriatric orthopedic unit. She reported to her daughter, who was visiting over the weekend, that she fell at home getting out of the bathroom. Her daughter took her to the hospital, and Mrs. J was diagnosed with intertrochanteric fracture with no other injury. Mrs. J is now being discharged to her home with her daughter's assistance. She has a home nurse coming to evaluate her needs at home and progress daily. She will receive needed equipment, which has already been delivered, have outpatient home visits by a nurse on a daily basis, and receive physical and occupational therapy and evaluations at home.

QUESTION 1

What Are the Most Important Next Steps?

A classic study found that nearly 20% of patients experience adverse events within 3 weeks of discharge, nearly three-quarters of which could have been prevented or ameliorated (Forster, Murff, Peterson, Gandhi, & Bates, 2003). ADEs are the most common postdischarge complication, with hospital-acquired infections and procedural complications also causing considerable morbidity (Forster et al., 2003). More subtle discharge hazards arise from the fact that nearly 40% of patients are discharged with pending test results, and a comparable proportion are discharged with a plan to complete outpatient workup. This places patients at risk, unless timely and complete follow-up is ensured. Nearly 20% of Medicare patients are hospitalized within 30 days of discharge. Minimizing postdischarge adverse events has become a priority for the U.S. healthcare system (Jencks, Williams, & Coleman, 2009).

QUESTION 2

What Should Be Completed Next?

Medication reconciliation (MR) should be performed and compared at each point during transitions in care such as primary provider office, hospital, long-term care, rehabilitation or subacute facilities, surgery, or other levels of care transition or transfer (e.g., between hospital units). MR includes three steps:

- **Verification** involves the collection of an accurate medication history from the patient, family, or other healthcare professionals involved in the patient's care.
- **Clarification** is ensuring medication(s) name, dosage, route, and time of administration are accurate.
- **Reconciliation** includes the documentation of any changes made to medication orders.

QUESTION 3

What Is the Most Important Step in Reconciliation?

Transmission is the final step, in which the updated medication list is communicated to the next care provider (IHI, 2011). MR reduced patients' ADEs caused by admission prescribing changes by 43% (Boockvar et al., 2011). A recent study reported a reduction in emergency admissions with MR; however, two review articles reported difficulties in effective MR using health IT and reported insufficient evidence to support its value (McKibbon et al., 2011).

See Resources: Medications at Transitions and Clinical Handoffs, MATCH

Monitoring for ADEs

Hospitalizations related to ADEs in U.S. older adults are more often related to drugs that require regular monitoring. Safety measures for monitoring high-risk medications such as warfarin, anticonvulsants, and digoxin have been endorsed by the National Quality Forum (Budnitz et al., 2011). 52% of ADE-related hospitalizations can be attributed to monitoring problems. ADEs due to errors in or lack of medication monitoring occur more frequently than prescribing errors in older adults recently discharged from the hospital and those in the community (Budnitz et al., 2011). Monitoring signs, symptoms, and laboratory parameters can determine whether an adverse event has only mild and short-term consequences or major long-term effects on morbidity and mortality (Steinman et al., 2011). Monitoring warfarin closely increases the benefit and decreases bleeding risk by increasing time in the therapeutic INR range. Ongoing monitoring with detection and mitigation of possible harms may improve the use of a very important medication often underprescribed in older adults (Steinman et al., 2011).

As an example, anticoagulants are most likely to cause harm to hospitalized patients because of a variety of factors, including complex dosing, the need for frequent monitoring, and transitions between parenterally and orally administered agents, such as in preparation for surgery or at the time of hospital discharge. Goals and strategies for improving anticoagulation management in inpatient settings have been identified and documented in the 2014 National Action Plan for Prevention of ADEs (see "Resources"). Furthermore, The Joint Commission (2019) identified the National Patient Safety Goal to reduce medication errors (omissions, duplications, dosing error, and drug interactions) by requiring MR at transitions from one level of care to another on admission and discharge.

Other strategies to improve monitoring include using health information technology to link laboratory data with pharmacies, delineation of risk, and patient outreach using a multidisciplinary team-based approach to patient management (direct patient contact and follow-up). Steinman et al. (2011) suggest initial prescribing requires that benefits and harms of drugs are actively monitored, managed, and reassessed over time. They also recommend the use of risk assessment tools. Those individuals predicted to be at risk should be followed with more intensive monitoring of medication regimens. Likewise, patient outreach and activation for lab follow-up is recommended to improve monitoring. Medication management led by pharmacists or nurses in contacting patients after beginning a drug requires that patients be asked about any side effects along with conducting target symptom assessment (Steinman et al., 2011). This would allow for efficient follow-up with the prescribing provider.

Computerized Provider Order Entry (CPOE)

Computerized Provider Order Entry (CPOE) has shown benefits and advantages over paper order writing. This method allows for similar drug names, drug interactions, and specific errors to be integrated into the patients' electronic medical and clinical record to support clinical decisions and ADE reporting. Furthermore, CPOE allows for expedited transmission of lab, pharmacy, and/or radiology results. A meta-analysis reported that the likelihood of prescribing errors decreased by 48% when CPOE was used rather than paper-based orders and reported to equal ~17.4 million medication error preventions in U.S. hospitals (Radley et al., 2013).

The Health Information Technology for Economic and Clinical Health Act (HITECH) was enacted in 2009 with the objective of improving overall health and patient care while decreasing errors and costs (Buntin, Burke, Hoaglin, & Blumenthal, 2011). Many criteria, such as electronic health record (EHR) use, had to be met prior to implementing CPOE and a Meaningful Use Program. Many CPOE systems include drug safety alerts that help to reduce prescribing errors and identify potential drug–drug interactions to improve patient safety. However, there are barriers to CPOE such as cost, efficiency and workflow, and lack of technical support, to name a few (Kruse, Regier, & Rheinboldt, 2014).

Formal surveillance systems and clinical pharmacists' involvement in patient care decision-making within multidisciplinary geriatric teams, in conjunction with CPOE, are likely to minimize ADR occurrences. In addition, several actions can be taken in hospitals to stimulate appropriate prescribing and to ensure adequate communication between primary care and hospital care. Use of team-based approaches to monitoring include:

- Pharmacist-based outreach programs
- Automated reminder calls to patients
- Provider computer alerts
- Collaborative agreements between physicians and pharmacists, in which physicians delegate test-ordering and prescribing authority to pharmacists
- Providing a legal mechanism for collaboration

Finally, engaging patients as active participants in monitoring use of systems that are acceptable to MR at admission and discharge to other levels of decision support in CPOEs can be a good tool to improve patient safety.

However, it is important to note that such methods may impair patient safety if poorly designed (Charles, Cannon, Hall, & Coustasse, 2014).

Evaluation and Management of Medication Adherence

Evaluation for adherence is very challenging as there is no gold standard other than observing a patient taking medication, which is typically not feasible. Managing patient adherence is a monitoring process that involves patients, providers, health systems, and their social networks (Vrijens et al., 2012). Research includes the following six measures for evaluating adherence: pharmacy refills, pill counts, electronic medication events monitoring systems (MEMS caps), biological measurements, self-reporting, and physician judgments. MEM devices contain a microprocessor inside a medication container that, when opened, activates an indication that a pill has been taken (Jansen & Brouwers, 2012). This recording can then be downloaded at an office visit. However, it is not a perfect measure as a patient may remove more than one medication at a time, thus not accurately representing the adherence with high costs, and frequent return visits too are limiting implementation (Jansen & Brouwers, 2012; Nieuwlaat et al., 2014).

In a systematic review, Viswanathan et al. (2012) reviewed medication adherence interventions in chronic disease. The study showed evidence for adherence improvement in diabetes using care coordination, behavioral support for hyperlipidemia, and a virtual clinic for osteoporosis. Improvement in health outcomes related to adherence in hypertension, depression, heart failure, and asthma were also reported with blister packs improving adherence for hypertension. It also showed reminder calls and pharmacist-led interventions aided in improving heart failure adherence. Case management and collaborative care enhanced antidepressant medication taking, while self-management and shared decision-making improved asthma treatment adherence (Viswanathan et al., 2012).

In another systematic review, financial incentives revealed an increase in adherence by a mean of 20% in 13 studies (Turner, Matthews, Linardatos, Tell, & Rosenthal, 2008). They also reported the following interventions improved adherence: reduced out-of-pocket costs, case management, and patient education. Other methods of monitoring adherence included self-reporting, questionnaires, interviews and/or logs, and simply asking patients and their families about problems or difficulties experienced with taking medications. Topinková, Baeyens, Michel, and Lang (2012) also reported that patient behavioral interventions showed a significant impact on adherence versus educational interventions (Topinková et al., 2012). E-prescribing is another intervention method used to improve medication adherence. In 2013, 92% of community pharmacies and 73% of office practices participated in some form of e-prescribing (Hubbard, O'Mahony, & Woodhouse, 2013) that allows pharmacist follow-up with patients when medications are not filled, which could lead to improvements in medication adherence. Furthermore, e-prescribing has been found to be increasingly expected by patients, with reports of better communication regarding use of medication between patient and provider (Schleiden, Odukoya, & Chui, 2015).

Reducing ADEs

There are three essential areas nurses must be vigilant toward in reducing ADEs: iatrogenic prevention including identification of system issues (avoiding interruptions during medication passing), monitoring potential inappropriate medications, and evaluating risk of nonadherence. Care should also focus on medication decisions from both the patient and his or her family (Dwamena et al., 2012) along with proper education on cultural competencies that may pose adverse medication effects. Likewise, nurses must take a collaborative, proactive, and interdisciplinary role with patients, patients' families, doctors, advance practice nurses, pharmacists, and any other care team member to prevent/reduce adverse medication outcomes.

A systemic review (Spinewine, Fialová, & Byrne, 2012) reported collaborative care by pharmacists and Geriatric Evaluation and Management (GEM) interdisciplinary teams improved appropriate use of medications during hospitalization admission and discharge, along with proactive medication review and education in patients over 70 years old. Also, similar research has shown that collaborative and proactive support among healthcare teams and geriatric medicine can improve proper medication taking in patients (Topinková et al., 2012).

The following outlines further interventions to reduce ADEs:

- Ask detailed questions about OTC medications/supplements, "recreational" drugs, alcohol use, and herbal or folk remedies. Provide a list of herbal remedies and folk medicines to choose from (Tachjian et al., 2010). Be specific about the actual amount and under what circumstances these substances are used. Accurate information can help explain symptoms that otherwise may not make sense.
- Evaluate for duplicate medications or medication classes that occur because of unrecognized trade names versus generic names, and OTCs with the same active ingredients in them, especially acetaminophens.

- Consider medications as the underlying cause when falls or other new symptoms occur.
- Consider recently added medications that are high risk for causing falls such as BZDs, diuretics, and psychotropics.
- Collaborate with the interdisciplinary team to effect change in reducing the numbers of ADEs and ADRs, many of which are preventable (Topinková et al., 2012). Consider an interdisciplinary approach including a medication care team (nurse, pharmacist, primary physician/nurse practitioner, social worker) with specific functions assigned to review medications at admission and discharge utilizing evidence-based recommendations. Discharge interventions may be performed by various team members (see Box 24.2).

BOX 24.2

Evidence-Based Interventions to Improve Adherence

Promising interventions to improve adherence and other key medicine-use outcomes, which require further investigation to be more certain of their effects, include:

- Simplified dosing regimens
- Interventions involving pharmacists in medicine management, for example, medicine reviews, pharmaceutical care services (consultation between pharmacist and patient to resolve medicine problems, develop a care plan, and provide follow-up)

Other strategies showed some positive effects, particularly relating to adherence and other outcomes, but their effects were less consistent overall and so need further study. These include:

- Delayed antibiotic prescriptions
- Practical strategies, such as reminders, cues, and/or organizers, reminder packaging, and material incentives
- Education delivered with self-management skills training, counseling, support, training, or enhanced follow-up; information and counseling delivered together; or education/information as part of pharmacist-delivered packages of care
- Financial incentives

Several strategies also showed promise in promoting immunization uptake, but require further study to be more certain of their effects. These include:

- Organizational interventions, reminders and recall, financial incentives, home visits, free vaccination, lay health worker interventions, and facilitators working with physicians to promote immunizations. Education and/or information strategies also showed some positive, but even less consistent, effects on immunizations
- Positive effects on adherence
- Positive effects on adherence and knowledge
- Effective in decreasing antibiotic use but with mixed effects on clinical outcomes, adverse effects, and satisfaction
- Positive, although somewhat mixed effects on adherence
- Positive effects on adherence, use of medicines, clinical outcomes, and knowledge, but with mixed effects in some studies
- Positive, but mixed, effects on adherence
- Needs further assessment of effectiveness and investigation of heterogeneity

There are many different potential pathways through which consumers' use of medicines could be targeted to improve outcomes, and simple interventions may be as effective as complex strategies. However, no single intervention was effective in improving all medicine-use outcomes across all diseases, medicines, populations, or settings.

Despite a doubling in the number of reviews included in this updated overview, uncertainty still exists about the effectiveness of many interventions, and the evidence on what works remains sparse for caregivers and people with multimorbidity.

Source: Data from Ryan, R., Santesso, N., Lowe, D., Hill, S., Grimshaw, J., Prictor, M., … Taylor, M. (2014). Interventions to improve safe and effective medicines use by consumers: An overview of systematic reviews. *The Cochrane Database of Systematic Reviews, 4*, CD007768. doi:10.1002/14651858.CD007768.pub3

Other recommendations for which to consider using an interdisciplinary approach include the following.

- *Reminder systems* may be instituted by pharmacists in collaboration with nurses that have been reported effective, particularly outreach to the patient at home for monitoring and follow-up of lab results (Steinman et al., 2011).
- *Pharmacist–physician or nurse collaboration* to review medication list at admission, when new medications are added, and prior to discharge for potential for drug–drug interactions, drug–disease interactions, and/or inappropriate medications. Monitoring and management of drug levels and medication changes in consultation with primary provider (preferably using

a computer-based program); see Chapter 9, Assessing Cognitive Function in the Older Adult, and Chapter 19, Late-Life Depression).

- *Assess abilities and limitations* such as functional ability, including the ability to read the medication label, to open the medication container, and consume or self-administer the prescribed medication as intended (Petrovic et al., 2012; see Chapter 10, Assessment of Physical Function in the Older Adult). The plan of care should address actual and potential problems and the need for reassessment at regular intervals and after major medical events (e.g., cerebrovascular accident or delirium).
- *Provide devices to accommodate impairments or barriers*. For example, tamperproof lids are often difficult for older adults to remove, particularly if there are arthritic changes. A simple request to the pharmacist to provide a nonchildproof lid may improve the safe and effective use of prescribed medication. Consult with occupational therapy for suggestions.
- *Assess health literacy*. Query whether the older person understands what the drug is to be used for, how often it is to be taken, circumstances of ingestion (e.g., with food), and other aspects of drug self-administration that signal intelligent drug use; use teach-back method to verify understanding.

SUMMARY

Finally, there is mounting evidence to reflect the impact and success of rigorous and reliable intervening models in the complex phenomena of ADEs. The age-friendly health system approach, as previously referenced along with efforts demonstrated by the NICHE, HELP, and ACE models, shows promising improvement when implemented reliably (Capezuti et al., 2012; Fulmer & Berman, 2016; Strijbos, Steunenberg, van der Mast, Inouye, & Schuurmans, 2013; Vollbrecht et al., 2015). Evaluations using a CGA may be helpful in simplifying drug prescriptions in older adults with complex medical problems and needs. It will also aid in prioritizing pharmacological and healthcare needs, resulting in an improvement in quality of prescribing. Prescriptions should be evaluated for benefit versus harm, choosing the safest and best medication for the individual. Prior to prescribing, providers should consider the individual's comorbidities such as liver or kidney disease or any other disease with possible drug interaction (Salvi et al., 2012). Likewise, consideration of life expectancy and health status should be evaluated in addition to the presence of frailty, which may increase the risk of ADEs and affect quality of life.

While many researchers have looked at reducing PIMs in research, the yield has been low. Computerized decision-support systems, pharmacist interventions, and CGA have shown more positive outcomes (Salvi et al., 2012). Nonpharmacological interventions, such as complementary and alternative medicine (CAM) therapies, are underutilized in healthcare and should be considered prior to prescribing or as an adjunctive therapy to prescribing.

NURSING STANDARD OF PRACTICE

Protocol 24.1: Reducing Adverse Drug Events in Older Adults

I. GOAL

To proactively identify older adults at risk for adverse drug events (ADEs).

Around 31% of all adverse events in hospitals are caused by medication-related problems. The use of prescription drugs has increased by 90% over the past 25 years with a consequent increase in ADEs reported to the FDA (National Center for Health Statistics [NCHS], 2012). ADEs, whether from drug–drug or drug–disease interactions, inappropriate prescribing, poor adherence, or medication errors, lead to serious or potentially fatal outcomes for older adults. Between 2004 and 2008, there was a 52% increase in the number of ADEs reported in U.S. hospitals (Lucado, Paez, & Elixhauser, 2008). In U.S. hospitals, ADEs increase costs to patients, healthcare expenditures, length of hospital stay, and morbidity and mortality, yet nearly half are likely preventable. Increase in ADEs has become common partly because of a considerable increase in prescription drug use. Analysis from NCHS reported that older adults taking five or more prescription drugs within a 30-day span increased by 28.4% between 1988 and 1994 and between 2013 and 2014 (National Center for Health Statistics, 2016–2017). Overall, ADEs continue to be a main priority in the U.S. healthcare system.

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

II. BACKGROUND

A. Definitions
   1. Adverse drug events (ADEs): Defined as an injury resulting from medical intervention related to a drug (Kohn et al., 2000). ADEs, compared with medication errors, are a more direct measure of patient harm.
   2. Medication errors: Refer to any "preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of a health care professional, patient, or consumer" (National Coordinating Council for Medication Error Reporting and Prevention, n.d.-a, para. 2).
   3. Adverse drug reaction: Any noxious or unintended and undesired effect of a drug that occurs at normal human doses for prophylaxis, diagnosis, or therapy. Inappropriate prescribing of high-risk medication to older adults and medication errors are all considered iatrogenic (World Health Organization, 1972). They are also preventable causes of harm to patients (Lavan & Gallagher, 2016).
   4. Drug–drug interactions: When one therapeutic agent alters either the concentration (pharmacokinetic interactions) or the biological effect of another agent or pharmacodynamic interactions (Levinson, 2018).
   5. Medication adherence: Defined as the extent to which a person's medication-taking behavior corresponds with agreed recommendations of a healthcare provider (Sabaté, 2003). It is also a two-way form of communication in which a patient and medical provider assume active roles in fulfilling the set therapeutic regimen (Lo et al., 2016).
   6. Drug–disease interactions: Undesired drug effects (exacerbation of a disease or condition caused by a drug) that occur in patients with certain disease states. Common drug–disease interaction is aspirin given in peptic ulcer disease and beta blockers given in diabetes (Salvi et al., 2012).
   7. Pharmacokinetics: The time course of absorption, distribution across compartments, metabolism, and excretion of drugs in the body. The metabolism and excretion of many drugs decrease, and the physiological changes of aging require dose adjustment for some drugs (Levinson, 2018; Steinman & Holmes, 2014).
   8. Pharmacodynamics: The response of the body to the drug that is affected by receptor binding, postreceptor effects, and chemical interactions. Pharmacodynamic problems occur when two drugs act at the same or interrelated receptor sites, resulting in additive, synergistic, or antagonistic effects. The effects of two or more drugs together can be either *additive* (combination of drugs "add up" to increase effect), *synergistic* (one agent magnifies the effect of the other), or *antagonistic* (one medication inhibits the effect of the other; Steinman & Holmes, 2014).
   9. Medication reconciliation: Defined by The Joint Commission (2010) as "the process of comparing the medications a patient is taking (and should be taking) with newly ordered medications" (p. 4). It is a process of comparing the patient's current medication regimen against the physician's admission, transfer, and/or discharge orders to identify discrepancies (The Joint Commission, 2010).

B. Epidemiology
   1. Older adults are the greatest consumers of medications, with older Americans taking three OTC medications and up to six or more prescription medications (Petrovic et al., 2012). Half of all prescriptions are prescribed to older adults, with those in office practices taking six or greater medications. Medicare patients (>65 y.o.) have the highest rates of ADEs, representing 75.3 per 10,000 discharges.
   2. Older adults experience a 10.7% prevalence rate of hospital admissions caused by ADRs; however, a confounding factor in the accuracy is the different methods and studies employed to gather the data (Kongkaew et al., 2013).

C. Etiology

Older adults, especially frail older adults, become increasingly susceptible to ADEs as they age (Hubbard et al., 2013). Physiological change and characteristics of aging predispose older adults to experience adverse events. ADEs increase the costs, length of hospital stay, and mortality yet often go unreported, and nearly half are likely preventable (Levinson, 2018; Salvi et al., 2012). Persons older than age 65 experience medication-related problems for five major reasons:

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

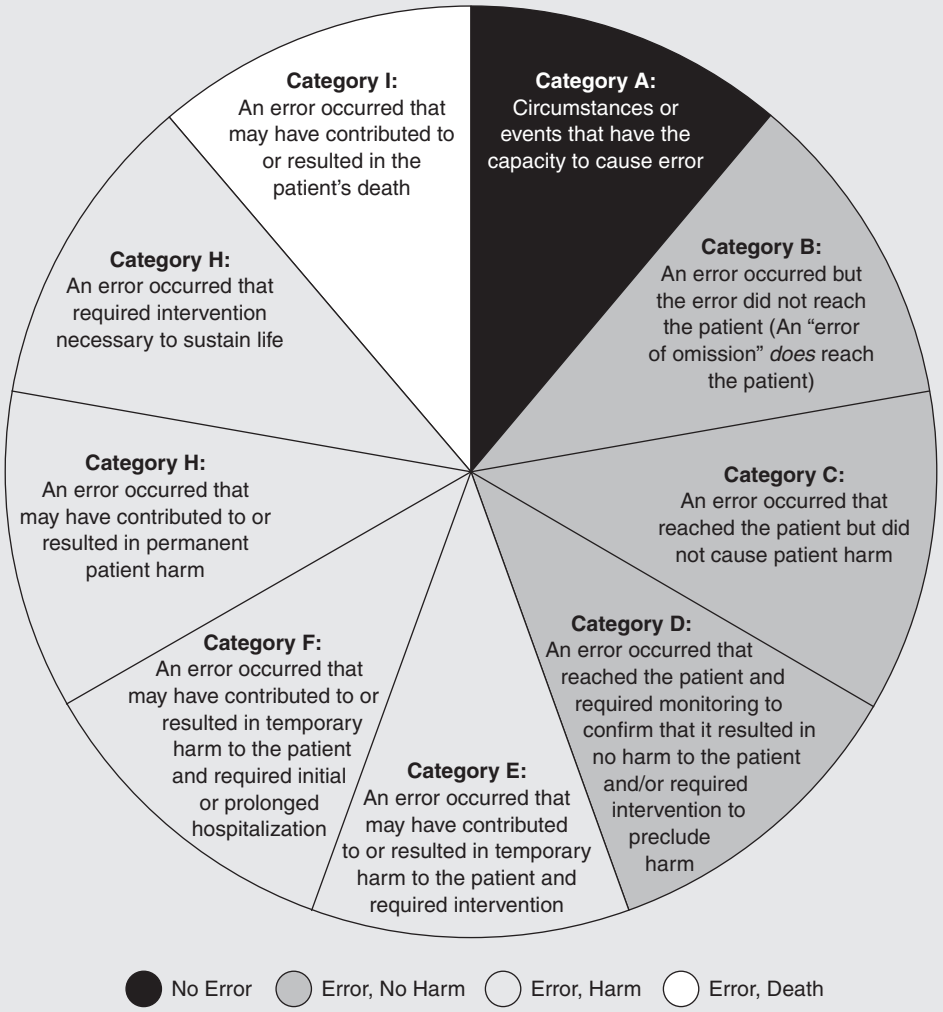
1. Age-related physiological changes that result in altered pharmacokinetics and pharmacodynamics (Levinson, 2018; Rochon, 2019; Steinman & Holmes, 2014)
2. Polypharmacy (multiple medications) that are often prescribed by multiple providers (Fulton & Riley Allen, 2005; Qato et al., 2016)
3. Therapeutic failures—over- or underdosing of medications (more than or less than a therapeutic dosage; Fillit et al., 2016; Marcum et al., 2012)
4. Medication consumption for the treatment of symptoms that are not disease dependent or specific self-medication and/or prescribing cascades (Rochon, 2019)
5. Iatrogenic causes such as:
   a. ADRs, including drug–drug or drug–disease interactions (Heuberger, 2012).
   b. Inappropriate prescribing for older adults (Hamilton et al., 2011).
   c. Problems with medication adherence (Lo et al., 2016; Marcum et al., 2012; Steinman & Hanlon, 2010; Steinman & Holmes, 2014).
   d. Medication errors (Charles et al., 2014; Steinman et al., 2011).

III. ASSESSMENT TOOLS AND STRATEGIES

A. Assessment Tools
1. Beers Criteria: American Geriatrics Society (2019) Beers Criteria for Potentially Inappropriate Medication Use in Older Adults. Use to assess medication list for medications that should generally be avoided in older adults (American Geriatrics Society, 2019).
2. STOPP Criteria: Screening Tool of Older Persons—used to identify potentially inappropriate medications (Gallagher et al., 2011; Hamilton et al., 2011)
3. START Criteria: Screening Tools to Alert Doctors to the Right Treatment—use criteria to identify medications that are underutilized and potential prescription omissions (Gallagher et al., 2011; Lang et al., 2012).
4. Drug–Drug Interactions: Tables 24.1 and 24.2. Review list of common medications known to interact with other medications or using computer decision-support and computer drug–drug interaction alerts (Clyne, Bradley, Hughes, Fahey, & Lapane, 2012).
5. Cockroft–Gault Formula—Exhibit 24.1. Useful for estimating creatinine clearance based on age, weight, and serum creatinine levels (Terrell et al., 2006). A creatinine clearance of less than 50 mL/min places older adults at risk for ADEs (Fouts, Hanlon, Pieper, Perfetto, & Fernberg, 1997).
6. Brown Bag Method—used to assess all medications. Ask older adult to place all medications, OTCs, and herbal remedies in a bag and bring it to the hospital/other care setting to ensure med list is accurate (Nathan et al., 1999; Weiss et al., 2016).
7. Drug Regimen Unassisted Grading Scale (DRUGS) Tool—Used at transfer to other levels of care. Standardized method for assessing potential medication adherence problems. This requires a higher level of functioning (Edelberg et al., 1999; Hutchison, Jones, West, & Wei, 2006).
8. Functional capacity—Evaluate activities of daily living (ADL) and independent activities of daily living (IADL), Use Mini-Cog or Mini-Mental State Exam (MMSE) and evaluate ability to self-administer medications (see Chapter 9, Assessing Cognitive Function in the Older Adult and Chapter 10, Assessment of Physical Function in the Older Adult).

B. Assessment Strategies

See Figure 24.4.



1. *Identify aging changes* in pharmacokinetics and pharmacodynamics when assessing medications in older adults (Levinson, 2018; Steinman & Holmes, 2014).

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

FIGURE 24.4

National Coordinating Council (NCC) for Medication Error Reporting and Prevention (MERP) index for categorizing medication errors.

Note: Harm, impairment of the physical, emotional, or psychological function or structure of the body and/or pain resulting therefrom; Monitoring, To observe or record relevant psychological signs; Intervention, May include change in therapy or active medical/surgical treatment; Intervention Necessary to Sustain Life, Includes cardiovascular and respiratory support (e.g., CPR, defibrillation, intubation, etc.)

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

2. *Perform a Comprehensive Geriatric Assessment:* Geriatric evaluation and management reduced inappropriate and unnecessary medications. A comprehensive assessment is important as it is a more global assessment that ensures a more specific plan for each single patient (Avelino-Silva et al., 2014; Petrovic et al., 2012).
3. Perform a comprehensive medication history (FitzGerald, 2009)
   a. Currently prescribed drugs, doses, route of administration, frequency taken, and duration of treatment
   b. Over-the-counter drugs and herbal remedies
   c. Drugs taken in the recent past
   d. Previous drug hypersensitivity reaction and the nature (rash or anaphylaxis)
   e. Previous adverse drug reactions and nature
   f. Adherence to therapy (what medications are you having difficulty with? Or how many pills have you missed this week/month?)
   g. Obtain up-to-date medication list from primary provider or pharmacy
   h. Check with pharmacy regarding prior ADRs and last order dates for each medication
   i. Inspect drugs and their container for name, dosage, and number of meds taken since dispensed
   j. The comprehensive medication assessment must include a formal evaluation of the ability to manage medications on an individual basis (Topinková et al., 2012). Perform at discharge and at times between transition between units
   k. Regular medication review to evaluate list for PIMs/PIPs (Beers Criteria and STOPP Criteria); consider drugs to discontinue (Gallagher et al., 2011).
4. Evaluate for patient-related and medication-related risk factors for ADRs (see Box 24.1).
5. Perform medication reconciliation at admission, discharge, transfers, and transitions to other levels of care in consultation with a pharmacist, geriatric expert, or computer-based program (Frankenthal et al., 2014).
6. At discharge from hospital, use appropriate tools to assess individual's ability to self-administer medications (Ho, Bryson, & Rumsfeld, 2009).

V. INTERVENTIONS AND NURSING CARE STRATEGIES

A. Reducing ADEs (during and post hospitalization)
   1. Patient/Family-centered care and decision-making include collaboration with interdisciplinary team members. Patients should be given the necessary information and the opportunity to exercise the degree of control they choose over healthcare decisions that affect them. Patients involved in decision-making are less likely to make decisions that may lead to ADRs, such as abruptly discontinuing a medication that should be tapered off (Parchman, Zeber, & Palmer, 2010).
   2. Comprehensive Geriatric Prescribing:
      a. *Evaluate prescriptions* for benefit versus harm.
      b. *Choose the safest* and best medication for the individual based on geriatric assessment and goals of care.
      c. *Prior to prescribing*, consider the individual's comorbidities such as liver or kidney disease or a disease that may interact with a drug (Salvi et al., 2012).
      d. *Prescribing principles*. Although bedside nurses are not involved in prescribing, they are involved in reviewing and signing off medications, and thus should be aware of prescribing principles.
      e. *Monitoring for appropriate prescribing* and alerting the prescriber to potential problem areas; monitoring for and reporting lab/drug levels to primary provider; monitoring for toxicity and medication effectiveness; and seeking consultation when necessary (Rochon, 2019).
         i. *Reduce the dose.* "Start low and go slow," providing the lowest possible dose and slow upward titration to obtain clinical benefit; many ADEs are dose related (Rochon, 2019). Primary provider should be notified if the dosage ordered is higher than the recommended starting dose (e.g., digoxin maximum dose less than 0.125 mg for treatment of *systolic* heart failure).

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

ii. *Discontinue unnecessary therapy*. Prescribers are often reluctant to stop medications, especially if they did not initiate the treatment. This practice increases the risk for an adverse event (Rochon, 2019; e.g., therapeutic activity kit for agitation).
iii. *Recommend safer drugs*. Avoid drugs that are likely to be associated with adverse outcomes (review Beers Criteria).
iv. *Assess renal function* using the Cockroft–Gault formula (for renally cleared drugs) to determine accurate dosage prior to prescribing, such as for many routinely prescribed intravenous (IV) antibiotics. Dosage recommendations are available based on this formula and are presented in common prescribing resources.
v. *Optimize drug regimen*. When prescribing medications, focus on risk versus benefit where the expected health benefit (e.g., relief of agitation in dementia with psychosis) exceeds the expected negative consequences (e.g., morbidity and mortality from falls that result in hip fracture).

f. *Initiation of new medication*. Assess risk factors for ADRs, potential drug–disease and drug–drug interactions, correct drug dosages, and follow-up to evaluate response to new medication.
g. *Avoid the prescribing cascade*. Avoid the prescribing cascade by *first* considering any new symptom as being an adverse effect of a current medication prior to adding a new medication.
h. *Avoid inappropriate medications*. Review Beers and STOPP criteria for PIMs, drug–disease interactions, and potential drug–drug interactions (see AGS website in references).
i. *Evaluate for patient concern regarding difficulties in adherence to medication* (Steinman & Hanlon, 2010).

B. Computerized Order Entry and Decision-Support Systems
1. Monitor and attend to alerts for potential drug–drug interactions
2. Pharmacist-based support of CPOE and electronic prescriptions direct to pharmacy
3. Reminder systems for monitoring (Charles et al., 2014)

C. Monitoring (Steinman et al., 2011)
1. Evaluate patient for adverse effects and efficacy after a new medication is started.
2. Educate patients about anticipated benefits and potential problems associated with a new drug. Partner with the patient to actively engage as a partner to assess drug effectiveness, adherence, and adverse effects. Partner with the patient to actively engage as a partner to assess drug effectiveness, adherence, and adverse, especially with patients taking drugs with narrow therapeutic ranges.
3. Report questionable dosing amounts or schedule and medication allergy prior to medication administration. (See also Documentation of Drug Allergies post hospital.)
4. Monitor for drug interactions and inform primary provider of new or recent medications that may be related to the cause.
5. Use health information technology (HIT) to monitor labs where available, for example, lab tracing systems.
6. Use team-based approaches to monitor medications.
7. Risk assessment tools—individualize monitoring based on individual risk.
8. Report generated when lab tests are not performed with follow-up mechanism.
9. Policy standards that mandate ability to track and report overdue lab tests easily.

V. EXPECTED OUTCOMES

A. Patients will:
1. Experience fewer adverse outcomes from medication-related events.
2. Demonstrate understanding of their medication regimens upon discharge from the hospital and keep an updated medication list.
3. Become active members of medication decision-making and monitoring.

B. Healthcare providers will:
1. Use a range of interventions to prevent, alleviate, or ameliorate medication problems with older adults, including nonpharmacological and complementary therapies.

(*continued*)

Protocol 24.1: Reducing Adverse Drug Events in Older Adults (*continued*)

2. Improve prescribing practices by documenting indications for initiation of new drug therapy, maintaining a current medication list, and documenting response to therapy as well as the need for ongoing treatment and follow-up monitoring.
3. Evaluate nature and origins of medication-related problems in a timely manner.
4. Increase their knowledge about medication safety in older adults.
5. Increase referrals to appropriate practitioners for collaboration and medication safety (e.g., pharmacist, geriatrician, geriatric/gerontological, or psychiatric clinical nurse specialist, nurse practitioner, or consultation-liaison service, social worker, case manager, or interdisciplinary team).

C. Institution will:
1. Provide a culture of safety that encourages safe medication practices.
2. Provide education to healthcare providers regarding prevention, identification, and reporting of ADRs.
3. Make information on ADRs accessible to patients.
4. Enhance surveillance and reporting of ADRs using a national surveillance system. Consider use of computerized physician order entry system and drug interaction software.
5. Track and report morbidity and mortality related to medication problem.
6. Provide a system for medication reconciliation, and follow up its effectiveness regarding rehospitalization rates caused by ADRs.
7. Review for careful documentation of iatrogenic medication and other iatrogenic events for continuous quality improvement (CQI).
8. Provide ongoing education related to safe medication management for physicians, other licensed independent providers, pharmacists, and nursing staff.

VI. FOLLOW-UP

A. Healthcare providers will:
1. Provide consistent and appropriate care and follow-up in the presence of a medication-related problem.
2. Monitor and evaluate with physical exam and/or laboratory tests (as appropriate) on a regular basis to ensure that the older adult is responding to therapy as expected.
3. Review the medications list, including OTC and herbal remedies, regularly and reconcile medications at transitions in care.
4. Monitor high-risk medications more frequently for potential adverse events.

B. Institutions will:
1. Provide ongoing assessment of staff competence in assessing and intervening for prevention of ADEs.
2. Embed reduction of ADEs in the institution's culture of safety.

Urinary Incontinence in the Older Adult*

Annemarie Dowling-Castronovo, Joanna Long, and Christine Bradway

25

EDUCATIONAL OBJECTIVES

On completion of this chapter, the reader should be able to:

1. Discuss transient and established etiologies of urinary incontinence (UI).
2. Describe the core components of a nursing assessment for UI in older adults.
3. Discuss the importance of nurse collaboration within the interprofessional team in an effort to best assess, treat, manage, and document the type of UI.
4. Develop an individualized plan of care for an older adult with UI.

OVERVIEW

Despite evidence supporting UI management strategies (DuBeau, Kuchel, Johnson, Palmer, & Wagg, 2010; Fantl et al., 1996; Qaseem et al., 2014), nursing staff and laypersons often solely use containment strategies, such as adult briefs or other absorbent products, to manage UI (Meng, Busby-Whitehead, & Palmer, 2016). Individuals with UI believe that UI is a normal consequence of aging (Bush, Castellucci, & Phillips, 2001; Dowd, 1991; Kinchen et al., 2003; Milne, 2000; Mitteness, 1987a, 1987b; Strickland, 2014) and feel that UI is a personal problem that is difficult to discuss (Bush et al., 2001). Evidence suggests that persons with UI prefer self-help strategies, including containment, rather than seeking professional advice (Milne, 2000; Park, Yeoum, Kim, & Kwon, 2017) and that personal care strategies are often the result of information gained through lay media and personal contacts, not necessarily from healthcare professionals (Cochran, 2000; Miller, Brown, Smith, & Chiarelli, 2003; Milne, 2000; Park et al., 2017). However, patients also express a desire for help from nurses to control UI (Dowling-Castronovo, 2014; Gibson, Thomas, Harrison, & Watkins, 2018; Kohler, Mayer, Kesselring, & Saxer, 2018; Meng et al., 2016). Nurses should be empathetic "managers" of UI (Dowling-Castronovo, 2014; Kohler et al., 2018).

BACKGROUND AND STATEMENT OF PROBLEM

UI is defined as the complaint of involuntary urine loss (Abrams et al., 2003; Haylen et al., 2010) or involuntary loss of urine sufficient to be a problem (Fantl et al., 1996; National Association for Continence, 1998). Although UI should not be considered an inevitable consequence of aging, UI is more common among older adults (da Silva, Soler, & Wysocki, 2017; Erekson, Cogn, Townsend, & Ciarleglio, 2016; B. Hodgkinson, Synnott, Josephs, Leira, & Hegney, 2008; Holroyd-Leduc, Mehta, & Covinsky, 2004; Shamliyan, Wyman, Bliss, Kane, & Wilt, 2007; Jimenez-Cidre et al., 2014). Incidence and prevalence

* For a description of evidence levels cited in this chapter, see Chapter 1, Developing and Evaluating Clinical Practice Guidelines: A Systematic Approach.

rates of UI must be viewed cautiously. Numerous factors, such as underreporting and underassessment of UI (Milne, 2000; Park et al., 2017), variable or poorly articulated UI definitions (Abrams et al., 2003; Homma, 2008; Palmer, 1988), and a wide variety of measurements used to assess UI, some without age-standardization (Milsom et al., 2014), affect the accuracy of these rates. Nevertheless, it is important to understand how common UI is across healthcare settings.

In different healthcare settings across the globe, prevalence rates range between 5% and 70%, with most reporting between 25% and 45%. Prevalence estimates are lowest in the Asian population, ranging between 1.5% and 15.2%; whereas estimates for European and American populations are between 1.8% and 30.5% and 1.7% and 36.4%, respectively (Milsom et al., 2014). In the United States, more than 33 million individuals report some type of UI or bladder condition (https://www.nafc.org/urinary-incontinence). In comparison to acute care settings, UI has been studied more in older adult populations living in the community or long-term care settings. Among community-dwelling adults, the prevalence of UI ranges from 8% to 46% (Du Moulin, Hamers, Ambergen, Janssen, & Halfens, 2008; Erekson et al., 2016; Gorina, Schappert, Bercovitz, Elgaddal, & Kramarow 2014; Kwong et al., 2010; Lee, Cigolle, & Blaum, 2009; Sims, Browning, Lundgren-Lindquist, & Kendig, 2011); 37% of those living in residential care facilities; 40% of those receiving home care services; more than a third of short-term nursing home residents; and close to 75% of long-term NH residents have UI (Gorina et al., 2014). In acute care, 10% to 42% of older adults suffer from UI on admission (Dowd & Campbell, 1995; Fantl et al., 1996; McDowell et al., 1999; Palmer, Bone, Fahey, Mamon, & Steinwachs, 1992; Schultz, Dickey, & Skoner, 1997), and 12% to 36% develop UI during a hospital stay (e.g., new-onset UI, meaning that these individuals were continent on hospital admission; Kresevic, 1997; Palmer, Baumgarten, Langenberg, & Carson, 2002; Palmer, Myers, & Fedenko, 1997; Sier, Ouslander, & Orzeck, 1987; Zisberg, 2011). For medically complex vulnerable elderly, the annual prevalence of UI ranges from 35.8% to 38.6% (Luo et al., 2015).

In addition to being a common geriatric syndrome, UI significantly affects health-related quality of life (HRQOL; DuBeau, Simon, & Morris, 2006; Dugger, 2010; Goksin & Asiret, 2018; Hamid, Pakgohar, Ibrahim, & Dastjerdi, 2015; Kwong et al., 2010; Shumaker, Wyman, Uebersax, McClish, & Fantl, 1994). The consequences of UI may be characterized physically, psychosocially, and economically. For example, an episode of urge UI occurring once weekly, or more frequently, has been associated with falls or fracture in adults (Brown, Sawaya, Thom, & Grady, 2000; Chiarelli, Mackenzie, & Osmotherly, 2009; Hasegawa, Kuzuya, & Iguchi, 2010; Luo et al., 2015; Noguchi, Chan, Cumming, Blyth, & Naganathan, 2016). Other physical consequences associated with UI include skin irritations or infections, urinary tract infections (UTIs), bloodstream infections, pressure ulcers, and limitation of functional status (Fantl et al., 1996; Luo et al., 2015).

UI is associated with psychological distress (Bogner et al., 2002; de Vries, Northington, & Bogner, 2012), including depression, poor self-rated health, decreased quality of sexuality, social isolation, and condition-specific functional loss (Bogner et al., 2002; Fantl et al., 1996; Luo et al., 2015; Meng et al., 2016; Sims et al., 2011; Yilmaz, Kumsar, Demirel, & Yesildag, 2016). Post-stroke, UI is a risk factor for poor outcomes (Arkan, Beser & Ozturk, 2018; John, Primmaz, Crichton, & Wolfe, 2018; Pettersen, Saxby, & Wyller, 2007). Via an international survey, those with increased daily episodes of UI (mean age 54; majority female) experienced less employment (Jimenez-Cidre et al., 2014), which may affect healthy aging. An emerging focus of interprofessional scholarship addresses the relationships among common geriatric syndromes: sleep disturbances, impaired mobility, and impaired cognition and UI (Vaughan et al., 2018). Therefore, it is essential that nurses assess and treat UI when addressing other coexisting health problems, such as depression or falls.

Although there is conflicting evidence regarding the role of UI as a predictor for nursing home placement, UI has been identified as a marker of frailty in community-dwelling older adults (Engberg & Li, 2017; Holroyd-Leduc et al., 2004) and a predictor of 1-year mortality among older adults hospitalized for an acute myocardial infarction (Krumholz, Chen, Chen, Wang, & Radford, 2001). Furthermore, UI is associated with a 24% increase in all-cause mortality in older adults living in long-term care facilities (Damián, Pastor-Barriuso, García López, & de Pedro-Cuesta, 2016).

The negative psychosocial impact of UI is not limited to the individual, but includes family caregivers (CGs; Brittain & Shaw, 2007; Cassells & Watt, 2003; Gotoh et al., 2009; Jansen, McWilliam, Forbes, & Forchuk, 2013). Economically, varied study methods estimate the cost for all incontinent individuals to be in the billions among developed nations (Landefeld et al., 2008; Milsom et al., 2014; Wilson, Brown, Shin, Luc, & Subak, 2001). Estimates of costs varied with inclusion of absorbent products, provider visits, diagnostic testing, treatments, and time lost from work.

Nurses in all settings are in a key position to identify and manage UI, a quality indicator (Donald et al., 2013; Wenger et al., 2011). For example, UI is a known hazard of hospitalization, but is amenable to improvement through education of hospital staff (Wilkerson, Iwata, Wilkerson, & Heflin, 2014). This chapter reviews the etiologies and consequences of UI, with emphasis on the most common types of UI encountered among older adults. Assessment parameters and care strategies for UI are highlighted, and a nursing standard-of-practice protocol focused on comprehensive assessment and management of UI for older adults is included. This chapter will not focus on surgical options (Gomelsky et al., 2019).

ASSESSMENT OF UI

Adverse physiological consequences of UI that have been known for some time include an increased potential for UTIs and indwelling urinary catheter use, dermatitis, skin infections, and pressure ulcers (Sier et al., 1987). In addition, UI that results in functional decline predisposes older individuals to complications associated with bed rest and immobility (Harper & Lyles, 1988).

Etiologies of UI
