INTRODUCTION

The transitional, formative, and malleable nature of adolescence makes it arguably the most important period of development for the study of developmental psychopathology. As a transitional period, adolescence is marked by rapid and dramatic intraindividual change in the realms of biology, cognition, emotion, and interpersonal relationships and by equally impressive transformations in the major contexts in which children spend time: the family, the peer group, and school. These transformations present both opportunities and challenges that require adaptation on the part of the developing adolescent.

For a significant proportion of adolescents, the interaction between changes in intraindividual functioning and changes in context can result in the emergence of emotional and behavioral problems. Adolescence is often accompanied by the onset of behavioral and emotional problems that are rarely seen prior to adolescence, such as substance use, disordered eating and body image, and major depression. Beyond these disorders, adolescence is a period of experimentation with a broad range of risk-taking behaviors and, for some youth, the escalation of conduct problems into illegal activity. Although not considered a diagnosed psychopathology, risk-taking and criminal behavior during adolescence

nevertheless increase morbidity and mortality during this developmental period.

As a formative period, adolescence is important to the study of developmental psychopathology because after this age, some patterns of emotional and behavioral problems may be more difficult to alter. For reasons not yet understood, there appears to be relatively more consolidation of psychopathology in adolescence than in earlier developmental periods. Prospective longitudinal studies suggest that the majority of chronic and recurrent psychiatric problems that afflict adults are rooted in adolescence. Indeed, the initial manifestations of affective disturbance, antisocial behavior, and substance abuse emerge less frequently during the adult years compared with earlier developmental periods, and typically, these behavioral and emotional disorders emerge during the adolescent years (Paus, Keshavan, & Giedd, 2008). This applies both to problems with behavior, as in the disruptive behavior disorders, as well as to problems with emotion regulation, as in the mood and anxiety disorders (Moffitt, Caspi, Harrington, & Milne, 2002; Pine, Cohen, Gurley, Brook, & Ma, 1998).

In addition to being a heightened period of risk for the emergence of psychopathology, it is notable that adolescence is also critical in setting lifestyle trajectories with enormous long-term implications for adult health. These trajectories include early patterns of behavior in the realms of exercise; nutrition; the use of tobacco, caffeine, alcohol, and other mood-altering substances; and sleep and other health habits. Furthermore, adolescence is the period for establishing the foundation for advanced education, major life roles, relationships, and working toward long-term productive goals. As such, adolescence is an important developmental period for intervention efforts that aim to promote successful adaptation and prevent the development of more serious psychopathology in adolescence and adulthood.

Despite its formative nature, evidence increasingly suggests that adolescence is a period of malleability or developmental plasticity. Patterns of neural connections among and between systems of emotion, motivation, and cognitive processes undergo a natural reorganization during adolescence (Dahl, 2004; Spear, 2010). These neurological changes affect, and are likely affected by, experience. For example, the onset of puberty is associated with biologically based changes in motivational and emotional brain systems linked to reproductive behavior in ways that contribute to the development of sexual and romantic interests. A second example is how the developing concept of *self,* the cognitive abilities to imagine future versions of this self, and affective experiences of fears or excitement linked to tragic or heroic versions of the future self, emerge during adolescence. Early experiences not only influence youth in psychological and emotional domains but also have an impact through brain–behavior interactions on the patterns of connections among neural systems. The impact of this continued brain maturation on emotional, cognitive, social, and behavioral development has yet to be thoroughly studied, particularly within individuals, but the evidence for ongoing developmental processes and apparent plasticity of brain development in adolescence suggests that this period may present unique opportunities for prevention and intervention (including cognitive-behavioral, contextual, psychopharmacological, or other psychotherapeutic treatments).

Our goal in this chapter is to stimulate a research agenda that integrates neurobiological and contextual influences on the development of psychopathology, with the goal of pinpointing the developmental processes that underlie specific types of psychopathology in ways that can be used to leverage prevention and intervention efforts. For example, a better understanding of the processes underlying changes in affect regulation during pubertal maturation, and how context may affect that vulnerability, may ultimately inform interventions targeted toward children at high risk for developing a depressive disorder (such as individuals with symptoms of anxiety or those with a strong family history of depression) *before* the development of a more serious disorder. Similarly, a deeper understanding of the developmental processes and unique opportunities in this maturational interval can eventually inform a range of policies and programs designed to decrease vulnerability and risk, and promote healthier adolescent development, which hopefully will ultimately increase resilience.

The organization of this chapter begins with several general observations about development during adolescence and a conceptualization of adolescence as a unique period of both risk and opportunity. We then turn to a description of brain-based frameworks for understanding adolescent psychopathology, normative changes in brain development, and the developmental processes that are critical for the emergence of adolescent psychopathology. Following our overview of brain-based frameworks for understanding adolescent psychopathology, we examine several aspects of developmental and contextual change that occur in adolescence. In particular, we focus on the primary changes of adolescent development, how these changes are linked with psychopathology, and identifying individuals who change in the most vulnerable ways. The

chapter concludes with a call for new, interdisciplinary research that examines the interplay among neurobiological, psychological, and contextual influences on psychopathology in adolescence.

ADOLESCENCE AS A DEVELOPMENTAL PERIOD: GENERAL OBSERVATIONS

Adolescence as a Time of Transition

Adolescence as a developmental period is characterized by major transitions that can be organized broadly into biological, cognitive, and contextual domains. Change occurs universally in each of these domains and with virtually no exceptions, as adolescents undergo these transformations in every society. While the fundamental changes of adolescence can be sorted into one of these three domains, it is important to note that these categories are not mutually exclusive, and that transformations in one domain likely influence ongoing processes in the other domains. As such, interactions between and among biology, cognition, and context are noted throughout this chapter.

The past decade of scientific study on adolescence has yielded rapid increases in our understanding of the adolescent brain, its protracted development across the adolescent years, and the associated motivational and affective outcomes of this process. Much work has been focused on how the putative immaturity of the adolescent brain and associated developmental changes in affective and motivational processes might increase risk for psychopathology. Furthermore, research has begun to focus on a much broader array of contextual influences on adolescent development and how they might affect psychopathology. Given the salience of changes in adolescence across biological, cognitive, and contextual domains, we discuss in depth each of these major developmental transitions throughout this chapter.

The most formative biological change of adolescence is puberty, which culminates in reproductive capability. Across adolescence, individuals undergo rapid changes in physical appearance (the secondary sex characteristics, including breast development in females and the development of facial hair in males) and the development of reproductive capability (the primary sex characteristics directly affecting the sex organs). A second formative biological change of adolescence is continued maturation of the brain. In the past, the majority of research on brain development focused on the periods of infancy and early childhood, with the notion that the period from birth to age three was the most critical stage for neural development. Data revealing that the brain continues to mature well into the second decade of life, and perhaps beyond, have shifted research attention to the neurodevelopment of the adolescent period. Undoubtedly, rapid and fundamental changes in biology affect not only how the adolescent functions, but also how an adolescent is treated within his or her interpersonal relationships and by society as a whole, as well as the adolescent's self-perceptions. These major biological changes of adolescence are described in detail later in this chapter.

Concurrent with biological transformations such as puberty and brain maturation, adolescents undergo major changes in cognition and cognitive ability across adolescence. Continued development of brain structure and function occur throughout this developmental period, with these changes likely underlying the developmental gains in sophisticated thinking abilities that characterize adolescence. Compared with earlier developmental periods, adolescents are better able to think about hypothetical situations, abstract concepts, and what the future holds. The implications of these cognitive abilities are pervasive, enabling adolescents to think more hypothetically and abstractly about themselves, their relationships, and society. Moreover, the changes of puberty alter various brain-based affective and motivational processes, including reward orientation and cognitive control. The continued development of brain structure and function underlie the gains in cognitive control and regulatory competence that are observed across the adolescent period. Despite these cognitive gains, adolescence still represents a time of maturation and refinement of cognitive ability, and, as we discuss in a later section, this continued development is linked to risk for psychopathology.

The third domain of transitional change of adolescence is social or contextual in nature. First, behavioral autonomy increases across adolescence, as parents give their children increasing control over their activities and actions (Gutman & Eccles, 2007). Moreover, as adolescents transition into the teen years, time spent with parents declines and time spent within the peer group context increases (Larson, Richards, Moneta, Holmbeck, & Duckett, 1996). Although parents still hold influence over their adolescents (see subsequent section on the family context), it is certainly the case that adolescents spend more time with peers, either in structured (school, sports) or unstructured activities (hanging out), than with any other socialization agent (Brown & Larson, 2009). Notably, individuals also begin dating during the adolescent years, and thus navigation of romantic relationships, sex, and sexuality all occur – at varying times – throughout the second decade of life. More so than in earlier eras, modern adolescents are

exposed to a broad range of media and typically engage in high levels of media use (i.e., TV, music, gaming, and social networking). Finally, all of these contextual changes are nested within the adolescent's neighborhood and society, each of which may have direct, indirect, and interactive effects on the development of psychopathology.

Any discussion of developmental psychopathology in adolescence must also consider the broader historical context. Recent biological and social changes, together, have greatly expanded the length of this maturational stage. Most contemporary writers, including the present authors, define adolescence as the interval between the onset of puberty (ordinarily seen as the most important marker of the beginning of the period) and the transition into adult roles (ordinarily seen as the most important marker of the period's conclusion). Both historical data and anthropological studies indicate that the mean age of sexual maturation in premodern societies was around 16 or 17 years—very close to the age at which young people began assuming the adult responsibilities of work and family formation. Thus, throughout most of human history, adolescence—the interval between the onset of sexual maturity and the assumption of adult responsibilities—was often only a few years in length.

More recently, however, the physical manifestations of puberty have been occurring at earlier ages. A number of studies have documented this secular trend among females (Euling et al., 2008) and researchers have begun to document the trend among males as well (Herman-Giddens et al., 2012). At the same time, and especially in the most recent decades, the end of adolescence (taking on full adult roles and responsibilities) has been occurring at a relatively later time, with the prolongation of formal schooling and the extension of the adolescent's economic dependency on his or her family of origin. In the United States, for example, the *average* age of menarche (one of the final steps in pubertal maturation in girls) occurs at 12 years (Steinberg, 2011), but full entry into adult roles is delayed for the majority of the population until at least 20 years of age, and often well beyond (Arnett & Tanner, 2005). Thus, in most contemporary industrialized societies, many youth spend close to a decade with sexually mature bodies and reproductively activated brains, prior to taking on adult roles or status.

This general expansion of the adolescent interval makes early- and mid-adolescence in contemporary industrialized society a period of particular vulnerability for maturational disjunctions across biological, cognitive, and contextual domains. More specifically, this confluence of historical and individual changes in patterns of biological maturity, contextual demands, and contextual supports appears to have opened a window of risk for behavioral and emotional health problems for many young members of modern societies as they negotiate the transition from childhood to adolescence and from adolescence to adulthood.

Taken cumulatively, then, the adolescent years are characterized by dramatic changes in biology, cognition, and context from the start of puberty to the acquisition of adult roles. As we discuss in the subsequent sections of this chapter, these transitions of adolescence make the developmental period a time of risk for psychopathology, but also a malleable part of the life span, where prevention and intervention efforts may be powerful.

Adolescence as a Time of Risk

Although many adolescents navigate the important transitions of the period effectively, changes in the function of any one domain—or the interaction of multiple domains—introduce vulnerability to the onset of psychopathology. Adolescence is therefore a period of heightened risk in general because change occurs in more domains concurrently than in other developmental periods, with some individuals at greater risk than others. A portion of children clearly begin to struggle with various forms of psychopathology as they move into adolescence. Children at greatest risk include those who enter this demanding transition already vulnerable, as well as those whose prior vulnerability becomes expressed during this time (due to genetic predispositions and/or earlier adverse experiences); those for whom the disjunctions between developmental domains are greatest; individuals that encounter the greatest challenges during the transition; children with the least contextual support; and those with both few resources and heightened genetic vulnerability, developmentally acquired vulnerability, or some combination of these factors. The application of a developmental psychopathology approach to the study of adolescence can aid in identifying when these problems emerge, under what conditions, how they are maintained or integrated into these domains, as well as how they change with development. Thus, one of the most important goals of research on psychopathology in adolescence is to achieve a better understanding of the processes and mechanisms by which biology, cognition, and context interact during this transition, culminating in increased vulnerability and risk which, for some individuals, can spiral into significant long-term impairments and psychopathology.

On the other hand, risk does not inevitably lead to poor outcomes. Risk is defined as the probability of a

specific outcome within a group or population. During adolescence, teenagers can manifest considerable resilience despite their status as a member of a group at risk for negative outcomes. It is equally important to understand why certain individuals navigate this interval of development successfully, despite vulnerability, so that patterns and processes of protection and resilience can be better understood. An informative research agenda will thus need to focus both on mechanisms and on the trajectories of development during the adolescent transition, as well as preceding transitions. The adolescent transition may activate preexisting risk conditions—conditions that may reflect a cumulative chain of risk, divergence into a pathway of vulnerability, biological embedding of experiences over time, or the expression of a latent problem from an earlier critical period—or introduce new risks that are specific to this developmental period. Increasing our knowledge of these developmental processes is crucial to inform policies and programs aimed at improving the health and well-being of adolescents and the adults they will become. The very fact that multiple transformations are occurring in adolescence may provide not only heightened risk, but windows of opportunity for positive influence (Cicchetti & Blender, 2006).

One of the goals of the study of adolescent psychopathology is to identify and understand features of adolescence that increase vulnerability to psychological disorders and maladjustment. Examination of biological and contextual factors that are specific to adolescence has provided important perspectives on *why* adolescence is a period of vulnerability to psychopathology. Fundamental biological changes occur during adolescence in the domains of brain development, pubertal maturation, and sleep, in combination with key contextual changes occurring in relationships with parents, peers, and the community. These fundamental biological and contextual factors tend to follow an established ordering of events and are evident across cultures, but the wide individual variability seen in the characterization of these factors such as their timing, rate of change, or their interaction with each other has provided important explanations for why the period of adolescence renders some individuals vulnerable to psychopathology.

Adolescent Brain

Relative to childhood and adulthood, the adolescent brain shows remarkable change in both structure and function. For example, even relatively simple structural measures, such as the ratio of white to gray matter in the brain, demonstrate large-scale changes into the late teenage years (Giedd, 2004; Giedd & Rapoport, 2010; Sowell, Trauner, Gamst, & Jernigan, 2002). The continued maturation of neural systems and structures during adolescence may make individuals more vulnerable to the development of disorders. Given this developmental pattern, the last decade has seen an increase in brain-based frameworks for understanding the emergence of psychopathology during this period. Although we discuss these perspectives in detail later in the chapter, generally these frameworks suggest that changes in the connections within and between core neural circuits that play a role in generating and regulating emotion, motivation, and cognition place adolescents at risk for psychopathology. For example, continued elimination of unused synaptic connections, decreases in cortical grey matter volume and thickness, and the degree of myelination are all neural processes occurring during the adolescent transition which could impact development of psychopathologies. Neural connectivity and neurotransmission properties are another explanation for the age-related and psychopathology-related differences found involving adolescent brain function. Other brain-based explanations for increased vulnerability to psychopathology include exposure to stress and perturbations in stress hormone production and regulation during adolescence that would be expected to impact neural systems still undergoing refinement (Eiland & Romeo, 2013). Still other adolescent-specific risk mechanisms that operate through the brain may be related to when pubertal hormones are generated, particularly if a mismatch is created between changes in levels of pubertal hormones and development of brain circuits that are needed to support adaptation to the physical and social changes instantiated by the onset of puberty.

The mechanisms that contribute to psychopathology are likely diverse and complex. Through three illustrative examples, puberty, sleep, and changes in the parent-child relationship, we illustrate how a variety of changes in biology, cognition, and context may contribute to the underlying risk for psychopathology that emerges during adolescence.

Puberty

Because puberty brings a constellation of intraindividual changes that impact a child's physical appearance, motivations and drives, social interactions and relationships, and risk taking, puberty inherently casts the period of adolescence as a time of risk for psychopathology. Pubertal processes introduce vulnerability in a variety of ways during adolescence. With regard to puberty itself, the timing/age of pubertal onset and the tempo/rate of

pubertal change can increase risk for psychopathology, with these factors having differential effects for boys and girls in terms of well-being and adjustment. For example, early onset of puberty in girls is linked to a wide range of problems in multiple domains including psychological, academic, and health (Graber, Lewinsohn, Seeley, & Brooks-Gunn, 1997; Stice, Presnell, & Bearman, 2001; Wichstrom, 1999). In addition, the rate of change in pubertal status has been associated with change in depressive symptoms particularly in boys but not girls (Mendle, Harden, Brooks-Gunn, & Graber, 2010). Other work has shown that both pubertal timing and tempo are especially important for predicting psychological outcomes in girls, while showing a weaker association with outcomes among boys (Marceau, Ram, Houts, Grimm, & Susman, 2011). Vulnerability to psychopathology is also heightened in adolescence because pubertal changes coincide and interact with social-contextual changes, including increased salience of peers, burgeoning romantic relationships and exploration of one's sexuality, and more advanced cognitive abilities that permit rumination and social comparison about one's changing body and physical attractiveness (Mendle, Harden, Brooks-Gunn, & Graber, 2012). The hormonal changes of puberty may also heighten an adolescent's stress reactivity (Sontag, Graber, Brooks-Gunn, & Warren, 2008; Stroud et al., 2009; E. Walker, Sabuwalla, & Huot, 2004), while also augmenting his/her orientation toward and motivation for thrill seeking, exploration outside the home, and rewarding stimuli. Finally, the link between early maturation and girls' problem behavior may be partly due to common genetic influences (i.e., genes that influence both the timing of puberty and involvement in delinquency; Harden & Mendle, 2012).

Sleep

Notable changes occur in the regulation of sleep patterns during adolescence, which appear to be intricately linked to pubertal development (Carskadon, 2011). Dahl, Trubnick, al-Shabbout, and Ryan's (1997) longitudinal study of normal sleep found that changes in REM sleep showed a strong link to pubertal increases in reproductive hormones, whereas changes in stages 3 and 4 non-REM sleep appeared to be more strongly linked to the rapid physical growth at puberty (as measured by body mass index). There is also a circadian shift (delay of sleep) resulting in a biologically based tendency to stay up later (and sleep in later) that occurs in early to midpuberty and an increase in objectively measured daytime sleepiness, which may represent an increased biologic need for sleep during pubertal maturation (Carskadon, 2011). There are further maturational changes in the effects of sleep loss in adolescence. By midpuberty, adolescents show much greater objectively measured sleepiness, as well as complex changes in mood and affect regulation, in response to sleep loss (Gregory & Sadeh, 2012).

The impact of pubertal change on sleep and arousal may have important implications for the development of psychopathology, with, for example, adolescent depression directly associated with disturbed sleep (Gregory & Sadeh, 2012) and, particularly, difficulties falling asleep (Gangwisch et al., 2010). Furthermore, compromised sleep in early adolescence is associated with poor performance when processing emotional information (Soffer-Dudek, Sadeh, Dahl, & Rosenblat-Stein, 2011). In addition to the direct effects of sleep loss on outcomes such as mood, attention, and motivation, sleep loss in adolescents can also increase stimulant use during the day (e.g., caffeine, nicotine, methylphenidate, and illicit stimulants), which may in turn increase risk for psychopathology. Accumulated sleep loss results in a variety of behavioral adaptations such as extensive catch-up sleep on the weekends (by sleeping in very late). These types of adjustments ultimately can have negative effects on the circadian system, as it is slow to adapt to alterations in sleep schedules. Neuroimaging work suggests that sleep-deprived individuals have difficulty moderating emotional responses, as evident by an altered amygdala response to negative emotional stimuli and less co-activation between the amygdala and associated prefrontal cortex regulatory regions (Walker & van der Helm, 2009). Poor sleep quality in adolescence may also be related to negative mood and risk taking as well as how the brain processes rewarding stimuli (Holm et al., 2009). In these ways, it appears that insufficient sleep can sometimes contribute to a spiral of problems associated with emotional dysregulation.

Contextual factors have also been found to negatively impact adolescent sleep-wake cycles. A consistent finding is that the timing of bedtime shifts to later hours in the night from middle to high school (Carskadon, 2011). While part of the bedtime delay stems from biologically driven changes in circadian timing, adolescents also engage in high levels of media use (e.g., television, computer games, internet, mobile phones) at night, often resulting in increased arousal levels that keep teenagers up very late (Cain & Gradisar, 2010). Despite the later bedtime, the high school transition often introduces the need for adolescents to wake sooner due to an earlier start of their school day, thereby creating a shorter sleep period and increased vulnerability to emotional dysregulation. To ameliorate such risks, interventions could be used to help parents

and adolescents to set appropriate sleep schedules and to encourage schools to delay start times for adolescents and provide information about sleep to families.

Parent-Child Relationships

As individuals transition into adolescence, there are many changes in the parent-child relationship. For example, during adolescence parents and children must negotiate increasing need for autonomy during adolescence. Parents who are able to balance encouraging adolescent independence and maintain a supportive bond facilitate self-esteem and social functioning (Van Petegem, Beyers, Vansteenkiste, & Soenens, 2012), which in turn protect against psychopathology. With respect to other dimensions of the parent-child relationship, conflict tends to decline across the adolescence years, although when conflicts arise they frequently pertain to matters of adolescents' personal choice (Laursen, Coy, & Collins, 1998; Smetana & Villalobos, 2009). Warmth between adolescents and parents remains relatively consistent across this age period (Trentacosta et al., 2011), although harsher, aloof parent–child interactions continue to place a youth at risk for development psychopathology.

It is likely that the changing nature of the parent-child relationship during adolescence is at least partially the result of the adolescent's biological and cognitive maturation. Increases in cognitive abilities during adolescence allow a child to begin the process of autonomy seeking, but also may place the adolescent at risk for increased conflict with parents (Smetana, 2011). Several studies have found that puberty, not age, is associated with increases in bickering between adolescence and their parents and diminished closeness between the parent and adolescent. (De Goede, Branje, & Meeus, 2009; McGue, Elkins, Walden, & Iacono, 2005). Relatively earlier maturation is linked with greater discrepancy between an adolescent's desired autonomy, and parent's age-based expectations about appropriate levels of autonomy (Weichold, Büttig, & Silbereisen, 2008), which may lead to greater conflict in the parent–child relationship. Consistent with this account, early maturing males and females report greater conflict and decreased closeness with parents compared with later maturing adolescents (Huddleston & Ge, 2003; Weichold et al., 2008).

Who Is More Vulnerable? What Are the Risk Factors?

During adolescence people vary in developmental processes that make them differentially vulnerable to psycho pathology, such as neural development, pubertal development, and changes in circadian rhythms. Some of the primary factors that increase individual vulnerability to psychopathology include being easily aroused emotionally, having poor self-regulation, seeking out opportunities that involve risk, being highly sensitive to interpersonal interactions, and experiencing contextual risks (e.g., poverty, extreme stress, abuse, or trauma). For example, we hypothesize that the increased intensity and duration of emotion, in combination with the increased strength of some appetitive drives, create new regulatory challenges, particularly with respect to self-regulation in the face of high-intensity emotions and motivations. During adolescence, there is a shift in regulatory capability away from regulation assisted by external agents, such as parents, toward regulation that is primarily internal, cognitive in nature, and involving higher order executive functioning. The type of executive function that is manifest during the adolescent transition is in fact an integration of a number of specific cognitive achievements, particularly in planning, monitoring, evaluating, and reflecting. Together, these can be thought of as an executive suite that comes increasingly, but gradually, under conscious control during adolescence (Keating, 2004). Because the maturation of regulatory systems (e.g., cognitive control) relevant to the modulation of emotion and motivation is not driven by pubertal development and is still taking place during late adolescence (Smith, Chein, & Steinberg, 2013a), adolescents may be relatively more vulnerable than children (whose levels of arousal and motivation are lower) or adults (whose regulatory capabilities may be stronger) to extremes in affective and drive states, which may leave adolescents more susceptible to psychopathology. These extremes in affective and drive states may be linked more strongly to social contextual change. As such, regulatory problems may result either from inadequate or incompletely developed regulatory capacities or both. Bringing the potent and novel affective and motivational systems into an integrated, functioning system is a lengthy and effortful process. Thus, emotional and behavioral disorders may result from underregulation (e.g., where the underregulation of anger may lead to conduct problems) or inappropriate regulation (e.g., where the overregulation of sadness by rumination may lead to the development of depressive disorder). As regulatory capacities mature, individuals become less susceptible to the development of psychopathology.

We also hypothesize that various forms of psychopathology in adolescence are directly related to the neurobehavioral changes of puberty, primarily through their association with changes in brain systems regulating arousal and appetite that subsequently influence the intensity and duration of emotion and motivation (not

the regulatory systems that undergo development across adolescence). Adolescents, we hypothesize, experience emotions and motivations that are qualitatively and subjectively stronger than those experienced by prepubertal children. Thus, for example, whereas children experience sadness, euphoria, anxiety, and anger, the biological changes of puberty result in the capacity of individuals to feel sadder, more euphoric, more anxious, and angrier and, furthermore, to experience these more intense affective states for longer periods of time. Similarly, the biological changes of puberty stimulate changes in the intensity and duration of various drives, not only the sex drive, which is presumed to intensify at puberty, but all drives relevant to reward, novelty, and stimulation seeking. In addition, motivational drives related to social status appear to increase during adolescence.

Adolescence as a Time of Plasticity

It is important to acknowledge that adolescence is also a period of plasticity. Plasticity is apparent through the reorganization that occurs among biological, cognitive, and emotion systems during adolescence. Given that these systems are reorganizing, it stands to reason that adolescence presents an opportunity for biological, cognitive, and emotional systems to be shaped in ways that may protect against psychopathology and other negative outcomes. The impact of continued brain maturation on emotional, cognitive, and behavioral development has yet to be thoroughly studied, but the evidence for continued development in these processes and for apparent plasticity of brain development in adolescence suggests that this period may present some unique opportunities for prevention and intervention (including cognitive-behavioral, psychopharmacological, or other psychotherapeutic treatments), particularly compared with the periods before and after adolescence.

We hypothesize that during the period of greatest disjunction between affect and appetitive motivations on the one hand, and regulatory competence on the other, individuals may be protected from extremes in emotion or drive by a context that provides adequate external regulation in the form of support, control, and predictability. Thus, although many individuals may experience emotions and drives whose intensity and duration exceeds their regulatory competence, those adolescents who enjoy supportive home, peer, school, and neighborhood contexts are buffered from the ill effects of the disconnection between high emotionality and still maturing cognitive control and self-regulation. In addition, their transition to an internal, consciously controlled regulatory system is more effectively scaffolded by contextual supports compared with individuals lacking in such support. Conversely, individuals whose environments do not provide sufficient support, control, and predictability are relatively more vulnerable to the development of psychopathology, perhaps because they lack the external regulatory control that supplements still maturing self-control.

The adolescent is not merely the passive recipient of contextual support, however. We view context as a resource that is both provided by outside agents (such as parents or teachers) and also actively recruited by adolescents. An important, yet remarkably understudied, question is how individuals develop the capacity to identify, enlist, and employ sources of contextual support during times of extreme emotions, drives, and stress as a means of protection against the development of emotional and behavioral difficulty. In this regard, resilience in the face of adversity may reflect in part the ability to engage contextual resources in the service of self-protection.

CURRENT BRAIN-BASED FRAMEWORKS FOR UNDERSTANDING ADOLESCENT PSYCHOPATHOLOGY

In the last decade, our knowledge of the protracted brain development that occurs during adolescence has increased exponentially. Driving this research and because of this research, major brain-based explanations of adolescent psychopathology have emerged. The brain can be conceived as a central arbiter of our behavior. That is not to say that biology is destiny, but rather that behavior is instantiated via the brain within the context of individual differences and environmental influences. To advance our understanding of the emergence of psychopathology in adolescence from a brain-based perspective, several explanatory models have been proposed over the last decade. One common theme across several of these models is an emphasis on the weighting of input from various neural systems and how alterations in the balance among these systems changes with maturation or psychopathology. In addition, these models have been put forth to explain specific behavioral changes during adolescence (e.g., risk taking, depression) as well as to provide a framework for understanding vulnerability to psychopathology more generally in adolescence. We highlight here three main approaches that have been foundational for generating several research agendas aimed at understanding adolescent psychopathology: Dual Systems approaches,

the Triadic Model, and the Social Re-Orientation model. While other approaches have been offered (Crone & Dahl, 2012; Luciana & Collins, 2012; Pfeifer & Allen, 2012), we highlight these three approaches as the most researched.

Increased risky behavior in adolescence is a normative and common occurrence relative to childhood and adulthood. One explanation from the field of developmental neuroscience suggests that this increase in risky behavior is the result of a temporal dissociation in the developmental course of two neurobiological systems across adolescence (Steinberg et al., 2008). These two distinct neurobiological systems center on a socioemotional system involving limbic and paralimbic regions of the brain, including the amygdala, ventral striatum, orbitofrontal cortex (OFC), medial prefrontal cortex (mPFC), and superior temporal sulcus, and a cognitive control system, which comprises the lateral prefrontal and parietal cortices and their interconnections with areas of the anterior cingulate cortex (ACC) (Steinberg, 2007). According to this dual systems model, adolescent risk taking is hypothesized to be sparked by a rapid and dramatic increase in dopaminergic activity within the socioemotional system around the start of puberty, a neurochemical change presumed to lead to increases in reward seeking behavior. However, this increase in reward seeking behavior precedes the full structural development of the cognitive control system and its connections to areas of the socioemotional system, a maturational process that more gradually unfolds over the course of adolescence, permitting more adult-like self-regulation and impulse control skills. The temporal gap between the arousal of the socioemotional system, which onsets in early adolescence, and the longer maturational course of the cognitive control system, creates a period of heightened vulnerability to risk taking during middle adolescence (Casey, Jones, & Somerville, 2011; Steinberg, 2008). That is, the temporal gap described by this model can account for normative increases in risky behavior during adolescence, but it also suggests that a wide gap between the development of these two neurobiological systems could explain why some adolescents may be more prone to risky behavior in general, engage in risky behaviors for a longer period of time, or take part in extreme forms of risky behavior. As one writer described, these processes are akin to starting a car engine without a skilled driver behind the wheel (Dahl, 2001). Similar perspectives have postulated that adolescent vulnerability to negative outcomes more generally is the result of an imbalance in input from socioemotional and cognitive control neural circuitry due to maturation.

Another important framework from the field of developmental neuroscience is the triadic model of motivated behavior (Ernst & Fudge, 2009). The triadic model differs from the dual systems model in that it emphasizes the interplay among distributed networks that drive behavior more generally and includes a second socioemotional neural system that underlies avoidance behavior. In the triadic model, motivated behavior is characterized as being dominated by input from either avoidance or approach neural systems (or equal contributions from both), and then regulated by a cognitive network. The triadic model also provides flexibility to account for all types of motivated behavior, such that both avoidance and approach systems are relevant to and influenced by social and non-social contexts. The key node of the avoidance systems is the amygdala, given its established association with fear and threat processing. For the approach system, the striatum more generally, and the ventral striatum more specifically, is the key node due to its well-documented role in reward processing. Functioning of the control network is relegated to the prefrontal cortex as the primary neural substrate of cognitive executive control (Miller & Cohen, 2001).

A third brain-based theoretical framework, the social re-orientation framework, is rooted in the dramatic social restructuring and continued brain refinement and maturation that accompany adolescence (Nelson, Leibenluft, McClure, & Pine, 2005). Given the changes in brain structure across adolescence, it is expected that social cognitive processes recruited for successful social interactions change during adolescence. These social and biological changes in adolescence have been interpreted based on the social information processing network (SIPN) model (Nelson et al., 2005). The SIPN model identifies three networks of nodes that process social stimuli in an interactive and integrated fashion. The detection node, including the superior temporal sulcus, intrapariental sulcus, fusiform face area, as well as inferior temporal and occipital cortical regions, is responsible for perceiving and categorizing basic social properties of stimuli. Following detection, the affective node further processes social stimuli in regions that include the amygdala, ventral striatum, hypothalamus, bed nucleus of the stria terminalis, and, in conditions involving emotion, the OFC. These regions are engaged generally by reward or punishment cues; thus, the affective node imbues social stimuli with emotional salience. Finally, the cognitive-regulatory node, which comprises the medial and dorsal prefrontal cortex (PFC) and areas of the ventral PFC, including the OFC, performs complex cognitive processes related to social stimuli such

as perceiving others' mental states, inhibiting prepotent responses, and generating goal-directed behavior. The SIPN model suggests that, during adolescence, changes in social-cognitive processing and social behavior reflect alterations across these three neural nodes via hormonal changes, brain maturation, and the influence of experience on neural networks. Because the major social changes in adolescence are intertwined with intense emotions and motivations, and intense emotions and motivations can tip from normative to psychopathological, heightened sensitivity to and enhanced salience of social experiences are particularly relevant to the development of psychopathology. Adolescents also find themselves having to navigate and integrate with new social networks and supports, behaviors that draw on input from key brain regions delineated by the SIPN model. As such, neural activations are expected to be linked to motivation, self-esteem, and being judged in a social context that will be augmented in the affective node of the SIPN during the adolescent period, with extreme activations relating to psychopathology.

An extension of the SIPN model has further suggested that the prolonged maturation of the PFC parallels the slowly emerging ability for flexible social behavior across the adolescent period (Nelson & Guyer, 2011). Flexibility in social behavior is fundamental for competent interactions with others and can buffer some individuals from the development of psychopathology. Three aspects of social flexibility are thought to be supported specifically by the ventral regions of the PFC, including emotional value computation, inhibitory control of behavior, and acquisition and generation of rules. Within the ventral PFC, the more lateral areas of the orbital gyrus and inferior frontal gyrus are suggested to subserve rule use and inhibitory control in social contexts whereas the medial part of the OFC is thought to support valuation of a social stimulus. A body of evidence now documents that the brain is sensitive to social experiences in adolescence and that perturbations in the process of developing social flexibility may relate to some forms of psychopathology in adolescence, such as social anxiety (Guyer, Lau, et al., 2008).

Each of these perspectives—dual systems models, triadic model, and the social re-orientation framework—suggest that the developmental changes in the brain during adolescence incur risk for psychopathology. In the sections that follow, we review the major adolescent changes that occur in biology and in context. We focus on the types of change that may place individuals most at risk for psychopathology and the individuals who are at risk for psychopathology.

MAJOR BIOLOGICAL CHANGES OF ADOLESCENCE

Pubertal development and changes in brain development are the two major biological changes of adolescence. These processes are inextricably intertwined, as puberty can affect the development of the brain during the adolescent years. In this section, we describe pubertal changes, changes in the brain that occur during adolescence, and the links between puberty and brain maturation in both human and animal models. We discuss how each of these major developmental changes increases risk for psychopathology.

Pubertal Development in Humans

The onset of puberty—the developmental process that encompasses the transition from childhood to sexual maturity—is one of the defining milestones of the adolescent transition, so much so, that the terms adolescence and puberty are used interchangeably (Spear, 2010). From a hormonal standpoint, puberty is marked by activation of the hypothalamic-pituitary-gonadal (HPG) axis for the first time since early childhood, with an increasing number and magnitude of gonadotropin-releasing hormone (GnRH) secretions from the hypothalamus that stimulate the production of follicle-stimulating hormone (FSH) and leutenizing hormone (LH) by the pituitary gland. Together, these hormones induce secretion of gonadal steroid hormones (e.g., estrogen, testosterone, other androgens) that lead to gametogenesis, or production of sex-specific cells, such as sperm. The production of gonadal steroids is also responsible for the development of secondary sex characteristics and changes in reproductive behavior, such as increased interest in sex. While the effects of gonadal hormones on the nervous system were originally thought to be organizational and limited to the perinatal period, more researchers have recognized that puberty is yet another ontogenetic period during which gonadal hormones have the opportunity to influence neural development and behavior (see Sisk & Zehr, 2005, for a review).

Puberty and Psychopathology

Although the specific mechanisms connecting pubertal maturation and various psychopathologies in adolescence have yet to be established, there are two areas where considerable research has been conducted. First, much evidence suggests that an early onset of puberty may incur risk for the emergence of psychopathology. Second, evidence is growing to suggest that part of the association between

puberty and risk for psychopathology may be due to the puberty-related changes in affective and motivational systems that regulate emotions and behavior.

Numerous studies have shown that individuals who go through puberty earlier than their same-age peers are especially vulnerable to a wide range of affective and behavioral disorders. Indeed, one of the most robust findings in the literature on pubertal development and adolescent adjustment is that early maturing females, and to a lesser extent early maturing males, evince relatively higher rates of virtually all sorts of adjustment difficulties, including depression and suicide, delinquency, risk taking, and emotional disorders and other psychological difficulties (Ge, Conger, & Elder, 1996; Graber et al., 1997; Orr & Ingersoll, 1995). As with the case of pubertal status and psychopathology, the underlying links between pubertal timing and psychopathology have remained largely unexplained. Some investigators have emphasized the effects of off-time development (i.e., maturing at a different age than one's peers) as the key factor in risk for depression (Graber et al., 1997), whereas others have attributed increased vulnerability of early maturers to a wider array of problems (Stattin, Kerr, & Skoog, 2011). Another strong possibility that has been suggested (e.g., Dahl, 2001) is that the disjunction between changes in affective arousal (which are linked to puberty) and the development of self-regulatory competence (which is likely pubertal-independent) is wider among early maturers than their peers.

Beyond psychopathology, it is important to note that variation in pubertal timing contributes to risk for a broad range of negative health outcomes. Early pubertal timing has been linked to many deleterious health outcomes (Golub et al., 2008), including obesity (Prentice & Viner, 2013), type 2 diabetes (Lakshman et al., 2008), cardiovascular disease (Prentice & Viner, 2013), and reproductive cancers (Hamilton & Mack, 2003). Yet earlier timing of puberty may also relate to the development of psychosocial problems (e.g., sexual abuse, conduct disorder; see Golub et al., 2008).

Part of the reason for the association between pubertal development and risk for psychopathology may be because pubertal development is associated with intense affective experience. From a neuroscience perspective, emotions have been conceptualized as brain states associated with rewards and punishments (Rolls, Critchley, Browning, Hernadi, & Lenard, 1999), with a group of interconnected brains structures including (but not limited to) the amygdala, extended amygdala/ventral striatum, medial cortex and OFC (Davidson, 2000, 2002; Davidson, Jackson, & Kalin, 2000; Drevets, 2003; Rolls et al., 1999) contributing to affect regulation. Not surprisingly, there is evidence that the development of romantic interest and sexual motivation is directly influenced by pubertal processes (Udry, 1987). Furthermore, it has been shown that some aspects of emotional reactivity and intensity (e.g., parent-adolescent conflict) are more closely linked to pubertal maturation and not age (Belsky et al., 2007). Furthermore, evidence has suggested that there is a correlation between pubertal status and processing of facial expressions indicating social threat (Forbes, Phillips, Silk, Ryan, & Dahl, 2011), as well as pubertal status and brain activation patterns induced by reward-related events and depressive behaviors (Forbes et al., 2010). Studies that have indicated a positive association between pubertal status and the risk for affective disorders (Angold & Costello, 2006; Angold, Costello, & Worthman, 1998) provide even more evidence for an influence of pubertal hormones on affective processes.

Finally, part of the association between puberty and externalizing issues during adolescence may be explained by changes in the associations between pubertal development and sensation seeking. During the adolescent transition, risky behavior, and in particular sensation seeking, is prominent (Shek & Yu, 2012; Steinberg et al., 2008), with this behavior escalating significantly from childhood into early adolescence and declining thereafter into adulthood (Steinberg et al., 2008). In 11–14-year-olds, pubertal status, but not age, is positively correlated with measures of sensation seeking (Martin et al., 2002). In another study that investigated the association between self-reported measures of pubertal status and sensation-seeking using a broader age range (i.e., 10–16-year-olds), a significant relationship between sensation seeking and pubertal status was observed for males but not for females (Steinberg et al., 2008). Interestingly, measures of impulsivity were not significantly correlated with pubertal status for either sex in that same study, indicating that the effects were specific to the construct of sensation seeking. More developmental research is needed to identify the role of puberty in the expression of adolescent typical behaviors, as well as to determine the instances in which developmental processes independent of puberty contribute to the adolescent phenotype.

Lessons From Animal Models

The broader adolescent period has been modeled across a variety of mammalian species, including non-human primates and rodents (for a review see Spear, 2000b). The advantage of examining these processes within animal populations is that we are better able to determine the

specific timing and magnitude of developmental change than in humans. Although not all aspects of puberty can be represented using animal models (e.g., menarche), there are physical indications of sexual maturation in rats with which pubertal timing may be assessed, such as a female change in vaginal opening and a male change in preputial separation and presence of sperm occurring within a constrained expectable period that maps to an adolescence (Vetter-O'Hagen & Spear, 2011b). In both humans and rodents, another indication of the onset of puberty, as described previously, is the increase in gonadal hormones (Harris & Levine, 2003; Sisk, Richardson, Chappell, & Levine, 2001; Vetter-O'Hagen & Spear, 2011b). Physiological and hormonal indices of puberty generally begin to emerge at approximately P28 (i.e., postnatal day 28) in rats, with some pubertal processes lasting until about P55, with males usually entering puberty later in life relative to females (Vetter-O'Hagen & Spear, 2011b).

Animal models have also been particularly useful in illuminating possible mechanisms that trigger the onset of puberty that are not possible to study directly in humans. Initiation of the rising and pulsatile secretions of GnRH from the arcuate nucleus of the hypothalamus (ARC) is likely triggered via a constellation of both internal and external/environmental signals. For example, it has been suggested that insulin and leptin levels are potential physiological signals for induction of puberty (for reviews see Kaplowitz, 2008; Shalitin & Phillip, 2003), perhaps as permissive factors that signal adequate nutrition/body fat has been achieved for successful reproduction. In animal models, as in human evidence, other external factors such as social context (Coppola & Vandenbergh, 1985; Slob, van Es, & van der Werff ten Bosch, 1985) may also play a role in the onset of puberty.

Although mechanistically it is not entirely clear what neurobiological events are responsible for the activation of GnRH secretion at the onset of puberty, recent evidence has begun to demonstrate that kisspeptin (and signaling through its receptor, GPR54) is a contributor to this event (for reviews see Popa, Clifton, & Steiner, 2008; Roa et al., 2009), as kisspeptin appears to stimulate GnRH release from the ARC (Castellano et al., 2006; Gottsch et al., 2004). Expression of kisspeptins (a family of peptides encoded by the Kiss1 gene) is low prior to puberty, with abrupt rises in kisspeptin activity associated with the onset of puberty in rats (Irwig et al., 2004) and mice (Gottsch et al., 2004).

Taken together, these studies demonstrate that the onset of puberty is apparent on both a hormonal and neural level in rodents, with the timing relatively consistent across species and strains, and females tending to enter the pubertal transition earlier than males. These data indicate that, indeed, animal models may be appropriate for investigating the extent to which certain adolescent-typical behavioral and neural transformations may or may not be related to activation of pubertal processes.

Pubertal Contributions to Adolescent-Typical Behaviors in Rodent Models

In comparison to their human counterparts, the behavioral repertoire of rodents is more limited and not nearly as complex. Therefore, it is not possible to fully model human adolescence using rodents, and it may be particularly difficult to use animal models as tools to investigate psychopathological conditions. Nevertheless, animal models provide a sound foundation with which we can more directly assess relationships between pubertal development and neurobehavioral changes of adolescence. These models present many experimental advantages that are not possible in human studies, such as tight control of experimental conditions and the subjects' histories, which allows for a more direct assessment of the impact of specific variables. For example, the organizational versus activational properties of gonadal hormones on neurodevelopment and adolescent-typical behaviors can be examined with animal models. Removal of the gonads (i.e., gonadectomy; GDX) prior to or after puberty in combination with hormone replacement strategies can more directly assesses whether the presence of gonadal hormones at a critical ontogenetic period is necessary to observe a particular behavior or neurobiological event (i.e., organizational effect), or if their presence in the system is required for a particular event or behavior to take place (i.e., activational).

Although numerous studies have used animal models to investigate the organizational influence of early life (neonatal period) sex steroids on later behavior, less attention has been paid to the influence of these hormones specifically during the pubertal period. Evidence now suggests, however, that there are indeed many instances in which the presence of pubertal hormones is necessary to observe a variety of behavioral responses, as described below. For instance, when considering adult-typical sexual/reproductive behaviors, evidence has shown that pubertal hormones are directly involved in the onset and continued expression of these behaviors (Schulz, Molenda-Figueira, & Sisk, 2009). Schulz, Sisk and colleagues demonstrated that adult male rodent sexual, agonistic, aggressive, and submissive behaviors were

dependent upon adolescent exposure to pubertal hormones (Schulz et al., 2004; Schulz & Sisk, 2006). In male rats, the typical increased expression of rough-and-tumble play observed during adolescence (Varlinskaya & Spear, 2006) was reported to not occur when rats were castrated prior to puberty (Cooke & Woolley, 2009), suggesting that pubertal hormones are involved in the expression of this adolescent-typical behavior.

Using behavioral tests that are thought to index anxiety-related processes, some studies have shown that pubertal hormones are also involved in the expression of sex-related differences in anxiety-like behavior in adulthood. Male rats given the opportunity to interact with a conspecific in a novel environment will exhibit significantly less social interaction relative to animals that are placed together in a familiar environment. This reduction in social interaction is thought to reflect anxiety-like behavior and has been shown to depend on pubertal exposure to gonadal hormones, as castration before puberty prevents the adult-typical anxiogenic response but gonadectomy in adulthood does not affect this behavior (Primus & Kellogg, 1989, 1990). Using other behavioral assays of anxiety-like behavior, evidence has emerged with both the open field test (Brand & Slob, 1988; Slob, Huizer, & Van der Werff ten Bosch, 1986) and elevated plus-maze test (Zimmerberg & Farley, 1993) to suggest that pubertal sex hormones contribute to the expression of sex-related differences in anxiety later during adulthood, although these effects are complicated and differ according to the behavioral test being examined. Nonetheless, these findings provide some links between pubertal hormones, detrimental social experiences, and anxiety that may relate to the emergence of human adolescent anxiety.

In contrast to the studies described previously, there are instances in which animal models have demonstrated that the expression of certain adolescent-related behaviors is independent of gonadal hormones. Novelty seeking, for instance, is an adolescent-typical behavior that has been observed in both humans and in rodent models (Caster, Walker, & Kuhn, 2007; Collins & Izenwasser, 2002; Stansfield & Kirstein, 2006), with novelty-directed behavior having been found to be especially rewarding during adolescence (Douglas, Varlinskaya, & Spear, 2003). Novelty-directed behavior was systematically assessed across the adolescent-to-adult transition in male and female rats and, although it was reported to peak between P32-P36 in both sexes before declining into adulthood, no significant correlations between physical and hormonal indices of puberty and novelty seeking were found (Vetter-O'Hagen & Spear, 2011b). Subsequently, the same group observed that neither prepubertal nor adult gonadectomy influenced the expression of novelty-directed behavior when animals were tested as adults (Vetter-O'Hagen & Spear, 2012). In contrast to these results, however, administration of Antide (a GnRH antagonist) prior to puberty and throughout adolescence was shown to reduce an adolescent-typical preference for a novel object in male but not female adolescent rats (Cyrenne & Brown, 2011). Although the reasons for these divergent results are as yet unknown, it is likely that different methodologies for elimination of gonadal hormones (e.g., gonadectomy vs. Antide) and measurement of novelty-directed behavior were contributing variables. Nevertheless, these data indicate that more research is necessary to fully elucidate the role of pubertal hormones in adolescent novelty seeking behavior.

Perhaps related to sensation-/novelty-seeking, ethanol consumption also appears to peak ontogenetically during the adolescent transition, both among humans (SAMHSA, 2011) as well as in animal models (Doremus, Brunell, Rajendran, & Spear, 2005; Vetter, Doremus-Fitzwater, & Spear, 2007). Studies from Spear and colleagues have demonstrated that adolescent-associated increases in ethanol intake in male and female rats are largely unaffected by pubertal hormones (Vetter-O'Hagen & Spear, 2011a), with prepubertal gonadectomy not altering ethanol intake during the adolescent period in either males or females. Instead, it seems that testosterone may impart an activational role on ethanol intake of adult males, as gonadectomy prior to puberty or during adulthood reduces ethanol intake only during adulthood (Vetter-O'Hagen & Spear, 2011a) and testosterone replacement reinstates low levels of ethanol consumption that are typical of adult males (Vetter-O'Hagen, Sanders, & Spear, 2011). While the mechanisms underlying adolescent-associated increases in ethanol consumption still are not understood, these data would suggest that organizational effects of gonadal hormones that happened prior to puberty, or puberty-independent neural alterations occurring during the adolescence transition, are contributors to these age-dependent ethanol intake patterns.

As a whole, the emerging literature in this area has begun to demonstrate the complex relationship between sex steroids and expression of certain behaviors. While we may not be able to fully model human psychopathology using animal models, studies like these provide invaluable data for helping to identify certain facets of adolescent behavior that may be influenced (or not) by pubertal changes and, therefore, provide insight into where to focus our research efforts in humans.

Normative Changes in Brain Development

Despite the widely held notion that the brain changes at puberty, only recently have researchers begun to directly examine the links between brain development and pubertal maturation. In this section, we begin by reviewing neuroscience data that has identified general changes in brain development during the adolescent transition, including studies conducted in both humans and animal models. Specifically, we discuss gross brain alterations, as well as changes on a neuroanatomical and functional level. Subsequently, we will discuss research that has attempted to distinguish between aspects of brain development and function that are closely tied to some aspect or facet of puberty and those that appear to occur relatively independent of pubertal processes (i.e., that follow a timeline distinct from that of puberty or are instead influenced by other aspects of development or experience).

Brain development in mammalian species follows an orderly progression that begins with differentiation of the brain and spinal cord in the longitudinal, circumferential, and radial dimensions prenatally. This process is followed by increases in cell numbers (neurogenesis), repositioning of cell locations (migration), and maturation of connections among brain cells and supporting constituents, which can occur through both activity-independent (i.e., innate) and activity-dependent (i.e., dictated by experience–environment) mechanisms (Nowakowski & Hayes, 1999). Later in development, whole brain volume has been reported to increase from childhood into early and mid-adolescence, declining thereafter from mid-adolescence into adulthood (Courchesne et al., 2000). In addition to gross changes in volume, adolescence is marked by significant changes with respect to neurons and synapses. In terms of gray matter (which is comprised of cell bodies and their projections), adolescence is a time of refinement—synapses are culled and, overall, gray matter is pruned, especially within the cerebral cortex (De Bellis et al., 2001; Sowell et al., 2002). Beyond decreases in the total number of neurons, there is evidence of prolonged changes in the morphology and functional integrity of dendrites, as synapses exhibit marked changes in absolute number and precise localization on dendrites during adolescence (Kolb, 1999). Conversely, there is evidence of extensive myelination during adolescence, which is indicated by general increases in white matter (defined mostly as myelinated axons and glial cells) that is also occurring particularly in the cerebral cortex. Together, these reductions in gray matter concomitant with increases in white matter may result in a functionally more efficient adult brain. Some evidence would suggest that synaptic pruning tends to take place earlier in adolescence, whereas proliferation of white matter seems to occur during late adolescence/early adulthood (Sowell, Thompson, Tessner, & Toga, 2001).

Studies in animal models have similarly reported neuronal loss during adolescence that is accompanied by increases in glial cells, with these changes dependent upon brain area of interest (Cressman et al., 2010; Markham, Morris, & Juraska, 2007; Yates, Markham, Anderson, Morris, & Juraska, 2008). Similarly for humans, the timing of these changes during ontogeny has been shown to be regionally specific, and also influenced by sex (De Bellis et al., 2001; Lenroot & Giedd, 2010; Sowell et al., 2001), which will certainly have implications for determining how pubertal processes might influence these alterations, as well as their contribution to adolescent psychopathology.

From a neurocircuitry standpoint, numerous studies have now demonstrated that substantial reorganization occurs in brain regions and circuits important for a variety of processes, including but not limited to emotion regulation, motivation, inhibitory control, and learning and memory (Crews, He, & Hodge, 2007; Doremus-Fitzwater, Varlinskaya, & Spear, 2010; Yurgelun-Todd, 2007). Overall PFC volume declines, while significant synaptic alterations result in a change in balance from excitatory to inhibitory inputs—general decreases in glutamatergic inputs take place and increased dopaminergic afferents occur (Spear, 2000b, 2007). As shown by Benes et al. (2000), at approximately P28 (i.e., postnatal day 28), dopaminergic inputs to the mPFC began to increase in the rat and continued to exhibit ontogenetic increases into early adulthood (Benes, Taylor, & Cunningham, 2000). Mechanistically, electrophysiological studies have indicated that enhanced sensitivity of inhibitory interneurons in the PFC to dopaminergic inputs are involved in this ontogenetic change (Tseng & O'Donnell, 2007), with developmental increases in postsynaptic PKA activity likely driving augmented L-type Ca2+ function that would be responsible for maturation of prefrontal function (Heng, Markham, Hu, & Tseng, 2011). Furthermore, preclinical data have demonstrated that substantial alterations in connectivity between the PFC and subcortical brain areas happen during adolescence. For instance, when considering GABAergic interneurons in the PFC, afferents from the basolateral amygdala to these interneurons are increased during adolescence, which would have implications for emotional and cognitive processes and the development of psychopathology during this developmental period (Cunningham, Bhattacharyya, & Benes, 2008). We discuss

implications for brain maturation and these developmental processes later in this chapter.

Neural connections between the PFC and nucleus accumbens undergo considerable change throughout adolescence as well. Overall, afferent projections from the PFC to accumbens increase in number during adolescence, along with a late-adolescence elevation in the percentage of these cells that express dopamine D1 receptors (D1-Rs) (Brenhouse, Sonntag, & Andersen, 2008). Electrophysiological properties of both D1-Rs and dopamine D2 receptors (D2-Rs) on medium spiny neurons in the nucleus accumbens to NMDA (N-methyl-D-aspartate)-related stimulation and cortical GABA (Gamma-aminobutyric) stimulation, respectively, have also been shown to differ in adolescent rats relative to their adult counterparts (Benoit-Marand & O'Donnell, 2008; Huppe-Gourgues & O'Donnell, 2012a, 2012b). The magnitude and timing of developmental pruning of dopamine receptors in these brain areas seems to be regionally specific, as D1- and D2-Rs have been reported to markedly decline in early adulthood in the PFC (Andersen, Thompson, Rutstein, Hostetter, & Teicher, 2000), whereas pruning of dopamine receptor levels in the nucleus accumbens appears to occur slightly earlier and to a lesser extent than that observed in the PFC or dorsal striatum (Andersen et al., 2000; Tarazi & Baldessarini, 2000). Alterations in cortico-striatal dopamine projections, receptor expression, and receptor functionality that occur during adolescence together suggest that this circuit is a likely contributor to ontogenetic alterations in reward-related behaviors during adolescence, as well as a vulnerable target for abnormal development and psychopathologies.

While we have focused thus far on dopaminergic systems in cortical circuits, there are, of course, many other brain regions, circuits, and neurotransmitter systems that undergo developmental change during adolescence and might impart vulnerability for psychopathologies. For example, the cannabinoid system has been implicated in the etiology of schizophrenia (Bossong & Niesink, 2010; Giuffrida & Seillier, 2012) and adolescence is a time of elevated cannabis use (SAMHSA, 2011) as well as an ontogenetic period characterized by an increase in the onset of symptoms of schizophrenia (Markham, 2012). Current research suggests that presynaptic (CB1) cannabinoid receptors regulate both inhibitory GABAergic and excitatory glutamatergic activity within the brain, thereby functioning as a protective mechanism that would prevent over-stimulation of excitatory activity at critical periods of development (Bossong & Niesink, 2010). Within PFC regions in particular, endocannabinoids seem to play an important role in modulating GABA/glutamate and dopamine interactions. Studies examining the development of the endocannabinoid system have reported ontogenetic alterations, with CB-1 receptors showing developmental patterns of expression in cortex (Heng, Beverley, Steiner, & Tseng, 2011), and striatum (Van Waes, Beverley, Siman, Tseng, & Steiner, 2012) across the transition to adulthood and developmental alterations in endocannabinoid levels reported as well (Ellgren et al., 2008).

While the increased risk for schizophrenia with drug use during adolescence does appear to be relatively specific to marijuana, it is important to consider that the magnitude of the brain alterations occurring during adolescence imparts a significant liability for disruption of normative brain changes by any drug or environmental perturbation. On the other hand, adolescent-related brain maturational processes may impart vulnerability for drug use, whether due to neurobiologically induced increases in sensation-seeking behavior, increases in motivational- and reward-related behaviors, or simply altered sensitivity to certain drugs of abuse. Though likely a combination of these possibilities, drug use during the adolescent transition is a risk factor that may interact with genetic–environmental vulnerabilities and thus contribute to the onset of psychopathology at this maturational interval.

Puberty and Adolescent Brain Development

Brain alterations occurring during adolescence take place on a variety of levels, from neurotransmitter and receptor expression, to synapse formation, to alterations in myelination. Given the vast number of changes, it is not surprising that evidence to date indicates that some brain alterations seem to be puberty dependent, whereas others appear to not be influenced by pubertal maturation. As reviewed by Ladouceur and colleagues (2012) human neuroimaging studies have provided growing, albeit indirect, evidence for an influence of pubertal maturation on white matter development. Furthermore, neuroimaging studies have indicated that some of the sexual dimorphisms in brain anatomy that arise during adolescence (Lenroot & Giedd, 2010) are likely influenced by the presence of pubertal hormones, as there are cases in which adolescents experienced abnormalities in pubertal hormones and did not exhibit typical sex-related differences in brain development (Giedd et al., 2006).

In parallel to these neuroimaging studies with humans, animal models have also been used to more directly assess the influence of pubertal hormones on adolescent-related brain reorganization. The general picture that has emerged

is that some adolescent-associated brain alterations appear to be influenced by pubertal hormones, whereas others occur independent of pubertal processes (Schulz et al., 2009; Sisk & Zehr, 2005). For example, the sexually dimorphic development of the anteroventral periventricular nucleus (AVPV), SDN and medial amygdala appears to be affected by prepubertal gonadectomy, although the nature of the influence of these pubertal hormones is region and sex dependent (for a review see Juraska, Sisk, & DonCarlos, 2013; Schulz et al., 2009). Another instance in which pubertal hormones exert an influence on adolescent brain development is with respect to sex differences in the magnitude of cell death in the visual cortex during puberty, with prepubertal ovariectomy attenuating the sexually dimorphic size differences in this structure during adulthood (Nunez, Lauschke, & Juraska, 2001; Nunez, Sodhi, & Juraska, 2002). In contrast, sex differences in the overexpression and subsequent pruning of D1 and D2 dopamine receptors in the PFC and striatum of rats during the adolescent transition have been reported to occur independently of the presence of pubertal hormones (Andersen, Thompson, Krenzel, & Teicher, 2002). Taken together, results from this growing literature suggest that not all aspects of adolescent brain development are related to puberty. Yet careful examination of these adolescent-related brain alterations using both human neuroimaging studies and animal models will help to fully characterize the influence of pubertal hormones on specific brain changes as potential contributors to the onset of psychopathology during adolescence.

DEVELOPMENTAL PROCESSES CRITICAL IN ADOLESCENT PSYCHOPATHOLOGY

Over the past decade, there has been a tremendous interest, both from the scientific community and the media, in how adolescent neurodevelopment might contribute to the behavioral and emotional health problems that become prevalent during the teen years. Many of these problems have been conceptualized as involving dysregulation of intense emotions (e.g., depression, anxiety disorders) or poor decision making in the face of emotional influences (e.g., unsafe sex, risky driving, substance abuse). As described earlier in this chapter, researchers and policy-makers have emphasized dual process models that seek to explain increased rates of adolescent psychopathology as a function of a gap between input via an affective salience system, believed to be heightened during adolescence, and input from a cognitive control system, which undergoes a prolonged course of development, that serves to regulate the affective system (Casey, Jones, & Hare, 2008; Dahl, 2004; Ernst, Pine, & Hardin, 2006; Steinberg, 2005; Steinberg et al., 2006). Although to date developmental neuroscience research has provided some empirical support for dual process models, the boundaries, and thus operationalization, of what such a gap implies for maturity of adolescent brain anatomy and structure remains unspecified. Researchers have also recently argued for greater recognition of the complex nature of adolescent brain development, indicating that the interrelationships between neurodevelopment and the development of psychopathology may be more complex than previously thought (Crone & Dahl, 2012; Luciana & Collins, 2012; Pfeifer & Allen, 2012). For example, attention is needed on the direct relationship between brain structure and function and its joint association with psychopathology as well as how neural processes change within individuals and in tandem with changes in psychopathology over time. Although many questions still remain to be answered, we review the developmental changes in affective and cognitive control systems that occur during adolescence and discuss their potential role in the development of psychopathology during this period.

Changes in Social Motivation Systems

As we have discussed previously and will discuss in depth later in this chapter, adolescence involves a reorganization of social relationships, with teens investing more time and energy into forging new bonds with peers and pursuing romantic interests, while spending less time with family members (Larson & Richards, 1994; Steinberg & Morris, 2001). Researchers have proposed that the convergence of social changes and neural and endocrine changes in adolescence place an increased motivational salience on the goals of obtaining and maintaining social rewards (i.e., status, admiration, acceptance) and defending against social threats (i.e., rejection, exclusion; Crone & Dahl, 2012; Nelson et al., 2005; Silk, Davis, McMakin, Dahl, & Forbes, 2012). These motivational changes are likely interrelated with processes involved in identity formation (Erikson, 1980), which are strongly influenced by social comparison during adolescence (Pfeifer, Lieberman, & Dapretto, 2007; Pfeifer et al., 2009). In other words, adolescents come to understand who they are largely through the lens of how others view them and how they compare to others. Affiliation, admiration, and acceptance from peers and romantic partners represent salient social rewards during this period, but adolescents are also exposed to

frequent social threats, such as rejection, loss of status, exclusion, or embarrassment. This is particularly true for modern teens, given that they receive status feedback from social media technologies on a near continuous basis. Social threats are among the most highly salient human stressors (Dickerson & Kemeny, 2004) and may be particularly important for adolescents, given that their peer groups involve complex social hierarchies (Brown & Larson, 2009; Connolly, Furman, & Konarski, 2000).

Increased social motivations during adolescence may be related specifically to changes in the dopamine system during this period, which, as discussed previously, tend to increase incentive motivation (Luciana & Collins, 2012). Social incentives, such as obtaining approval from an admired peer, or being asked out on a date, are likely to be particularly salient for teens. Motivational changes during adolescence may also be related to the pubertal rise in sex hormones that occurs during this period. For example, testosterone, which increases in both males and females at puberty, appears to activate motivational tendencies that facilitate an increased orientation toward social status (Forbes & Dahl, 2010; Pfeifer & Allen, 2012).

While there is a pressing need for more research in human adolescents, studies of animals and adult humans converge to support the role of testosterone as a social hormone that enhances motivation to obtain and defend social status (Bos, Panksepp, Bluthe, & van Honk, 2011; Carney & Mason, 2010; Dabbs & Dabbs, 2000; Eisenegger, Haushofer, & Fehr, 2011). For example, in a study of adolescent primates, testosterone was associated with increased social dominance *and* sensitivity to threatening faces, but not with reactions to nonsocial emotional stimuli (Richards et al., 2009). Although the relationship between hormones and behavior is complex, non-human research suggests that it may be at least partially mediated by the influence of sex hormones on neural circuits that support socio-emotional behavior (Hermans et al., 2010; Manuck et al., 2010; Schulz et al., 2009; Stanton, Wirth, Waugh, & Schultheiss, 2009; Van Wingen et al., 2010), as indicated by high densities of steroid hormone receptors in areas involved in social and emotional information processing, such as the striatum, amygdala, hippocampus, and PFC (Sarkey, Azcoitia, Garcia-Segura, Garcia-Ovejero, & Don-Carlos, 2008; Simerly, Chang, Muramatsu, & Swanson, 1990). Although less understood, other hormones, such as estradiol and oxytocin, may also play a role in increasing the motivational salience of social interactions during adolescence (Gabor, Phan, Clipperton-Allen, Kavaliers, & Choleris, 2012). Greater attention to hormones' impact on brain and behavior in human adolescents, especially as a function of pubertal development, is an important priority for future research, and particularly for understanding psychopathology (Paus et al., 2008).

Increased orientation toward the social world beyond the family context is normative during adolescence, yet may also contribute to the development of problems such as substance abuse, anxiety, and depression. The field of social cognitive neuroscience has made major progress in mapping the neural substrates of social interaction and social perception during adolescence. These studies have identified a network of regions known as the mentalizing or theory of mind (ToM) network, which undergoes structural and functional change during adolescence (see reviews by Blakemore, 2008; Burnett, Sebastian, Cohen Kadosh, & Blakemore, 2010). However, relatively little is known about how changes in the mentalizing and ToM network might contribute to the development of psychopathology during this period. In contrast, more research has focused on how adolescent neurodevelopmental changes in the brain circuitry that responds to the affective salience of social stimuli might be implicated in the development of psychopathology. Altered functioning in a ventral affective salience network that includes regions of the brain that are involved in the processing of both negative emotional stimuli and rewards have been identified in some forms of adolescent psychopathology, such as anxiety and depression.

Changes in Reward Systems

We use the term reward systems to refer broadly to interrelated systems involved in approach motivation, sensation seeking, reward processing, and incentive motivation. As summarized in several recent reviews (Ernst, Romeo, & Andersen, 2009; Galvan, 2010; Galvan, 2013; Wahlstrom, Collins, White, & Luciana, 2010), adolescence is associated with an increase in reward-seeking, sensation-seeking, and novelty-seeking behaviors that also occurs in other species (Spear, 2000a, 2011). Self-reported sensation seeking increases from early to middle adolescence before declining from adolescence to adulthood (Harden & Tucker-Drob, 2011). Adolescents appear to seek out experiences that create high-intensity feelings, even when these experiences carry risks (Martin et al., 2002). This shift toward greater novelty-seeking and risk-taking may have evolutionary value, as it would serve to encourage adolescents to explore novel territories and roles beyond the home and interact with new potential mates outside of the family unit (Spear, 2000a). More generally, it may encourage a sense of independence and agency during the transition from childhood to adulthood.

This change in reward-seeking behavior is believed to be related to changes reviewed above in dopaminergic systems in adolescence, including changes in the firing rates, density, and concentration of dopamine fibers and receptors and a shift in the balance of dopamine receptors across brain regions. Luciana and Collins (2012) have argued that the increase in reward- and sensation-seeking behaviors in adolescence could be mediated by increases in tonic levels of dopamine in neural regions supporting affective motivation during adolescence. Others have suggested that heightened dopaminergic prediction error responsivity contributes to adolescent reward seeking (Cohen et al., 2010). However, methods for investigating changes in tonic and phasic dopamine firing in human adolescents are currently limited.

Neuroimaging studies provide some evidence for developmental changes in activation of reward circuitry during adolescence. This circuitry includes the striatum, amygdala, ACC, and mPFC (Depue & Collins, 1999). Most studies of adolescents have focused on the ventral striatum, and have relied on monetary reward tasks to probe neural response to anticipation and receipt of reward. These studies suggest that, relative to children, adolescents show increased striatal activity during the anticipation and receipt of reward (Cohen et al., 2010; Galvan et al., 2006; Somerville, Hare, & Casey, 2011; Van Leijenhorst et al., 2010). When compared with adults, adolescents have also been shown to exhibit increased striatal reactivity to reward (Cohen et al., 2010; Ernst et al., 2005; Galvan et al., 2006; Somerville et al., 2011), although conflicting data also exist (Bjork et al., 2004; Bjork, Smith, Chen, & Hommer, 2010; Forbes et al., 2010). Spear (2011) and Galvan (2010) suggested that these discrepant findings may be related to differences in responding to reward anticipation versus receipt of reward or other contextual features such as the type and magnitude of the reward. For example, it may be that adolescents have a decreased response to small rewards but an increased response to large rewards. This remains an important area for continued research.

Another important question is the extent to which changes in reward processing are related to pubertal development. Martin and colleagues (2002) found that adolescents further along in self-reported pubertal development were also higher in self-reported sensation seeking, even when controlling for the effects of age. Forbes and colleagues (2010) examined puberty-specific changes in reward responding based on a large sample of early adolescents matched for age but differing in pubertal status. They found that adolescents with more advanced pubertal maturation exhibited less striatal and more mPFC reactivity during reward receipt than age-matched adolescents with less advanced pubertal maturation. Similarly, they found that adolescents with higher circulating levels of testosterone exhibited lower striatal reactivity to reward receipt. In contrast, for boys only, testosterone was associated with increased striatal reactivity during reward anticipation, suggesting the possibility of different puberty-related developmental effects on anticipation and receipt of reward. These findings raise the possibility that later stages of puberty are associated with greater involvement of the mPFC, which aids in learning associations between events (e.g., outcome of receiving a reward) and generating adaptive emotional responses (Euston, Gruber, & McNaughton, 2012), and less involvement of the striatal regions implicated in motivation and reward seeking.

Over the past decade more ecologically valid paradigms have been developed that aim to simulate peer interactions during neuroimaging and psychophysiological assessment (Guyer, Lau, et al., 2008; Masten et al., 2009; Silk, Stroud, et al., 2012). This has allowed researchers to study typical and atypical neural responses to social rewards, such as peer acceptance, during adolescence. For example, the Chatroom Task (Guyer et al., 2014; Guyer, Choate, Pine, & Nelson, 2012; Guyer, Lau, et al., 2008; Guyer, McClure-Tone, Shiffrin, Pine, & Nelson, 2009; Lau et al., 2012) has been widely used to investigate adolescents' neural response to anticipated and rigged feedback (both positive and negative) from virtual peers they believe have evaluated them as potential interaction partners for an upcoming online chat session. Davey, Allen, Harrison, Dwyer, and Yucel (2010) investigated how adolescents and young adults respond to being liked by asking participants to view photos of other virtual participants whom they were led to believe had rated them as likable based on their own photographs. These peer feedback tasks have shown that acceptance from virtual peers activates regions involved in reward processing and positive affect, particularly the ventral striatum (Davey et al., 2010; Giedd & Rapoport, 2010; Guyer et al., 2012; Guyer et al., 2009; Moor, van Leijenhorst, Rombouts, Crone, & Van der Molen, 2010). Several studies have now investigated changes across adolescence in response to positive social feedback. Existing data show increased striatal and mPFC activity to happy relative to neutral faces (Pfeifer et al., 2011) and to virtual peer acceptance relative to rejection (Gunther Moor, van Leijenhorst, Rombouts, Crone, & Van der Molen, 2010; Guyer et al., 2012) across adolescence. Silk and colleagues (2012) also found evidence for increased visual biases toward acceptance feedback across adolescence using eye tracking during engagement in a simulated peer interaction task.

Another exciting discovery over the past decade has been the finding that the presence of peers enhances risk taking and reward processing measured through both behavioral and neural indices in adolescents. In a behavioral study, Gardner and Steinberg (2005) demonstrated that adolescents took more risks on a simulated driving task when they were watched by two peers, compared with when they performed the task alone. In the peer condition, these adolescents were more likely to risk crashing to earn a potential reward, whereas they made safer driving decisions when they were alone. Interestingly, the influence of peers on risky driving was stronger in adolescents than in adults, suggesting that the influence of peers on reward seeking and risk taking may be particularly heightened during adolescence. Another study showed that adolescents had a greater preference for immediate over delayed rewards when performing a delay discounting task in the presence of peers than when playing alone (O'Brien, Albert, Chein, & Steinberg, 2011). These effects were replicated even in the presence of unknown peers (Weigard, Chein, Albert, Smith, & Steinberg, 2014) and even when the probabilities of negative outcomes were known (Smith, Chein, & Steinberg, 2014). Through the use of neuroimaging, Chein and colleagues (2010) investigated the neural correlates of this peer enhancement effect on risk-taking behavior by conducting a neuroimaging study in which adolescents completed the simulated driving task in the fMRI scanner while their performance was observed by two peers. Findings showed that increased risky driving in the presence of peers was associated with enhanced activity in the ventral striatum and OFC during the peer observation condition among adolescents but not adults.

Changes in Reward System and Psychopathology

Increases in risk-taking and sensation-seeking behaviors in adolescence likely contribute to adolescent experimentation with rewarding and pleasurable substances and experiences, such as taking drugs and alcohol, and sexual activity (Colder et al., 2013). Most drugs exert their initial reinforcing effects on reward processing through ventral striatal dopamine release (Baler & Volkow, 2006), and heightened reward responsivity has been associated with early onset drinking and substance use problems (Castellanos-Ryan, Rubia, & Conrod, 2011; Crowley, Raymond, Mikulich-Gilbertson, Thompson, & Lejuez, 2006). Data also show that adolescents who tend to respond to rewarding stimuli with greater striatal activation in the laboratory engage in more self-reported risk-taking behaviors (Bjork, Chen, Smith, & Hommer, 2010; Galvan, Hare, Voss, Glover, & Casey, 2007). Furthermore, greater ventral striatal response measured during the simulated driving task discussed previously predicted greater risk taking on the task (Chein et al., 2010).

At the other end of the spectrum, the failure to experience normative levels of reward responsiveness during adolescence may be related to increased risk for depression. Rates of depression rise dramatically during this period of development, especially for girls (Angold et al., 1998). Epidemiological studies indicate that as many as 1 in 7 adolescents will experience an episode of Major Depressive Disorder prior to adulthood (Kessler, 1994; Kessler et al., 2012). While healthy adolescents tend to show increased reward seeking during adolescence, youth with depressive disorders and heightened depressive symptoms show behavioral evidence of reduced positive affect and reward-seeking behaviors (Forbes, Shaw, & Dahl, 2007; Jazbec, McClure, Hardin, Pine, & Ernst, 2005). In neuroimaging studies, adult depression has been associated with reduced activation to positive stimuli in the striatum (Epstein et al., 2006; Lawrence et al., 2004; Surguladze et al., 2005) and enhanced activation in ventromedial areas of the PFC that are involved in evaluating contingencies (Keedwell, Andrew, Williams, Brammer, & Phillips, 2005). Neuroimaging studies of reward processing in adolescents also show decreased striatal activity and increased mPFC activity in depressed youth relative to healthy controls (Forbes et al., 2009; Forbes et al., 2006). Studies have also reported decreased striatal activity in healthy youth at high risk for depression (Gotlib et al., 2010; Monk, Klein, et al., 2008), suggesting that diminished striatal response to reward could be a biomarker for depression risk. Although most of the studies have focused on response to monetary reward, Whittle et al. (2012) demonstrated that adolescents with higher depressive symptoms also show reduced striatal activity to video clips of their own and unfamiliar mothers' positive behavior. Two recent studies, however, have suggested that depressed adolescents may actually show increased activation of the amygdala in response to social rewards (Davey, Allen, Harrison, & Yucel, 2011; Yang et al., 2010), highlighting the potential for a differential depression-related response to stimuli representing monetary and social value.

It is not clearly understood why youth vulnerable to depression might show diminished reward responding during the transition through adolescence compared with typically developing youth. Some data suggest that diminished sensitivity to reward might represent an endophenotype of risk for depression that is present earlier in life (Bress, Foti, Kotov, Klein, & Hajcak, 2013; Olino

et al., 2011), and could be exacerbated during adolescence (Morgan, Olino, McMakin, Ryan, & Forbes, 2013). Given high rates of interpersonal sensitivity and interpersonal concerns among depressed youth (Hammen & Brennan, 2001; Rudolph, Flynn, Abaied, Groot, & Thompson, 2009), it may be that depressed youth are sensitive to both positive and negative social evaluation, but do not experience high levels of social acceptance or positive social reward, or anticipate that they will not receive it and do not pursue it. Overall, future work in this area is needed that integrates neuroimaging approaches with observational and sociometric investigations of peer relationships, to obtain a fuller picture of how the actual social experiences in adolescents' daily lives are linked with their changing neurobiology.

Changes in Negative Affect Systems

Although no longer considered a period of pervasive storm and stress (Hall, 1904), the adolescent period still conjures up images of increased negativity, especially in affect. Consistent with this view, ecological momentary assessment (EMA) studies, in which adolescents' emotions are sampled repeatedly in everyday life, have shown that adolescents do tend to experience more frequent negative emotions than children or adults and that changes in emotional states are linked with changes in daily activities (Larson, 1989; Larson, Csikszentmihalyi, & Graef, 1980). Several neuroimaging studies have demonstrated increased sensitivity to negative emotional stimuli in adolescents compared with adults across regions of the affective salience network, especially the amygdala. For example, adolescents have been found to have greater amygdala reactivity relative to adults to sad and fearful faces (Guyer, Monk, et al., 2008; Killgore & Yurgelun-Todd, 2007) and greater activation in the amygdala, mPFC, and ACC compared with adults during passive viewing of emotional faces (Monk et al., 2003). Research is lacking, however, that tracks neurodevelopmental changes in response to negative emotional stimuli during the transition from childhood to adolescence. One study has shown increased amygdala activity when inhibiting response to negative versus positive emotional faces in adolescents compared with younger children and adults (Hare et al., 2008), but most existing neuroimaging research compares adolescents to adults rather than to younger children. This is partially a methodological issue, as it is difficult to have younger children perform the same complexity of tasks as older individuals and also to require young children to be still in the scanner. Nevertheless, it would strengthen the current literature to have an understanding of these patterns across broader periods of development.

Researchers have also begun to probe the neural correlates of social threat and social rejection using simulated interaction paradigms such as the Cyberball ball tossing task (Eisenberger, Lieberman, & Williams, 2003) and the Chatroom and Likeability social evaluation tasks (Gunther Moor et al., 2010; Guyer, Lau, et al., 2008). Findings indicate that anticipated and perceived social exclusion/rejection in adolescents activates the ventral affective salience network including the amygdala, ACC, and anterior insula, as well as ventrolateral areas of the prefrontal cortex (vlPFC) involved in the regulation of social distress (Guyer, Lau, et al., 2008; Masten et al., 2009; Sebastian et al., 2011). While social exclusion in adults appears to activate a dorsal portion of the ACC (Eisenberger, Gable, & Lieberman, 2007), studies of adolescents implicate the subgenual ACC (sgACC) in response to social exclusion (Masten et al., 2009; Sebastian et al., 2011; Silk et al., 2014). Emerging data suggest that adolescents, especially girls, exhibit age-related increases in the neural response to peer rejection in these affective and self-evaluative networks (Gunther Moor et al., 2010; Guyer et al., 2009; Silk et al., 2014). Youth also show increased pupillary reactivity to peer rejection across adolescence (Silk, Stroud, et al., 2012). Activity in the vlPFC, which is implicated in regulating responses to social distress, also is increased during adolescence (Gunther Moor et al., 2010), but decreased in adolescents compared with adults (Sebastian et al., 2011). Together, these results would suggest that adolescents are less effective at recruiting regulatory resources in response to social exclusion threat.

Only a few studies have investigated responses to negative or threatening emotional stimuli as a function of puberty. Silk et al. (2009) found that mid to late pubertal youth had a greater pupillary response to emotional words than pre- to early pubertal youth, controlling for participants' age, although this effect was seen in both positive and negative emotional words. Similarly, Moore et al. (2012) found increased amygdala reactivity to both negative and positive emotional faces relative to neutral faces among early adolescents more advanced in pubertal status. Moore et al. (2012) suggested that puberty may reorient adolescents toward social stimuli, such that emotional faces become particularly relevant. However, another recent study observed that activity in the amygdala and vlPFC while viewing fearful faces was stronger during early puberty than later puberty (Forbes, Phillips, Silk, Ryan, & Dahl, 2011), indicating potential nonlinear effects. There is also evidence that sensitivity to peer rejection may vary as

a function of puberty, with increased amygdala and sgACC activation to peer rejection among youth more advanced in pubertal development (Silk et al., 2014). New evidence suggests that pubertal testosterone may exert its effects on increased threat reactivity during adolescence partially through disrupting functional connectivity between the amygdala and orbitofrontal cortex (Spielberg et al., 2014). Additional work is needed to pinpoint more precisely which phases of puberty show neural changes to emotional stimuli of various classes, and to link such changes with psychopathology.

Changes in Negative Affect Systems and Psychopathology

Normative increases in reactivity to negative emotional information may lead to the development of problems such as anxiety and depression during the transition to adolescence in vulnerable youth. The role of threat and fear processing has been most strongly investigated in relation to anxiety disorders, although focus has also turned to reward processing in anxiety (Caouette & Guyer, 2014). Although some forms of anxiety, such as separation anxiety and specific phobias, tend to decrease in adolescence, overall rates of anxiety increase, particularly social anxiety (Beesdo, Pine, Lieb, & Wittchen, 2010), and especially for girls, with 11% of 12–19 year olds experiencing clinically significant anxiety (Costello, Copeland, & Angold, 2011). Behavioral studies demonstrate that anxious children and adolescents show an attentional bias toward social threat words and faces (Telzer et al., 2008) and report more threatening interpretations of ambiguous social scenarios (Creswell, Schniering, & Rapee, 2005), although little research has investigated whether these anxiety-related attentional biases are heightened during adolescence. Adolescence is filled with ambiguous social cues that may easily be misinterpreted as threatening by youth vulnerable to anxiety (Creswell et al., 2005). It seems plausible that the increased focus on social status and evaluation during adolescence could contribute to increased vigilance for social threat during this period of development, possibly contributing to increased anxiety during adolescence (Caouette & Guyer, 2014; Silk, Stroud, et al., 2012). Consistent with this possibility, neuroimaging studies show that anxious symptoms in adolescents are associated with increased amygdala and vlPFC activity to threatening faces (McClure et al., 2007; Monk, Telzer, et al., 2008). Several studies have also investigated response to peer rejection in anxious adolescents using the Chatroom task. These studies show that adolescents with anxiety disorders expect peers to rate them as less desirable (Guyer, Lau, et al., 2008), especially peers with which they did not want to interact, while also exhibiting increased insula and amygdala reactivity to rejection feedback (Lau et al., 2012). Two studies also found evidence for altered amygdala–vlPFC connectivity in adolescent anxiety (Guyer, Lau, et al., 2008; Monk, Telzer, et al., 2008), suggesting potential disruptions in top-down regulation of threat responding.

In a recent study that considered both developmental stage and clinical diagnosis, neural responses to emotional facial expressions were compared between adults and adolescents with social anxiety disorder. Greater activation in the amygdala and rostral ACC was found in response to angry and fearful, but not neutral faces in both adolescents and adults with social phobia. Although this was a cross-sectional study, the similar patterns of neural activation in adolescent and adult social anxiety disorder suggest persistence across development in the neural mechanisms underlying social anxiety disorder (Blair et al., 2011).

Changes in negative affect systems during adolescence may also be implicated in increased rates of depression during this period. EMA studies show that depressed adolescents experience more sadness, anger, and anxiety in daily life compared with healthy youth, and these differences are exacerbated by pubertal development (Silk et al., 2010). Specifically, depressed adolescents in the midst of puberty show more marked differences in the experience of negative emotions compared with their healthy postpubertal peers. Neuroimaging studies also provide evidence for a link between heightened responsivity to negative affective stimuli and adolescent depression. Although relatively few studies have been conducted with depressed adolescents, these studies have generally demonstrated amygdala hyper-reactivity in response to negative emotional faces in depressed youth compared with healthy controls (Beesdo et al., 2009; Roberson-Nay et al., 2006; Yang et al., 2010). Recently, two studies have investigated the neural response to peer rejection in adolescent depression. Masten et al. (2011) showed that when adolescents were being socially excluded during the Cyberball task, greater activity in the sgACC and the dorsomedial PFC was associated with increases in depressive symptoms over one year in a community sample of adolescents. Silk and colleagues (2014) demonstrated increased activation to being rejected by peers in a clinical sample of depressed youth, compared with healthy controls, in the same subgenual region of the ACC, and in the amygdala, insula, and nucleus accumbens. Taken together, these data suggest that depression in adolescents is characterized by increased neural reactivity to negative affective stimuli, particularly affective stimuli that

represent potential social threat. Such vulnerability of girls to depression during puberty may relate to a more rapid course of cortical thinning in the frontal lobes in males than in females (Raznahan et al., 2010). As such, a differential tempo in cortical brain development between males and females may create different windows of imbalanced connections between affective and cognitive-control neural systems that render females vulnerable to contextual or other risks that lead to depression. A similar mechanism of vulnerability to depression in girls may also relate to the timing and tempo of pubertal changes instantiated through adrenal and gonadal axes (Berenbaum & Beltz, 2011; Schulz et al., 2009).

Changes in Cognitive Control

The models proposed to understand how adolescent neurodevelopment and psychopathology are intertwined emphasize not only increases in emotional reactivity during adolescence, but also challenges in recruiting cognitive control processes to regulate these emotions. Cognitive control is defined as "a set of neurocognitive processes that are important for achieving short- and long-term goals, particularly when individuals are required to adjust their thoughts and actions adaptively in response to changing environmental demands in order to achieve their goal" (Crone & Dahl, 2012, pp. 636). This includes executive functions such as response inhibition, working memory, and task switching. Research on the neural substrates of cognitive control focuses on lateral portions of the PFC as well as parts of the parietal cortex (Miller & Cohen, 2001). As discussed previously, the PFC undergoes substantial remodeling of neuronal connections during adolescence, as well as changes in the amount of input received from neurotransmitters involved in emotional responding such as dopamine and gamma-amino-butyric acid (Lewis, 1997). Much attention in recent years has been drawn to the fact that areas of the PFC involved in higher order cognitive processing continue to change and undergo refinement through adulthood. For example, the dorsolateral PFC does not reach its adult volume until early adulthood (Giedd, 2004; Giedd et al., 1999). Synapse elimination and gray matter volume reduction in the PFC also continue into early adulthood relative to other areas of the brain (Giedd, 2004; Huttenlocher, 1990).

Despite solid evidence of these structural changes in adolescence, their relationship to functional and behavioral changes is still poorly understood. Specifically, evidence that delayed structural maturation of the PFC translates into immature capacity for cognitive control is unclear (Pfeifer & Allen, 2012). In general, the ability to engage in cognitive control processes improves and becomes more integrated throughout childhood and adolescence (Huizinga, Dolan, & van der Molen, 2006; Luna, Padmanabhan, & O'Hearn, 2010), and this is well established when measured behaviorally but recent reviews highlight the complexity of associating changes in the brain with age-related behavioral improvements (Crone & Dahl, 2012; Pfeifer & Allen, 2012). Some neuroimaging studies suggest that, rather than having *less* PFC activation than adults, adolescents have more diffuse, potentially inefficient patterns of activity in the PFC during cognitive control tasks compared with adults (Andrews-Hanna et al., 2011; Bunge, Dudukovic, Thomason, Vaidya, & Gabrieli, 2002; Geier & Luna, 2009; Luna et al., 2001; Velanova & Luna, 2009). A meta-analysis of neuroimaging studies conducted from 2001 to 2011 found substantial evidence for both increases and decreases in adolescence relative to adulthood or childhood in PFC activity during cognitive control tasks as well as evidence for a mid-adolescent peak in PFC activity during cognitive control tasks (Crone & Dahl, 2012), with the direction of effects differing across PFC subregions and tasks. As a whole, findings from the available literature underscore the importance of examining neural activation patterns in terms of both their magnitude (e.g., height of response), location (e.g., focal or diffuse response), and distribution (e.g., connections within and between regions) at multiple phases of development. As such, future work should compare samples of children, adolescents, and adults longitudinally in that it may demonstrate a progression of cognitive control function that goes from being focal to diffuse to distributed.

The discrepant findings in age-related differences in PFC activity do not necessarily support the idea that adolescents are less able to exert control over their hyperactive affective response systems relative to adults. Given that, it is important to bear in mind that there is no standard benchmark of maturity in the brain systems involved in cognitive control over behavior (or affective systems for that matter), and that assessments of relative neural activity within specific regions cannot solely be used to provide information for establishing such benchmarks. In fact, some studies suggest that by mid-adolescence, teens do not differ greatly from adults in the *capacity* for cognitive control (Luna, Garver, Urban, Lazar, & Sweeney, 2004; Steinberg et al., 2009). For example, Luna et al. (2004) showed that by age 15, most adolescents have reached adult levels of response inhibition. In many ways, an important index of maturity may be in the connectivity between the PFC and other regions, particularly with those within the affective system,

to the extent that tighter and more specific connections between cognitive control and affective regions support more mature or adult-like behavior (Dosenbach et al., 2010). Importantly, the convergence of connections within and between cognitive control and affective systems in adolescence is likely subject to influences such as attentional focus, arousal, or social factors like the presence of peers (Guyer, Lau, et al., 2008). Adolescents may therefore differentially recruit cognitive capacities based on contextual factors, motivational incentives, and affective salience. This perspective is consistent with studies suggesting that when tasks include both a cognitive and affective component, adolescents tend to be more strongly influenced by the affective demands of the task (Monk et al., 2003; Somerville et al., 2011). However, adolescents can improve cognitive performance when the affective salience of the task is enhanced by providing rewards for performance (Jazbec et al., 2005).

Changes in Cognitive Control and Psychopathology

Over the past decade, many researchers have discussed the possibility that problems in emotional and behavioral regulation during adolescence might result from immature cognitive control, as a function of the PFC's protracted period of development, particularly in the context of increased emotional demands during the adolescent transition (Casey et al., 2011; Dahl, 2004; Ernst et al., 2006; Steinberg et al., 2006). Despite the intuitive appeal of this model (see Pfeifer & Allen, 2012), some of the data reviewed above suggests that these "dual process" or "developmental mismatch" models may have oversimplified the relationship between adolescent neurodevelopment and psychopathology (Crone & Dahl, 2012; Luciana & Collins, 2012; Pfeifer & Allen, 2012). This can be seen in the example of risk-taking behavior. Adolescents are more likely than children or adults to engage in risky behaviors, including binge drinking, smoking, unprotected sex, and risky driving (Steinberg, 2008). There is now convincing evidence that adolescent risk taking is *not* a function of limited understanding of the cognitive consequences of risk (Reyna & Farley, 2006). Rather, risk taking may be better thought of as the result of a biasing of behavior by social and motivational factors during adolescence (Dreyfuss et al., 2014; Smith, Chein, & Steinberg, 2013b). In other words, it is not that cognitive control is weak but rather that motivations toward obtaining reward, especially social motivations, are particularly strong. In support of this view, Chein et al. (2010) found that although adolescents showed greater activation of the reward system during peer observation, activity in the cognitive control system did not vary based on the presence or absence of peer observers. This finding supports the suggestion that adolescents are driven to engage in risky and reward-seeking behaviors because social and motivational factors play a stronger role in shaping such behaviors than does cognitive control at this developmental interval, particularly given the interconnected nature of these cognitive control and affective neural systems. More generally applied across forms of psychopathology, it may be that greater connectivity between cognitive control and affective neural systems during adolescence affords some protection from the onset of psychopathology, whereas less connectivity could render an adolescent vulnerable to the influence of intensely felt and reactive emotions, highly arousing motivations, and demanding social-contextual conditions.

Age-related refinement in cognitive control neural systems may play a role in the development of depression during adolescence. Dual process models suggest that rates of depression increase during adolescence as a function of increased negative emotional arousal relative to insufficient regulatory control. However, these models cannot fully account for the fact that rates of depression remain stable from adolescence through adulthood, despite stabilization of structural development of cognitive control neural regions by early adulthood. Davey et al. (2008) have proposed an alternative model, suggesting that increased rates of depression during adolescence might be a function of the more advanced nature of cognitive capabilities seen in adolescence, rather than the relative immaturity of cognitive neural structures reported in adolescence relative to adulthood. Specifically, the model proposes that the continued development of the PFC facilitates advanced hypothetical thinking during adolescence, allowing for representation of increasingly complex social and future-oriented rewards. Yet, these abstract social rewards (i.e., becoming popular, falling in love, being successful) are also tenuous and easily frustrated. Davey et al. (2008) suggest that repeated failure or frustration of these socially oriented rewards during adolescence may lead to suppression of the reward system, eventually resulting in anhedonia and depression (Bogdan & Pizzagalli, 2006; Frewen, Dozois, Joanisse, & Neufeld, 2008). Additional research is needed to support this model, as alternative hypotheses remain to be tested. For example, deficits in cognitive control could lead to excessive rumination, a key component of depression. The model nonetheless highlights an emerging recognition that, despite the historical neurodevelopmental focus on the imbalance of too little cognitive control and too much emotional reactivity, the

progression of cognitive control capacities from childhood to adolescence should also be examined as a contributor to the development of psychopathology during this period.

CONTEXTS OF ADOLESCENT DEVELOPMENT

Adolescence is characterized not only by the biological and cognitive changes within the individual adolescent but also by changes in the contexts in which adolescents live and in their interactions with those contexts. As articulated in ecological models and developmental systems theory (Bronfenbrenner, 1979; Ford & Lerner, 1992; Gottlieb & Halpern, 2002; Thelen & Smith, 2006), individual development is embedded in processes of interaction with family, peers, school, neighborhood, and society. As they age, adolescents in many modern societies spend increasing amounts of time outside the supervision of their parents and in the company of peers, make transitions to secondary schooling, begin to navigate employment and romantic relationships, and engage with media in many forms, often for many hours a week (Brown & Larson, 2009; Brown & Bobkowski, 2011; Steinberg & Morris, 2001). The nature of these contexts and the interactions of adolescents with them have been widely implicated in the development, maintenance, and prevention of psychopathology, although the conceptual models of how and why context and psychopathology may be linked continue to be refined. Moreover, the lion's share of research on contextual influences on the development of psychopathology has not formally examined how context may interact with the biological, emotional, and cognitive changes that concomitantly occur during adolescence.

During the transition from childhood into adolescence, and over the course of early adolescence in particular, contextual interactions may play a key role in protecting or exacerbating the adaptation of individuals who enter the transition with regulatory vulnerabilities. That is, during early adolescence, individuals need the assistance and protection provided by a structured and supportive context. In concrete terms, adolescents need the presence of other individuals and institutions during this potentially challenging developmental transition. At the same time, this ontogenetic period is particularly risky for young people with little or no contextual support and those with high vulnerability.

Context and adolescent psychopathology connections were studied initially in terms of risk factors for psychopathology and problems, such as delinquency, substance abuse, school dropout, depression, eating disorders, and suicidal behavior, all of which were linked in some way to bad environments. Poor parenting, poverty, divorce, and many other stressful life events, as well as unsafe neighborhoods and deviant peers, have each been studied as risk factors for psychopathology. Extensive evidence pointed to unsupportive or dangerous environments and relationships as predictors of psychopathology, although the processes accounting for these outcomes were not well understood. It also became clear that risky conditions often co-occurred, such that some youth faced very hazardous transitions to adolescence, fraught with stressful experiences and little in the way of positive resources; psychopathology was often associated with high net or cumulative risk (Masten & Coatsworth, 1998; Masten & Narayan, 2012; Sameroff, Gutman, & Peck, 2003). Moreover, strong overlap was noted among risk factors, with a given risk factor such as a chaotic home environment or unsafe neighborhood being associated with multiple forms of psychopathology (Monahan, Oesterle, Rhew, & Hawkins, 2014; Steinberg & Avenevoli, 2000).

With the emergence of developmental approaches to psychopathology, thinking about the connections of context and emotional and behavioral outcomes has changed in several respects. First, the role of context in normative developmental transitions has received closer examination, in an effort to use findings from research on typical development to inform our understanding of maladaptive developmental pathways. Second, more dynamic models of person-environment interaction have gained ground, emphasizing the role of adolescents as agents in the shaping of their own experiences and the importance of relationships in the development and course of problematic and positive behavior during adolescence. Attention is increasingly focused on how contexts and adolescents interact or co-act to shape development either toward or away from psychopathology, with more focus on regulatory processes and concepts such as self-regulation, co-regulation, and scaffolding. Finally, there has been a movement toward studying the ways in which multiple, interdependent, and sometimes nested contexts may interact to influence patterns of individual development, rather than investigating the effects of a single context considered in isolation. These changes reflect the influence of developmental systems theory on conceptualizations of normative and deviant development and also herald an evolving framework for a developmental psychopathology of adolescence.

In the three decades since Hill (1980, 1983) first published his framework for research on adolescence, there have been marked changes in the study of context in relation to adolescent development. Studies of traditional

contexts, such as peers, families, and schools continue, but the focus of this work has shifted to addressing more complex and dynamic questions. There has been more intensive and focused investigation of contexts that had previously received scant attention, including romantic relationships, work, extracurricular activities, and media. Emerging technologies have created virtual contexts for adolescent interaction, including electronic friendships, neighborhoods, fantasy worlds, and many other kinds of contexts and contextual interactions. These same technologies have altered the study of context-adolescent interaction as investigators capitalize on computers, tablets, and cell phones to assess the ongoing interactions of adolescents with their environments. This section highlights some of these changes, as investigators try to understand the nature of adolescent interactions with their environments and how these interactions may contribute to the etiology, maintenance, prevention of, or recovery from psychopathology and other problems in adolescent development.

Over the past 20 years, several overarching themes in the study of psychopathology and context in adolescence have emerged. First, there is growing evidence that the role of context in the development of psychopathology is typically nonspecific. That is, it is difficult to find links between specific contextual stressors (either chronic or acute) and specific manifestations of dysfunction. Divorce, poverty, maltreatment, exposure to neighborhood violence, and peer rejection, for example, are risk factors for many types of problems in adolescence (Bond, Toumbourou, Thomas, Catalano, & Patton, 2005; Monahan, Oesterle, et al., 2014; Steinberg & Avenevoli, 2000). Thus, it appears likely that specificity in the manifestations of emotional and behavioral disorder (i.e., why one individual develops depression but another develops alcohol dependence) likely reflects individual differences (genetic or acquired) in biological diatheses rather than specific differences in contextual experience.

Second, the impact of contextual stress on psychopathology is cumulative. Individuals whose lives are characterized by a greater number of contextual risks are more likely to show manifestations of internalizing, externalizing, or addictive problems than are those whose lives are characterized by fewer risk factors.

Third, there are significant links among contextual risk factors that make it difficult to study them as independent influences. Adolescents who grow up in dysfunctional family environments, for example, are more likely to experience poverty, attend inadequate schools, encounter antisocial peers, and witness neighborhood violence. By the same token, adolescents who enjoy one form of contextual benefit (e.g., supportive teachers) are also more likely to have lives that are characterized by multiple advantages. As such, studies that examine one context in isolation ignore that certain risk factors are nested and highly likely to co-occur, and that other factors may protect against risk or promote adaptation more generally (Rutter, 2001).

Fourth, contextual risk exerts its impact on psychopathology through both objective and subjective means (Boyce et al., 1998). Thus, in research on context and psychopathology, it is important to document both the objective level of stress, as well as the adolescent's subjective appraisal of stress. This is especially important in research involving adolescents from various demographic groups, because the same contextual stressor may be appraised differently by individuals from diverse backgrounds. What might be considered harsh parenting among middle-class suburban adolescents, for example, may be considered supportive among impoverished inner-city youth. To the extent that the impact of parenting is mediated by the way it is interpreted by the adolescent, we would expect that parental strictness would have different effects across these various settings. Similarly, the objective assessment of peer characteristics and the subjective report of perceived peer characteristics demonstrate different associations with adolescent psychopathology (Brechwald & Prinstein, 2011)—examination of both is needed.

Fifth, contexts interact in ways that may exacerbate, compensate for, or cancel out each other's influence on normative and atypical development. Additionally, contemporary research on contextual influence, reflecting the work of Bronfenbrenner (1979) and others, has documented the importance of examining how the influence of proximal settings, such as the family, is moderated by factors within the broader contexts that contain them, such as neighborhoods (Leventhal, Dupéré, & Brooks-Gunn, 2009). Understanding the development of psychopathology necessitates that attention be paid to the interactive and nested relations among contexts. Contemporary research also stresses the importance of examining interactions between social and neurobiological contexts. For example, recent studies demonstrate that the quality of parenting influences brain function and structure during adolescence in regions of the brain that respond to social and emotional stimuli (Casement, 2014; Morgan, 2014; Tan, 2014; Whittle, 2014).

Finally, adolescents are not the passive recipients of contextual influence, but are active agents who choose, transform, and recruit contextual resources. Unlike younger children, who have little control over where and with whom they spend time, adolescents are more

active in selecting the contexts to which they are exposed; although adolescents have little say over their family or school environments, they choose their friends, decide whether to work or engage in extracurricular activities, and pick the media to which they are exposed. This fact poses a challenge to researchers interested in demonstrating causal influences of context on psychopathology, because often it is not clear whether it is the context that is driving the psychopathology or the reverse. Thus, for example, the links between externalizing problems and affiliation with antisocial peers may result from the self-selection of antisocial adolescents into deviant peer groups, as well as the recruitment of alienated youth into deviant groups (Monahan, Steinberg, & Cauffman, 2009). Deviant peer association may then function to exacerbate antisocial behavior through reinforcement, modeling, opportunities, or combined influences of this kind. It is not easy to sort out causality when there is so much reciprocal influence. In addition, and operating above and beyond any selection process, is the fact that adolescents actually influence their parents, friends, teachers, and neighbors in ways that affect the home, peer, school, and community contexts, which then, in turn, influence the adolescent's development. An important but understudied issue is how, under what circumstances, and through what processes adolescents actively employ contextual resources (from relationships with parents, friends, and teachers to video games and Internet chat rooms) as a means of protection against the adverse effects of environmental stress, as well as the amelioration of psychological distress. A detailed review of the vast literature on specific aspects of context that have been associated with various forms of psychopathology in adolescence is beyond the scope of this chapter. In the sections that follow, we highlight points of consensus and areas of converging evidence in different contexts.

The Role of the Family

Of the many contexts that have been studied in relation to adolescent psychopathology, none has received as much attention as the family. Parent-adolescent relationships characterized by warmth, support, age- and context-appropriate monitoring, and clear expectations for positive behavior—the kind of parenting known as authoritative in style (Baumrind, 1973, 1991)—continues to be widely associated with positive adaptation in adolescence (Steinberg, 2001), including less psychopathology. Conversely, families that provide little warmth, structure, or resources or that expose the adolescent to high levels of hostility may not only exacerbate risk for psychopathology, but also fail to scaffold successful transitions in adolescence, leaving their adolescent children unprotected during a challenging time of change (Ge, Lorenz, Conger, Elder, & Simons, 1994; Repetti, Taylor, & Seeman, 2002).

If is, of course, quite possible that parents who do not function well transmit genetic vulnerability to psychopathology along with providing a risk-laden or neglectful environment. This is a classic confound in diathesis-stress models of psychopathology, and the issue has reemerged in contemporary debates about the importance of parenting in development (Collins, Maccoby, Steinberg, & Hetherington, 2000; Masten & Shaffer, 2006; Repetti et al., 2002; Scarr & McCartney, 1983). Nonetheless, research implicates parenting as a key mediator of adverse life experiences and psychosocial disadvantage on adolescent behavior (Bowes, Maughan, Caspi, Moffitt, & Arseneault, 2010; Bradley & Corwyn, 2002; McLoyd, 1998; Odgers et al., 2012). In these models, adversity undermines parental functioning, which in turn affects adolescent functioning. Not surprisingly, adolescents who achieve more positive adaptation in the presence of adversity or psychosocial risk often have better functioning parents or other adults who provide effective parent resources for them in spite of high-adversity exposure (Masten, 2001; Odgers et al., 2012). Moreover, high quality parenting appears to buffer against exposure to other risk factors, such as delinquent peers, suggesting that parenting may both promote positive adjustment and also protect against negative adjustment in the presence of risk (Chester, Jones, Zalot, & Sterrett, 2007; Germán, Gonzales, & Dumka, 2009). Studies also hint at the potential role of parenting in scaffolding self-regulation skills in the transition to adolescence. In a study of competence development among rural African American adolescents living in poverty, the effects of effective parenting on competence in young adolescents was mediated by self-regulation in the adolescents (Brody, Murry, Kim, & Brown, 2002). Conversely, in a sample of typically developing community youth, harsh parenting was associated with diminished development of self-control across early adolescence (King, Lengua, & Monahan, 2013). Moreover, interventions to facilitate or protect the quality of parent functioning under adverse conditions appear to be effective in altering the risk for problems developing in children and adolescents (Hawkins et al., 2003; Van Ryzin, Stormshak, & Dishion, 2012; Wolchik et al., 2002). Studies of families also focus on indirect and possible long-term effects that families may have in protecting or harming development during adolescence indirectly, through their influence on the opportunities, peers, schools, and neighborhood resources available to

their children. Long before the challenges of adolescence arrive, effective parents may facilitate the successes of their children in peer relations and schools, indirectly increasing the likelihood of bonding to prosocial peers and school engagement that may be a key to avoiding increases in antisocial and other risk-taking behaviors that tend to accompany transitions to adolescence (Brown & Bakken, 2011; Brown, Mounts, Lamborn, & Steinberg, 1993; Collins et al., 2000; Galambos, Barker, & Almeida, 2003; Pettit, Bates, Dodge, & Meece, 1999).

Understanding of the importance of the parent-child relationship during adolescence must be coupled with recognition that the relationship changes across the adolescent years. A meta-analysis of studies of parent-adolescent conflict indicates that, although conflict generally declines across adolescence, the intensity of affect characterizing these conflicts rises in early adolescence (Laursen et al., 1998). An especially relevant aspect of the parent-child relationship is the negotiation of the child's emerging autonomy needs—a critical task that has been linked to numerous indices of adolescent adjustment (Laursen & Collins, 2009). Parents' role in this process consists of striking a balance between encouraging adolescent independence and maintaining a supportive connection when needed—a balance that bolsters adolescent self-esteem, ego development, and social functioning (Van Petegem et al., 2012). Thus, this transition period may be a time during which responsive changes in parenting behavior are critically important for the child maintaining a positive trajectory of adaptive social behavior; and lack of appropriate parental responsiveness to these developmental changes may deflect this pathway into maladaptive functioning. Sufficient data are not yet available to discern subtle patterns or differentiate age, context, and pubertal effects in these parent-adolescent interactions. However, studies do corroborate the general idea prominent in many theories of adolescent maturation that reorganizations occur in parent-adolescent interactions around adolescence and that these transformations involve affect regulation. It is therefore important to understand how variations in parenting practices may contribute to the development of regulatory competence and how developmental variation in parenting across adolescence is important for the emergence of psychopathology. From a vulnerability perspective, it stands to reason that parents who respond poorly to the changing needs of the adolescent across adolescence may place their child at risk for the development of psychopathology, by failing to provide a supportive and appropriate structural context.

Peers as Positive and Negative Influences on Adolescent Development

During the adolescent years, individuals spend substantial amounts of time in the peer context and simultaneously report greater susceptibility to peer influences than in earlier or later developmental periods. These changes in peer socialization make the peer group one of the most salient contexts for adolescent development. In most modern societies, adolescents spend more unsupervised time in the company of their peers than do younger children, and it is widely accepted that peers play an increasing role in the lives of adolescents as compared with younger children (Brown & Larson, 2009; Steinberg & Morris, 2001). As children grow older, they typically have more freedom of choice about whom they associate with. Adolescents may choose peers who reinforce their own beliefs, enable them to explore new roles, or engage in exciting activities. They also may be recruited by peers for similar reasons. Thus, peers have increasing potential as part of the regulatory systems available to adolescents. Adolescents may self-regulate by actively seeking peer interactions; peers also may deliberately act to cheer up, calm down, or recruit a friend for illicit activities.

Evidence suggests that adolescents actively select peer contexts that reflect their personalities or preferences and that peer groups in turn influence adolescents' mood states and behavior (Brechwald & Prinstein, 2011; Brown & Larson, 2009; Cairns & Cairns, 1994). Across adolescence, more popular teens tend to have higher levels of positive adaptation (i.e., greater prosocial behavior), but also have increased risk for problem behaviors, including aggression (Cillessen & Mayeux, 2004; Rose, Swenson, & Waller, 2004). With respect to psychopathology, antisocial behavior can lead to rejection by normative peers in middle childhood and also to affiliation with deviant peers, who subsequently encourage negative behaviors ranging from delinquent activities to health-risk behaviors (Dishion, Andrews, & Crosby, 1995; Dodge & Pettit, 2003; Laird, Pettit, Dodge, & Bates, 2005). Other children may withdraw from social interaction with peers due to shyness or anxiety and become more lonely and sad as a result (Rubin, Hymel, & Mills, 2006). It is interesting to note that anxious solitude may protect against antisocial behavior in adolescence, suggesting that this characteristic (likely reflecting high inhibition or social anxiety) may function as a risk factor for internalizing problems and a protective factor for externalizing problems (Burt, Obradović, Long, & Masten, 2008; Gazelle, 2010; A. S. Masten et al., 2005; Moffitt et al., 2002; Pine, Cohen, Cohen, & Brook, 2003). In general, individuals who fail to develop appropriate

peer relationships or who associate with peers with negative peer characteristics are at risk for a range of types of psychopathology.

One dimension of peer relationships that has received substantial attention in the past decade is popularity, and specifically perceived popularity, which refers to how much status an individual carries within the peer group (Cillessen & Rose, 2005). Some evidence suggests that perceived popularity is associated with the norms associated with risk taking behavior during adolescence. If, for instance, smoking marijuana becomes something that is valued by the peer group, popular adolescents will start getting high more regularly (Allen, Porter, McFarland, Marsh, & McElhaney, 2005). When popular adolescents start to engage in a particular behavior, that behavior often becomes more admired. Even behaviors such as bullying or carrying a weapon, which most adolescents do not approve of, become more acceptable when popular adolescents start to engage in them (Dijkstra, Lindenberg, & Veenstra, 2008; Dijkstra et al., 2010).

In contrast to popularity, being unpopular with peers is a risk factor for many forms of psychopathology. In general, research shows that unpopular, withdrawn children are excessively anxious and uncertain around other children, often hovering around the group without knowing how to break into a conversation or activity (Rubin, LeMare, & Lollis, 1990). Their hesitancy, low self-esteem, and lack of confidence make other children feel uncomfortable, and their submissiveness makes them easy targets for bullying (Olweus, 1993). Many of these youngsters are especially sensitive to being rejected, a trait that may have its origins in early experiences with parents (Downey, Lebolt, Rincón, & Freitas, 1998). Some youth are depressed, and their depression leads them to behave in ways that make them targets of harassment (generally speaking, people of all ages do not prefer to spend time with depressed individuals; Kochel, Ladd, & Rudolph, 2012). Unfortunately, the more these children are teased, rejected, and victimized, the more hesitant they feel around others, and the more they blame themselves for their victimization, which only compounds their problem—creating a cycle of victimization (Graham & Juvonen, 1998). Interestingly, children who are victimized but who have a best friend are less likely to be caught in this vicious cycle than those who are friendless (Hodges, Boivin, Vitaro, & Bukowski, 1999).

Although psychologists used to believe that aggressive adolescents are likely to be rejected by their classmates, it turns out that some teenagers are both aggressive and popular (de Bruyn, Cillessen, & Wissink, 2010). Evidently, it is not aggression alone, but the combination of aggression and difficulty controlling emotions or a lack of social skills, that leads to problems with peers (Dijkstra, Lindenberg, Verhulst, Ormel, & Veenstra, 2009; Farmer, Estell, Bishop, O'Neal, & Cairns, 2003). Interestingly, adolescents who see themselves as well-liked and socially competent fare well over time, regardless of whether they are genuinely popular among their classmates (McElhaney, Antonishak, & Allen, 2008).

Although relational aggression was first noticed in observations of girls, studies show that both genders employ it, but that girls are more aware of it, more distressed by it, and more often the victims of it (Card & Hodges, 2008; French & Conrad, 2001; Pronk & Zimmer-Gembeck, 2010; Sullivan, Farrell, & Kliewer, 2006). One study of adolescents' reasoning about excluding people from group activities found, for example, that girls are more likely than boys to say that it is morally wrong to exclude someone simply on the basis of the crowd to which he or she belongs (Horn, 2003). Although relational aggression is more covert than fighting or yelling, the use of relational aggression is nevertheless associated with rejection by peers (Crick, 1996; Rys & Bear, 1997). Interestingly, adolescents whose aggression is atypical for their gender (that is, girls who are highly physically aggressive and boys who are highly relationally aggressive) show more maladjustment than their peers whose aggression is more gender-stereotypic (Crick, 1997). As psychologist Amanda Rose has pointed out, however, preventing relational aggression is easier said than done (Rose et al., 2004). She has shown that adolescents who use relational aggression are more popular than their peers. In some ways, this is hardly surprising, because the whole *point* of using relational aggression is to maintain one's status and popularity, and because the same social skills that make one popular (e.g., learning how to read other people, adjusting one's behavior to maintain one's status) are useful when one is spreading rumors, gossiping, or trying to undermine someone else's reputation.

Much evidence suggests that rejection from peers incurs risk for psychopathology. Peer rejection and friendlessness are associated with subsequent depression, behavior problems, and academic difficulties (Bellmore, 2011; French & Conrad, 2001; Wentzel, 2009). But studies show that the specific consequences of peer rejection may differ for rejected youth who are aggressive versus those who are withdrawn. Aggressive individuals who are rejected are at risk for conduct problems and involvement in antisocial activity as adolescents, not just as a direct result of their rejection, but because the underlying causes of their

aggression (for instance, poor self-control) also contribute to later conduct problems (Laird et al., 2005; Rubin, Chen, McDougall, Bowker, & McKinnon, 1995). In contrast, withdrawn children who are rejected are likely to feel exceedingly lonely and are at risk for low self-esteem, depression, and diminished social competence—again, both as a result of being rejected and in part because the underlying causes of their timidity (for instance, high anxiety) also contribute to later emotional problems (Card & Hodges, 2008; Hoza, Molina, Bukowski, & Sippola, 1995; Pedersen, Vitaro, Barker, & Borge, 2007; Rubin et al., 1995). Rejection is especially likely to lead to depression in adolescents who place a lot of importance on their standing in the peer group and who believe that they, rather than the peers who reject them, are at fault (Prinstein & Aikins, 2004). Adolescents who are both aggressive and withdrawn are at the greatest risk of all (Rubin et al., 1990).

Peer–Family Joint Effects on Psychopathology

One of the advances in the study of peer and family contexts in recent years has come in the form of considering how each of these systems may influence the effects of the other. Parents vary significantly in the extent to which they attempt to manage their teenagers' peer relationships, and some evidence suggests that more active management is associated with more positive peer relationships (e.g., higher quality, less delinquency) (Mounts, 2002, 2004, 2007; Stattin & Kerr, 2000; Tilton-Weaver & Galambos, 2003). Poor parenting may elevate the risk for association with deviant peers; concomitantly, lack of monitoring may increase unstructured time with antisocial peers, facilitating deviancy training (Dekovic, Wissink, & Meijer, 2004; Dishion, McCord, & Poulin, 1999; Dishion, Nelson, & Bullock, 2004; Oxford, Harachi, Catalano, & Abbott, 2001; Werner & Silbereisen, 2003). Negative peer relations have been found to increase the influence of negative parenting on externalizing behavior (Lansford, Criss, Pettit, Dodge, & Bates, 2003). High quality attachment to parents is linked with better peer interactions and fewer emotional and behavioral problems (Allen, Porter, McFarland, McElhaney, & Marsh, 2007). On the positive side, close parent-adolescent relationships may enhance the likelihood of exposure to positive peer networks as well as the socioemotional skills to engage effectively with peers (Chester et al., 2007). Evidence also suggests that good-quality relationships with parents may moderate the influence of deviant friends (Galambos et al., 2003).

Romantic Relationships and Adolescent Development

One of the key psychosocial milestones of adolescence is the development of romantic relationships. Increasingly, researchers have begun to focus on the context of adolescents' burgeoning romantic relationships (Collins, Welsh, & Furman, 2009). Romantic relationships emerge in adolescence, though they may remain exploratory until early adulthood; this domain can be conceptualized as an emerging developmental task in adolescence and a salient developmental task of early adulthood (Collins et al., 2009; Roisman, Masten, Coatsworth, & Tellegen, 2004). These special peer relationships, spurred by new motivational systems, pubertal processes, and a culture promoting adolescent sexuality and romance, offer a new realm of possibilities for adolescents to experience emotional extremes of happiness, excitement, disappointment, and despair.

Romantic feelings appear to be powerful activators of behavior; concomitantly, romantic relationships appear to be powerful regulators of arousal and affect (Collins et al., 2009; Connolly & McIsaac, 2009; Furman, Brown, & Feiring, 1999; Larson, Clore, & Wood, 1999). We noted previously that early maturing is a risk factor for a variety of problems; for some girls, this risk appears to be mediated by romantic relationships with older boys (Steinberg & Morris, 2001). Breakups of romantic relationships also may trigger great distress in adolescents (Larson et al., 1999) and have been linked to subsequent emotional disorders such as depression (Hankin & Abramson, 2001). Much like the classic finding that associating with deviant peers is linked with antisocial behavior, dating a partner who is high in antisocial influence and behavior is associated with maintaining involvement in antisocial behavior across adolescence and into early adulthood (Cauffman, Farruggia, & Goldweber, 2008; Monahan, Dmitrieva, & Cauffman, 2014). Though still limited, the growing literature on romantic relationships in adolescence suggests that these relationships may play complex roles in social development and the regulation of affect, with positive and negative ramifications. In general, individuals who are more susceptible to romantic partner influence and those with more difficult or low-quality romantic relationships may be the most vulnerable to psychopathology, due to increased sensitivity to the social influence and increased risk for negative socialization.

Schools and Psychopathology in Adolescence

School contexts play a salient role in the lives of modern youth for many years and in multiple ways. The transition

to secondary schooling in adolescence presents new challenges and opportunities for learning, peer relationships, and extracurricular activities, with all the attendant complexities of cognitive, emotional, social, and cultural processes (Elmore, 2009). Transitions into junior high school and high school often are accompanied by normative changes in motivation, attendance, involvement, and achievement. Psychopathology has been linked to school failure and disengagement in various ways. For example, adolescents who are antisocial, anxious, or depressed may not go to school or perform well when in attendance; academic failure may increase the likelihood of dropping out, affiliating with deviant peers, or developing internalizing symptoms; or youth may be victimized at school (Masten et al., 2005; National Research Council and Institute of Medicine, 2009). Perhaps the most striking conclusion to be drawn from studies of competence in the school context and either externalizing or internalizing symptoms in adolescence is the *salience* of academic success or failure to an adolescent as a mediator, outcome, and predictor of adolescent symptoms and disorders (Burt et al., 2008; Burt & Roisman, 2010; Hawkins, Kosterman, Catalano, Hill, & Abbott, 2005; Hawkins et al., 2003; A. S. Masten, 2003).

Interventions to promote positive bonding to school and academic achievement have shown success, increasing academic attainment and reducing dropout and delinquency. The mediating processes by which these interventions work are not well understood, though increasingly, interventions are designed strategically to shed some light on the mediating processes. Hawkins and colleagues (Hawkins et al., 2003), in the Seattle Social Development Project, have shown that multifaceted elementary school interventions increase positive bonding to school in the high school years, which is associated with school success and lower risk for multiple problems. Moreover, the positive effects of this intervention for youth outcomes are documented into adulthood (Hawkins et al., 2005), suggesting that earlier intervention may engender long-term benefits. A study of mentoring as an intervention suggested that the Big Brother Big Sister program improves relationships with parents along with school involvement and achievement (Rhodes, Grossman, & Resch, 2000). Mentoring may have some direct influences on school values and behavior, but these interventions also may provide indirect benefits in the lives of adolescents that are mediated by parent-adolescent relationships.

Recent attention also has focused on the role of extracurricular activities in adolescent development (Mahoney & Vest, 2012). Such activities may provide opportunities for personal ups and downs in accomplishments, but also may serve the more mundane but important function of bonding youth to the normative school context, peers, and behaviors, with important socialization sequelae. Little is known about the general regulatory role sports and other activities may play in the healthy development of adolescents, although studies of the joys and stresses of sport involvement suggest intense possibilities for affect regulation, for good or ill (Gatz & Messner, 2002; R. E. Smith, Smoll, & Cumming, 2009). For example, engagement in sports provides many youth with social bonds, goals, and exercise; however, participation in sports can also introduce opportunities for underage drinking or other risky behaviors. Structured activities of diverse kinds could play a powerful regulatory role in stress management and arousal regulation, may help adolescents acquire self-control and related regulatory competencies, and may serve to facilitate relationships with peers and coaches who can also play such regulatory roles. Moreover, these activities may provide a positive outlet for increases in sensation seeking that are noted during adolescence.

Work as a Context for Adolescent Development

During adolescence, individuals typically begin their foray into the world of employment. The impact of work on adolescent development and psychopathology has received increased attention, particularly with respect to the relative risks and benefits of work (Monahan, Lee, & Steinberg, 2011; Mortimer, 2003; Mortimer, Staff, & Oesterle, 2003; Roisman et al., 2004). In terms of psychopathology or positive adaptation, work may exacerbate stress and distress or increase self-efficacy, take time from schoolwork or motivate youth to succeed in school. Generally, moderate work hours in the lives of ordinary adolescents who are succeeding in other aspects of their lives appear to have at least short-term benefits (e.g., extra money and self-confidence) and few costs. For some youth, steady low-intensity work during adolescence may also have long-term benefits in vocational development (Mortimer, 2003). However, working long hours at unskilled jobs may contribute to symptoms of psychopathology, either directly (stress) or indirectly, by contributing to school problems, psychosocial development, and increased behavioral problems (Monahan et al., 2011). Indeed, even in high-risk samples—whom work is suspected to benefit—long hours employed during adolescence is a risk for antisocial behavior *unless* youth are also engaged in school (Monahan, Steinberg, & Cauffman, 2013).

The extent to which work may contribute to regulatory competence likely depends on the nature of the work environment, the number of hours per week the adolescent works, and the extent to which working facilitates or interferes with the successful negotiation of other tasks, such as those affecting achievement in school (Roisman et al., 2004). In an appropriately challenging job with adequate supervision, where the adolescent is acquiring skills and not unduly stressed by demanding work hours, employment may contribute to the development of responsibility, time management skills, and self-confidence. However, in a menial job with inadequate supervision, where work is stressful and hours long, employment may contribute to mental health problems, alcohol and drug use, and diminished attachment to school (Monahan et al., 2011; Monahan et al., 2013; Staff, Messersmith, & Schulenberg, 2009). These adolescents in menial, stressful jobs working at a high intensity of hours are likely at risk for psychopathology.

Community, Society, and Culture

One of the marked changes characteristic of adolescence in many modern societies is the increased level of mobility in society and the potential for engaging and being engaged by more aspects of community, culture, and society outside the family and school contexts. Evidence suggests that neighborhoods are potent sources of risks, assets, and moderators of adolescent development (Duncan & Raudenbush, 2001; Leventhal et al., 2009). There are hints in this literature that social structures in neighborhoods may function as regulatory systems for the behavior of youth, although it is difficult methodologically to sort out the role of larger social systems from the influence of the individuals and families that compose them (Duncan & Raudenbush, 2001). Studies of resilience in youth at risk due to family adversity or poverty suggest that external regulatory systems in communities (e.g., provided by churches, boys' and girls' clubs, recreational centers and teams) may play a protective role for the development of competence (Masten & Coatsworth, 1998). Who chooses to engage such systems and why remains an intriguing mystery. Coaches and youth ministers may seek out youth, youth may seek out competent and trustworthy adults, or juvenile systems may assign youth to some of these connections. Yet, for these external systems to work, adolescents must participate, and it seems likely that the bonding of youth to positive community systems is scaffolded through the relationships they form with mentors and other program participants.

Community based efforts at prevention have received increasing attention in recent years. The Community Youth Development Project addresses individual risk and protective factors at a community level, allowing communities to pick and choose from a menu of tested and effective individual- and school-based programs. The result is a community-specific approach to prevention that serves the needs of the youth in a given community. Evidence suggests that these approaches to prevention hold promise for reducing youth externalizing behaviors during the adolescent years (Hawkins, Oesterle, Brown, & Arthur, 2009; Hawkins et al., 2012).

Macrosystem influences on the regulation of adolescent risk behavior and, accordingly, vulnerability to certain forms of psychopathology, also have been studied. Examples include studies of cigarette tax policy on adolescent tobacco use (Chaloupka, Cummings, Morley, & Horan, 2002), the impact of gun-control policies on access to weapons (Elliott, Hamburg, & Williams, 1998), the effects of condom distribution in school-based health (Blake et al., 2003), and the impact of graduated driver's licensing policies on automobile accidents (Ulmer, Ferguson, Williams, & Preusser, 2001). Although these policies are rarely thought of as interventions designed to prevent or reduce psychopathology, they can be viewed as attempts to impose external regulation on individuals whose judgment and regulatory competence is not yet fully mature. One interesting but unstudied question is the relative effectiveness of policies designed to impose regulatory control on adolescents as a means of limiting risk behavior versus those designed to limit risk behavior by increasing adolescents' regulatory competence (e.g., through educational intervention).

Media and Virtual Contexts

Whereas many of the traditional contexts of adolescence development—involving family, peers, school, neighborhoods, and work—readily fit an embedded systems model of development, as proposed by Bronfenbrenner (1979) and others, other elements of context in adolescents' lives do not fit so neatly. Yet, these experiences may play an enormous and growing role in adolescent development. In particular, music, movies, and television, as well as the new virtual worlds of electronic games, web sites, and social media, saturate the lives of many adolescents many hours a day, penetrating most other contexts of interaction. The media diet (Brown & Bobkowski, 2011; J. D. Brown & Witherspoon, 2002) of American teenagers reflects a rapidly changing and increasingly

individualized context for learning, self-regulation, victimization, friendship formation, sex, violence, illegal activity, and self-discovery, among other processes. Teenagers clearly utilize music, phones, movies, games, chat rooms, instant messaging, email, and other electronic media to meet all kinds of needs. Increasingly, these media can be tailored to individual desires, so that adolescents can fine-tune their own experiences. Concomitantly, the same strategies can be utilized by marketers to recruit teenagers as consumers, often with the promise of happiness or sex appeal through consumption of food or drugs or the purchase of goods and services. The role of these transactions in the development or avoidance of psychopathology, misery, antisocial behavior, or risk-taking behavior is only beginning to be considered, as concern grows about the unmonitored interactions of adolescents through these media on violence, depression, self-injurious behavior, substance use, and many other problems or risky behaviors (Brown & Bobkowski, 2011). While exposure to types of media may not change per se from childhood to adolescence, it is the case that adolescents have more autonomy when selecting media exposure than previous developmental periods.

With the rise in exposure to various forms of technology during adolescence, the past decade has seen an increase in studies of how technology, such as Facebook, video games, or cyberbullying are associated with psychopathology. Although the study of these issues is nascent, in general, there is weak evidence of an association between exposure to these forms of media and psychopathology. Studies of Facebook have generally suggested that social media use can influence mood, with positive feedback boosting self-esteem and negative comments causing increase in negative mooed (Valkenburg, Peter, & Schouten, 2006). The increased feelings of social connectedness and inclusion that Facebook leads to may actually promote better adaptation in individuals, especially when they feel isolated from people in the real world (Sheldon, 2008). Increased social evaluation that has come about in part because of increased exposure to social media has raised general public concerns about cyberbullying. Yet cyberbullying appears to be less prevalent than media reports would suggest. For example, in a study of two large longitudinal samples of adolescents, one from the United States and one from Norway, Olweus (2012) documented that cyberbullying is a low-prevalence phenomenon. However, the negative effects of the cyberbullying have not received much attention from the research community. Greater investigation of the effects of media usage on psychopathology is needed.

New Approaches to Context in Relation to Adolescent Psychopathology: A Call for Future Research

Over the past 30 years, there has been a rapid expansion of research and theory on the significance of context-adolescent interactions for adolescent development and psychopathology. Work, romantic relationships, and media have gained more attention, as have the moderating and mediating roles of one context in regard to another. A profound change has occurred in the conceptualization of context in relation to adolescent development. Relationships, media, drugs, food, and activities, for example, are viewed as ways for adolescents to develop and exercise regulatory competence and to modulate levels of negative affect. Our point is that entry into adolescence is marked by changes in these types of contextual experiences: some new contextual experiences emerge, as is the case with work and romantic relationships, and others lead to increases in adolescent autonomy and control, such as provided by media. Moreover, the extent to which adolescents may be more or less sensitive to these contextual influences on affect developmental and regulation, and how in turn these contexts may stimulate different development of affective and motivational processes, remains unknown.

Concerns about deviant outcomes from adolescents' experiences in the contexts they come into contact with because such experiences have increased, perhaps in part as a function of the decreasing control of adults over these adolescents' time. Major concerns include social contagion of maladaptive behaviors, such as violence, self-injury, depression, or suicide. On the other hand, emerging contexts for adolescent development, such as virtual friends and support networks, could conceivably offer just as many positive as negative opportunities (Brown & Bobkowski, 2011; Brown & Witherspoon, 2002). The extensive and expanding contexts available to adolescents may be challenging and overwhelming or supportive and protective. As adolescents, who might be viewed as novice adults, negotiate the many changes of adolescence and the transition to self-regulated behavior, they may call on people in the various contexts of their lives for help. At the same time, adults, especially parents, may deliberately scaffold this long-term transition to adulthood through provision of adequate structure, support, and opportunities to facilitate success. If disparate developmental timing occurs in the functional maturity of affective, sexual, cognitive, and social systems utilized by adolescents to adapt, resources in the external context, in relationships, and in formal and informal institutions may provide compensatory or

protective effects that temporarily close the functional gaps in emotional and cognitive maturity with and across individuals. Conceptualizing the role of context in this way may offer important perspectives for interventions to prevent and ameliorate behavioral and emotional problems in adolescence, particularly when coupled with the study of the biological and cognitive changes that mark this developmental period.

CONCLUDING COMMENTS AND FUTURE DIRECTIONS

The framework we have advanced in this chapter articulates psychopathology during adolescence that is grounded in the understanding that the biological, cognitive, and contextual transitions of adolescence are dynamic, dramatic, and potentially determinative of psychopathology. In the past 10 years we have seen an explosion of research on the neurobiological changes of adolescence, and the framework we propose for the development of psychopathology is grounded in the notion that these neurobiological changes affect, and are affected by, the adolescent's social-contextual world.

We begin from the premise that adolescence is characterized by an increased need to regulate affect and behavior in accordance with long-term goals and consequences, often at a distance from the adults who provided regulatory structure and guidance during childhood. From this vantage point, adolescence is a time of especially heightened vulnerability to psychopathology specifically as a result of disjunctions between and among developing brain, behavioral, and cognitive systems that mature along different timetables and under the control of both common and independent biological processes. These disjunctions, in turn, create gaps between affect, thinking, and action. Viewed from this perspective, symptoms of various types of psychopathology in adolescence can be profitably understood as reflecting difficulties in the coordination of emotional, intellectual, and behavioral proclivities, capacities, and capabilities. By all indications, adolescence may well be a sensitive or critical developmental period for both normative and maladaptive patterns of development through the shaping of future trajectories and in the biological embedding of developmental experiences as the principal method through which this occurs.

Although adolescence is a time of increased vulnerability to psychological dysfunction, the fact remains that only a minority of adolescents develop psychopathology. To be useful, then, any framework that purports to aid in our understanding of psychopathology in adolescence must account not only for the heightened vulnerability that is characteristic of the period in general, but also for the wide variability between individuals in whether and to what extent this vulnerability is ever actualized. Virtually all adolescents will experience the sorts of disjunctions between affect, cognition, and behavior to which we have alluded, but most individuals will weather these difficulties and move into adulthood having experienced no or few serious difficulties.

In our view, individual differences in emotional and behavioral dysfunction during this period exist among adolescents in the nature and extent of these dysfunctions and in the availability of contextual support and the presence of contextual risk during times of heightened neurobiological vulnerability. Research on early maturing girls is a case in point. As we have noted, early maturing girls are, on average, at greater risk for the development of emotional and behavioral problems than their on-time or late-maturing peers. This is likely because earlier pubertal maturation brings with it changes in arousal that precede, by a fairly long stretch of time, the development of the regulatory competence necessary to modulate these drives; this is the sort of disjunction between arousal and regulatory competence that heightens vulnerability to problems. Moreover, the physical changes that accompany puberty also elicit new interactions with context (e.g., attracting attention from older peers and unwelcome advances from adult strangers) that may be difficult for a young girl to handle. Yet, most early maturing girls do not develop psychopathology. This is because early puberty is a risk factor for psychopathology among adolescent girls only under conditions of specific contextual risk: in families that expose the adolescent to stressful life events, in schools in which older boys are present, in communities in which students are especially body conscious, and in cultures that place a premium on thinness (Steinberg, 2011).

The past decade has seen considerable progress in our understanding of the most important sources of contextual risk and support. We now have a very good sense of what adolescents need in the family, school, peer, and neighborhood contexts to maximize positive youth development and minimize emotional and behavioral problems. There is an especially rich literature on familial risk and protective factors and, to a lesser extent, on the influence of peer, school, and work settings and media. Overall, the study of environmental influence on psychopathology in adolescence has yielded a solid basis for the development of preventive interventions and treatments, but research has focused largely on the influence of family and friends,

and much work remains to be done on understudied contextual influences, such as those of romantic partners, neighborhoods, and electronic media. This is particularly challenging in the changing landscape of society and culture, both of which dictate youth exposure to these various contexts.

There is no doubt that today we are on the cusp of a biological revolution in the study of normative and atypical adolescent development—a revolution made possible by tremendous advances in the study of molecular genetics, endocrinology, neurotransmission, and brain structure and function. These advances will enable the field to move beyond sweeping generalizations about the significance of puberty, or of changes in certain brain regions in the development of psychopathology in adolescence, and to begin to identify the specific characteristics and indices of pubertal maturation and brain development that are linked to specific forms of psychological malady. This will require a careful unpacking of puberty as a multifaceted phenomenon that involves endocrinological, neuroendocrinological, somatic, and social processes, and an equally careful unpacking of brain development in adolescence that links maturational change within and across specific systems to changes in behavior, cognition, and affect. Recent breakthroughs in neuroscience generate considerable enthusiasm for expanding knowledge on the mechanisms behind adolescent changes in behavior associated with successful or unsuccessful transitions in development.

For the field to advance in its understanding of how context and biology shape the emergence of psychopathology during adolescence, it is necessary for scholars to engage in collaboration with others trained in different disciplines. Although calls for interdisciplinary work are undoubtedly clichéd, there is no better way to begin to understand the interplay between biology, cognition, and context. At the nexus of these interdisciplinary efforts will be key information for translation of findings to prevention and intervention science. Indeed, beyond building interdisciplinary collaborations, it is our hope that this chapter spurs scientists to engage in translational efforts, moving science into prevention and intervention practice. Despite its obvious importance, the biological revolution that is currently unfolding in the study of adolescence will not suffice in the search for a complete understanding of the development, prevention, and treatment of psychopathology during this stage of life. Biological vulnerabilities may set the stage for psychopathology, but they by no means determine its course. Nor will the answer to questions about the onset, nature, and course of psychopathology be found in the study of context alone. We have noted numerous times in this chapter that the sources of contextual risk and protection in adolescence are nonspecific, interactive, and cumulative. Ultimately, we believe that the dramatic changes of adolescence are a paradox, in that adolescence is a developmental period with a heightened risk for psychopathology, but it is also a time of plasticity and has a potential to be a final developmental period for the successful implementation of prevention and intervention efforts.

Future progress in the developmental psychopathology of adolescence demands an integration of research on biology, cognition, and context. This will require cross-training and collaboration of scientists who specialize in neuroscience, behavioral development, and influential contextual systems, including families, peers, communities, media, policy, and multiple aspects of culture. Finally, it will also require a generation of scientists who are active in prevention science. In this chapter, we have offered a framework that we hope will launch many such efforts.

Social neuroscience is an examination of the associations and influences between social and biological levels of organization, particularly of the underlying neural, hormonal, cellular, and genetic mechanisms of interpersonal behaviors and cognitions. Traditionally, the development of the nervous system has been studied in isolation, ignoring the influences of the social environments in which humans and nonhuman animals live and grow. Yet, humans are a social species, and as such organizational structures naturally emerge, ranging from individual dyads to families, groups, and cultures (Cacioppo & Berntson, 1992). Like other social species, humans cannot survive and reproduce without others. Even our day-to-day existence is governed by direct and indirect contact with others. Consider the case of a solitary walk: we almost always bring others with us and virtually all of our actions are directed toward or are responses to others (Batson, 1990). Human social organizations, civilizations, cultures, and institutions are extensively developed, particularly in comparison to other species on the planet. These emergent structures have evolved hand in hand with neural and hormonal mechanisms to support them, as their consequent social behaviors helped these organisms survive, reproduce, and care for offspring sufficiently long that they too survived to reproduce (Cacioppo & Decety, 2011a).

The writing of this chapter was supported by National Institute of Mental Health R01 Grants (1R01MH087525–01A2 and 1R01-MH084934) and a grant from the John Templeton Foundation (The Science of Philanthropy Initiative) to JD.

Changes in the environment are thought to feed into individual biology, and their effects may travel into the storehouse of genes (Gottlieb, 1998; Gazzaniga, 2008) and there is growing evidence that social context (including cultures) fundamentally impacts living organisms at various levels across species, including their genetic expression (Rogers, 2014). For instance, physiological differences between mature queens of the two social forms (monogynous or polygynous) of the fire ant *Solenopsis invicta* are due largely to differences in the social (pheromonal) environment of the colonies in which the adults mature, rather than being due to intrinsic genetic differences between the forms (Keller & Ross, 1993). In primates (including humans), there is a relationship between social group size and the volume of the neocortex (Byrne & Bates, 2007; Dunbar, 2014). Thus the social brain must be studied in the context of the environment in which it develops and thrives. A diverse variety of organisms, from simple to complex, share many common behaviors including courtship and mating, aggression, and parenting. Indeed, many of the social behaviors exhibited by simple animals harken to social behaviors in complex animals, and their underlying neurobiological mechanisms—from cellular to neural networks—are highly conserved across species (Sokolowski, 2010).

The social environments humans have created shape our genes, genetic expression, brains, and bodies. While humans uniquely impact the environment and vice versa, much of the biological heritage is shared with other species.

For that reason, translational animal models testing specific aspects of human functioning and investigations of our evolutionary lineage are extremely valuable. Even though humans are what we are ultimately interested in, we share a lot of genes with other animals, even with simple organisms such as *C. elegans*. In order to understand how biological systems implement social behavior, it is imperative to investigate how the molecular and cellular mechanisms underpinning social interaction have evolved across species, using translation animal models. While research across multiple domains has helped to elucidate many of the complexities of the developing social brain, much remains to be explored about how the social and cultural environment influences genetic, hormonal, neural, and behavioral development (Ebstein, Israel, Chew, Zhong, & Knafo, 2010).

This chapter begins with a focus on the promises and challenges of developmental social neuroscience. Next, three specific illustrations of research in developmental social neuroscience are discussed: moral cognition, theory of mind, and empathy. These programs are led by interdisciplinary efforts, within multiple domains (social, cognitive, and neural), using multiple methods (EEG/ERP, fMRI, MRI, eye-tracking, hormonal measures, psychophysiological methods), and across multiple levels of analysis (behavioral, functional, neural, genetic). These examples highlight the utility of a multiple-level, contextually informed approach to the understanding of both normative and abnormal development. Finally, we discuss attempts to translate evidence from social neuroscience into research and policy regarding specific developmental psychopathologies.

SHAPING THE DEVELOPING BRAIN

The brain is not a static object that is the same from birth through adulthood. Rather, it is dynamic, plastic for much of development, experiencing periods of growth and pruning long after an infant has left the womb. For example, children's prefrontal cortex (PFC) is functional by age 4, yet it undergoes extensive fine-tuning and specialization over childhood and adolescence (Tsujimoto, 2008). This dynamic development is further evidenced by the longitudinal studies indicating peak cortical density in the PFC around age 8, followed by rapid pruning of neural pathways (Giedd et al., 1999). Many networks become increasingly integrated through myelination of pathways over development and maturation continues to late adolescence. Social experience is thought to be a primary driving factor enhancing certain networks (the ones often recruited together) and allowing others (less recruited) to be pruned for neural efficiency. To this point, both increases in functional connectivity and decreases in other networks have been documented across development (Stevens, 2009).

Early adversity in rodents' caregiving relationships impacts amygdala–medial prefrontal cortex (mPFC) circuits that in adulthood serve to regulate the activity of the amygdala circuits (Quirk et al., 2003). Analogously, in humans, previously institutionalized children, who experienced early maternal deprivation, also exhibit atypical amygdala–mPFC connectivity characterized by adolescent-like maturation of the connectivity (negative amygdala–mPFC coupling) (Gee et al., 2014). This connectivity is mediated by cortisol levels (collected immediately before and after MRI scanning), suggesting that stress-induced modifications of the hypothalamic–pituitary–adrenal axis impact the development of the amygdala–mPFC circuitry. Another example of this can be seen in the development of emotion processing. Children, as well as adults, will usually engage a large network of neural circuits, including the ventromedial prefrontal cortex, the amygdala, and visual cortices when emotional information is presented. This fine-tuned network, pruned through early experience, allows for the simultaneous perception, experience, and regulation of an emotion (e.g., Wismer Fries & Pollak, 2007). In studies of early deprivation, where children have not received extensive social input in infancy and early childhood (e.g., post-institutionalization), children's behavioral emotion processing appears limited and the structure and function of neural structures in this network are modulated (Pollak et al., 2010). What is clear from nearly two decades of research in developmental psychology, developmental social neuroscience, and behavioral neuroscience, is that environment and experience bi-directionally influence both structural and functional brain development.

MULTIPLE LEVELS OF INFORMATION

Since the mid-twentieth century, theorists in cognitive science, psychology, and neuroscience have argued for the integration of multiple levels of information in the study of any behavior. Forging an analogy with the computer, Marr (1982) introduced the notion of computational, algorithmic, and implementational levels of analysis. Marr's levels and corresponding emphasis on the computational and algorithmic levels were born out of the early movements of artificial intelligence, cognitive psychology, and cognitive

science, which were based on the idea that one could ignore the underlying biological mechanisms of cognition, focusing instead on identifying important computational or cognitive level properties. Indeed, these traditional approaches assumed that the brain works like a standard computer, and that Marr's computational and algorithmic levels were much more important than the mere details of the underlying neurobiological implementation (O'Reilly & Munakata, 2000). Naturally, few scholars in social and affective neuroscience today would agree with Marr's view that the implementational level is largely irrelevant. On the contrary, there is mounting evidence that the cellular level (e.g., genetic polymorphisms) has an impact in brain-behavior relationships, and the brain cannot be seen as a computer (Decety & Cacioppo, 2011).

Social neuroscience is an incorporation of information from multiple levels of analysis towards an understanding of behavior, similar to the developmental psychopathology approach (Cicchetti & Valentino, 2007; Gottlieb, 1998). Human behavior can be parsed into levels of organization, ranging from the atomic to the societal (Bronfenbrenner, 1995). Often what guides a level of organization, at least at the lower scales of representation, is knowledge of genetics, anatomy, and physiology, but the ultimate criterion is the usefulness of the organization in shedding light on some type of behavioral outcome. Social neuroscience, as a theoretical approach, describes a complementary relationship between the different levels of organization, spanning the social and biological domains (e.g. molecular, cellular, system, person, relational, collective, societal) and advocates for the use of multilevel analyses to explore the mechanisms underlying the human mind and behavior without needing to specify each individual action by its simplest components (Cacioppo, Berntson, Sheridan, & McClintock, 2000). It can help us understand developing brain function and, in turn, can be informed and refined through integration with theories and methods from social and behavioral sciences. Generative theories lead to hypotheses about the manifestation of behavior across multiple levels of organization, and provide a platform for conducting empirical tests, which can be used to support, reject, or refine these theories (Gergen, 1985).

THE COMPLEX INTEGRATION FROM MULTIPLE LEVELS OF ANALYSIS

As a social species, our behavioral and psychological functions can be best interpreted as the confluence of information processing from multiple levels: social, behavioral, neural, and genetic. This is the heart of social neuroscience and facilitates the focusing of intellectual energy and the unification of scholarly activity across levels of organization to produce more comprehensive accounts of the human brain, mind, and behavior (Cacioppo & Decety, 2011b). The study of developmental social neuroscience necessitates a large amount of information from multiple levels of analysis, using multiple methods, and from multiple informants, thus a more comprehensive account of a phenomenon can be forwarded. However, the challenge lies in creating the inclusive account, assimilating information from so many sources and levels. In incorporating evidence in developmental social neuroscience, three principles are key: multiple, nonadditive, and reciprocal determinism.

1. A target behavior at one level of organization can have multiple antecedents within or across levels of organization (multiple determinism; akin to equifinality; Cicchetti & Rogosch, 1996). On the biological level, for instance, scientists might identify the contribution of individual differences in the endogenous opioid receptor system in drug use, whereas on the social level investigators have noted the important role of social context. Both are important and inform our more complete understanding of the same outcome, drug abuse (Dalley et al., 2007). Similarly, immune functions were once considered to reflect specific and nonspecific physiological responses to pathogens or tissue damage. It is now clear that immune responses are also influenced by central nervous processes that, in turn, are affected by social interactions (Hawkley, Bosch, Engeland, Marucha, & Cacioppo, 2007). Human immunocompetence can thus be considered the consequent of either, or both, and any theoretical conception of it would be inadequate in the absence of considerations of social and behavioral factors. Theories of behavior will require information on comprehension of factors from multiple levels of analysis. Accordingly, advances in the neurosciences and the social sciences may occur by increasing the scope of analysis to include the contributions of factors and processes from both social and neuroscientific perspectives. Yet with additional levels of analysis, integrating and mapping becomes more complex (e.g., many to many). The likelihood of overly complex and potentially obscure mappings increases as one skips levels of analysis. This is perhaps one reason that going from the genotype to endophenotype and from endophenotype to phenotype has proven to be more fruitful than going directly from the genotype to phenotype (Bell, Richerson, & McElreath, 2009).
2. Properties of the whole are not always the simple sum of the properties of the parts (nonadditive determinism). Consider an illustrative study of the effects of

amphetamine on primate behavior (Haber & Barchas, 1984). The behavior of nonhuman primates was examined following the administration of amphetamine or placebo. No clear pattern emerged between the drug and placebo conditions until each primate's position in the social hierarchy was considered. When this social factor was taken into account, amphetamine was found to increase dominant behavior in primates high in the social hierarchy and to increase submissive behavior in primates low in the social hierarchy. The importance of this study derives from its demonstration of how the orderly mapping between the biological and social levels of organization would remain opaque until knowledge of the modulatory social status of the primates is included. A strictly physiological or social analysis, regardless of the sophistication of the measurement technology, would not have revealed the orderly relationship that actually existed.

3. Biological and social factors can be mutually influential in producing behavior and often bi-directionally interact with each other in such production (reciprocal determinism). To illustrate this point, consider that not only has the level of testosterone in nonhuman male primates been shown to promote sexual behavior, but the availability of receptive females influences the level of testosterone in nonhuman primates (Bernstein, Gordon, & Rose, 1983). This principle, too, implies that comprehensive accounts of behavior cannot be achieved if the biological or the social level of organization is considered unnecessary or irrelevant.

Overall, social neuroscience is characterized by its multilevel, integrative analyses across species. The conceptual questions in social neuroscience have captured the imagination of a talented, new generation of scientists. To address many of the big questions in the field requires larger and more interdisciplinary teams than were common in the prior century, however, and this is certainly the case in social neuroscience and developmental psychopathology as well.

METHODS IN SOCIAL NEUROSCIENCE

In social neuroscience, multiple methods at each level of analysis provide a more complete understanding of a behavior. These levels include behavioral, molecular, neurophysiological, social, and environmental. Common behavioral-level assessment methods include self-questionnaires, computerized experimental tasks, paper-and-pencil surveys and paradigms, as well as desktop games, quite common in developmental studies. Similarly, the children's behavioral characteristics and social interaction abilities are often measured using surveys of parents and teachers (multiple informants are crucial for providing a full picture of the environment, as well as the child's daily behaviors), as well as observation in various social interactions. Measuring the social and environmental levels varies greatly based on the nature of the subjects. As nonhuman research plays a critical role in social neuroscience, many researchers can systematically control both the social and general environment. In humans, strategic control of the social environment is limited and as such, measurement is based heavily on self, parent, and teacher reports.

The use of behavioral and molecular genetic methods has become common in social neuroscience. Many methods are used in the study of genetics in humans and nonhumans. Some of the earliest methods used in humans were twin, family, and adoption studies. These investigations were based on the knowledge that identical twins share (on average) all of their genes, whereas fraternal twins or siblings share half, allowing for heritability estimation. Other human genetic approaches include: linkage analyses (studying the transmission of particular genes in families with respect to other genes), candidate gene (tracking the association of particular behavioral characteristics of groups with varying alleles of a gene), and recently, DNA/ genomic sequencing (for a review of behavioral and molecular methods with humans, see Wilcutt et al., 2011). Human studies provide valuable information regarding genetic level differences, however. Due to ethical and feasibility constraints, studies using genetic methods in humans are limited to correlations and observations. In contrast, nonhuman animal studies provide the ideal venue for researching genetic contributions to behavior. Commonly used genetic methods in animal research include: transgenic or knockout methods (inserting a foreign gene or deleting a specifically targeted gene in a new strain of animals), phenotypic selection studies (selecting for animals that display extreme high or low phenotypes and selectively breeding them over successive generations), and inbred strain methods (animals who are the offspring of generations of siblings).

In addition to behavioral, social, environmental, and genetic research, several different methodologies within the neural level of analysis will be discussed. In developmental neuroscience, the most common methods utilized are electroencephalography (EEG), event-related potentials (ERPs), structural magnetic resonance image (MRI), functional magnetic resonance imaging (fMRI), functional near infrared spectography (fNIRS), pupillometry, and

TABLE 20.1 Techniques for Studying the Developing Brain in Humans

Technique	Description
Postmortem analysis	Brains are retrieved and processed after death to allow analysis of macroscopic and microscopic features of brain tissue.
Structural MRI	Noninvasive method that provides high spatial resolution (1 mm) images of the living brain and features of brain tissue.
Diffusion Tensor Imaging	Relies on the detection of microscopic movement of water within brain tissue to allow visualization of white matter and effective connectivity.
Functional MRI	Measures changes in blood oxygenation. Provides good spatial resolution but more limited temporal resolution.
Electroencephalography	Measures the electrical activity of the brain via electrodes placed on the scalp. Provides excellent temporal resolution, but limited spatial resolution.
Event-related potentials	Refers to averaged EEG responses that are time-locked to more complex processing of stimuli.
Near-infrared spectroscopy	Measures blood oxygenation. Limited currently to cortical regions.

eye tracking. Many developmental scientists have also integrated measures of autonomic arousal, such as heart rate variability (EKG) and skin conductance (GSR).

Each method can provide interesting and useful information, but all have drawbacks. A brief description of each method can be found in Table 20.1. For an extensive review of developmental neuroimaging methods see de Haan & Gunnar (2009).

Moral Cognition

The past decade has seen an explosion of empirical research in the study of morality. Among the most exciting and novel findings and theories, evolutionary biologists and comparative psychologists have shown that moral cognition has evolved to facilitate cooperation and smooth social interactions, and that certain components of morality are present in nonhuman animals (Decety & Howard, 2013). Moreover, the precursors to complex morality have been demonstrated much earlier in development than originally thought, and are clearly in place before children turn 2 (Hamlin, 2014). In several studies, infants as young as 6 months of age appear to be sensitive to an agent that helps another versus hinders another (Hamlin, Wynn, & Bloom, 2007). Additionally, infants as young as 12–15 months of age look longer at unequal distributions of resources (Schmidt & Sommerville, 2011; Sloane, Baillargeon, & Premack, 2012). Around 14–18-month-old infants exhibit spontaneous, unrewarded instrumental helping behaviors (Warneken & Tomasello, 2009). These early attention differences to fair versus unfair distributions have consequences in the behavior of infants and toddlers as well. Those who looked longer at an unequal distribution of resources were also the first to offer a preferred toy to another individual (compared with an unattractive toy; Schmidt & Sommerville, 2011).

Behavioral investigations of moral development in the last decade have been dominated by infant and toddler research; however, there is a rich history of studying moral development in later childhood and adolescence (Kohlberg, 1976; Turiel, 1998). For decades, children's moral knowledge and judgment have been documented and segregated into stage-type progressions. Behavioral level analyses of moral development across all ages of childhood have led to several prominent conceptions in the field, primarily the early onset of rudimentary moral sensitivities, the discrepancy between early sensitivity and later integration the activity into verbalized moral knowledge and subsequent moral behavior, and the importance of social context in morality, namely, situational constraints to moral judgment as well as domain-general mechanisms that may underlie moral thought and action (Blasi, 1980; Hoffman, 1977). To tease apart many of these conceptions, information about neural structure and function is useful.

Social neuroscientists have begun to map brain circuits implicated in moral decision making and identify the contribution of neuropeptides to moral sensitivity (Young & Dungan, 2012). Much of current social neuroscience research on morality with adults uses a classic philosophical thought experiment. Participants are provided with hypothetical moral dilemmas and asked to determine the morality of the agent in the story's actions. For example, in several studies, the trolley dilemma was used as a tool for differentiating emotionality and reasoning (Foot, 1967; Thomson, 1976). In the trolley dilemma, a trolley is bounding down a train track toward a group of individuals. The individuals are tied to the track and cannot escape. The study participants are asked: should they divert the trolley to a track where there are only two people tied down as opposed to six (i.e. should they kill two to save the six)? This is compared with a situation where the individual is asked if they should push a large man off a bridge in front of the trolley, saving the six but killing the one. In the first, the decision is impersonal, whereas the second involves a personal level of violation. In one functional MRI study, participants responding to personal moral dilemmas, compared with impersonal and nonmoral dilemmas,

produced increased activity in regions associated with social-emotional processing, including the medial frontal gyrus, posterior cingulate gyrus, and bilateral STS (Greene et al., 2001). By contrast, impersonal and nonmoral dilemmas compared with personal dilemmas produced increased activity in areas associated with working memory: dorsolateral prefrontal and parietal areas. Another study used similar moral dilemmas to look at the role of intentionality in moral decision making (Young & Saxe, 2008). Participants had greater activation in the posterior STS (also called the temporal-parietal junction [TPJ]) as well as the anterior cingulate cortex (ACC), when judging the intentionality of an individual in a moral dilemma (i.e., one person purposefully poisoning another compared with one person accidentally poisoning another). Our current knowledge of the neural bases of moral judgment also relies on lesion studies (e.g., Gleichgerrcht, Torralva, Roca, Pose, & Manes, 2011). Patients with vmPFC damage exhibit increased utilitarian judgments (Koenigs et al., 2007), which support the crucial role of this region in judgments and knowledge of right and wrong. In recent studies, patients with developmental-onset lesions to the vmPFC, unlike patients with damage during adulthood, made significantly more self-serving judgments that break moral rules or inflict harm on others than those with adulthood damage (Taber-Thomas et al., 2014).

Consistently, all studies implicate the vmPFC in moral decision-making, as a region argued to be important in processing aversive emotions that arrive from perceiving or imagining harmful intentions (Blair & Cipolotti, 2000; Koenigs et al., 2007). This part of the prefrontal cortex projects to the basal forebrain (the major cholinergic output) and brainstem regions, which contain all the afferent and efferent systems necessary for survival, including basic affective responses (Ongür & Price, 2000). It is also reciprocally connected with the amygdala and hypothalamus, and is therefore involved in the autonomic component of emotion and is essential in the evaluation of harmful intent. In studies using EEG recording, signals from the vmPFC and amygdala regions have been shown to encode the emotional value of stimuli (Decety & Cacioppo, 2012; Elliott, Agnew, & Deakin, 2010), and impairments of that region are not associated with deficits in mental states understanding, suggesting no effects on cognitive reasoning (Young et al., 2010).

The integration of neural and psychophysiological level analyses into the study of moral development is more recent. One functional MRI study, involving a large sample of individuals aged 4 to 37 years, combined moral evaluations, eye-tracking, and fMRI measures in response to short animated visual scenarios (Decety, Michalska, & Kinzler, 2012). Participants were shown sequences of pictures that depicted either people or objects being injured, intentionally or unintentionally. Intentionality is a critical aspect in this design because its detection is postulated to be the primary cue in determining whether an action is malicious or not (Cushman 2008; Killen et al., 2011; Malle & Guglielmo, 2012). After scanning, they were presented with the same stimuli and were asked to judge whether the action performed by the perpetrator in the video clip was intentional or not. Participants were also asked to respond to a set of questions probing moral judgment (wrongness and punishment), empathic concern for the victim, personal distress, and understanding of the perpetrator's mental state. Perceived intentional harm to people (as opposed to accidental harm) was associated with increased activation in brain regions sensitive to the perception, prediction, and interpretation of others' intentions such as the right pSTS/TPJ (Blakemore et al., 2003; Pelphrey & Carter, 2008) as well as regions processing the affective consequences of these actions, namely, the temporal poles, insula, vmPFC, and amygdala. The more participants reported being personally distressed about harmful actions, the higher the activity in the amygdala. Interesting developmental trends were also examined. For example, age was negatively correlated with empathetic sadness for the victim of harm in the video clips, with the youngest participants exhibiting the greatest personal sadness. Ratings of sadness for the victim correlated with activity in the insula, thalamus, and subgenual prefrontal cortex. This latter region has extensive connections with circuits implicated in emotional behavior and autonomic/neuroendocrine response to stressors, including the amygdala, lateral hypothalamus, and brainstem serotonergic, noradrenergic and dopaminergic nuclei (Drevets et al., 1997). Damage to the subgenual prefrontal cortex is associated with abnormal autonomic responses to emotional experiences and impaired comprehension of the adverse consequences of pernicious social behaviors (Bechara et al., 1996). Moreover, the BOLD (blood oxygenated level dependent) signal in older participants increased in the mPFC and vmPFC, regions associated with cognitive representation and decision making that enable us to reflect on the values linked to outcomes and actions.

That study also demonstrated that patterns of functional connectivity between prefrontal cortex and amygdala during the perception of intentional harm relative to accidental harm were different with age. The functional integration between vmPFC and amygdala were observed, such that the older participants showed significant

coactivation in these regions during the perception of intentional harm relative to accidental harm, whereas the youngest children only exhibited a significant covariation between the vmPFC and periaqueductal gray. Moreover, young participants showed weaker connectivity between vmPFC and pSTS/TPJ while viewing moral relative to nonmoral actions than adult participants, suggestive of developmental changes in functional integration within the mentalizing system.

In another study, 51 healthy male participants aged 13–53 were scanned while viewing international affective picture system (IAPS) pictures that did or did not depict situations considered to represent moral violations, and were asked to rate the severity of moral violation (Harenski et al., 2012). These severity ratings were associated with increased activity in the amygdala, pSTS/TPJ and posterior cingulate cortex activity in both adolescents and adults, however the magnitude of activity in the pSTS was positively correlated with age. Given the role of the pSTS region in mentalizing, and the fact that its underlying neural substrates undergo extensive developmental changes from adolescence to adulthood, the authors hypothesized that adolescents use these types of theory of mind inferences less during moral judgment than do adults.

Overall, findings from affective developmental neuroscience indicate that both affective reactions and cognitive reasoning contribute to moral judgments, yet in many contexts, automatic affective processes dominate. Converging results from lesion and functional neuroimaging studies implicate the specific role of a neural circuit of reciprocally connected regions in moral cognition (Moll, de Oliviera-Souza, & Eslinger, 2003). Moral reasoning has been argued to be supported by specific neural circuitry, but in fact these circuits are not necessarily unique to morality (Decety et al., 2012; Young & Dungan, 2012). Rather, morality involves regions and systems, which underlie various states of feelings, cognitive, and motivational processes. Most importantly, moral reasoning involves a complex integration between affective and cognitive processes that gradually changes with age and can be viewed in dynamic transaction across the course of ontogenesis. Finally, taken together, evidence from lesion studies and functional neuroimaging, offer compelling support for the proposal that early dysfunction in the systems underlying morality, particularly vmPFC and amygdala, may constitute a neuropathophysiological mechanism for the development of psychopathy (Taber-Thomas et al., 2014), a neurodevelopmental disorder associated with callous disregard for the well-being of others, guiltlessness, and little appreciation of moral wrongdoing.

Theory of Mind

The development of social cognition, particularly the understanding of others, is critical for social and peer interactions, and general social competence (Dunn & Cutting, 1999). Theory of mind (ToM; also called mentalizing) is the ability to explain, predict, and interpret behavior by attributing mental states such as desires, beliefs, intentions and emotions to oneself and to other people. Research in ToM and early social cognition has traditionally focused on behavioral development, characterized by task-related increases in overall performance (e.g., Wellman & Liu, 2004). Through the use of behavioral testing measures, children have been shown to have a step-like progression in their ability to pass false-belief tasks, false-appearance tasks, and even deception tasks (Wellman, Cross, & Watson, 2001). In a standard false-belief change location task, children witness two individuals in a room. One hides an object in A location, then leaves the room. The other individual moves the object from A location to B location. When the first individual comes back to the room, the child is asked where the individual will look for the object. To pass the task, children have to understand that the individual will not have the same knowledge of the change-of-location that they themselves have and will search in the original location (Wimmer & Perner, 1983). In meta-analyses of theory of mind development, the ability to pass this task is often not expressed in children until late preschool (Wellman & Liu, 2004). However, rudimentary theory of mind abilities have been shown in children only 15 months old (Onishi & Baillargeon, 2005). Infants look longer at instances where the individual who left the room searches in the B location than in the A location. These results suggest early knowledge of theory of mind, but the lack of an explicit ability to act upon this knowledge, hence children's apparent failure in change-of-location tasks in early preschool.

Complementary findings from developmental literature suggest that by as young as the second year of life, and definitely by preschool age, children are able to integrate conceptions of others into their choice of whom to learn from, a phenomenon referred to as selective trust (Koenig, Clement, & Harris, 2004). In selective trust experiments, children are shown familiar objects and two speakers label the objects, one does so correctly and the other does so incorrectly. Both speakers then label novel objects for the child, and the child is asked what the object is called. This early calculation of another individual's knowledge is also a form of early social cognition (Koenig, Clement, & Harris, 2004).

Recently, developmental and social neuroscientists have also investigated theory of mind and social cognition, including the temporal, developmental, and spatial dynamics of neural and electrophysiological activity underlying behavioral performance and developmental transitions between stages of theory of mind. Several methods have been employed in the study of ToM from a neural level including functional neuroimaging (fMRI), electroencephalography (EEG), event-related potentials (ERP), eye tracking, and pupillometry.

The spatio-temporal dynamics of developing social cognition have been characterized using two methods: collecting resting state electrophysiology (continuous recording while the participants closes and opens their eyes), and analyzing alpha or gamma band frequency frontal asymmetry or coherence (as they relate to behavioral outcomes; e.g., Sabbagh et al., 2009) and collecting stimulus/time locked recordings, wherein discrete waveform/latencies are examined during task acquisition (e.g., P300, LSW studies) (Sabbagh & Taylor, 2000). The event related potential (ERP) technique examines the exact timing of electrophysiological signals after a particular stimulus is presented; however, in order to perform reliable ERP analyses, many trials are needed (e.g., Luck, 2005). In the examination of theory of mind behaviorally, it is common to have a single false-location or false-contents trial. However, in electrophysiology, the variability in waveform latency and amplitude is quite large on a single-trial basis (Luck, 2005), leading to results that may depend on the neurological equivalent of outliers.

In one study using an ERP design, the change in location task was modified such that participants (adults) were shown a number of short stories. In half of the stories, the character's belief regarding the location of two objects was described and the other half, a character was described taking a photograph of two objects (Sabbagh & Taylor, 2000). Thus, most features of the vignettes were matched, except the belief dimension (belief or photo). Significantly greater amplitude in the p300 (a positive deflection approximately 300–400 ms post stimulus) was found for belief versus photo trials. The p300 waveform is oftentimes an index of differential attention allocation, and as such, belief understanding was theorized to depend on additional attention allocation when compared to simply taking a picture (with no mentalizing component). Additionally, differences in late slow wave (LSW) (approximately 900 ms post stimulus, argued to indicate secondary reappraisal) were observed for belief *versus* photo trials. Differences in temporal signatures related to ToM understanding, particularly LSW, were also explored in a series of studies with adults and children (Bowman et al., 2012). In this study, children and adults who could pass false belief (versus children who failed a false belief paradigm) showed a modulated LSW over frontal electrodes for belief versus reality, suggesting the necessity of secondary reappraisal and controlled cognitive processing in focusing on the mental states of others.

For several decades, EEG resting state activity, particularly alpha (or theta) frequency activity and coherence (6–9 Hz in children, 8–13 Hz in adults) have been seen as a relatively stable dispositional state (see Coan & Allen, 2003 for a review). The relationship between EEG resting alpha coherence and ToM development has also been explored (Sabbagh et al., 2009). In this study, frontal scalp alpha power density asymmetries were localized to the dorsolateral prefrontal cortex (dlPFC) and the posterior superior temporal sulcus and predicted children's behavioral representational ToM ability. Source localization, which attempts to provide information on the likely underlying neural sources that would produce scalp electrical signatures consistent with those present in the study, were employed (Phillips, Rugg, & Friston, 2002). Such algorithms attempt to solve what is known as the inverse solution; the use of these algorithms in developmental psychology has become more common (Reynolds & Richards, 2009), but remains a source of contention.

In sum, studies utilizing ERP/EEG methodologies have provided evidence that representational and belief understanding can be characterized by unique temporal neural signatures, primarily by differences in Late Slow Wave and p300 amplitudes. Additionally, resting state alpha frequency asymmetries predict representational ToM abilities. While ERP/EEG methods have provided a great deal of information regarding temporal neural responses related to ToM, their spatial resolution is not ideal and the use of source localization methods, particularly in children, remains contentious. Thus in order to more accurately examine the spatial aspect of neural activation of social cognition, functional magnetic resonance imaging (fMRI) has been the primarily utilized method. Several studies have documented the role of areas such as the medial prefrontal cortex (mPFC) and the dorsolateral prefrontal cortex (dlPFC) as well as the posterior superior temporal sulcus (pSTS) (e.g., Brunet et al., 2000; Fletcher et al., 1995; Ruby & Decety, 2003; Saxe, Xiao, Kovacs, Perrett, & Kanwisher, 2004) in mental states understanding and perspective-taking ability. The specificity versus generality of regions involved in social cognition and representational understanding remains an outstanding issue. One argument has been the importance

of a relatively domain-specific intentionality area specialized for processing information related to intention, the right pSTS (e.g., Young & Saxe, 2008). However, given the relative inability to disentangle cognitive aspects of ToM (e.g., executive function abilities) from the assessment of intentional understanding, many have argued for the necessity of a network of areas working together that are also involved in attention, executive function, and working memory (Decety & Lamm, 2007; Griffith, Pennington, Wehner, & Rogers, 1999). This debate is particularly salient when the information from the neural level of analysis with respect to representational understanding is integrated into our conceptions of abnormal development, particularly in populations where intentional and representational understanding are impaired (e.g., autism spectrum).

Empathy

The operational and conceptual definitions of empathy are both numerous and highly debated (Batson, 2009; Coplan, 2011; Decety & Jackson, 2004). While empathy to most theorists entails feelings of concern for others (known as empathic concern, a motivational state aimed at improving another's welfare), the definition also includes the capacity to take the perspective of another to understand her subjective experiences—feelings, desires, beliefs, and intentions. An additional and crucial component of empathy involves the natural ability to share or become affectively aroused by the emotions of others, referred to as emotional sharing or contagion (Decety, 2010a).

While empathic understanding is often considered as relatively specific to humans (and perhaps apes), emotional contagion and empathic concern are shared with other primates and mammals and depend on evolutionarily ancient systems for attachment, caregiving, and social communication. These systems rely on subcortical neural pathways (connecting the brainstem, hypothalamus, amygdala, basal ganglia and ventromedial prefrontal cortex) and hormones (Decety, 2011).

Several studies have documented empathetic-like behaviors in nonhuman animals. For instance, rodents exhibit emotional contagion and helping behaviors. Rats in an arena with a cagemate trapped in a restrainer learned to intentionally and quickly open the restrainer and free their cagemate, even when social contact was prevented (Ben-Ami Bartal, Decety, & Mason, 2011). When liberating a cagemate was pitted against chocolate contained within a second restrainer, rats opened both restrainers and typically shared the chocolate. To investigate whether pain behavior can serve the function of soliciting a primitive form of empathic concern, Langford and colleagues (2010) used a social approach paradigm to test mice in various dyadic or triadic conditions. In this study, some mice were restrained and administered an intraperitoneal injection of acetic acid to incite pain. A similar group of test mice were unrestrained, free to approach or avoid the distressed conspecifics. Only female mice approached a familiar same-sex conspecific in pain (suggesting empathetic arousal), and the frequency of contact by the test mouse was negatively correlated with the pain behavior of the jailed mouse, suggesting that the proximity of a familiar unaffected conspecific may have analgesic properties. Interestingly, genetic relatedness alone does not motivate helping as demonstrated by a new study that fostered rats from birth with another strain. Results showed that, as adults, fostered rats helped strangers of the fostering strain but not rats of their own strain (Ben-Ami Bartal et al., 2014). Thus, strain familiarity, even to one's own strain, is required for the expression of pro-social behavior in rodents. Additional evidence for empathy-elicited behaviors has been also well documented in chimpanzees and capuchins. For instance, chimpanzees will actively sooth fellow chimps that are distressed or are the targets of aggression (Flack & de Waal, 2000) and capuchins have been found to prosocially offer food to familiar monkeys (de Waal, Leimgruber, & Greenberg, 2008).

Foundational to the experience of empathy in adults and children is the ability to emotionally resonate with the affective states of others (Decety & Sveltova, 2012). Human infants are sensitive to the emotional expressions of others, especially when these expressions are vocalized. This predisposition for sensitivity has been shown in neural approaches to the study of the development of empathy. Neonates appear to possess a neural mechanism for vocal affective discrimination, as demonstrated by a mismatch electroencephalographic response over the right hemisphere in response to emotionally laden (happy and fearful vs. neutral) syllables within the first few days of life (Cheng, Lee, Chen, Wang, & Decety, 2012). In 3–7-month-olds, said vocalizations are associated with a selective increase of hemodynamic activity in brain regions involved in the processing affective stimuli, such as the orbitofrontal cortex and insula (Blasi et al., 2011). The results of these two studies suggest remarkably early functional specialization for processing the human voice and emotions.

Due to the methodological constraints of functional neuroimaging with children, much of our knowledge of regions of the brain associated with empathy come from studies with adults. In adult participants, numerous neuroimaging studies have demonstrated the reliable

activation of a neural network involved in pain perception, including the anterior mid-cingulate cortex (aMCC), anterior insular cortex, supplementary motor area (SMA), and periaqueductal gray area (PAG). Activation in this network has been reported in response to facial expressions of pain (Botvinick et al., 2005; Lamm, Batson & Decety, 2007), body parts being injured (Cheng, Yang, Lin, Lee, & Decety, 2008; Jackson, Meltzoff, & Decety, 2005), imagining the pain of others (Decety & Porges, 2011; Jackson, Brunet, Meltzoff, & Decety, 2006), or simply observing a signal indicating that someone will be receive a painful stimulation (Singer, Seymour, & O'Doherty, 2004). These vicariously instigated activations of the pain matrix are not specific to the sensory qualities of pain, but instead are associated with more general survival mechanisms such as aversion and withdrawal when exposed to danger and threat (Decety, 2010b). In fact, based on a systematic review of electroencephalographic and functional MRI studies that examined neural systems triggered by nociceptive stimuli, activity of this cortical network reflects a salience system involved in detecting, processing, and reacting to the occurrence of salient sensory events regardless of the sensory channel through which these events are conveyed (Legrain, Iannetti, Plaghki, & Moureaux, 2011), which elicit defensive and protective behaviors.

Of particular importance is the aMCC, a region that implements a domain-general process integral to negative affect, pain and cognitive control, which contains pain-responsive neurons that are activated by both anticipation of pain, and instrumental escape from pain (Shackman et al., 2011). Furthermore, activation of the anterior insula is clear in studies of pain empathy. This response can even be elicited automatically, as shown when participants viewed color photographs depicting human body parts in painful or neutral situations and performed either pain judgment (painful–nonpainful) or laterality judgment (left–right) of the body parts in the absence of explicit task requirements and attentional demands (Gu et al., 2010).

One study has attempted to investigate the development of empathy using functional neuroimaging methods. In this cross-sectional study participants ranging from 7 to 40 years of age were shown visual stimuli depicting individuals being physically injured by accident or intentionally by another (Decety & Michalska, 2010). In subjective evaluations of the stimuli, collected after scanning, a gradual decrease in the judgment of pain intensity for both conditions (accidental vs. intentional) across age, with younger participants rating the scenarios as significantly more painful than older participants, was observed. For younger participants, greater activation in amygdala, posterior insula, and medial OFC was seen when watching others in painful situations. In contrast, a positive correlation was found in the anterior portion of the insula. A posterior-to-anterior progression of increasingly complex rerepresentations in the human insula is thought to provide a foundation for the sequential integration of the individual homeostatic condition with one's sensory environment, and motivational condition (Craig, 2003). The posterior insula receives inputs from the ventromedial nucleus of the thalamus, an area that is highly specialized to convey emotional and homeostatic information, and serves as a primary sensory cortex for both of these distinct interoceptive feelings from the body. In response to others' physical distress, younger participants recruited the posterior portion of the insula, in conjunction with the amygdala and medial OFC, more than adults. This finding speaks to the children's tendency to be aroused by the perception of others' distress in a more direct sense leading to a heightened experience of discomfort associated with a visceral response to a potential threat, whereas adult participants tend to use more abstract secondary representations of pain when perceiving others in distress.

This latter study also found that age was related to activation in the prefrontal regions, such as the dlPFC and IFG, areas involved in cognitive control and response inhibition (Aron, Robbins, & Poldrack, 2004; Swick, Ashley, & Turken, 2008). Similarly, age-related change was observed in the OFC in response to the pain inflicted by another, shifting activation from the medial portion in younger participants to the lateral portion in older participants. The OFC has intrinsic networks that are defined on the basis of their cortico-cortical connections and also connections with other parts of the cerebral cortex and subcortical structures. These connections extend to the mediodorsal nucleus of the thalamus, sensory areas, and virtually all limbic structures (including the amygdala and brainstem), each subserving distinct functions (Ongur & Price, 2000). Since the medial part of OFC is involved in regulating both motor and visceral responses, and its lateral part is involved in executive control of emotion reactivity (Hurliman, Nagode, & Pardo, 2005), this pattern of developmental change is indicative of a gradual shift from the monitoring of somatovisceral responses in young children (consistent with their tendency to process others' pain information at a proprioceptive level) to a more cognitive evaluative level associated with executive control of higher order emotion processing in older participants.

TRANSLATIONAL DEVELOPMENTAL SOCIAL NEUROSCIENCE

As developmental social neuroscience is a relatively new field, the predominant focus of research has been on normative populations, answering first-level questions of observation, as is evidenced by our three examples (i.e., moral reasoning, theory of mind, and empathy). However, recent investigations have begun to use this knowledge from the developmental social neuroscience approach to inform the investigation of abnormal development and psychopathology. Two areas where this translation of social neuroscience is most evident are in the study of autism and in the study of conduct disorders, antisocial behavior, and callous unemotionality.

Autism

Children with autism spectrum disorder (ASD) exhibit widespread deficits in social cognitive abilities such as ToM and executive functions (Baron-Cohen, Campbell, Karmiloff-Smith, Grant, & Walker, 1995; Hughes, Russell, & Robbins, 1994; Ozonoff, Pennington, & Rogers, 1991; Russell, 1997). Decades of research with twins and siblings have shown that ASD and the range of social cognitive deficits associated with it, are highly heritable, with some studies reporting over 70% heritability (e.g., Constantino et al., 2013; Hallmayer et al., 2011). In the last 20 years, preliminary investigations of the genetic underpinnings of ASD have identified dozens of candidate genes in which specific mutations are associated with the severity of certain ASD symptomatology, such as the neurexin 1, neuroligin 1, RELM, OXTR, and AVPR1 genes (e.g., Kim, et al., 2008; Marshall et al., 2008; Persico & Bourgeron, 2006; for a review of the current state of behavioral and molecular genetics of autism, see Krumm, O'Roak, Shendure, & Eichler, 2014). However, recent estimates suggest that variations in these candidate genes accounts for less than 20% of ASD cases (Geschwind, 2011). Phenotypic differences in ASD, such as deficits in face processing, social affiliation, motor imitation, working memory, executive function, and phonological processing are unlikely to be based on the mutation of a single gene. Instead, mutations to multiple genes, each a risk factor for the diverse syndrome, are presumed to account for variability (Dawson et al., 2002).

Starting from an early age, children with autism appear to lack the appropriate emotional response to another person's distress or fear (Sigman, Kasari, Kwon, & Yirmiya, 1992). Moreover, infants with autism are far less likely to engage in the imitation of adult facial gestures (Griffith et al., 1999). This early (1–3 weeks of age) normative developmental ability (Meltzoff & Moore, 1977) is likely to interfere with social cognitive experience, leading to future domain-general deficits. Infants can first distinguish between familiar and unfamiliar faces around 3–4 months of age (Tronick & Cohn, 1989). At around 4 months of age infants begin to become sensitive to emotional and social responsiveness of their caregivers. These abilities may be viewed with step-wise progression, wherein, the inability to distinguish between familiar and unfamiliar faces at early ages, may illustrate a general inability to recognize one's familiar sources of support (caregivers). This lack of recognition, coupled with the later inability to attune to a caregiver's emotional responses, can lead to interactional synchrony (Isabella & Belsky, 1991). In this situation, the infant and caregiver's discrepant patterns of responsiveness toward each other in the dyadic relationship predict abnormal social development.

Since the discovery of the mirror neurons in the primate brain (di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992) and the finding of a supposedly similar set of circuits in the human brain (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995), many studies have explored the mirror neuron system (MNS) as it develops in individuals with autism. The predominant function of mirror neurons was thought to relate to action understanding (Rizzolatti & Craighero, 2004), but it is also theorized to be important for other social-cognitive processes, including imitation, theory of mind and empathy (Gallese & Goldman, 1998).

Early developmental failure of the MNS has been postulated to contribute to imitation deficits followed by varied social-cognitive difficulties characteristic of ASD (Williams, Whiten, Suddendorf, & Perrett, 2001). Importantly, in the studies investigating MNS functioning in individuals with autism, results are inconsistent (e.g., Katagiri, Inada, & Kamio, 2010).

In particular, some studies have reported that activity in the MNS of individuals with ASD differed from those of control participants through indirect measures of neural activation, such as resting-state EEG (*mu*) suppression over the sensorimotor cortex (Oberman et al., 2005), or BOLD signal (fMRI; Dapretto et al., 2006) during the observation of goal-directed hand actions and emotional expressions. However, other studies have reported a normal MNS response in individuals with ASD (Dinstein et al., 2010). In one study, the observation of action without requesting imitation elicited significant mu suppression (Bernier, Dawson, Webb, & Murias, 2007), particularly when the action was attributed to a familiar individual

(Oberman, Ramachandran, & Pineda, 2008). In another study, individuals with ASD and control subjects were shown a series of videos depicting standard goal-directed actions, while using the EEG coupled with eye tracking (Fan, Decety, Yang, Liu & Cheng, 2010). Participants with ASD watched a right hand manipulating objects, and showed significant suppression of the mu rhythm, similar to the mu suppression shown in control participants (nondifferentiation between ASD and controls). These results, in conjunction with other recent findings challenge the notion that individuals with ASD have an abnormal mu suppression in response the observation of hand movement (Oberman et al., 2005) or retain their imitation ability to hand–object interaction (Hamilton, Brindley, & Frith, 2007). A recent study using fMRI and EEG in individuals with ASD exhibit heightened empathic arousal but impaired social understanding when perceiving others' distress. Furthermore, both ASD and control groups showed comparable mu suppression, indicative of typical sensorimotor resonance (Fan, Chen, Chen, Decety, & Cheng, 2013).

The last two decades have seen a focus on the role of the MNS in the developmental psychopathology of autism, yet the results have not provided a clear picture that the MNS is of primary importance from a neural level of analysis. Other studies investigating neural developmental differences in individuals with autism have focused either on specific target areas (e.g., the FFA) or diffuse networks of difference (e.g., a combination of frontal, temporal, and parietal areas) (Pelphrey & Carter, 2008).

Several studies indicate that the perception of faces is associated with the specific activation of the so-called fusiform face area (FFA; Weigelt, Koldewyn, & Kanwisher, 2012). In populations with autism, the FFA is activated when processing both faces and objects (not necessarily due to visual expertise; Dalton et al., 2005). However, most studies have documented atypical response in a network of regions, comprised of the FFA, as well as the orbitofrontal cortex (OFC), the medial prefrontal cortex (mPFC), the amygdala, the posterior superior temporal sulcus (pSTS) and the inferior frontal gyrus (IFG; Pelphrey & Carter, 2008). This network view of the abnormal processing in ASD further illustrates differences seen behaviorally in social perception, goal-directed action understanding, social cognition, gaze processing, and executive functioning (Kaiser et al., 2010).

As is quite clear from the brief review of the findings regarding ASD, a multiple-levels-of-analysis approach to understanding this psychopathology, and its underlying mechanisms, is necessary. Preliminary investigations have shown developmental differences in behavioral functioning, differential temporal and spatial processing of belief, desire, and representational understanding, both for children that cannot pass theory of mind tasks, as well as individuals with autism.

Conduct Disorders and Callous Unemotional Traits

Another example of translational developmental social neuroscience is the study of conduct disorders, aggressive behavior, and callous unemotional traits. Socioemotional dysfunction has dire consequences in social cognitive development that dramatically impact interpersonal relationships. This is particularly the case in children with conduct problems or conduct disorders (CD), a serious behavioral and emotional disorder that can occur in children and teens. Children with CD and high levels of antisocial behavior and callous-unemotional traits usually lack guilt and remorse and have difficulty in social situations, showing deficits in affective arousal and empathic concern for the well-being of others (Hawes & Dadds, 2012). The capacity to experience the distress of others as aversive is critical for the development of moral emotions (e.g., guilt and remorse) as distress cues are assumed to activate tendencies to withdraw (Blair, 1999). Moreover, adolescents with higher psychopathy scores also tend to interpret both moral and conventional violations as more permissible than adolescents with low psychopathy scores (Dolan & Fullam, 2010).

Atypical responses to the distress of others are evident as early as childhood and have long-term consequences. For instance, general disregard for others, particularly for the distress of others, as early as 14 months of age is related to later development of antisocial behavior in middle childhood and adolescence (Rhee et al., 2013). Some evidence suggests that there are consistent patterns of psychophysiological empathic responding in both aggressive and nonaggressive toddlers (Gill & Calkins, 2003). Indeed, a meta-analysis of the developmental links between empathic development and aggressive behavior indicated that adolescents exhibit a greater negative relationship between affective empathy and aggressive behavior than children (Lovett & Sheffield, 2007). Gender differences, particularly earlier in development, have been shown in the relationship between empathic responding and conduct disorder/antisocial behavior, wherein young males showed the highest relation between antisocial behavior and lower empathic responding (Dadds et al., 2009). Moreover, from extensive evidence with school age children and adolescents, the mechanisms

that lead to aggressive or antisocial behavior can be identified across multiple domains, from genetics (there is a high incidence of intergenerational aggressive antisocial behavior) to environment (see Tremblay, 2010 for a full review).

Children with psychopathic tendencies also exhibit reduced electrodermal responses to distress cues (e.g., a crying face) and threatening stimuli (e.g., a pointed gun) relative to controls (e.g., Blair, 1999). A study using electroencephalography recently examined this phenomenon by assessing how callous-unemotional traits in juvenile psychopaths are related to empathic arousal deficits (Cheng et al. 2012). In this study, juvenile offenders with high callous-unemotional traits, juvenile offenders with low callous-unemotional traits, and age-matched typically developing adolescents were shown images of people in physical pain while EEG/ERPs were recorded. Results demonstrated that youth with high callous-unemotional traits exhibit atypical neural dynamics of pain empathy processing in the early stages of affective arousal. This abnormality was exemplified by a lack of the early ERP negative deflection (N120), thought to reflect an automatic attention to negative stimuli, and was coupled with relative insensitivity to actual pain (as measured with the pressure pain threshold). Nevertheless, their capacity to understand intentionality was not impaired. This uncoupling between affective arousal and emotional understanding likely contributes to psychopaths' callous disregard for the rights and feelings of others. A recent emphasis has been placed on exploring the genetic and biological mechanisms underlying the expression of callous unemotionality. In a sample of urban and rural children, differences in several genetic polymorphisms related to oxytocin receptors predicted callous unemotional traits in children and adolescents (Dadds, Moul, Cauchi, Dobson-Stone, Hawes, Brennan, Urwin, et al., 2014). High callous unemotionality was also associated with greater methylation of oxytocin receptor genes and lower blood concentration of oxytocin (Dadds, Moul, Cauchi, Dobson-Stone, Hawes, Brennan, & Ebstein, 2014).

Functional MRI studies have reported that adolescents with disruptive psychopathic traits show reduced activity to increasing perceived pain intensity within structures typically implicated in affective responses to others' pain, including the anterior cingulate cortex, insula, and amygdala (Marsh et al., 2013). Another recent study found reduced neural response to others' physical pain in children with conduct problems in the insula and ACC (Lockwood et al., 2013). Youths with psychopathic traits exhibit reduced amygdala responses to fearful facial expressions and during affective theory of mind tasks (Marsh et al., 2008). Adolescents with conduct disorders also show reduced activation in the amygdala and right anterior insula during affective ToM tasks than non-conduct disordered adolescents (Sebastian et al., 2012). It is worth mentioning that psychopathic traits are not exclusively associated with amygdala hyporeactivity. A study that included 200 young adults with self-reported psychopathy assessment found that amygdala reactivity to fearful facial expressions is negatively associated with the interpersonal facet of psychopathy, whereas reactivity to angry expressions is positively associated with the lifestyle facet (Carré et al., 2013). Interestingly, one functional neuroimaging study of youth with aggressive conduct disorder and psychopathic tendencies found increased activation in the ventral striatum and amygdala when adolescents viewed people being intentionally hurt by others (Decety, Michalska, Akitsuki, & Lahey, 2009). The extent of amygdala activation to viewing others in pain was positively correlated to the participant's number of aggressive acts and their ratings of daring and sadism scores. These results are consistent with the view that increased activity in the amygdala, particularly when coupled with the ventral striatum, reflects a general arousing effect of reward (Murray, 2007).

Much of our knowledge on psychopathy/callous unemotionality comes from a rich literature with adults, primary incarcerated psychopaths (e.g., Harenski, Harenski, Shane, & Keihl, 2011). In these studies, several consistent findings have arisen. Adult psychopaths consistently fail to experience distress cues as aversive. They lack fear of punishment, have difficulty regulating their emotions, and do not experience insight into or empathy for the effect their poor behavior has on others (Blair & Blair, 2009). Offenders with high levels of psychopathy show reduced autonomic arousal when viewing a confederate receiving electric shocks (Aniskiewicz, 1979), and often exhibit weaker psychophysiological reactions to emotional stimuli (for example, decreased skin conductance reactivity) and poor passive-avoidance learning (Kosson et al., 2006). Structural neuroimaging studies associate psychopathy with a host of morphological brain abnormalities, including reduced gray matter volumes of the amygdala, temporal poles and temporal cortex (particularly in the right pSTS), and increased volume of the striatum. Furthermore, psychopaths often exhibit signs of reduced structural integrity of the uncinate fasciculus (Koenigs, Baskin-Sommers, & Newman, 2010) connecting areas of the limbic system (such as the hippocampus and amygdala) with the ventromedial prefrontal cortex. The integrity of this circuit

seems to be necessary for moral decision making and empathic concern.

Overall, a lack of affective arousal in psychopathic individuals reinforces the importance of emotion stimulation and perception in the development of care-based morality. This type of moral reasoning necessitates that distress cues become associated with representations of stimulus–outcome learning. Affective arousal plays an important role in eliciting empathic concern (Barnett & Thompson, 2001). The dysfunction of the connectivity between the amygdala and vmPFC partially explains low socioemotional responses to others' distress, though it is important to note that blunted empathic arousal alone does not explain offensive behaviors. Behavior is caused by rewards and stopped by punishments, with the former influencing behavior more effectively than the latter in most individuals. Offending behavior exists and persists because it is rewarding, and these rewards in turn affect the activity of the mesolimbic dopamine system (one of the dopaminergic pathways). For example, pathological reward seeking in individuals with impulsive-antisocial psychopathic traits increases the likelihood of engaging in behaviors that are dangerous to others and themselves, and predicts ventral striatum dopamine release in response to pharmacological and monetary reinforcers (Buckholtz et al., 2010).

Most social interactions hinge on the degree to which individuals have the ability to process socioemotional information and make inferences about another person's cognitive and emotional states in the service of adaptive interpersonal behavior. A lack of emotional response to the distress of others is generally associated with psychopathic and antisocial tendencies, suggesting an important link between arousal and empathy. Integrating our understanding of conduct disorder and callous unemotional traits with adult psychopathy clarifies both normative and atypical development of socioemotional responding.

CONTROVERSIES AND FUTURE DIRECTIONS

Controversies

Developmental psychologists have long debated about domain-general versus domain-specific mechanisms (e.g., Gallistel, Brown, Carey, Gelman, & Keil, 1991). As social neuroscience and its theoretical approach have gained popularity, conceptions of the social brain as a domain-specific set of neural networks or regions interacting or the social brain as the integration of domain-general mechanisms or networks have been in conflict. This debate is particularly pertinent to developmental psychopathology in that many identified neural regions of interest, or even circuits, are postulated to be solely responsible for social cognitive function (e.g., the Facial Fusiform Area; Downing, Jiang, Shuman, & Kanwisher, 2001; Gauthier, Skudlarski, Gore, & Anderson, 2000). Oftentimes these areas show deficits in either structure or function in abnormal populations (e.g., ASD spectrum individuals). Thus, attempting to use a domain-specific approach to social neuroscience may yield potential information for psychopathology and intervention. However, it is important to emphasize that conceptions of domain-specific areas for theory of mind or intention understanding are now commonly being replaced by more complex understandings of multiple overlapping neural networks, not specific to a particular behavioral phenomenon (Decety et al., 2012). In addition, current research shows that complex socioemotional cognitions and behaviors have their neural bases in dynamic coalitions of networks of brain areas, none of which should be conceptualized as specifically affective or cognitive (Pessoa, 2008). As illustrated with examples from the literature in social neuroscience, both types of interpretations still abound. Some neuroscientists argue for specific areas of functioning, others argue for networks of interconnected functioning. The aim of social neuroscience is not the discovery of social modules in the brain. Rather, it is to understand the reciprocal relationships between social, cognitive, and neurobiological levels, and not brain systems specific to social information (Ochsner & Lieberman, 2001).

In interpreting data from multiple levels of analysis, two meta-integration methods have come to the forefront: integrative approaches and reductionist approaches. Similar to biology, physics, and chemistry, developmental neuroscientists have been encouraged to discover explanations of behavior that are at the most scientifically basic levels: molecular, genetic, and biological. Reductionist thought in developmental science is the idea that all explanations should be founded in one of these basic scientific levels.

Ultimately, the study of developmental psychopathology and social neuroscience necessitates an integrative, multiple-level-of-analysis approach (Cicchetti & Valentino, 2007). All the complex constructs that are studied in social and affective neuroscience such as self-regulation, attachment, empathy, trust, and moral reasoning, can hardly be seen as specialized somewhere in the brain or relying on a single region, the consequence of a specific genomic mutation, or the product of a specific hormone. Instead, they need to be broken down into sub-components with

the challenge of avoiding narrow definitions that fail to capture the breadth of a function and vague concepts that may well resonate with lay knowledge and common sense but have little if any scientific validity and utility.

Future Directions

There is great excitement in developmental social neuroscience and developmental psychopathology regarding the potential integration of commonly used behavioral methods with genetic, hormonal, and neural analyses. While these analyses provide insight into development, and may help to clarify some theoretical and behavioral distinctions, it is clear that the methods available and the subsequent information from studies using multiple levels of information are not sufficient to unravel the neurobiological mechanisms mediating social cognition and interaction. However, it is equally clear that, because many of these analyses, such as behavioral, genetic, hormonal, neuroimaging, and electrophysiological measures are noninvasive, they have an important role to play in testing and refinement of developmental theories of complex psychological processes that are difficult to study in nonhuman animals.

Future studies in developmental social neuroscience research need to take into account three primary considerations. First, behavioral analyses and assessments of complex psychological constructs are important and are the core of the field of developmental social neuroscience (Cacioppo & Decety, 2009). In order to use multiple levels of analysis, psychological constructs need to be broken into their component, representations, and processes that could plausibly be implemented by the brain. These behavioral investigations allow for a fine-tuning of tasks and measures that can be used in the study of the genetic, neural, and development change in any construct. Moreover, a strong theoretical perspective will be able to easily integrate evidence from multiple-levels of analysis.

Second, multiple methods at each level of analysis are key. In the neural level, the brain does not operate exclusively at the spatial level of molecules, cells, nuclei, regions, circuits, or systems, nor does it operate exclusively at the temporal level of milliseconds, seconds, minutes, hours, or days. Neuroimaging provides a partial view of brain activity within a very limited range of spatial and temporal levels. For instance, the smallest regions detectable by fMRI still involve hundreds of thousands of cells, cells that are seldom homogeneous in their function or connections, so such studies identify neural circuitry only in a gross sense. Different cells within the amygdala have been identified that respond to appetitive versus aversive stimuli (Paton, Belova, Morrison, & Salzman, 2006). Detection of amygdala activation by fMRI in response to appetitive and aversive stimuli does not mean the same neural circuitry has been activated. Therefore, converging evidence from measures in each level of analysis (e.g., neural, behavioral, environmental) that gauge similar events from different informants, perspectives, or scales (e.g., fMRI and EEG) leads to a more complete picture of any given phenomenon and allows for greater scope in future hypothesis testing.

Third, human and nonhuman animal investigations are critical to the future of developmental social neuroscience. The field of developmental social neuroscience is not limited to the study of humans. In fact, much of the current knowledge comes from neural, behavioral, and environmental translational animal models. These are crucial as human neuroimaging, behavior, and surveys are, by nature, correlational measures. Experimental studies including lesion, transcranial magnetic stimulation, and pharmacological interventions (e.g., ligands, drugs) in human and nonhuman animals are essential to further elucidate the causal role of any given neural structure, circuit, or process in a given task. Lesion methods in particular remain a fundamental and indispensable approach. Lesion is a means to test, at the system level, the necessity and specificity of a particular region and can thus provide complementary information to neuroimaging and behavioral data.

New investigations conscious of these considerations can facilitate advances in our understanding of brain function, development, and psychopathology. The primary message is that multiple levels of analysis, when implemented and interpreted with caution, are critical to the study of development, particularly developmental psychopathology.

Conclusions

The integration of multiple levels of information into developmental social neuroscience and psychopathology results in a reconceptualization of the division between psychological, hormonal, genetic, and neural functions. The presence of so many open questions in the field is both a daunting challenge and an exciting opportunity. With genetic sequencing, hormone analyses, and neuroimaging and electrophysiological measures becoming increasingly affordable and commonplace, the field of developmental science and developmental psychopathology is on the brink of a series of breakthroughs. We encourage this exploration and at the same time advise caution in the

nature of interpretation, particularly in reducing complex psychological phenomenon to activation in areas of the brain, or mutations in a single candidate gene. We should always be cautious that there is no 1:1 relationship between a psychological construct and its neurobiological instantiation.

INTRODUCTION

Research into the long-term consequences of early adverse life experiences, such as childhood abuse, neglect, or loss, on subsequent emotional, social, cognitive and physical development has gained increasing attention in recent years. As early as at the end of the 19th century, Sigmund Freud already had recognized that stressful or traumatic experiences in early life play an important role in the development of later mental disorders, such as melancholia (Freud, 1896). Today, an abundance of epidemiological and clinical studies supports that early-life stress (ELS) is an extraordinarily common and potent risk factor for the development of a wide range of psychiatric disorders as well as certain classic medical diseases in adulthood (e.g., Anda et al., 2006; Felitti et al., 1998; Heim, Shugart, Craighead, & Nemeroff, 2010; Shonkoff et al., 2012). Among the psychiatric disorders, depression and anxiety disorders have been most prominently linked to ELS. In addition, ELS induces risk for including ischemic heart disease, lung disease, cancer or cancer progression, gastrointestinal disorders, and chronic fatigue and pain syndromes among others. Many of these disorders are elicited or aggravated by acute stress, and individuals with ELS have decreased thresholds for exhibiting symptoms, even upon mild challenges (Hammen, Henry, & Daley, 2000). The precise mechanisms that mediate the detrimental and persistent impact of ELS on long-term health and adaptation have been subject to intense inquiry over decades. Advances in neuroscience have provided compelling insights into the enormous plasticity of the developing brain as a function of experience. For example, visual sensory input early in life is required for normal development of the visual cortex and perception, and disruptive experiences during such critical periods of plasticity lead to lifelong and sometimes irreversible damage (Weiss & Wagner, 1998). The same principle may be applied to early traumatic experiences during critical periods that may permanently impact on the development of brain regions implicated in the regulation of emotion and stress responses. Such enduring programming effects of ELS on the brain and its regulatory outflow systems, i.e., the autonomic, endocrine and immune systems, may then lead to the development of a vulnerable phenotype with increased sensitivity to

CH, NJ, and JO are funded by the NeuroCure Excellence Cluster and German Ministry of Science and Education. We thank Juliane Wissmann and Andrea Katzenbach for their contributions.

subsequent stress and risk for a range of psychiatric and somatic disorders (Heim, Plotsky, & Nemeroff, 2004). Indeed, a rapidly accumulating body of research suggests that there are pronounced alterations in stress physiology and the immune system as well as brain anatomy and function in regions relevant to emotional processing and stress regulation that occur as a function of ELS in humans. In addition, there is increasing insight into gene–environment interactions predicting the pathologic outcomes after ELS at the symptomatic and biological levels as well as changes in the molecular or epigenetic regulation of gene activity that mediate some of the outcomes of ELS in humans (Heim & Binder, 2012).

The present chapter aims to provide an overview of the contribution of ELS to the development of psychopathology and medical disease throughout the life span. We will first discuss the definition and prevalence of ELS as well as the association of ELS with psychopathology and medical disorders in adulthood. We will then provide an overview of the neurobiology of stress by describing the major regulatory outflow systems of the brain: the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic-adrenomedullary system (SAM), central nervous system (CNS) stress mediators, and brain structures and neurocircuits implicated in the regulation of stress responses and emotion. We will further discuss interactions between the neuroendocrine stress response system and the immune system. Based on this overview, we will then discuss the impact of ELS on stress neurobiology and the relationship of these biological effects of ELS to the development of psychopathology and medical disease. Given that some individuals remain resilient despite significant exposure to ELS, whereas others develop disorders, we next focus on factors that mediate the emergence of interindividual differences in the effects of ELS. In this context, we will discuss the role of sex differences in the effects of ELS as well as the potential existence of sensitive developmental periods, during which the brain might be particularly vulnerable to the effects of ELS. In addition, the role of genetic disposition in moderating the effects of ELS will be discussed. Finally, we will discuss more recent insights into the molecular mechanisms of gene regulation by stress that may account for the development of altered stress responsiveness and risk for psychiatric and medical disorders after ELS, including epigenetic programming with long-term impact on gene expression. We will conclude this chapter by discussing the implications of insights from neurobiological research on the long-term consequences of ELS for novel diagnostic and therapeutic approaches that target the mechanisms involved in the persistent effects of ELS, to prevent or reverse the detrimental long-term consequences and thereby reduce the manifestation of negative health outcomes in these victims.

DEFINITION AND PREVALENCE OF EARLY-LIFE STRESS

To define ELS, two main criteria must be considered: the developmental age range that is subsumed under *early life* and the characteristics of the events that would be considered as stressful. There is no such generally agreed upon definition of ELS in humans. Many investigators use an upper age limit to define the early-life criterion, usually between 12 and 18 years. More appropriate approaches refer to the developmental stage by using the onset of sexual maturation (i.e., menarche in females, to more precisely define the early-life period). As for the stress criterion, prevailing models suggest that stress is generally experienced when an individual is confronted with a situation, which is appraised as personally threatening and for which adequate coping resources are unavailable. In addition, threats to physiological homeostasis, such as injury or illness, elicit stress responses. Any such situation occurring within the defined developmental period may be classified as ELS in humans.

The most salient forms of ELS include different forms of maltreatment or deficient caregiving, such as physical, sexual or emotional abuse as well as emotional or physical neglect, as well as exposure to domestic violence. In the following, we provide definitions of each form of maltreatment:

- *Physical abuse* is defined as the intentional use of physical force against a child causing impairment to the child's health and development, which can even cause infanticide. Violent actions like hitting, beating, kicking, shaking, biting, strangling, scalding, burning, poisoning, and suffocating can be subsumed under physical abuse (Martins, Baes, & Juruena, 2011). A particular form of physical maltreatment is the so-called shaken baby syndrome, mainly occurring in infants younger than 1 year. This vigorous manual shaking of the baby is a leading cause of death and disability in childhood (Vitale, Vicedomini, Vega, Greco, & Messi, 2012).
- *Sexual abuse* of a child can be defined as engaging a child in sexual activities that the child is not able to comprehend or to consent to. It includes fondling, rape, and exposing a child to other sexual acts that the child is not mentally prepared for or that violate the

laws of collective taboos of society. Often, perpetrators are known to the child, and sexual offenses are committed by a parent, caregiver, or another person in a custodial role.

- *Emotional or psychological abuse* refers to a failure of a parent or caregiver to provide a developmentally appropriate and supportive environment for the child. Abuse of this type includes behaviors that harm a child's self-esteem, mental health, dignity or safety by restriction of movement or hostile treatment, shaming, blaming, rejecting, threatening, discriminating or withholding love (Martins et al., 2011).
- *Emotional or physical neglect* refers to the failure to meet a child's basic needs in one or more areas, including health and access to medical care, education, emotional development, nutrition, shelter, and safe living conditions. It can occur as isolated incidents or in terms of enduring patterns (Martins et al., 2011).
- *Exposure to domestic or intimate partner violence* of caregivers can also be considered as a form of ELS, because the child experiences stress from witnessing violent actions or by getting directly involved in conflicts, for example by the attempt to intervene. Observing consequences of intimate partner violence such as noticing bruises or sadness and despair of one of the parents can be a further psychological burden (Simmel & Shpiegel, 2013).

Other forms of ELS include accidents, physical illness, surgeries, natural disasters and war or terrorism-related events. Less obvious experiences, that pose significant distress on a child, include unstable families, inadequate parental care due to mental or physical illness, and poverty. Another form of ELS that often goes unidentified is factitious disorder by proxy, a complex condition in which a parent or caretaker induces or invents illness in a child combined with unnecessary, often invasive medical treatments (Berg & Jones, 1999; Shaw, Dayal, Hartman, & DeMaso, 2008). It should be noted that ELS is often complex, inasmuch as various forms of ELS coexist or are associated among each other. While ELS may be a single event, in most cases it occurs as chronic or ongoing adversity in most cases. Unfortunately, lack of identification of maltreatment cases contributes to the fact that these children often live under chronic adversity. Enhanced recognition of child maltreatment cases will be a critical step in reducing the long-term outcomes and devising early interventions.

Early-life stress can only be a significant risk factor with public health relevance, if it occurs frequently enough in the population to explain the relatively high prevalence of disorders associated with ELS, such as depression. However, precise prevalence estimates of ELS are difficult to obtain. Data obtained from child protection agencies are underestimating the prevalence of child maltreatment, as many cases are never reported. Data obtained from retrospective studies in adults are based on retrospective case reports with questionable validity. Indeed, statistics of maltreatment cases tend to underestimate the prevalence (Gilbert, Kemp, et al., 2009). Nevertheless, the prevalence of ELS in these studies is exceedingly high and child maltreatment constitutes a major public health and social-welfare problem.

The National Child Abuse and Neglect Data System (NCANDS, 2009) of the U.S. Children's Bureau provides data on the prevalence of reported and identified cases of child maltreatment. These numbers are derived from data collected by child protective services from 52 states in the United States. Each state frames its own definitions of child abuse and neglect, whereas most states apply the four major types of maltreatment: neglect and physical, emotional, and sexual abuse. In 2011, approximately 3.4 million referrals were received by the child protective services. These referrals were estimated to include 6.2 million children. Of these referrals, 60.8% of the allegations were screened in and received an investigation or assessment for abuse and neglect. More than 3.7 million children were subject to at least one report. 681,000 unique victims were counted in the year 2011. The number of victims slightly decreased compared with the previous years, but it can be assumed that this number only represents the tip of the iceberg, while most cases go unreported. Among reported cases, more than 75% are victims of neglect, 17.6% experienced physical abuse, and nearly 10% suffered sexual abuse. Important to note is the fact that the youngest age group (birth to 1 year) had the highest rate of victimization. One explanation could be that these cases are more often detected and reported. Nearly 1,600 children died as a result of abuse or neglect in 2011 in the United States. Among these children, 81.6% were younger than 4 years of age. Also, as reports show, about 80% of maltreatment cases were committed by parents or caregivers. Furthermore, the majority of the infanticides (78.3%) were caused by one or more parents. With regard to sexual abuse, statistics indicate that in most cases perpetrators are relatives or other persons in the child's immediate environment (Gilbert, Kemp, et al., 2009).

Girls seem to be more often exposed to sexual abuse (Gilbert, Kemp, et al., 2009). Of note, children with other developmental disorders, disabilities or complex medical

problems are also at greater risk to become victims of violence in comparison with healthy children at the same age. A record-linkage study from the United States showed a cumulative prevalence of maltreatment of 9% for nondisabled children and 31% for disabled children. The overall prevalence of any recorded disability was 8%, whereas a quarter of all identified maltreated children had a disability (Jones et al., 2012).

As an alternative methodological approach to estimate the prevalence of ELS, retrospective studies have been conducted to assess the frequency of different forms of maltreatment in the population. For example, Briere and Elliott (2003) presented results from a survey in a community sample: among female respondents, 32% reported experiences of sexual abuse before the age of 18, whereas 14.2% of the male participants were victims of sexual abuse. Approximately 20% (22.2% of men, 19.5% of women) of the total sample experienced physical abuse. More than one third (37%) of the respondents were victims of either type of abuse, 21% experienced both forms of abuse. In a study by Gould et al. (1994), similar numbers have been reported: 44% experienced any type of sexual, physical or emotional abuse, 22% reported multiple types of early maltreatment. Retrospective studies confirm that girls are 2.5 to 3 times at higher risk to experience sexual abuse compared with boys (Fergusson, Horwood, & Lynskey, 1996; Finkelhor, 1993; Sobsey, Randall, & Parrila, 1997). Data from the National Comorbidity Study suggests that nearly 16% of women experience childhood sexual abuse (Molnar, Buka, & Kessler, 2001). The Adverse Childhood Experiences study, a large population-based study conducted by the U.S. Centers for Disease Control and Prevention (CDC) in a sample of more than 17,000 members of an health maintainance organization (HMO) in the San Diego area, reported prevalence rates of 21.6% of sexual abuse, 20.6% of physical abuse, and 14% of witnessing domestic violence; 34.6% of these cases reported exposure to multiple types of ELS (Edwards, Holden, Felitti, & Anda, 2003). Inconsistencies in prevalence rates across studies may reflect differences in the definition or assessment of ELS. A point of criticism with regard to these studies is the retrospective and noncorroborated assessment of childhood maltreatment. Problems concerning the credibility of self-reports of childhood trauma include simple forgetting, nonawareness, nondisclosure, and reporting biases due to mood states. Moreover, declarative biographical memory before the age of 5 years is sparse because the hippocampus is not fully developed. ELS itself leads to hippocampal damage, a brain structure relevant to declarative memory, which might impair recall of childhood experiences. However, a meta-analysis of studies using external corroboration of self-reports revealed that false-negative reports are more frequent than false-positive ones, leading to downward biases in estimated associations between ELS and outcome variables (Hardt & Rutter, 2004).

Taken together, it can be concluded that both the definition of ELS is complex and the estimation of its prevalence is hampered by methodological difficulties. Nevertheless, it can be stated that ELS, in its many forms, clearly is common enough in our society to represent a significant risk factor for the development of diseases later in life, such as depression and other disorders.

RELATIONSHIP BETWEEN EARLY-LIFE STRESS AND RISK FOR PSYCHIATRIC AND MEDICAL DISORDERS

An enormous body of literature from epidemiological, clinical, and twin studies provides strong evidence that ELS is one of the most potent risk factors that predisposes individuals to develop a wide range of psychiatric disorders and classical medical diseases throughout the life span. Given the high prevalence of ELS and the large effect sizes in the prediction of psychiatric and medical disorders, ELS is one of the most significant public health problems in our society. Of note, the association of ELS with disease risk seems to be nonspecific: for example, different types of ELS increase the risk for major depression (e.g., Maniglio, 2013), and conversely, similar types of ELS increase the risk for a wide variety of different disorders. It should be further noted that ELS-related disorders often occur in comorbidity with each other and manifest or aggravate in response to additional stresses (see, e.g., Martins et al., 2011), suggesting that ELS induces a core dysfunction, likely located in stress-regulatory systems, that is common across disorders related to ELS. In the following, we will selectively describe some of the seminal studies that confirm ELS as a major risk factor for psychiatric or medical disorders.

The aforementioned Adverse Childhood Experiences studies conducted by the CDC have provided particular strong data on the link between ELS and a range of adverse health outcomes in a large sample representative of the population. The aforementioned study by Edwards et al. (2003) not only suggested high prevalence rates of different types of ELS, but also showed that there was a clear dose–response relationship between degree of exposure and mental health problems in adulthood. A generally unstable family environment further

accentuated this relationship (Felitti et al., 1998). In terms of specific disorders, results from the same population suggest a 4-fold increase in the risk of depression as well as a dose–response relationship between the number of exposures to different types of ELS and the presence of a major depressive episode in the past year or lifetime chronic depression (Chapman et al., 2004). The experience of any ELS increased the risk of attempted suicide in childhood, adolescence or adulthood 2- to 5-fold; in persons who experienced 7 or more types of ELS, risk for attempting suicide was 31-fold increased (Dube et al., 2001). These CDC studies are in line with other epidemiological studies. For example, McCauley and colleagues (1997) recruited more than 1900 women from internal medicine practices and found that childhood sexual or physical abuse was associated with increases in symptoms of depression, anxiety, addiction, and suicide attempts. Findings of the National Comorbidity Survey (Molnar et al., 2001), the Ontario Health Survey (MacMillan et al., 2001), and a New Zealand community survey (Mullen, Martin, Anderson, Romans, & Herbison, 1996) have provided concordant findings. A role of ELS in the development of major depression, beyond genetic factors, has been confirmed in twin studies (Kendler et al., 2000; Nelson et al., 2002). In addition to maltreatment, parental loss due to death or separation is also associated with increased risk for depressive disorders (Agid et al., 1999). An adverse family environment characterized by poor paternal relationships or maternal overprotection is also associated with increased risk for depression (Lizardi et al., 1995). These selected studies illustrate the general association between various forms of ELS and later depression. In addition, a recent meta-analysis of 16 epidemiological studies suggests that ELS is also associated with a less favorable course in individuals suffering from major depression, as characterized by more recurrent and more chronic depressive episodes as well as a higher likelihood of treatment resistance (Nanni, Uher, & Danese, 2012).

While depression is probably the most extensively studied outcome of ELS, ELS is also associated with the development of various anxiety disorders in adulthood, including social anxiety disorder, generalized anxiety disorder, and posttraumatic stress disorder (PTSD) (Chou, 2012). Depression and anxiety disorders in particular often coincide in individuals with ELS. The relationship between ELS and PTSD is more complex and can be direct or indirect. In the case of a direct relationship, the ELS experience itself represents the index trauma, to which the PTSD symptoms are related. PTSD related to ELS can then persist into adulthood and may be elicited or aggravated by other events (Pine & Cohen, 2002). Indirect relationships between ELS and PTSD occur in at least two ways: (1) ELS increases the risk of later trauma exposure that may, in turn, elicit PTSD (Sassetti, 1993); and (2) ELS increases the risk for the development of PTSD in response to traumas occurring in adulthood, such as combat (Bremner, Southwick, Johnson, Yehuda, & Charney, 1993).

Other psychiatric disorders that have been consistently linked to ELS include alcohol and substance abuse and dependence in adolescence and adulthood (Gilbert, Widom, Browne, Fergusson, Webb, & Janson, 2009), self-injurious behavior (Klonsky & Moyer, 2008; Yates, Carlson, & Egeland, 2008), eating disorders (Chou, 2012), bipolar disorder (Watson et al., 2013), and psychosis (Dvir, Denietolis, & Frazier, 2013). Personality disorders including borderline personality disorder are also more common after ELS (Ball & Links, 2009). Generally increased risk for psychiatric morbidity after ELS is further reflected in reports suggesting an increased frequency of psychiatric hospital admissions in individuals with ELS exposure (Chou, 2012; McCauley et al., 1997). It can be concluded that ELS is a potent developmental risk factor for psychiatric mental health problems that spans across nosological disease categories and reflects a core dysfunction that is common to these disorders.

Many medical health problems are also part of a spectrum of disorders linked to ELS. These include functional somatic disorders, such as chronic fatigue syndrome (Heim et al., 2006), fibromyalgia and other chronic pain syndromes (Imbierowicz & Egle, 2003), as well as functional gastrointestinal disorders (e.g., Goodwin & Stein, 2004). In addition, ELS promotes many of the illnesses that are leading causes of death in our society. These include ischemic heart disease (Dong et al., 2004), stroke (Felitti et al., 1998), metabolic syndrome and diabetes (Danese & McEwen, 2012), and lung disease (Felitti et al., 1998). In addition, ELS promotes autoimmune disorders, inflammation, and the progression of cancer (Danese & McEwen, 2012; Fagundes et al., 2012). The effect sizes are relatively large. For example, the risk for developing ischemic heart disease is increased by 360% after exposure to multiple types of ELS (Dong et al., 2004). Of note, depression in part mediates the association between ELS and heart disease and other medical diseases. In line with the notion that ELS is a significant risk factor for many illnesses that are the leading causes of death in our society, the Adverse Childhood Experiences Study of the CDC found that adults who reported 6 or more types of ELS experiences

died nearly 20 years earlier on average than those who did not report ELS, showing a detrimental impact of ELS on life expectancy (Brown et al., 2009).

The association between ELS and medical disease risk in adulthood is also in part mediated by a higher prevalence of health risk behaviors in individuals with ELS. These include smoking, inactivity, obesity, and promiscuity, resulting in higher prevalence of sexually transmitted disease (Felitti et al., 1998). In addition to these disorders and health risk behaviors, ELS further interferes with educational achievement and cognitive development, as evidenced in lower academic outcomes, poorer school performance, and more special educational needs (Shonkoff et al., 2012).

In sum, ELS is a major nonspecific risk factor for an array of psychiatric and medical disorders and health risk behaviors. These disorders often coincide and seem to share a common core dysfunction that may be programmed by experience early in life. This core dysfunction is likely located at the level of neurobiological systems mediating stress and emotion regulation. Upon further challenge (physical or emotional), the system may fail to adapt or compensate, leading to maladaptive responses in several physiological regulatory systems and behavior, which underlie the symptoms that reflect the clinical phenotypes of these disorders. This risk is then transmitted into the next generation, as children of mothers with ELS have increased rates of mental health problems (Beardslee, Gladstone, & O'Connor, 2011). A precise understanding of the psychobiological mechanisms that link ELS with this negative developmental trajectory is critical to identify modifiable targets for prevention and intervention.

NEUROBIOLOGICAL EFFECTS OF EARLY-LIFE STRESS

The enduring effects of ELS on disease risk is likely mediated by programming effects on stress neurobiological systems during periods of heightened plasticity throughout early development. Such developmental programming may lead to persistent changes in the set-point of stress response systems and the ability of the brain and organism to adapt or compensate in response to additional challenge, which ultimately might set the stage for the development of stress-related disorders. In the following, we provide an introduction to the neurobiology of stress, followed by a discussion on how ELS impacts on these systems in animal models and human studies.

Neurobiology of Stress

Two main outflow systems of the brain regulate the adaptation of the mammalian organism to stress, i.e., the sympathetic adrenomedullary system (SAM) as a component of the autonomic nervous system and the hypothalamic-pituitary-adrenal (HPA) axis. Both of these regulatory outflow systems are activated in response to stress, as a result of coordinated input from a neural network of brain regions implicated in the mediation and regulation of stress and emotion. We first describe the regulatory outflow systems, followed by a discussion of brain regions implicated in their control. We conclude this section with a discussion of neuroendocrine-immune interactions.

Sympathetic Adrenomedullary System

As early as in 1932, Walter Cannon suggested in his pioneering work that acute responses to threat involve the release of catecholamines and activation of the sympathetic nervous system, which serves to redistribute blood into muscles and to provide energy to the organism, while shutting down functions that are not instrumental for survival in this situation of threat, such as feeding, reproduction or sleep. This adaptive fight-or-flight response is evolutionary adaptive and serves to increase the likelihood of survival.

Anatomically, the cell bodies of the SAM are located in the interomediolateral cell column of the spinal cord. These sympathetic preganglionic neurons send axons from the spinal cord via the ventral route and form cholinergic direct synapses on the chromaffin cells of the medulla of the adrenal glands. When these chromaffin cells are stimulated, they release catecholamines in different proportions. Whereas stimulated chromaffin cells mainly secrete the hormone epinephrine (80%), smaller amounts of the hormone norepinephrine (20%) are released from the adrenomedullary neurons (Gunnar & Quevedo, 2007). Increases in epinephrine and norepinephrine ensure a rapid mobilization of metabolic resources and, hereby, enable the fight-or-flight response. More specifically, catecholamines, once secreted into the blood circulation, act on organs and tissues by binding to adrenergic receptors. As a consequence, for example, heart rate and pulmonary function are increased, blood vessels are constricted, and stomach, and upper intestinal actions are inhibited to slow down digestion. Further, glycogenolysis in the liver is stimulated leading to increases of glucose levels, which provide the energy for defensive responses. Even though the catecholamines epinephrine and norepinephrine do not

cross the blood–brain barrier, effects of these hormones are paralleled in the brain by norepinephrine production in the locus coeruleus. During stress, norepinephrine supports vigilance, arousal, and attention. Furthermore, norepinephrine in the CNS participates in the activation of the HPA axis (Gunnar & Quevedo, 2007).

Hypothalamic-Pituitary-Adrenal Axis

In addition to the fast-reacting SAM, the slower actions of the HPA axis are initiated as a consequence of internal or external stress experiences. This activation is mediated via ascending brain stem pathways that project to the parvocellular divisions of the paraventricular nucleus (PVN) of the hypothalamus. For example, the nucleus of the solitary tract (NTS) as well as C1-C3 regions project to the PVN via catecholaminergic connections. In addition, the PVN also receives input from the midbrain through serotonergic projections of the median raphé nuclei. The hippocampus and prefrontal cortex exert inhibitory influences on the hypothalamic PVN, via indirect connections (Ulrich-Lai & Herman, 2009). Upon stress, the secretion of corticotropin releasing hormone (CRH; also referred to as corticotropin-releasing factor [CRF]) and arginine vasopressin (AVP) is stimulated as a net result of these inputs from cells of the PVN. The axons of these neurons terminate in the median eminence onto small blood vessels, which is the site of neuroendocrine transmission, where a neuronal signal is translated into a hormone signal in blood. CRH and AVP are released into the portal circulation of the pituitary gland and reach the anterior pituitary corticotrophic cells, where they induce the secretion of adrenocorticotropic hormone (ACTH). ACTH stimulates the synthesis and release of glucocorticoids (corticosteroids in rats, cortisol in humans) from the adrenal gland into the blood circulation.

The release of glucocorticoids in response to stress serves to optimally adapt the organism to the change in demand, to ensure survival. Glucocorticoids exert important effects on the metabolism, by increasing blood sugar through gluconeogenesis and by breaking down proteins. With these actions, glucocorticoids make energy resources available to the organism. Glucocorticoids further have immune-regulating effects during stress. Importantly, glucocorticoids mediate negative feedback effects on their own release by binding to specific receptors at multiple levels of HPA axis control, including the hippocampus. Glucocorticoids also exert inhibitory feedback on locus coeruleus noradrenergic neurons, and hence serve as a stress brake into the brain to control endocrine, autonomic, and behavioral responses to stress.

The effects of glucocorticoids are dependent on specific receptors located in the cytoplasm of cells throughout body and brain. Upon activation, the hormone-receptor complex develops affinity for the nucleus, which induces translocation to the nucleus of the cell. In the nucleus, the activated glucocorticoid receptor (GR) binds to glucocorticoid response elements to regulate gene expression of various target genes. Because glucocorticoids act via the transcription of genes in the nuclei of cells, the effects of these hormones are slower and longer lasting than the fast actions of the SAM (e.g., Scheinman, Cogswell, Lofquist, & Baldwin, 1995). Essentially, there are two types of receptors to which glucocorticoids can bind, that is, the mineralocorticoid receptor (MR) and the GR (De Kloet, 1991). In the brain, glucocorticoids bind to both receptor types, whereas outside the brain, glucocorticoids solely act via GR. Important with regard to the regulation of the stress response is the fact that glucocorticoids have a higher affinity to bind to MR. Therefore, under nonstress conditions, when glucocorticoid levels are normal, mainly MR are activated, which serves to regulate basal functions such as maintaining the HPA axis circadian rhythm and maintaining homeostatic blood pressure. Upon acute stress, when glucocorticoids levels increase, GRs become involved to regulate the stress responses. As noted already, the activity of the HPA axis is subject to negative feedback mechanisms that are mediated via glucocorticoids. Here, limbic forebrain structures are critically involved in the inhibition of the HPA axis via GR and MR that are expressed in these sites. For example, the hippocampus is rich in both receptor types. The medial prefrontal cortex also expresses high levels GR; however, less expression of MRs can be observed, indicating the mPFC being less responsive to lower levels of glucocorticoids. Experiments in rodents show that deletion of the GR in the cortex, hippocampus, and the basolateral amygdala is associated with increased levels of basal glucocorticoids as well as persistent glucocorticoid responses to psychogenic stressors. In addition, these animals do not exert negative feedback inhibition of the HPA axis as a consequence of exogenous glucocorticoids (Boyle et al., 2005). In addition to these findings, the overexpression of GR in the forebrain has been linked to reduced HPA axis activity, supporting the assumption of the forebrain's role in the attenuation of the stress response (Wei et al., 2007; Wei et al., 2004).

It is important to note that the release of glucocorticoids during stress is highly adaptive and necessary for survival. However, under conditions of severe or chronic stress, overexposure of the brain to glucocorticoids can become toxic to neurons, leading to damage particularly in the

hippocampus, but also in the prefrontal cortex. Effects of heightened levels of glucocorticoids in the hippocampus include reduced excitability of cells, dendritic atrophy, and neuronal death particularly in the CA3 region, and decreased neurogenesis in the dentate gyrus (Lupien, McEwen, Gunnar, & Heim, 2009). These effects can lead to perpetuation where increasing damage to the hippocampus leads to further disinhibition of glucocorticoid release with further damaging effects to the brain, which may ultimately underlie the development of symptoms such as depression. Conversely, insufficient release of glucocorticoids may also have adverse effects due to lack of regulatory effects of the hormone on controlling central stress responses as well as immune activation in response to stress (Heim, Ehlert, & Hellhammer, 2000). Lack of glucocorticoid effects on the brain may also be observed if receptors for glucocorticoids become resistant in target cells (Raison & Miller, 2003). Hence, an optimal balance of glucocorticoid release during stress and a functional GR are essential for healthy adaptation to stress.

Corticocotropin-Releasing Hormone System: Integrator of Stress Responses

Corticotropin-releasing hormone neurons integrate information relevant to stress not only at the hypothalamic PVN, which forms the central component of the HPA axis, but also act in a widespread circuitry throughout the brain, including the neocortex, limbic regions, and brain stem. The 41-amino acid peptide is generally accepted to be the main CNS coordinator of the mammalian stress response, including behavioral, autonomic, immune, and endocrine components (Heim & Nemeroff, 2001). Injection of CRH directly into the brain of laboratory animals produces an integrated endocrine, autonomic, and behavioral response that closely parallels signs and symptoms of stress, depression, and anxiety. The behavioral effects of CRH include disruption of slow wave sleep, reduced reproductive behavior, reduced appetite, altered locomotor activity, increased startle response and facilitated fear conditioning as well as a behavioral despair syndrome in nonhuman primates. These global effects of CRH in integrating stress responses are possible due to the strategic localization of CRH neurons and their receptors in circuits linking the amygdala and the hypothalamus with brain stem nuclei.

There are two well-known CRH receptors, CRH-R1 and CRH-R2, distributed in the CNS. CRH-R1 deficient mice show a reduced hormonal stress response and blunted anxiety-like behaviors (Smith et al., 1998; Timpl et al., 1998). CRH-R2 deficient mice show exaggerated anxiety behaviors and are hypersensitive to stress (Bale et al., 2000; Coste et al., 2000). This would suggest that CRH-R1 is the primary CRH receptor mediating the stress response and CRH-R2 may help in modulating this response (Bale et al., 2002).

Microinjection studies in animals have shown that the behavioral effects of CRH are localized in an extrahypothalamic circuit, connecting the amygdala and hypothalamic PVN with the locus coeruleus in the brain stem. CRH and norepinephrine form a feedforward cascade in this circuit that integrates behavioral responses with endocrine and autonomic activation during stress. As noted before, glucocorticoids exert negative feedback effects on this circuit. Further inhibitory influences are exerted by gamma-amino-butyric-acid (GABA)-ergic neurons as well as oxytocin and neuropeptide Y (Arborelius, Owens, Plotsky, & Nemeroff, 1999; Heinrichs, Lapsansky, Lovenberg, De Souza, & Chalmers, 1997). Taken together, central nervous system (CNS) CRH neurons play a cardinal role as the main integrator of the behavioral, endocrine, and autonomic stress responses (Figure 21.1). Overproduction of CRH in these circuits, as a potential consequence of ELS, may conceivably produce sensitization to stress and vulnerability to depression and anxiety disorders.

Stress-Buffering Effects of Oxytocin

Early-life stress might also impact on neurobiological systems that are involved in buffering stress responses. Of particular relevance in this context is the neuropeptide oxytocin. Oxytocin is produced in magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus. It is transmitted to the posterior pituitary, from where it is released into circulation. Oxytocin is mostly recognized for its role as a peripheral hormone regulating parturition and lactation. However, oxytocin is additionally represented throughout the CNS where it affects a variety of neurobehavioral functions. In the brain, oxytocin serves as a neuropeptide transmitter with a critical role in mediating social cognition and prosocial behaviors. For instance, oxytocin has been demonstrated to promote pair bonding and maternal care behavior, mother–child bonding, trust, and the use of social support. In addition, oxytocin exerts anxiolytic effects, as it dampens amygdala reactivity, and exerts inhibitory effects on HPA axis responses to stress (e.g., Heinrichs, 2000; Heinrichs, Baumgartner, Kirschbaum, & Ehlert, 2003). Because ELS oftentimes represents an adverse early social learning experience in the child's primary caretaker relationship, it may be hypothesized that ELS disrupts the optimal development of the brain's oxytocin system, which may then contribute to heightened stress reactivity

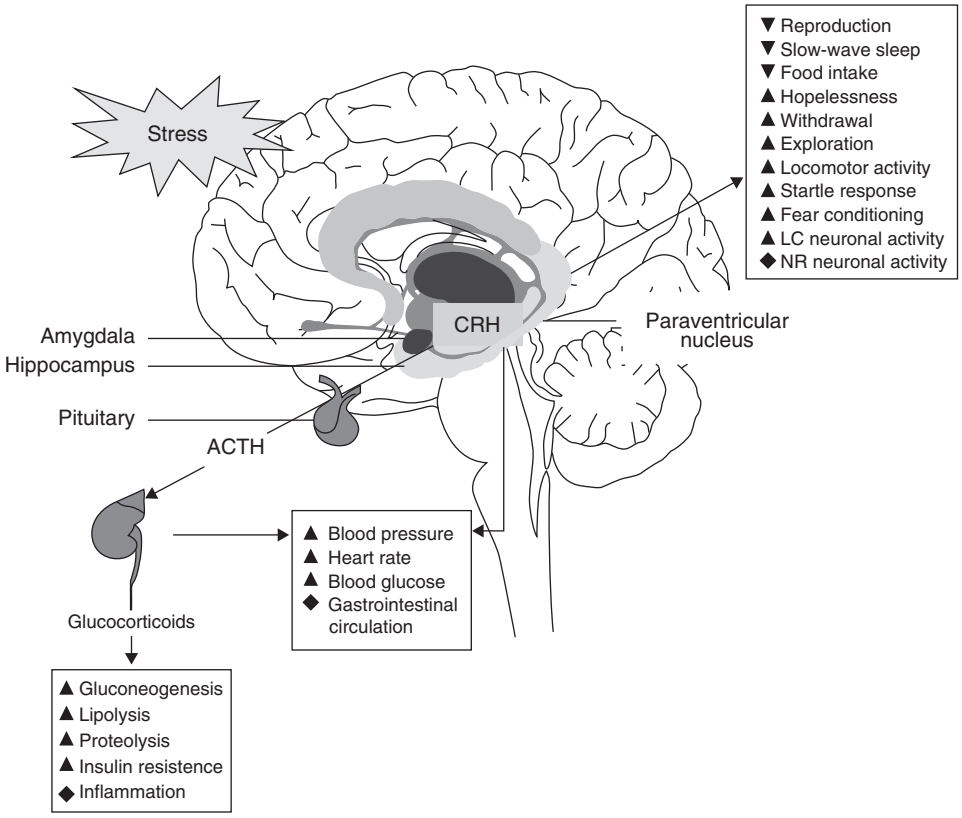

Figure 21.1 Central nervous system (CNS) corticotropin-releasing hormone (CRH) system and its effects in integrating endocrine, autonomic and behavioral responses to stress. Central effects of corticotropin releasing hormone. Symbols: ▲ = increase; ▼ = decrease; ◆ = bidirectional alterations. Abbreviations: ACTH = adrenocorticotropic hormone; CRH = corticotropin releasing hormone; LC = locus coeruleus; NR = nucleus raphé; PVN = paraventricular nucleus. *Source:* Adapted from L. Arborelius, M. J. Owens, P. M. Plotsky, & C. B. Nemeroff, The role of corticotropin-releasing factor in depression and anxiety disorders, *Journal of Endocrinology, 160*(1), p. 3, 1999.

as well as vulnerability for anxiety and depression. Deficits in oxytocin function may then also contribute to the transmission of ELS across generations, as oxytocin is critical for maternal behavior.

Brain Circuits Implicated in the Stress Responses

While systemic stressors and threats to homeostatic balance can readily induce a stress response at the hypothalamic and brain stem level, the response to psychological or emotional stressors requires appraisal and processing activities that involve higher brain regions. The activation of the HPA axis and a sympathetic stress response is the result of the interaction of a number of brain regions that exert influences on the regulatory outflow system.

As has been mentioned previously, brain stem nuclei as well as parts of the spinal cord are involved in the activation of the SAM and the HPA axis via several pathways. In addition to these ascending projections, several top-down processes are involved in tuning the stress response. Limbic forebrain structures, specifically the amygdala, the hippocampus, and the prefrontal cortex are involved in the processing of psychogenic stress. These limbic regions receive input from structures that are involved in higher order sensory processes (subcortical and cortical areas), memory (medial septum, entorhinal cortex, insular cortex), attention, and arousal (e.g., locus coeruleus, raphé nucleus). In turn, limbic structures project to subcortical relay sites and affect the HPA axis response (Ulrich-Lai & Herman, 2009).

Of special interest with regard to the modulation of the stress response is the central nucleus of the amygdala, which is critically involved in autonomic regulation and fear responses. In contrast to homeostatic perturbations and systemic stressors, the central nucleus of the amygdala is not directly activated by psychogenic stressors. However, studies indicate that lesions of the central nucleus of the amygdala impair bradycardic responses during psychosocial stress (Roozendaal, Koolhaas, & Bohus, 1990, 1991). On the other hand, the medial and basolateral amygdala are mainly activated in response to psychosocial stressors

and were shown to reduce HPA axis activation in the case of damage (Bhatnagar, Vining, & Denski, 2004; Dayas, Buller, & Day, 1999).

In addition to the amygdala, the hippocampus has been shown to be involved in the modulation of the HPA axis. Specifically, activation of the hippocampus is associated with a decreased glucocorticoid secretion in rodents as well as in humans (Dunn & Orr, 1984; Rubin, Mandell, & Crandall, 1966). Hippocampal lesions lead to increases in the release of glucocorticoids (Jacobson & Sapolsky, 1991), whereby effects of hippocampal damage appear to be especially prominent in the termination of the HPA axis response to stress. In addition, the hippocampus seems to affect autonomous responses indirectly via the medial prefrontal cortex as it does not directly connect to the brainstem. The stress response is further modulated by the medial prefrontal cortex, which has been linked to the inhibition of autonomous (Akana, Chu, Soriano, & Dallman, 2001) and HPA axis activity, again mainly affecting the termination of the HPA axis response (e.g., Radley, Arias, & Sawchenko, 2006). Overall, the PFC is assumed to constitute the top of the hierarchical stress response in terms of a limbic coordination of the stress response.

Intermediate connections transmit information from the medial prefrontal cortex, the amygdala, and the hippocampus to the PVN and the medulla. Here, excitatory (amygdala) as well as inhibitory (hippocampus) limbic information is integrated. In addition, the brain stem and the PVN receive ongoing homeostatic feedback, which in turn is translated into appropriate HPA axis and SAM activation.

As noted already, CRH, norepinephrine, serotonin, GABA, oxytocin and other transmitters interact in these neural circuits. Stimulatory influences are mediated by CRH and norepinephrine on the stress responses, whereas inhibitory influences are mediated by GABA-ergic neurons and oxytocin. Serotonin exerts modulatory effects on stress responses. Glucocorticoids exert regulatory effects on these brain regions, given that there is a broad distribution of GR in these regions. Neurostructural and functional changes in these brain regions after ELS, as a consequence of experience-dependent developmental programming or glucocorticoid overexposure, may contribute to the manifestation of stress vulnerability and certain mental disorders.

Stress and the Immune System

In addition to the HPA axis and the SAM, the immune system is another regulatory system that is activated in response to stress. Indeed, there are complex interactions between these regulatory systems. Immune activation stemming from the periphery can induce stress responses in the brain, leading to signs and symptoms of stress and depression. Conversely, psychosocial stress alone can activate inflammatory responses in the organism. Hence, the relationship between the brain and the immune system is bidirectional (Raison, Capuron, & Miller, 2006; Raison & Miller, 2003).

Typically, the innate immune system is activated by a peripheral injury or infection, leading to activation of nuclear factor kappa B (NFκB) through Toll-like receptors, which then leads to an inflammatory response with release of proinflammatory cytokines, such as tumor necrosis factor (TNF)-α and interleukins 1 (IL-1) and 6 (IL-6). Of note, these cytokines can access the brain. Because these are large molecules, it has been discussed that access to the brain is possible through leaky regions in the blood–brain barrier, active transport molecules, or afferent nerve fibers. In the brain, cytokines impact on circuits implicated in stress responses and depression, including the monoaminergic neurotransmitters as well as the CNS CRH system. For example, administration of proinflammatory cytokines stimulates the HPA axis. In addition, proinflammatory cytokines have potent effects on synaptic plasticity through effects on growth factors, such as brain-derived neurotrophic factor (BDNF). Through such pathways, it can be explained that some individuals who suffer from infections develop a so-called sickness behavior that parallels depressive syndromes.

Conversely, exposure to psychosocial stressors can promote activation of inflammatory signaling via top-down influences. It has been suggested that sympathetic nervous system responses via release of norepinephrine stimulates the induction of NFκB, which then translates the stress signal into an inflammatory response. In addition, stressors also interfere with inhibitory motor vagal input. Accordingly, increases in proinflammatory cytokines have been observed in the periphery and in key brain sites implicated in stress regulation as a consequence of psychosocial stress in animal models (Madrigal et al., 2002; O'Connor et al., 2003). Studies in humans support these findings, as both, acute and chronic stress have been linked to increased concentrations of proinflammatory cytokines (e.g., Maes et al., 1999; Song et al., 1999). Increases in NFκB and inflammatory cytokines have been confirmed in humans in response to psychosocial laboratory stress (Bierhaus et al., 2003).

It is well known that glucocorticoids have suppressive effects on innate immunity. These suppressive effects are mediated by GR in immune cells. High levels of

inflammation in depression or stress-related states may be explained by the fact that the GR can become resistant. Of note, immune activation itself can contribute to the development of GR resistance through activation of protein kinase pathways, which would then lead to lack of inhibitory control of NFκB release by glucocorticoids during stress (Miller & Raison, 2006). It has been suggested that increased pro-inflammatory activity as a consequence of stress has an adaptive function as it allows a fast control of injuries and infections during periods of stress. However, increased innate immune activity as a consequence of stress might come at the prize of decreases in cellular and humoral acquired immune functions (Raison & Miller, 2003).

Given these complex interactions between stress pathways and the immune system, it can be assumed that ELS may also exert effects in immune function, which may contribute to elevated risk for certain immune-related disorders after ELS in humans.

Taken together, this section aimed to provide an overview of neurobiological systems that might be modified by ELS. In the following sections, we focus on the effects of ELS on these systems in animal models and human studies.

Summary of the Effects of Early-Life Stress on Neurobiological Systems in Animal Models

Numerous rodent and nonhuman primate studies have revealed a number of persistent neurobiological consequences of ELS (e.g., reviewed in Francis, Caldji, Champagne, Plotsky, & Meaney, 1999; Heim & Nemeroff, 2001; Kaufman, Plotsky, Nemeroff, & Charney, 2000; Ladd et al., 2000; Meaney, 2001). We here summarize selected results.

As early as the 1950s and 1960s, the pioneering work of Seymour Levine revealed that manipulation of neonatal rats, such as handling or mild shock, permanently alters behavior as well as corticosteroid responsiveness to later stressors (e.g., Levine, 1967; Levine, Chevalier, & Korchin, 1956). Levine's studies provided evidence that early handling, which involves brief separations (3–15 minutes) of pups from their mothers, improves developmental outcomes. More potent early stressors, such as maternal separation, which involves longer separations (3 or more hours) of pups from their mothers, have adverse effects on development. Maternal separation of rodents early in life is often used as a model of human parental neglect. Maternal separation in rats in the first 2 weeks of life has been found to result in heightened neuroendocrine and autonomic responses to stress as well as depression-like behavior (e.g., decreased preference for sucrose), anxiety (e.g., increased startle), alcohol preference, and cognitive impairment in adulthood. These changes that occur as a function of early maternal separation persist throughout life (Huot, Thrivikraman, Meaney, & Plotsky, 2001; Ladd et al., 2000). Similar changes have been observed in rats that were reared by mothers with naturally occurring low expression of maternal caregiving behavior (Meaney, 2001). In contrast, rats that were reared by mothers expressing high levels of care developed into adult rats with less anxiety and more stress resilience (Meaney, 2001). In fact, levels of maternal care are critical in mediating the positive effects of early handling: it has been shown that dams increase licking and grooming of rats that have been briefly handled (Barnett & Burn, 1967; Francis, Diorio, Liu, & Meaney, 1999).

These peripheral and behavioral changes that occur as a function of early environment occur due to changes in neural circuits that coordinate stress responses and behavior. Thus, maternal separation has been found to impact on several neurotransmitter systems, most notably central CNS CRH circuits. Maternal separation in rats results in increased CRH concentrations and increased CRH mRNA expression in the hypothalamus, locus coeruleus, and the amygdala (Plotsky et al., 2005). Further, maternal separation is associated with upregulation of CRH-R1 receptors in various brain regions and increased noradrenergic activity, which contribute to increased stress responsiveness (Plotsky et al., 2005). It should be noted that increased central CRH activity along with increased anxiety have been observed in a nonhuman primate model, in which infant macaques are exposed to a variable foraging demand condition that produces chronically stressed mothers which display decreased maternal care (Coplan et al., 1996).

Increased stress responsiveness might be mediated through impaired glucocorticoid feedback due to impaired glucocorticoid receptor function. Accordingly, decreased glucocorticoid receptor density and mRNA expression have been reported in the hippocampus and frontal cortex of rats exposed to maternal separation. Seminal studies by Meaney and coworkers have demonstrated the existence of direct epigenetic effects of variations in maternal care on a neuron-specific promoter region of the glucocorticoid receptor gene (Weaver et al., 2004). Specifically, altered cytosine-methylation of this gene has been documented as a function of early maternal care, leading to silencing of the gene and thus glucocorticoid resistance. Such early programming results in life-long effects on stress reactivity.

In addition, reduced neurogenesis has been observed in the hippocampus of maternally deprived rats, which might further contribute to disinhibition of the stress responses (Mirescu, Peters, & Gould, 2004). Other CNS changes reported after early maternal deprivation in rats include a decrease in 5-HT_{1B} receptor expression (Gutman & Nemeroff, 2002), decreased expression of $GABA_A$ receptors (Caldji, Francis, Sharma, Plotsky, & Meaney, 2000), and impaired dopamine transporter (DAT) expression (Meaney, Brake, & Gratton, 2002). Of note, early nurturing experiences also induce persistent changes in CNS oxytocin receptor expression in rats (Francis, Champagne, & Meaney, 2000). Nursery-reared rhesus monkeys exhibit decreased central oxytocin concentrations compared with mother-reared controls (Winslow, Noble, Lyons, Sterk, & Insel, 2003), suggesting that ELS in animals interferes with optimal development of the central oxytocin system.

Taken together, such preclinical studies provide unequivocal causal evidence that ELS induces a phenotype with multiple structural, functional, and epigenetic changes in brain regions implicated in stress and emotion regulation, which converge into increased physiological responsiveness to the environment and behavioral changes that are reminiscent of depression, anxiety, and substance abuse. These preclinical studies, which we selectively summarized here, served as an impetus for a large number of studies over the recent years that have investigated the neurobiological consequences of ELS in humans.

Neurobiological Effects of Early-Life Stress in Human Studies

Over the past two decades research has focused on whether findings on the effects of ELS in animal models can be transferred to humans.

Neuroendocrine and Autonomic Stress Responses

A number of studies have investigated whether ELS in humans is associated with persistent sensitization of the HPA axis and the autonomic nervous system to stress in adulthood. To test this hypothesis, our group (Heim et al., 2000) employed a standardized psychosocial stress protocol that consists of a public speaking and mental arithmetic task in front of an audience and which has been shown to reliably induce HPA axis and sympathetic activation (Kirschbaum, Pirke, & Hellhammer, 1993). This test was administered to 4 groups of women stratified by ELS and major depression. This design allowed for separating effects of ELS from correlates of Major Depressive Disorder (MDD). In remarkable parallel to results from animal models, women with a history of childhood abuse without and with current major depression exhibited increased ACTH responses to stress compared with controls. Net ACTH response was more than 6-fold greater in abused women with current major depression than in controls. These women also demonstrated increased cortisol and heart rate responses to psychosocial stress. Abused women who were not currently depressed exhibited normal cortisol responses, despite their increased ACTH response, perhaps suggesting adrenal adaptation to central sensitization as a marker of resilience against depression after early stress. Depressed women without abuse demonstrated normal neuroendocrine responses (Figure 21.2). These findings suggested that HPA axis and autonomic nervous system hyperreactivity, presumably due to CRH hypersecretion, may be a persistent consequence of ELS in humans that may contribute to the risk for psychopathology in adulthood. Of note, the effects of ELS were preserved when additionally controlling for adulthood traumas and major life events in the past year (Heim et al., 2002), suggesting that stress sensitization in these women indeed was secondary to ELS.

These findings were replicated in other studies. For example, Rao et al. (2008) showed in a sample of adolescents with major depression that ELS was associated with markedly elevated responses to psychosocial laboratory stress. However, there are also studies that report decreased HPA axis reactivity in adults with histories of ELS (e.g.Carpenter et al., 2007; Carpenter, Shattuck, Tyrka, Geracioti, & Price, 2011). It must be noted that the latter studies were conducted in a nonclinical sample. It therefore appears that HPA axis hyperactivity as a consequence of ELS might be most pronounced in those subjects who went on to develop depression, while individuals who remain resilient are able to downregulate the HPA axis. It is, therefore, plausible that ELS in interaction with genetic risk for depression produces HPA axis hyperactivity. Another factor that might play a role is exhaustion of the system due to continued chronic stressors after ELS. Hence, a study by Goldman-Mellor and colleagues (2012) revealed that subjects who experienced ELS and suffered from recurrent psychological distresses over time showed blunted cortisol reactivity to a laboratory stress task. In contrast, subjects with ELS but no further recurrent distresses exhibited elevated baseline cortisol, prolonged cortisol responses and increased total cortisol production (Goldman-Mellor, Hamer, & Steptoe, 2012). Generally, studies in children have also provided mixed results in terms of the direction of dysregulation of the HPA axis after maltreatment (see Cicchetti & Toth, 2005). However,

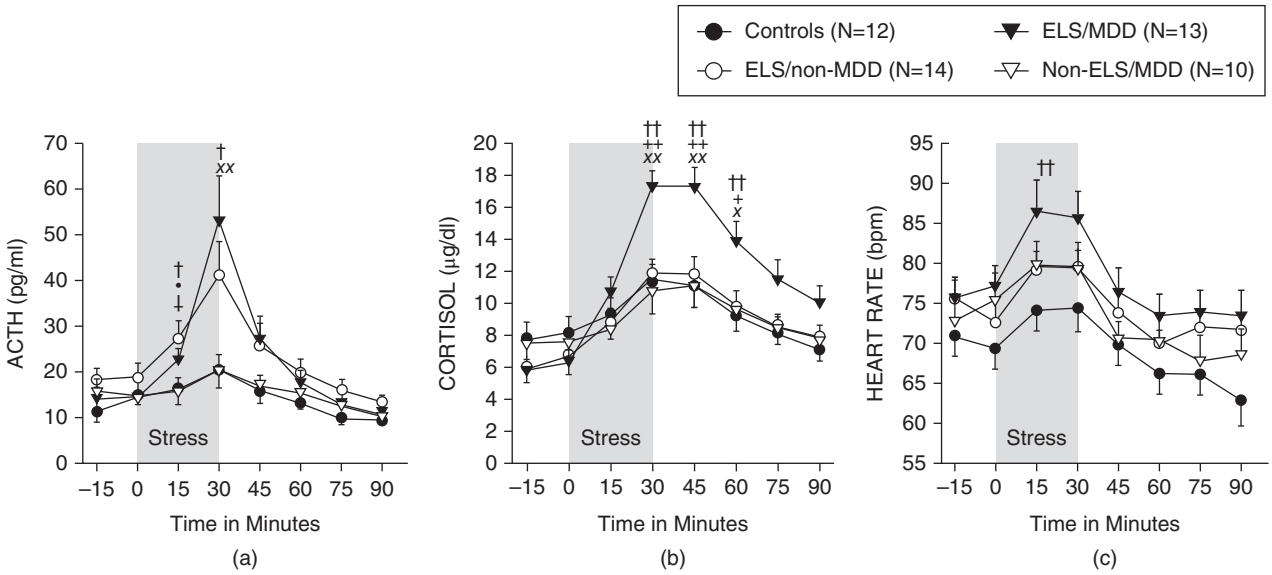

Figure 21.2 Sensitization to psychosocial laboratory stress in adult women with childhood abuse experience. *, $P<.05$ for controls vs ELS/non-MDD; †, $P<.05$ for controls vs ELS/MDD; ‡, $P<.05$ for ELS/non-MDD vs non-ELS/MDD; #, $P<.05$ for non-ELS/MDD vs ELS/MDD; +, $P<.05$ for ELS/non-MDD vs ELS/MDD; ††, $P<.01$ for controls vs ELS/MDD; ##, $P<.01$ for ELS/MDD vs non-ELS/MDD; ++, $P<.01$ for ELS/non-MDD vs ELS/MDD. *Source:* Adapted from Heim, C., Newport, D. (2000), Pituitary-adrenal and autonomic responses to stress in women after sexual and physical abuse in childhood. *Journal of the American Medical Association, 284*(5), p. 595.

these studies might be hampered by the fact that some of the children might still be living under adverse conditions. Taken together, additional studies are needed to identify the source of variability in the direction of HPA axis alterations after ELS in humans.

Pharmacological Challenge Tests of the HPA Axis

To identify changes in the dynamics of HPA axis regulation as a consequence of ELS, standard HPA axis challenge tests can be applied. Whereas psychosocial stress tests stimulate a stress response involving higher levels of cognitive and emotional processing, several neurotransmitter systems, and endogenous CRH release, the administration of a defined amount of synthetic CRH selectively stimulates ACTH release from the pituitary corticotrophs. Thus, the CRH stimulation test allows for an evaluation of the reactivity of the adenohypophysis to a defined amount of CRH. Changes in pituitary responsiveness to CRH stimulation may reflect CRH receptor changes on corticotrophs due to alterations in the activity of the PVN-median eminence CRH circuit. The administration of high doses of the biologically active $ACTH_{1-24}$ allows for the evaluation of the maximal responsiveness of the adrenal cortex (Heim & Ehlert, 1999).

In response to 1 g/kg ovine CRH stimulation, adult women with histories of ELS, who did not suffer from depression, exhibited increased ACTH responses, similar to their responses in the psychosocial stress test. In contrast, depressed women with and without histories of ELS exhibited blunted ACTH responses to CRH injection, which is a classic feature of major depression (Gold et al., 1984; Holsboer, von Bardeleben, Gerken, Stalla, & Muller, 1984). In response to 250 mg $ACTH_{1-24}$, women with histories of ELS, who did not suffer from depression, secreted less cortisol than controls and depressed women with or without ELS (Heim, Newport, Bonsall, Miller, & Nemeroff, 2001). These findings can be interpreted as reflecting sensitization of the pituitary and counter-regulative adaptation of the adrenal gland as a consequence of ELS. This pattern might be a risk factor for the development of depression and HPA axis hyperactivity. Specifically, because cortisol has important regulatory effects on the central CRH and noradrenergic systems, it may be suggested that relative decreased availability of cortisol might facilitate disinhibition of central stress responses, when these women are exposed to further trauma or severe stress, eventually promoting the development of symptoms of depression through CRH effects in extra-hypothalamic circuits.

Such disinhibition of central stress response systems after ELS might be particularly expected if there were also changes in glucocorticoid-mediated feedback control of the

HPA axis. In other words, if receptors for glucocorticoids in the brain were relatively resistant, one would expect enhanced stress responses and risk for depressive behaviors. Therefore, consideration of glucocorticoid-mediated feedback under conditions of challenge might be particularly relevant to understand altered stress reactivity after ELS and its contribution to depression. The combined dexamethasone/CRH test was developed as a standardized test to assess the capability of the HPA axis to maintain feedback control under challenge. For this test, a high dose of dexamethasone is administered orally in the evening, which results in shutting down HPA axis; the next day, CRH is injected to simulate challenge. In healthy individuals, the HPA axis remains relatively contained in this test, reflecting functional negative feedback; however, in depressed patients, a characteristic escape of the HPA axis from suppression can be observed, reflecting impaired negative feedback inhibition of the HPA axis. The dexamethasone/CRH test is considered to be the most sensitive measure of HPA axis hyperactivity in depression (Heuser, Yassouridis, & Holsboer, 1994). The test further possesses sensitivity to detect familial risk in asymptomatic first-degree relatives of depressed patients (Holsboer, Lauer, Schreiber, & Krieg, 1995; Modell et al., 1998), serves as surrogate marker for treatment response (Ising et al., 2005), and varies with a polymorphism in the FKBP5 gene, a GR-regulating co-chaperone of hsp-90, which is also associated with recurrence of depression and antidepressant response (Binder et al., 2004). Our group sought to determine the effects of ELS on results in the dexamethasone/CRH test in adult men with and without current major depression. Men with ELS as a whole demonstrated markedly increased cortisol responses to dexamethasone/CRH administration when compared with men without ELS, reflecting escape of the HPA axis from inhibition. When stratifying groups by ELS and major depression, men with ELS and current major depression exhibited the highest degree of escape, whereas depressed men without ELS demonstrated normal HPA axis regulation. Indeed, increased response, or escape of the HPA axis from inhibition, was correlated with the severity of the abuse (Heim, Mletzko, Purselle, Musselman, & Nemeroff, 2008). These results suggest that ELS is associated with impaired glucocorticoid-mediated feedback control of the HPA axis during stimulated conditions in humans. The dexamethasone/CRH test appears to be sensitive to detect environmental risk secondary to ELS. Similar results have been reported for women with borderline personality disorder (Rinne et al., 2002), suggesting that escape after ELS occurs independent of sex. Of note, we also measured decreased GR sensitivity in mononuclear blood cells in individuals with ELS compared with healthy controls, further suggesting relative glucocorticoid resistance (Klengel et al., 2013). These results concur with reports that ELS in rodents and in humans is associated with reduced expression of hippocampal GR and with DNA methylation at a neuron-specific promoter site of the GR gene (McGowan et al., 2009; Weaver et al., 2004). These results further concur with findings of epigenetic changes in the FKBP5 gene after ELS in FKBP5 risk allele carriers, leading to increased FKBP5 expression, which is concordant with GR resistance (Klengel et al., 2013). Impaired glucocorticoid feedback due to GR resistance may plausibly contribute to increased stress reactivity and promote symptoms of depression (Pariante, 2004).

Central Corticotropin Releasing Hormone Activity

The findings of increased HPA axis responsiveness to psychosocial stress, blunted ACTH response to CRH challenge, and impaired glucocorticoid feedback as well as GR resistance in individuals with histories of ELS and current major depression are consistent with the notion that activation of the CNS CRH system should be increased after ELS in humans. To directly evaluate CNS CRH activity in humans, CRH concentrations can be measured in cerebrospinal fluid (CSF) obtained through lumbar puncture. Concentrations of CRH in CSF most likely reflect CRH activity in extra-hypothalamic circuits. Elevated CSF CRF concentrations have been repeatedly reported in patients with major depression (Hartline, Owens, & Nemeroff, 1996; Nemeroff et al., 1984; Widerlöv, Bissette, & Nemeroff, 1988). In post-mortem studies, increased CRH content or mRNA expression was found in the hypothalamic PVN, locus coeruleus and prefrontal cortex (Bissette, Klimek, Pan, Stockmeier, & Ordway, 2003; Merali et al., 2006; Raadsheer, Hoogendijk, Stam, Tilders, & Swaab, 1994; Raadsheer et al., 1995) of patients with major depression. Given the evidence from animal models, that CRH systems are hyperactive after ELS in rodents and nonhuman primates (Coplan et al., 1996; Plotsky et al., 2005). Carpenter et al. (2004) evaluated whether ELS contributes to CRH hyperactivity in depression in humans. These authors reported that levels of perceived preschool stress (around the age of 5 years) predicted CSF CRH concentrations, more so than a diagnosis of depression. Our group measured CSF CRH concentrations in women with and without histories of ELS. When classifying the women according to abuse type, women who had been physically abused demonstrated higher CSF CRH concentrations than women with no physical

abuse experience. Additional analyses showed that women who had experienced both sexual and physical abuse had particularly elevated CSF CRH concentrations compared with women with no abuse experience. Accordingly, CSF CRH concentrations were correlated with the severity and the duration of physical and sexual abuse in these women (Heim, Newport, Mletzko, Miller, & Nemeroff, 2008). It can be concluded that severe childhood abuse, in particular a combination of sexual and physical abuse, contributes to CNS CRH hyperactivity in adult women. Because of the widespread effects of CNS CRH systems in mediating endocrine, autonomic and behavioral responses to stress, it can be assumed that CNS CRH hyperactivity may contribute to stress vulnerability and depression risk after ELS in humans.

Oxytocin Activity

As noted already, the neuropeptide oxytocin has received considerable attention in preclinical and human research for its role in mediating social affiliation, mother–child attachment, social support, and trust (Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005; Young & Wang, 2004). Oxytocin further has stress-protective effects and decreases amygdala reactivity in humans (Kirsch et al., 2005). Thus, the CNS oxytocin system may be profoundly impacted by disruption of the caretaker-child relationship during times of heightened plasticity, translating such experiences into stress vulnerability and disease risk. Early nurturing experiences induce persistent changes in the CNS oxytocin system in rodents and nonhuman primates (Francis et al., 2000; Winslow et al., 2003). Therefore, several studies have investigated potential changes in the CNS oxytocin system in humans as a function of ELS.

Indirect evidence for changes in central oxytocin function comes from a study by Seth Pollak and his group. Using a morphed face paradigm, in which children have to recognize and classify emotional expressions of ambiguous faces, maltreated children were less accurate in their emotion recognition and had a bias towards classifying ambiguous faces as angry (Pollak & Kistler, 2002). Although this study did not measure oxytocin levels, poor performance in similar tasks has been associated with oxytocin deficiency. Hence, a recent study in adults showed that intranasal oxytocin administration ameliorated the performance of women with histories of ELS in this task (Grimm et al., 2014).

Another study by Wismer Fries and colleagues (2005) measured urinary oxytocin excretion in children. Because it is unclear to what extent urinary oxytocin levels indeed do reflect CNS activity, this study used a behavioral paradigm consisting of a mother-child interaction task and compared increases in oxytocin excretion in response to the task between maltreated and nonmaltreated children. It can be reasonably assumed that the difference in the increase of oxytocin in response to this behavioral task reflects central oxytocin activation. The researchers observed that maltreated children activated their oxytocin system to a lesser degree in response to the task than nonmaltreated children, suggesting an early deficiency in the brain's oxytocin function after ELS (Wismer Fries, Ziegler, Kurian, Jacoris, & Pollak, 2005).

Measuring concentrations of oxytocin in CSF obtained by lumbar puncture is the only way to directly assess CNS oxytocin activity. Our group has measured CSF oxytocin concentrations in adult women with and without histories of ELS. Using validated cutoff scores for moderate-severe exposure across the five subscales for maltreatment (physical, sexual, emotional abuse; physical, emotional neglect) of the Childhood Trauma Questionnaire (CTQ; Bernstein et al., 2003), we found a dose–response relationship between the number of maltreatment types that were met and the degree of decrease in CSF oxytocin levels. Emotional abuse was most predictive of decreased CSF oxytocin levels. There was an inverse relationship between CSF oxytocin concentrations and levels of anxiety in these women (Heim, Young, et al., 2009).

Taken together, these results support the hypothesis that ELS not only leads to hyperactivity of stress mediators such as CRH, but also interferes with the development of brain systems implicated in social attachment, which may then lead to decreased resilience against stress and anxiety. Indeed, the mechanism translating early social stress into vulnerability may not simply involve changes in stress-mediating systems, but a disturbed balance between stress-mediating and stress-protective neural systems.

Indicators of Inflammation after ELS

As noted before, the innate immune system can be activated by psychosocial stress, through autonomic inputs, leading to induction of NFκB and a proinflammatory cytokine response, which in turn impacts onto the brain, leading to further perpetuation of stress responses and neurostructural damage (Raison & Miller, 2006). The pattern of neurobiological changes after ELS, characterized by increased autonomic stress responsiveness and relative GR resistance, would be concordant with the presence of a state of inflammation after ELS. Of note, patients with depression exhibit marked increases in acute phase proteins, such as C-reactive (CRP) and in proinflammatory cytokines (Raison & Miller, 2006). Our group observed

that depressed adult men, many of whom reported high levels of ELS, exhibit markedly increased plasma levels of IL-6 in response to a psychosocial laboratory stressor, when compared with healthy controls. The increase in IL-6 after psychosocial stress was associated with increases in the induction of NFκB in these men (Pace et al., 2006). Of note, Carpenter and colleagues (2010) reported that ELS exposure was associated with increased IL-6 responses to psychosocial stress in a healthy adult sample.

Of particular relevance in elucidating the impact of ELS in inflammation are studies that have been conducted by Danese and colleagues in a longitudinal prospective birth cohort sample in Dunedin, New Zealand (Danese et al., 2008; Danese, Pariante, Caspi, Taylor, & Poulton, 2007). For this sample, which has been followed over 30 years, there is prospective information on maltreatment available. Danese and colleagues (2007) demonstrated that histories of child maltreatment were associated with pronounced systemic inflammation across the life span, as indicated by increased CRP levels above the clinical cutoff, increased fibrinogen levels, increased white blood cell counts, and an increased composite score of inflammation. The effect of ELS on inflammation was maintained when controlling for a large number of potential confounders, including lifestyle factors. A subsequent analysis by the same group revealed that elevated levels of systemic inflammation were particularly pronounced in those individuals with a history of maltreatment that also suffered from major depression (Danese et al., 2008). Another recent study reported elevated levels of adiponectin, an inflammation marker that is involved in modulating metabolic processes, in adults with histories of ELS (Lehto et al., 2012).

Such systemic inflammation appears to be present already in children exposed to maltreatment. Danese and McEwen (2012) showed in the Environmental Risk Study, conducted in the UK, that elevated levels of CRP were already measurable in maltreated children as young as 12 years of age. Similarly, children living in neighborhoods with high rates of crime and poverty exhibit increased CRP levels at an early age.

Taken together, available data suggest a strong link between ELS and inflammation. It is well conceivable that a chronic state of systemic inflammation starting in childhood can potently increase the risk for developing heart disease, stroke, metabolic problems, and other disorders related to inflammation across the life span. Effects of proinflammatory mediators on brain structure and function can plausibly contribute the development of depression and anxiety disorders after ELS. The role of neuroinflammation after ELS is an area that should be further investigated in future studies, as it might be a target for prevention.

Structural and Functional Brain Changes Following Early-Life Stress

Neuroendocrine and autonomic responses to psychological or emotional stress underlie a complex network of brain regions that influence the hypothalamus and brain stem nuclei that regulate outflow systems (Ulrich-Lai & Herman, 2009). This network includes the hippocampus, the amygdala and the prefrontal cortex as well as the anterior cingulate cortex (ACC). The fact that ELS is associated with hyperactivity of the CNS CRH system, resulting in exaggerated cortisol secretion upon additional stress, suggests that the primary lesion after ELS might be located at the neural systems level and may involve failure of these circuits to compensate or adapt to challenge, leading to maladaptive responses. The brain regions involved in the regulation of stress and emotion exhibit substantial developmental plasticity as a function of experience. In addition, these regions exhibit a high density of GR and are therefore particularly vulnerable to the effects of stress or excessive glucocorticoid release. Accordingly, patients with depression, PTSD, and other psychiatric disorders exhibit marked structural and functional changes in these circuits (Mayberg, 2003). Animal models have provided the causal evidence that ELS induces altered development of brain regions involved in stress processing and emotion regulation, and these changes converge into heightened physiological responsiveness to subsequent stress and depression- and anxiety-like behavior (Meaney, 2001). It is conceivable that ELS in humans might be associated with structural and functional brain changes, contributing to stress vulnerability and risk for disorders. In the following, we will provide an overview of this rapidly growing field of research.

Hippocampus

The hippocampus is an essential component in the neural network mediating stress responses. It exerts important inhibitory regulation of the HPA axis and plays a critical role in contextual aspects of fear conditioning. Moreover, the hippocampus is one of the most plastic regions within the CNS, with a high degree of synaptic plasticity and neurogenesis occurring in adulthood. The hippocampus has a high density of GR and is therefore particularly vulnerable to the effects of stress. A large number of experimental animal and human studies have shown that stress or prolonged exposure to glucocorticoids affect the

hippocampus, resulting in decreased neuronal excitability, dendritic atrophy and apoptosis particularly in the CA3 region, and decreased neurogenesis in the dentate gyrus (Lee, Jarome, Li, Kim, & Helmstetter, 2009). Therefore, the hippocampus has been the subject of intense inquiry in relation to stress, including ELS. In the following, we will provide an overview of studies that investigated the impact of ELS on the hippocampus in adult and in child samples.

Several studies consistently report a smaller hippocampal volume in adults with histories of ELS compared with adults with no such histories (Vermetten, Schmahl, Lindner, Loewenstein, & Bremner, 2006; Woon & Hedges, 2008). For example, adult survivors of severe childhood abuse had a 12% smaller left hippocampus volume compared with adults with no history of maltreatment (Bremner et al., 1997). Sexual abuse has also been seen associated with reduced left hippocampal volume (Stein, Koverola, Hanna, Torchia, & McClarty, 1997). In a recent study with a sample of 148 healthy participants, high CTQ scores were associated with reduced grey matter volume in the hippocampus (Dannlowski et al., 2012). Our group has investigated the contribution of ELS to hippocampal volume loss in major depression. By stratifying depressed women into those with and those without histories of ELS, we demonstrated that hippocampal volume reduction was limited to those depressed patients who were exposed to ELS, whereas depressed women without ELS exhibited normal hippocampal volume (Vythilingam et al., 2002). This result was in remarkable parallel to neuroendocrine findings and suggests that MDD in the context of ELS has a distinct pathophysiology with changes in stress-mediating systems that likely reflect risk to develop depression in response to stress (Heim et al., 2004). Accordingly, Frodl and colleagues (2010) report reduced left hippocampal volume in patients with major depression and a history of emotional neglect compared with those depressed patients who have not suffered from ELS (Frodl, Reinhold, Koutsouleris, Reiser, & Meisenzahl, 2010). To date, most of the studies measured whole hippocampal volume; however, different subfields within the hippocampus are known to differ in terms of their sensitivity to stress and their role in regulating the neuroendocrine stress response. Therefore, it is crucial to use high-resolution imaging methods to investigate region-specific effects of ELS. Notably, using high-resolution hippocampal imaging, Teicher and colleagues (2012) reported that childhood maltreatment was strongly associated with a reduction of more than 4% particularly in the CA3 region, the dentate gyrus and the left subiculum. Hence, volume loss as a function of the severity of ELS indeed occurred precisely in the subfields, which are particularly sensitive to stress and glucocorticoids (Teicher, Anderson, & Polcari, 2012).

Whereas it is a consistent finding that ELS is associated with smaller hippocampal volumes in adults, studies in children are rare and less clear in showing effects of ELS on the hippocampus (Tottenham & Sheridan, 2009). De Bellis and colleagues (2001) did not find adversity-related differences in hippocampal volume and no differences in volume changes over a period of two years in maltreated children (De Bellis, Hall, Boring, Frustaci, & Moritz, 2001). Lupien and colleagues (2011) compared children exposed to maternal depressive symptomatology since birth with control children raised by mothers without psychiatric symptomatology and could not detect changes in hippocampal volume. Whereas the majority of studies in child samples did not report any changes in hippocampal volume as a consequence of ELS, one longitudinal study in children, unfortunately conducted without a control group, found a link between the severity of ELS and a decrease of hippocampal volume over time (Carrion, Weems, & Reiss, 2007). A recent longitudinal study in 3–5-year-old children showed that stress levels early in life appeared to predict the left smaller hippocampal volume in childhood when the participants were between 7 and 12 years old (Pagliaccio et al., 2014). The most profound effects were detected in CA2/3 and CA4/dentate gyrus subfields. Moreover, genetic factors moderated this link. Interestingly, in contrast to the effects observed in adults, Tupler and De Bellis (2006) reported larger hippocampal volumes in a child population with PTSD following childhood abuse compared with healthy children.

To summarize, despite the numerous findings showing decreased hippocampal volume in adults reporting ELS, the evidence of differences in hippocampal volume in children caused by ELS is less consistent. These inconsistencies may be explained by the timing of the measurement. According to the neurotoxicity hypothesis one might argue that detrimental effects of ELS on the hippocampus may emerge over the course of life, indicating accumulating effects of repeated or prolonged overexposure to glucocorticoids or inflammatory mediators over time, which then lead to small hippocampal volume and risk for depression in adulthood (Lupien et al., 2009). To investigate the impact of ELS on morphometric development of the hippocampus over time, as well as the mediation of this impact by prolonged overexposure to glucocorticoids or inflammatory mediators, longitudinal neuroimaging studies, coupled with neurobiological assessments, starting in early childhood should be conducted.

Prefrontal Cortex and Cingulate Cortex

The prefrontal cortex (PFC) is of particular relevance in the study of the consequences of ELS. The PFC mediates executive functions and the regulation of goal-directed behavior and is further involved in the inhibition of impulses and emotional regulation. In particular, the medial PFC is relevant for emotional regulation, via connections with cingulate cortex and the amygdala. The PFC also exerts inhibitory actions via indirect pathways on the HPA axis (Ulrich-Lai & Herman, 2009). Small volumes of the PFC as well as reduced blood flow in medial PFC have been reported as features of major depression (Mayberg, 2003). It has further been suggested that reduced activation in the medial PFC during emotional challenge is a neural marker of depression risk (Goldapple et al., 2004). Similar findings have been reported for PTSD. In the following, we will discuss several studies that investigated the effects of ELS on the PFC.

A decreased volume of the PFC is a consistent finding in adults with histories of ELS. Tomoda and colleagues (2009) investigated the effects of harsh corporal punishment, which is a significant developmental stressor. They reported that harsh corporal punishment during childhood was associated with reduced gray matter volume in the left dorsolateral PFC and the right medial PFC later in life. Van Harmelen and colleagues (2010) reported that emotional maltreatment before the age of 16 was associated with decreased volume in left dorsal medial PFC when compared with a group composed of healthy controls and patients without a history of ELS. The anterior cingulate cortex, a frontal cortical region that is relevant to attention and emotional regulation, also seems to be reduced in volume after ELS in humans (Baker et al., 2012; Heim, Mayberg, Mletzko, Nemeroff, & Pruessner, 2013; Treadway et al., 2009).

Despite the consistent finding of decreased volume in prefrontal cortical regions relevant to emotion regulation in adults, findings in children are mixed. One study reports an association between ELS at age 7–10 years and a reduced frontal lobe asymmetry as well as decreased cerebral frontal volumes in these children (Richert, Carrion, Karchemskiy, & Reiss, 2006). Several studies in children investigated prefrontal structures in the context of PTSD. One study comparing children suffering from maltreatment-related PTSD to a healthy, nonmaltreated group did not find any differences in prefrontal volume (De Bellis et al., 1999). In contrast, in a later study, De Bellis and colleagues (2002) did report smaller prefrontal volume and white matter changes in the maltreated group. However, two recent studies also investigated PTSD and reported greater gray matter volume of the middle-inferior and ventral regions of the PFC related to PTSD in maltreated children (Carrion et al., 2009; Richert et al., 2006). Hanson and colleagues (2010) report significantly smaller volumes of the right orbital frontal cortex in children with histories of physical abuse in comparison to nonabused control children, which in turn predicted poorer social functioning.

To summarize, studies in adults consistently report decreased volumes in prefrontal cortical regions whereas studies in children show mixed findings. Factors that might account for this lack of consistency may include timing of ELS as well as developmental trajectories leading to structural damage over time.

Amygdala

In addition to changes in the hippocampus and the prefrontal cortex, research has also considered changes in the volume and reactivity of the amygdala associated with ELS. The amygdala is a small structure in the medial temporal lobe which plays a critical role in evaluating potentially threatening information, fear conditioning, emotional processing, and memory for emotional events (Phelps & LeDoux, 2005). The amygdala exerts stimulating effects on the HPA axis via indirect projections (Ulrich-Lai & Herman, 2009). It may be particularly vulnerable to the programming effects of early experience due to a high density of GR and a postnatal developmental trajectory characterized by growth and increasing connectivity until early adolescence (Uematsu et al., 2012). Animal studies have shown that psychological stressors, such as immobilization and the administration of stress hormones, lead to increased amygdala volume by stimulating dendritic arborization and the formation of new spines (Mitra, Jadhav, McEwen, Vyas, & Chattarji, 2005; Mitra & Sapolsky, 2008; Vyas, Pillai, & Chattarji, 2004). Patients with major depression demonstrate increased reactivity of the amygdala, whereas studies on volume changes in depression provided mixed results (Hamilton, Siemer, & Gotlib, 2008). Given these findings, it is of interest to evaluate structural and functional changes of the amygdala as a consequence of ELS in humans.

Studies investigating the effects of ELS on amygdala volume in humans have provided mixed findings. Of note, ELS was linked to reduced volume of the amygdala in patients with dissociative identity disorder or borderline personality disorder (Schmahl, Vermetten, Elzinga, & Douglas Bremner, 2003; Vermetten et al., 2006; Weniger, Lange, Sachsse, & Irle, 2009). Other studies have reported no differences in amygdala volume following ELS

(Andersen & Teicher, 2008; Bremner et al., 1997). Studies in children are equally inconsistent. According to Woon & Hedges (2008), children who developed PTSD secondary to childhood maltreatment did not differ from children without a history of maltreatment in terms of amygdala volume. However, some recent studies in children have reported findings concordant to studies in animals. For example, prolonged institutional rearing characterized by severe deprivation has been associated with greater amygdala volume in these children. Mehta and colleagues (2009) reported greater volume in 14 adopted adolescents who had experienced severe early deprivation in Romanian orphanages compared with a group of nondeprived, nonadopted UK controls. Tottenham and colleagues (2010) found similar changes in preadolescent children who had been adopted from an orphanage when older than 15 months when compared with nonadopted controls or to children adopted before the age of 15 months. The reported significant association between the age of adoption and volume increase in the amygdala suggests that early and extended exposure to institutional deprivation is likely to lead to an aberrant development of key structures in emotional regulation. Interestingly, increased amygdala volume as a consequence of ELS appears not to be reversible, which is in line with animal research (Lupien et al., 2009). Another study reported enlarged amygdala volume in children, who had been raised by chronically depressed mothers with sensitivity to the infant (Lupien et al., 2011). In the latter study, it was shown that amygdala volume predicted affective symptoms and aberrant emotional processing in these children.

Studies examining structural changes of the amygdala as a consequence of ELS are complemented by functional neuroimaging studies. Functional neuroimaging studies indicate that ELS is associated with hyperactivity of the amygdala in response to emotionally threatening stimuli (Dannlowski et al., 2012). This sensitization of the amygdala is also apparent in response to subliminally presented stimuli. Hence, Dannlowski and colleagues (2013) observed increased neural activation of the amygdala to subliminally presented sad facial expressions in a maltreated sample, indicating that ELS was strongly associated with detectable changes in amygdala function even at early subconscious stages of emotion processing. This limbic bias, which has been hypothesized to be a feature of major depression, was only present in depressed patients with a history of ELS. Hence, in a sample of unipolar depressed patients with and without a history of ELS, Grant and colleagues (2011) consistently found increased amygdala reactivity to aversive stimuli only in patients who had experienced abuse in childhood, whereas this dysfunctional pattern of limbic activation was absent in depressed patients without a history of ELS (Grant, Cannistraci, Hollon, Gore, & Shelton, 2011). A recent study by the same research group investigated the connectivity between the amygdala and prefrontal areas (Grant et al., 2014). Functional connectivity between the PFC and the amygdala is thought to underlie the cortical inhibition of amygdala output. In accordance with the aforementioned studies, ELS was associated with a failure of inhibition in the MDD group based on decreased connectivity between the medial PFC and the amygdala. Studies in children provide concordant findings. Tottenham and colleagues (2011) report increased bilateral amygdala activity in response to fearful faces in children with a history of institutional care. Maheu and colleagues (2010) report similar findings for institutionalized children. A recent study in children with and without depression reported that amygdala hyper-reactivity was associated with greater levels of life stress and trauma in these children, but was not generally related to psychopathology (Suzuki et al., 2014).

A seminal recent study by Burghy and colleagues (2012) used a prospective sample, following children from birth into young adulthood. Of note, impaired functional connectivity between prefrontal cortex and the amygdala in young adulthood was observed as a function of ELS and was best predicted by glucocorticoid levels of these children when they were 4.5 years old. This association was significant for girls but not for boys. These findings suggest the existence of sensitive periods and sex differences in the consequences of ELS, which will be discussed in more detail in the following section. In accordance with studies suggesting changes in functional connectivity between frontal cortical and limbic regions after ELS, studies using diffusion tensor imaging in children suggest reduced white matter integrity between frontal and temporal regions associated with early deprivation (Govindan, Behen, Helder, Makki, & Chugani, 2010).

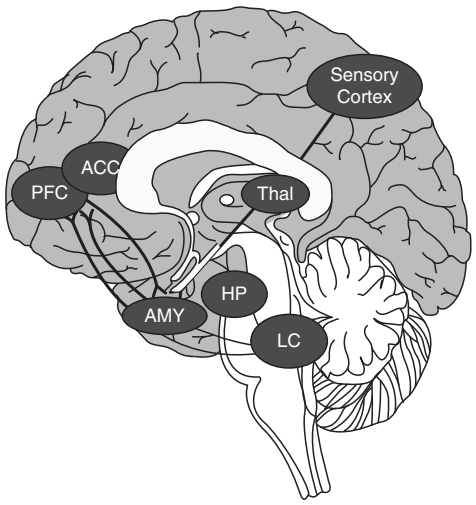
Taken together, these findings provide convincing evidence that ELS is associated with increased reactivity of the amygdala in humans as well as reduced functional connectivity between the PFC and the amygdala, whereas results on structural changes of the amygdala after ELS are somewhat mixed. Increased reactivity of the amygdala and reduced connectivity likely indicate an aberrant neural circuitry with failure to compensate or adapt in response to challenge. Specifically, loss of top-down control of emotional responses may then lead to increased physiological stress responses and risk for affective disorders.

Corpus Callosum

Developmental programming by ELS also affects other brain regions, such as the corpus callosum (CC). The CC is the largest white matter structure in the brain that mediates communication between the two hemispheres. While nerve fiber connections of the CC are fully developed during the prenatal period, myelination continues across childhood and adolescence (Teicher et al., 2004), providing a basis to suggest that the CC is vulnerable to effects of ELS. The CC is relevant for hemispheric exchange of motor, sensory, and cognitive information between the brain hemispheres. Dysfunction of the CC has also been linked to alexithymia, which refers to emotional blunting and is often observed in trauma survivors. Few studies in adult samples focused on the association between the CC and ELS. Kitayama and colleagues (2007) reported a decreased volume in the posterior mid body of the CC in women who suffered from maltreatment-related PTSD. Using diffusion tensor imaging, Paul et al. (2008) found reduced neuronal integrity in the genu of the CC as a function of ELS, while total volume of the CC was unchanged.

Studies in children mostly focused on the morphometry of the CC and consistently found decreases in volume, which were most prominently shown in the middle and posterior part of the CC (De Bellis & Keshavan, 2003; Jackowski et al., 2008; Teicher et al., 2004). For example, Teicher and colleagues (2004) found that children who experienced abuse or neglect exhibited a 17% smaller total volume of the CC compared with controls who had never experienced any form of maltreatment and compared with children with psychiatric disorders without maltreatment exposure. Furthermore, preliminary evidence suggests that these effects depend on type of maltreatment and sex of the child.

Sensory Processing Areas



Recent studies also found experience-dependent alterations in sensory systems and pathways that process and convey the adverse experience. For example, exposure to parental verbal abuse has been shown to be specifically associated with alterations in the auditory cortex (Choi, Jeong, Rohan, Polcari, & Teicher, 2009; Tomoda et al., 2011). More specifically, Tomoda and colleagues (2011) reported a greater gray matter volume in the left superior temporal gyrus of verbally abused subjects. Besides this finding of aberrant auditory cortex development, a diffusion tensor imaging analysis revealed decreased fractional anisotropy in the arcuate fasciculus, reflecting reduced white matter tract integrity to be associated with parental verbal abuse. Interestingly, the arcuate fasciculus interconnects Wernike's and Broca's area, which play a key role in perception and processing of language. These findings suggest that the development of auditory association cortex as well as relevant pathways that process the adverse sensory inputs are likely to be modified in response to early exposure to emotionally abusive language.

Similar results were reported for witnessing domestic violence and alterations in the primary and secondary visual cortex. Tomoda and colleagues (2012) reported differences in the thickness of the lingual gyrus, occipital pole and V2 in individuals with a history of visually witnessing episodes of domestic violence. In addition, the same group of researchers also found a reduction in the integrity of the inferior longitudinal fasciculus interconnecting visual cortex to limbic system in adults who witnessed domestic violence during childhood (Tomoda, Polcari, Anderson, & Teicher, 2012).

Along the same lines, a recent study by our group (Heim et al., 2013) using whole mantle cortical thickness analysis found that exposure to childhood sexual abuse was specifically associated with pronounced cortical thinning of the somatosensory genital field, when controlling for all other forms of maltreatment, as measured using the CTQ. The effect was precisely localized in the coordinates that were identified as representing the female genitals using functional MRI studies (Michels, Mehnert, Boy, Schurch, & Kollias, 2010) Interestingly, emotional abuse was specifically associated with cortical thinning in the precuneus, a region that is relevant for self-awareness and self-evaluation, as well as thinning in the anterior cingulate cortex, which is relevant for emotional regulation.

Taken together, these findings suggest that experience-dependent plasticity leads to effects of ELS on sensory processing areas in a regionally highly specific manner, determined by the type of adverse experience. This suggests that certain forms of childhood abuse induce altered cortical representation of specifically those sensory and processing areas that are implicated in the adverse experience. We have suggested (Heim et al., 2013) that this specific cortical thinning in sensory and processing areas may represent the most adaptive and protective response of the developing brain that may shield the child living under these conditions from the abusive experience, similar to sensory gating. In later life, these neuroplastic changes may represent a direct biological substrate for behavioral disorders.

Taken together, a history of ELS is associated with marked structural and functional changes in brain regions that are critical to stress processing and emotional

Neural Changes after Early-Life Stress:

- Smaller hippocampus volume in adults
- Larger amygdala volume and reactivity
- Cortical thinning and/or volume loss in areas relevant for:
  - emotional processing and regulation (medial prefrontal cortex, anterior cingulate cortex)
  - sensory processing of the abuse
- Altered frontal-limbic connectivity (functional, structural)
- Smaller corpus callosum and decreased neural integrity
- Sensitized locus coeruleus in animal models

➛ ***Converging into stress sensitization and risk for emotional disorders***

Figure 21.3 Neural changes after early-life stress.

regulation (Figure 21.3). The hippocampus seems to be adversely affected in adults with history of ELS, but not in children, suggesting that hippocampal volume loss might occur over time as a function of glucocorticoid toxicity. In addition, children and adults show evidence for changes in frontal cortical regions as well as a hyper-reactive and hypertrophic amygdala. Changes in sensory processing areas implicated in the perception of the abusive experience may serve as a protective mechanism to shield the child living under abusive conditions. Finally, there is first evidence for deficient communication between various brain regions after ELS, as suggested by functional and structural connectivity studies. The concatenation of these findings suggests that ELS induces a dysfunction at the neural systems level, with failure of this network to compensate and adapt in response to challenge, which would converge into behavioral consequences and enhanced neuroendocrine and autonomic responses to stress. Longitudinal studies in children are needed to better understand the mechanisms involved in altering trajectories of brain development after ELS, which may allow insights into precise targets and time windows of plasticity that are amenable to intervention.

INDIVIDUAL DIFFERENCES IN THE EFFECTS OF EARLY-LIFE STRESS

The adverse consequences of ELS are highly variable across individuals. This outcome variability does not only apply to the specific disorder(s) an affected person might develop, but also to the fact that there is a high degree of resilience in many individuals exposed to ELS. Certainly, not all persons exposed to ELS will develop stress vulnerability and psychiatric or medical disorders. Indeed, a remarkable percentage of individuals exposed to substantial ELS remains resilient, even when exposed to additional stressors in adulthood. Therefore, it is important to consider factors that might contribute to such resilience. Understanding risk versus resilience factors in the consequences of ELS will allow us to develop diagnostic tests that identify cases at risk for disorders after ELS. If we understand mechanisms of resilience, we will be able to develop interventions to augment resilience in those individuals with ELS who are at risk for adverse outcomes. Several factors may contribute to the variability in the effects of ELS. These include timing of the ELS, sex/gender, genetic factors, and psychosocial factors. Timing of ELS is particularly relevant, as there might be defined developmental windows of plasticity during which a stressor may have a particularly strong or specific effect, depending on the developmental stage of brain regions at the time of exposure. In addition, sex/gender and genetic factors are dispositional factors that may interact with ELS in determining outcomes. Finally, psychosocial factors, such as availability of social support or personality traits, contribute to risk versus resilience after ELS. In the following, we will review the literature concerning individual variation in the outcomes of ELS.

Timing as a Critical Factor: Sensitive Periods for the Effects of Early-Life Stress?

Few clinical studies have revealed that there might be timing-dependent effects of ELS on depression risk.

For example, Maercker and colleagues (2004) reported that political traumatization before the age of 12 years was associated with risk for major depression in adulthood, whereas traumatization from 12 years throughout adolescence was associated with increased risk for PTSD (Maercker, Michael, Fehm, Becker, & Margraf, 2004). Similarly, a study by Agid et al. (1999) suggested that parental loss before 9 years of age was associated with higher depression risk compared with parental loss between 9 and 17 years of age. While these studies did not include biological measures, it is noteworthy that puberty starts around the age of 9 years and menarche is reached by around 12 years. Increasing sex steroid levels may have important implications for neural plasticity and endocrine stress responses (Blakemore, Burnett, & Dahl, 2010; Paus, Keshavan, & Giedd, 2008; Romeo & McEwen, 2006). Thus, research is needed that identifies and characterizes periods of sensitivity to the depression risk-inducing effects of ELS, by combining psychological and neurobiological outcome data.

Concept of Sensitive Periods

It is well known from developmental neuroscience that there are periods of increased plasticity of the brain throughout development. During such periods, experiences may have profound programming and organizing effects (for detailed discussion see Andersen & Teicher, 2008; Rice & Barone, 2000; Weiss & Wagner, 1998). Critical periods refer to time windows where expected experiences are necessary for a particular brain function to develop normally. Once the critical period is over and the experience was missing, the window of opportunity has closed. However, during such times of heightened plasticity, the brain may also be particularly sensitive to unexpected experience, opening a window for the destructive effects of negative/toxic experiences, or the beneficial effects of enriching experiences (see Weiss & Wagner, 1998). Thus, it has been suggested that sensitivity to the effects of ELS may depend on temporal and regional processes of neural development and function in brain regions that are relevant to emotional experience (see Andersen & Teicher, 2008; Andersen et al., 2008; Rice & Barone, 2000; Weiss & Wagner, 1998). To define sensitive periods for the effects of ELS in humans, it is therefore critical to consider developmental trajectories of these brain regions in humans.

Brain Maturation and Periods of Plasticity

Maturation rates and the extent of plasticity across development are highly variable for different brain regions, including those involved in the processing and regulation of stress and emotion (see, e.g., Dobbing & Sands, 1973; Lupien et al., 2009; Tau & Peterson, 2010). While the sequence of maturational events in brain development is similar across species, the time scales drastically differ (Rice & Barone, 2000); therefore, animal studies may have limited validity in elucidating sensitive periods for the effects of ELS in humans. Generally, in humans, there is extensive plasticity consisting of synaptic proliferation and a prolonged period of reduction of synapses and number of axons in the postnatal period. The surviving axons are covered with myelin to increase functional efficiency. Primary sensory and motor areas are myelinated by age 6; in limbic and cortical systems, myelination continues through adolescence into adulthood, perhaps providing the basis for emotional maturation (Benes, 1989). In terms of postnatal maturational refinement, there is high regional specificity: the hippocampus has the largest increase in volume during infant/toddler years and then steadily declines; the prefrontal cortex develops slower and demonstrates peaks in maturation and plasticity during adolescence, approximately between 8 and 15 years of age (Andersen & Teicher, 2008; Giedd et al., 2009; Lenroot & Giedd, 2006; Marsh, Gerber, & Peterson, 2008). In contrast, the female amygdala reaches its full volume early in life with no further volume increases observed between the ages of 4 and 18 years, whereas in boys amygdala growth is more prolonged and slower (Giedd et al., 1996). Such differences might give rise to sex differences in the neurobiological effects of ELS. Of note, with increasing maturation, structural and functional connectivity between brain regions increases. In rats, connectivity between the amygdala and prefrontal cortex continuously increases into early adulthood (Cunningham, Bhattacharyya, & Benes, 2002). In humans, frontal cortical input to control amygdala response to fear cues appears to increase from adolescence to adulthood (Yurgelun-Todd & Killgore, 2006). Adolescents show increased amygdala responses and decreased habituation to an emotional task, and failure to habituate to repeated stimuli is associated with less functional connectivity between ventral prefrontal cortex and amygdala (Yurgelun-Todd & Killgore, 2006). Adolescents compared with adults also use a differential prefrontal neural network to regulate autonomic response during laboratory stress (Strang, Pruessner, & Pollak, 2011). All of these brain regions are generally modified by early-life stress and have been implicated in depression risk (Mayberg, 2003) and control of neuroendocrine reactivity (Lupien et al., 2009). However, little is known regarding timing effects of ELS impacting on developmental trajectories of these brain regions and linking these effects to symptoms.

Role of Puberty

The processes contributing to brain plasticity around adolescence are modulated by gonadal hormones. Puberty starts around the age of 9 years in girls and somewhat later in boys. The hormonal changes that lead to the onset of puberty start as early as the age of 6 years. By the age of 12 years, most girls reach menarche. Estrogen and progesterone have marked effects on brain structure and function (McEwen, 2001). Gonadal hormones have been shown to influence CRH mRNA expression, HPA axis function, and synaptogenesis in the hippocampus (see McEwen, 2001). Of note, HPA axis responses during puberty are prolonged (Vazquez & Akil, 1993) and potentiated with repeated stressors (Girotti et al., 2006). Adolescents may be more vulnerable to the effects of glucocorticoids because of pronounced increases in GR expression in the PFC during this developmental stage (Pryce, 2008). The large degree of plasticity during puberty may reflect another sensitive window for the effects of adverse life events experienced in this development stage. In addition, the dynamic changes during puberty in stress response systems, brought about by the increases in sex steroids, might potentiate earlier programming of the HPA axis due to earlier life stress. For example, one might speculate that ELS programs glucocorticoid resistance and hence increased stress response that develops into a behavioral effect with full maturation and increased density of PFC GR during puberty. On the other hand, the high degree of plasticity during puberty may perhaps also open an opportunity for interventions to reverse effects or damage of insults during early life (see Romeo and McEwen, 2006). Hormonal changes associated with puberty are also related to brain development during adolescence, potentially giving rise to sex-specific effects of ELS. For example, estrogen levels are positively related to gray matter development in limbic regions specifically in female adolescents (for a review see Blakemore et al., 2010). Psychiatric disorders often manifest around puberty (Andersen & Teicher, 2008; Angold & Costello, 2006; Paus et al., 2008) and gonadal steroid effects on brain development, structure, and function may account for higher prevalence rates of depression in women compared with men (Young & Korszun, 2010). Taken together, complex interactions between neurodevelopmental stage, sex, gonadal steroid status, and HPA axis reactivity at the time of ELS exposure may contribute to the development of a vulnerable phenotype with risk for disorders, although the precise mechanisms are not well understood and require further study in humans.

Evidence for Sensitive Periods in the Effects of Early-Life Stress

Based on the before, it is conceivable that ELS experienced at different developmental stages may lead to differential neurobiological phenotypes with differential vulnerability to develop disorders across the life span, as a function of the relative plasticity of different brain regions and the effects of sex hormones. However, there are very few studies that have systematically evaluated neurobiological outcomes of ELS experienced at different developmental stages. Studies in rodents and nonhuman primates suggest that the direction of the effects of ELS on the CRH/HPA system depend on timing of the ELS (Coplan et al., 2006; van Oers, de Kloet, & Levine, 1998). Further of note are findings that early weaning of 21 day old rats causes faster myelination in the amygdala, decreased brain-derived neurotrophic factor protein levels in the hippocampus and prefrontal cortex, and reduced neurogenesis in the dentate gyrus (Kikusui & Mori, 2009). However, these studies cannot easily be generalized to humans.

There is limited evidence from human studies for age-dependent effects of ELS. Altered concentrations of dopamine–beta-hydroxylase, the rate limiting step in norepinephrine synthesis, were observed in children who were maltreated in the first 3 years of life, but not in children maltreated later in childhood (Rogeness & McClure, 1996). Differential effects of child abuse before versus after the age of 6 years on CSF CRH concentrations and cortisol response in the dexamethasone/CRH test were also reported (Heim, Mletzko, et al., 2008; Heim, Newport, et al., 2008). Carpenter et al. (2004) reported that preschool stress, but not later childhood stress, modulates adulthood CSF CRH levels. The same group reported that cortisol response to stress in adults decreases with increasing onset age of emotional abuse (Carpenter et al., 2009). Insight into sensitive periods in humans is also revealed through studies of previously institutionalized and adopted children. In a seminal work, Gunnar and colleagues (2007) report that adoption of previously institutionalized children who were adopted into families after the age of 24 months were more likely to develop behavioral problems when compared with children adopted into families before this specific age (Gunnar, van Dulmen, & International Adoption Project, 2007). Using an earlier age cut, Pollak and colleagues (2010) reported that previously institutionalized children who were adopted into families after 1 year of age had more neuropsychological difficulties than earlier adopted children. In a recent report, late compared with early adoption (based on median split) was associated with enlarged amygdala volume, emotional regulation difficulties, and increased anxiety in previously institutionalized children

(Tottenham et al., 2010). All of these studies point to potential sensitive periods for the effects of early-life stress on brain development and behavior, although earlier age at traumatization or deprivation might also reflect longer duration of stressful circumstances.

Of note, earlier stress may not be linearly linked to poorer outcomes, but there might be discrete periods of sensitivity based on regional brain plasticity at a given age. A seminal study by Andersen and colleagues (2008) was the first to provide important evidence for differential effects of ELS on regional brain volumes in 26 young adult women aged 18–22 years as a function of timing of sexual abuse experiences. Hippocampal volume was reduced in association with childhood sexual abuse experienced at ages 3–5 years and ages 11–13 years, whereas frontal cortex volume was attenuated in women with childhood sexual abuse experienced at ages 14–16 years. These results provided very important first support for the notion that timing of ELS is critical in inducing differential effects on brain development.

Pechtel and colleagues (2014) recently investigated sensitive periods in the effects of ELS on amygdala development. An increase in amygdala volume in young adulthood was most strongly associated with high levels of stress at the age of 10 and 11 years. Whereas the amygdala might be particularly sensitive to stress very early in life, as shown already, this finding points to the existence of another time window of vulnerability late in childhood (Pechtel, Lyons-Ruth, Anderson, & Teicher, 2014). This is consistent with the developmental trajectory of the amygdala characterized by rapid initial growth followed by more sustained growth to peak volumes between 9 and 11 years when gradual pruning is taking over (Uematsu et al., 2012). Another recent study in young adults, using a prospective longitudinal design, suggested that changes in functional connectivity between the amygdala and prefrontal cortical regions as a function of ELS was best predicted by glucocorticoid levels at the age of 4.5 years, particularly in girls (Burghy et al., 2012).

Taken together, timing of exposure to ELS surely contributes to individual variability in the effects of ELS. Collapsing the assessment and quantification of ELS across childhood and adolescence (up to menarche or even up to the age of 18 years) as done in many retrospective studies, certainly fails to capture sensitive periods. The few existing studies that investigated timing of ELS in relation to neurobiological outcomes provide some evidence for sensitive periods for the effects of ELS in humans, although the time windows are not quite consistent within brain regions. Additional studies in larger samples are needed to study the effects of differential exposure ages on various neurobiological and clinical trajectories, ideally in longitudinal designs. Elucidation of these periods of plasticity will allow to define cases at risk for adverse outcomes and will allow for identifying time windows, during which given interventions might be maximally effective. For example, the effects of ELS in early childhood might be reversible during another plastic window in puberty.

Sex Differences in the Effects of Early-Life Stress

One important factor contributing to individual differences in the outcomes of ELS is sex or gender. The term ‘sex’ refers to biological differences between the sexes, whereas the term ‘gender’ describes differences that arise from different socialization or roles assigned to sexes. In the context of ELS, it is difficult to distinguish between sex and gender differences, as both biological dispositions related to sex as well as behaviors related to gender identity may contribute to outcomes of ELS. However, in the context of this chapter, we will discuss sex differences related to the neurobiology of ELS.

Sex differences in the outcomes of ELS may be related to 1) differences in the prevalence of ELS, or types of ELS, between girls and boys and 2) moderating effects of sex on the association of ELS with the risk for developing disorders later in life. In general, it must be noted that boys and girls overall have almost equal risk to be exposed to maltreatment according to the National Child Abuse and Neglect Data System. However, when differentiating between subtypes of maltreatment, boys may have a slightly higher risk to be exposed to physical abuse than girls (Edwards et al., 2003). On the other hand, girls are at higher risk to be exposed to sexual abuse than boys, according to data from the Child Welfare League of America. Hence, sex differences in the likelihood of being exposed to specific types of ELS may be one factor leading to differential risk of women and men for ELS-related disorders. It could be possible that higher rates of sexual abuse contribute to the well-known preponderance of women among patients suffering from depression and anxiety disorders (Gater et al., 1998; Kessler, 2003; Nolen-Hoeksema, 1987; Weissman & Klerman, 1977).

However, in addition to sex differences in the exposure to types of ELS, there are also moderating effects of sex in the response to ELS. Hence, sex interacts with ELS in predicting risk for various disorders. Specifically, it appears that women are at higher risk to develop depression and

anxiety disorders after ELS compared with men (Rind, Tromovitch, & Bauserman, 1998). For example, women with a history of ELS have a two-fold greater risk for developing PTSD than men with comparable experiences. Data from the National Comorbidity Survey confirm these results (Kessler, 2003). These data further suggest differential risk between men and women after ELS, with a higher risk for depression and anxiety disorders after ELS in women and a greater risk for substance use disorders after ELS in men.

Such sex differences in the strength of the association between ELS and risk for later disorders may be attributable to sex differences in the neurobiological responses to stress (see, e.g., Heim et al., 2008a; Heim et al., 2008b). Rodent studies suggest that females generally exhibit greater magnitude and duration of HPA axis responses to stress than males (Rhodes & Rubin, 1999), though findings in humans are not entirely consistent (Kudielka & Kirschbaum, 2005; Young, 1998). Sex differences in neuroendocrine stress responses have previously been attributed to direct effects of circulating estrogen on CRH neurons. For example, chronic estradiol treatment of ovariectomized rats enhances CRH mRNA expression in the PVN and increases ACTH/corticosterone responses to stress (Burgess & Handa, 1992; Swanson & Simmons, 1989). Short-term estradiol treatment of adult men induces increased ACTH, cortisol, and norepinephrine responses to psychosocial stress (Kirschbaum et al., 1996). Estrogen receptor mRNA has been localized in parvocellular CRH neurons of the PVN and there is evidence for an estrogen-responsive portion of the promoter region of the human CRH gene, which confers estrogen enhancement of CRH expression in CV-1 transfected cells (Vamvakopoulos & Chrousos, 1993). Sex steroids also interact with other neurotransmitter systems involved in the stress response, such as the serotonin system (Bethea, Mirkes, Su, & Michelson, 2002; Smith, Henderson, Abell, & Bethea, 2004). Progesterone has also been implicated in modulating these systems (Centeno et al., 2007).

However, sex differences in HPA axis responses to stress have now also been observed in humans, independent of acute gonadal steroid effects (Roca et al., 2005). Hence, other factors that might determine sex differences in the stress response therefore include genomic differences, organizational differences in brain structures or developmentally programmed effects of gonadal steroids (Kudielka & Kirschbaum, 2005; McEwen, 2001; Roca et al., 2005). Of note, sex steroids play a role in lifelong structural plasticity of several brain regions, including areas involved in stress responsiveness, i.e., the hippocampus and amygdala (McEwen, 2001). For example, it has been reported that estrogen levels in young women are correlated with gray matter volume in limbic regions (for an overview see Blakemore et al., 2010). Functional neuroimaging studies identified sex differences in the brain's response to fear stimuli (Schienle, Schafer, Stark, Walter, & Vaitl, 2005; Williams et al., 2005). Such processes may eventually converge into the basis of sex differences in the long-term neurobiological consequences of ELS that may translate into differential risk for psychopathology. Accordingly, female rhesus monkeys repeatedly separated from their mothers between 3 and 6 months of age exhibited increased cortisol responses to subsequent separation and flattened basal cortisol cycles at later ages; however, these changes were not observed in male macaques (Sanchez et al., 2005). Few studies in humans have systematically assessed sex differences in the neurobiological effects of ELS. Maltreated girls exhibit more dysregulation of the HPA axis than maltreated boys, even before puberty (Doom, Cicchetti, Rogosch, & Dackis, 2013). Of note is a recent longitudinal study that suggests that girls are more vulnerable than boys to exhibit impaired functional connectivity between PFC and limbic regions as a function of their cortisol levels at age 4.5 years (Burghy et al., 2012). A study by Buss and colleagues (2012) suggests that girls are more vulnerable to glucocorticoid levels of their mothers during mid gestation, with those girls exposed to high levels showing larger amygdala volumes and more affective symptoms at age 6–9 years; this association was not seen in boys. Scrutinizing the neurobiological basis of sex differences in the pathological effects of ELS will be an important area of future research. There is also emerging evidence for complex three-way interactions between sex, genotype, and ELS in predicting disease risk.

Gene–Environment Interaction in the Effects of Early-Life Stress

In addition to timing effects of ELS and sex differences, individual variation in genotype may interact with ELS to contribute to variability in clinical outcomes (see Heim & Binder, 2012, for review). Many of the disorders, for which ELS is a significant risk factor, have in part a heritable basis. For example, the overall heritability of major depression is estimated to be between 30 and 40%; however, this effect size also shows that environmental factors play a crucial role in this disorder. Of note, in a large meta-analysis of genome-wide association data for major

depression that included 5763 cases and 6901 controls, none of the tested polymorphisms reached genome-wide significance levels (Wray et al., 2012). These data suggest that major depression is likely not determined by main effect of genes, but rather by complex interactions of genes and environment, including ELS. While epidemiological and family data have long advocated the importance of gene–environment interactions in psychiatric disorders (Cadoret, Yates, Troughton, Woodworth, & Stewart, 1995; Kendler & Eaves, 1986), studies investigating these interactions on a molecular level have only been published since 2003. These studies have focused on candidate genes in neurobiological systems of known relevance to stress and emotion processing or neural plasticity. A rapidly growing number of studies have since documented an important role of gene–environment interactions in predicting the clinical outcomes of ELS. In addition to studying clinical outcomes, more recent studies have identified effects of gene–environment interactions on changes in neurobiological systems that mediate the link between ELS and a given clinical outcome, such as changes of the HPA axis or neural function, representing so-called intermediate phenotypes.

Serotonin Transporter Gene

The first study of a gene–environment interaction moderating the association between ELS and depression was published by Caspi and colleagues (2003). Using data from a prospective study of a representative birth cohort in Dunedin, New Zealand, it was shown that a common polymorphism in the promoter region of the serotonin transporter gene (5-HTTLPR), which is associated with altered transporter function, moderated the association between definite exposure to maltreatment and depression in adulthood. Specifically, carriers of one or two copies of the short allele (s/s or s/l) exhibited significantly more depressive symptoms, diagnosable depression, and suicide attempts in relation to ELS compared with individuals who were homozygous for the long allele (l/l). In the absence of ELS, this polymorphism had no effect on depression risk. Since the publication of this first finding, a surge of studies has attempted to replicate or extend the initial result. While the effect of the 5-HTTLPR in moderating the link between ELS and depression has been confirmed in a number of studies, including twin studies, there are also a number of negative studies that could not replicate the effect. While two early meta-analyses across studies suggested that the gene–environment interaction effect between 5-HTTLPR and ELS in the prediction of depression might not be valid (Munafo, Brown, & Hariri, 2008; Risch et al., 2009), a more recent meta-analysis of more available studies by Karg and colleagues (2011) confirmed a significant interaction effect between 5-HTTLPR allele status and ELS in the prediction of depression (Karg, Burmeister, Shedden, & Sen, 2011). Some of the inconsistencies across studies may be explained by the definition of the outcome variables. For instance, Uher and colleagues (2011) found that the interaction of 5-HTTLPR and ELS in the prediction of depression best predicts persistent depression, but not single episodes. Additional moderators, such as sex differences and ethnic background, also may contribute to further variability.

The 5-HTTLPR effect in moderating the link between ELS exposure and clinical outcome is not limited to the prediction of depression, but also impacts on other stress-related disorders and phenotypes, including PTSD, posttrauma suicide attempt, alcohol consumption, substance use, cigarette smoking, sleep disturbances, anxiety sensitivity, and impaired self-regulation of negative affect (see, e.g., Caspi, Hariri, Holmes, Uher, & Moffitt, 2010; Heim & Binder, 2012). Taken together, this would suggest that an interaction of 5-HTTLPR genotype and ELS moderates the susceptibility to a number of stress-related disorders, perhaps by determining the brain's response to stress or capacity for emotional regulation, particularly in circuits where serotonin serves as a transmitter to modulate these functions. Accordingly, neuroimaging studies have demonstrated an effect of the 5-HTTLPR genotype on amygdala reactivity as well as connectivity between the cingulate cortex and the amygdala (Hariri et al., 2005; Munafo et al., 2008; Pezawas et al., 2005). Interestingly, children carrying the s allele of the 5-HTTLPR show greater regional brain activation to sad movies compared with children carrying the long allele (Fortier et al., 2010). Hence, the reported decrease in function of the serotonin transporter in carriers of the s allele seems to lead to altered emotional brain activation pattern that might increase vulnerability to stress and the risk for a number of psychiatric disorders and medical diseases (Heim & Binder, 2012).

Corticotropin-Releasing Hormone Receptor Gene

In addition to the 5-HTTLPR, other genes involved in stress regulation have been studied as candidates in moderating the link between ELS and clinical outcomes. Given the importance of the CNS CRH system in mediating and integrating neuroendocrine, autonomic and behavioral responses to stress, and given the evidence that the CRH/HPA system is critically altered by ELS in animal models and human studies, variations in the gene that encodes for CRHR1, the receptor mediating

the stress-mediating effects of CRH, seem promising candidates for the investigation of gene–environment interactions in predicting the clinical outcomes of ELS.

In a first human study, our group demonstrated that polymorphisms in the CRHR1 gene interact with ELS, which was defined as sexual, physical, or emotional abuse, to predict adult depressive symptoms in an inner city African American sample of over 400 individuals (Bradley et al., 2008; Figure 21.4). We identified two protective CRHR1 haplotypes, which refer to a combination of polymorphisms. Individuals with high levels of ELS who were homozygous for the protective haplotypes had significantly less current depressive symptoms than abused individuals carrying other haplotype combinations. This finding has been replicated in additional cohorts with different ethnicities (Bradley et al., 2008; Polanczyk et al., 2009) as well as for a different type of ELS, namely physical neglect (Grabe et al., 2010); however, one study reported the effect of the CRHR1 haplotype in moderating depression risk after ELS only in African Americans, but not in European Americans (Kranzler et al., 2011).

It may be suggested that polymorphisms in the CRHR1 gene are associated with altered HPA axis responses to stress, which may then moderate the effects of ELS on HPA axis function. Accordingly, Tyrka and colleagues (2009) reported in healthy individuals that those exposed to ELS who carried the CRHR1 protective alleles showed a normal cortisol response to the dexamethasone/CRH test, whereas those individuals exposed to maltreatment who carried the risk alleles showed an escape from suppression in this test, indicating HPA axis hyperactivity. Notably, this effect of a genotypic variation in the CRHR1 receptor, that mediates CRH effects on the HPA axis, is not seen in the absence of ELS, indicating a gene–environment interaction at the neuroendocrine level. Our group (Heim, Bradley, et al., 2009) replicated and extended the aforementioned finding. We also observed an interaction effect between the CRHR1 protective haplotype and ELS in predicting cortisol responses to the dexamethasone/CRH test, with only risk allele carriers with ELS exhibiting escape from suppression. This effect was mainly present in male individuals who predominantly had experienced physical abuse, suggesting interactions between genes, sex, and type of abuse. Polymorphisms in the CRHR1 gene also interact in ELS to predict neuroticism (Deyoung et al., 2011). In nonhuman primates, it was shown that CRHR1 polymorphisms influence anxious temperament and metabolic activity in the hippocampus and amygdala. Taken together, the CRHR1 risk haplotype appears to be associated with increased CRHR1 signaling in neural circuits involved in stress and emotion processing, leading to a hyperactive HPA axis following exposure to ELS. However, the molecular mechanism for this effect is unknown (see Heim & Binder, 2012).

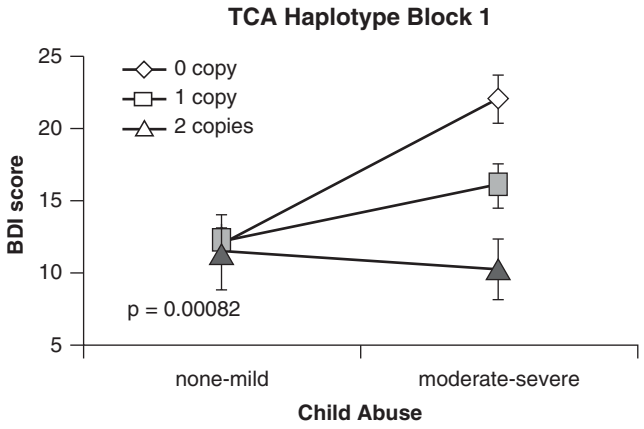


Figure 21.4 Example of a gene–environment interaction predicting depression risk after ELS. A protective TCA haplotype, formed by rs7209436, rs4792887, and rs110402, is associated with resilience against depression after ELS. *Source:* Adapted from R. G. Bradley, E. B. Binder, M. P. Epstein, Y, Tang, H. P. Nair, W. Liu, . . . K. J. Ressler, Influence of child abuse on adult depression: Moderation by the corticotropin-releasing hormone receptor gene, *Archives of General Psychiatry, 65*(2), 190–200, 2008.

Glucocorticoid Receptor and FK506 Binding Protein 5 Genes

A number of studies focus on candidate genes involved in feedback regulation of the CNS CRH system and the HPA axis. Given the well-established evidence that relative resistance of the GR contributes to HPA axis hyperactivity and risk for depression, especially after ELS exposure, several studies have investigated whether variations in the genes coding for GR as well as for co-chaperones of the GR, such as FK506 binding protein 5 (FKBP5), moderate the risk for developing depression or other affective disorders after ELS exposure.

In a longitudinal study of 906 elderly individuals, Bet and colleagues (2009) observed an interaction between GR polymorphisms 22/23EK and 9beta and ELS in predicting clinically relevant symptoms of depression. A larger number of studies have focused on the role of the FKBP5 gene in modulating the clinical outcomes of ELS. The FKBP5 gene codes for FKBP5, a co-chaperone of the GR, bound to hsp90, that fine-tunes GR sensitivity. Upon activation of the GR by cortisol, FKBP5 is removed from the hormone-receptor complex and replaced by FKBP4. The hormone-receptor complex develops affinity for the nucleus and trans-locates to the nucleus to bind to DNA.

Through binding to glucocorticoid response elements (GREs) in the FKBP5 gene, subsequent FKBP5 gene expression is increased, which binds to the GR and deactivates the GR. This mechanism represents an ultra-short feedback loop of GR activation and a molecular mechanism for increasing GR resistance (see Binder, 2009). A number of studies have shown that polymorphisms in the FKBP5 gene are associated with increased risk for depression and PTSD after ELS exposure (Binder et al., 2008; Luijk et al., 2010; Roy, Gorodetsky, Yuan, Goldman, & Enoch, 2010; Worthman, Kohrt, Ressler, & Binder, 2010; Xie et al., 2010; Zimmermann et al., 2009). It has been shown that polymorphisms in FKBP5 that are associated with increased risk for affective disorders after ELS disrupt the ultrashort negative feedback loop between FKBP5 and GR, leading to GR resistance and lack of feedback control of the HPA axis (Binder, 2009; Binder et al., 2008). Accordingly, FKBP5 risk allele carriers show a prolonged cortisol response to a psychosocial laboratory stressor (Ising et al., 2008). Taken together, these findings suggest that genetic variations interfering with feedback control of the stress response systems are associated with increased stress vulnerability and risk for developing psychiatric disorders after ELS. Compromised GR function as a result of gene–environment interactions may also plausibly contribute to inflammation and a range of physical diseases after ELS. Epigenetic mechanisms may be involved in the molecular mechanisms of gene–environment interactions regulating GR expression.

Other Candidate Genes

Other genes that have been studied as potential moderators of the link between ELS and clinical outcomes include genes involved in neuronal plasticity, such as brain-derived neurotrophic factor (BDNF), and stress protection, such as oxytocin receptor.

BDNF is a neurotrophin that is critically involved in neuronal plasticity, as it promotes the growth and differentiation of developing neurons in central and peripheral nervous systems. Synaptic atrophy and loss of dendrites in the hippocampus as a consequence of stress or glucocorticoid exposure is linked to reduced intracellular expression of BDNF. A common polymorphism in the BDNF gene (Val66Met) has been related to deficits in intracellular trafficking and the activity-dependent release of BDNF (Cardoner et al., 2013). Of note, Met allele carriers have a higher risk for depression after ELS compared with Val/Val allele carriers (Aguilera et al., 2009). In accordance with the role of BDNF as a neurotrophic factor, BDNF Met allele carriers, who were exposed to ELS, exhibited significantly less gray matter volume in the subgenual cingulate cortex compared with Met allele carriers without a history of ELS or Val/Val allele carriers. These findings are relevant given that the subgenual cingulate cortex plays a critical role in integrating emotional regulation between medial prefrontal cortex and limbic regions (Gerritsen et al., 2012).

As for the oxytocin receptor gene, it has been shown that carriers of the G/G alleles of the polymorphism rs53576 were overrepresented in a sample of patients with depression (Costa et al., 2009). The same polymorphism has been linked to modulating physiological stress reactivity (Rodrigues, Saslow, Garcia, John, & Keltner, 2009), making it an interesting candidate for investigating gene–environment interactions predicting clinical outcomes after ELS. Our group has shown that rs53576 in the oxytocin receptor gene interacts with ELS in the prediction of emotional dysregulation and attachment style later in life. Specifically, G/G allele carriers were at higher risk for developing emotional dysregulation difficulties compared with A/A and A/G allele carriers. Accordingly, Hostinar and colleagues (2014) found that maltreated children carrying the G/G allele genotype showed more internalizing symptoms than A/G or A/A allele carriers (Hostinar, Cicchetti, & Rogosch, 2014).

Of note, Bradley and colleagues (2014) reported that G/G allele carriers showed particular good health in the context of a supportive early family environment, suggesting that these genes are not *per se* risk genes, but rather reflect susceptibility to environmental influence, for better or worse. Hence, in the context of positive early environmental influences, these genes may confer plasticity leading to positive health outcomes and resilience (Bradley, Davis, Wingo, Mercer, & Ressler, 2013).

Further studies have investigated the potential importance of other genetic variants in moderating the effects of ELS. For example, the catechol-O-methyltransferase (COMT) gene interacts with ELS in predicting cognitive changes, emotion-elicited heart rate reactivity, and self-reported negativity, which are intermediate phenotypes for depression (Gatt et al., 2010b).

Defining the Environment

It should be noted that inconsistencies in results regarding gene–environment interactions may stem from different study designs that used different approaches to define the environmental exposure. For example, the original study by Bradley and colleagues (2008) identified a CRHR1 haplotype that moderates depression risk after ELS in a retrospective study of adults using the CTQ. Polanczyk

and colleagues (2009) were able to replicate this effect in another retrospective cohort in the UK using the CTQ, but failed to replicate the effect in the Dunedin cohort in New Zealand, which employed a mix of prospective and retrospective reports (not based on the CTQ). The authors speculate that the assessment method of ELS is critical in explaining inconsistencies. The CTQ may be more influenced by emotional memories and the CRHR1 haplotype might moderate recollection for traumatic events, which then might predict the development of emotional disorders. When we analyzed the same interaction effect of the CRHR1 gene and ELS exposure in the prediction of depression in an extended cohort of the original Bradley et al. (2008) sample, we observed that the interaction effect was carried by physical abuse, but not by sexual abuse (Heim, Bradley, et al., 2009). Because males experienced more physical abuse than females in our sample, this led to the appearance of a sex-gene-ELS interaction effect that suggested that CRHR1 moderated depression risk after ELS only in males. These examples illustrate the importance of precisely defining and measuring the exposure variables in gene–environment studies (Heim & Binder, 2012).

Multiple Genes and Environments

The rapidly increasing number of studies suggests that contributions to disorders related to ELS are more complex and go beyond single gene-single environment interactions (see Heim & Binder, 2012). As discussed previously, multiple studies have identified single candidate genes that moderated the link between ELS and depression or other disorders. These candidate genes were selected on the basis of their theoretical involvement in influencing stress responses and emotional regulation. Given the fact that multiple genes seem to play a role in predicting clinical outcomes after ELS, researchers have started to investigate several genes simultaneously, allowing for the elucidation of interactions between multiple genes and the environment in predicting clinical outcomes.

Several studies have now shown that there are complex interactions of multiple genes interacting with ELS in predicting clinical outcomes. Such interactions have been reported between 5-HTTLPR and polymorphisms in CRHR1, BDNF, and COMT in the prediction of depression (Aguilera et al., 2009; Conway, Hammen, Brennan, Lind, & Najman, 2010; Gatt, Nemeroff, et al., 2010; Gatt, Williams, et al., 2010; Kaufman et al., 2006; Ressler et al., 2010). For example, Ressler and colleagues (2010) reported that the 5-HTTLPR s allele appears to only increase risk for depression in carriers of CRHR1 risk haplotype. In addition, different types of environmental exposures can further moderate gene–environment interactions. For example, social support as well as general crime rate and unemployment rate have been shown to moderate the association between 5-HTTLPR and PTSD in victims of hurricane Kathrina (Kilpatrick et al., 2007; Koenen et al., 2009). In a sample of nearly 600 children, Cicchetti and Rogosch (2012) assessed polymorphisms in four genes, including 5-HTTLPR, CRHR1, dopamine receptor D4–521C/T, and oxytocin receptor, as well as maltreatment histories, and investigated gene–environment interaction effects in predicting resilient adaptive functioning in low-income children. Child maltreatment had a strong negative main effect on children's resilient functioning; however, no main effects for any of the genotypes were found. Gene–environment interactions were found for each of the assessed genotypes and child maltreatment in the prediction of resilient functioning. Across the four genes, a composite of the genotype had an effect on resilient functioning in nonmaltreated children, whereas genetic variation had a negligible effect on promoting resilience in maltreated children. It is likely that even more genes interact with even more environmental exposures to produce risk for a given disorder. Consequently, studying such multiple interactions will require large cohorts that provide sufficient power to detect effects (Heim & Binder, 2012).

Taken together, there is increasing and strong evidence for multiple gene-environment interactions in predicting clinical outcomes of ELS. It is noteworthy that main effects of genes are almost absent in the literature. Larger cohorts and consortia studies are needed to evaluate whether any of the candidate genes will remain a significant predictor when studying genome-wide effects on risk for disorders as a function of ELS. Such genome-wide association studies, that are hypothesis-free, may also identify novel genes that are important moderators of the link between ELS and a given disorder, leading to a novel understanding of the involved mechanisms.

Psychosocial Resilience Factors

In addition to the role of timing of ELS, sex differences, and individual genotypes in the prediction of clinical outcomes after ELS, several psychosocial factors and other environmental aspects moderate individual outcomes after ELS and can promote resilience. Oftentimes, ELS (i.e., maltreatment) occurs within the core family and the primary caregivers are the perpetrators. However, if available, an intact and positive bond between the child and one primary caregiver is probably the strongest psychosocial resilience factor (Wu et al., 2013). Furthermore, social

support from teachers and peers has been identified as a protective factor (Werner, 2012). Other factors that may augment resilience in the face of stress or trauma include positive affect and optimism (Folkman & Moskowitz, 2000), better overall physical health (Warner, Schwarzer, Schuz, Wurm, & Tesch-Romer, 2012), and higher IQ (Masten et al., 1999). In addition, the ability to reevaluate negative thoughts or situations, a skill also known as cognitive reappraisal, has been associated with resilience (Wu et al., 2013). With regard to coping, active coping styles such as behavioral and psychological strategies aiming at changing the quality or perception of the stressor are linked to greater adaptability and psychological resilience in comparison with avoidant coping styles characterized by emotional and behavioral withdrawal (Holahan & Moos, 1987). As mentioned before, a supportive social environment as well as support-seeking behavior is associated with resilient functioning even under circumstances of major adverse life events (Ozbay, Fitterling, Charney, & Southwick, 2008). Kaufman and colleagues (2006) reported that social support buffers the interaction effect of risk genes in combination with ELS on depression in maltreated children. More such studies are needed that investigate the influence of psychosocial resilience factors on clinical outcomes as a function of multiple interacting genetic and environmental risk factors, ideally in longitudinal designs.

Taken together, there is evidence that timing of ELS, sex differences, genetic makeup, and psychosocial resilience factors all contribute to individual variability in the clinical and neurobiological outcomes of ELS. Of note, gene–environment interactions may be subject to sensitive periods as well, as they may be relevant for developmental periods during which systems that use a particular neurotransmitter, such as serotonin, may be maximally plastic. Understanding the interplay and developmental trajectories of the effects of these various moderating factors may ultimately open novel strategies to develop predisease diagnostic tests that identify individuals with ELS who are at particular risk for developing a specific disorder or who might be responsive to a particular type of intervention. Understanding mechanisms of risk versus resilience after ELS will further identify modifiable targets for prevention and intervention of adverse clinical outcomes.

EPIGENETIC MECHANISMS OF THE EFFECTS OF EARLY-LIFE STRESS

As shown in the previous section, gene–environment interactions across a developmental trajectory with potential sensitive periods of plasticity produce neurobiological phenotypes with vulnerability to stress and risk for clinical disorders versus resilience. However, the molecular mechanisms that may underlie gene–environment interaction and their sensitivity to developmental timing are not well understood. In other words, how can social-emotional experiences between caretaker and child, such as maltreatment, interact with a stable DNA allele sequence to produce neurobiological changes that produces risk versus resilience to a range of disorders? In this context, epigenetic programming has been studied as a mechanism that may allow ELS to induce stable changes in gene regulation, leading to the long-term neurobiological consequences of ELS and risk for disorders. Such epigenetic programming may occur in dependence from risk allele status, thereby underlying gene–environment interactions in determining clinical outcomes (see Heim & Binder, 2012; Klengel et al., 2013).

Epigenetic programming refers to processes by which the environment regulates DNA transcriptional activity without altering the DNA sequence (Figure 21.5). Epigenetic changes are produced by DNA (de-) methylation, histone modifications, and noncoding RNAs (Jaenisch & Bird, 2003; Ptak & Petronis, 2010). Of these epigenetic processes, DNA (de-) methylation has been the most studied in relation to ELS. Specifically, DNA methylation refers to the addition of methyl groups to cytosines in cytosine-guanine (CpG) dinucleotides, which reduces the access of transcription factors to regulatory elements of the DNA, leading to transcriptional repression by decreasing the binding of specific transcriptional enhancers (Murgatroyd, Wu, Bockmuhl, & Spengler, 2010). Specific methyl CpG-binding domain (MBD) proteins bind to methylated DNA and interact with histone deactylases as well DNA methyltransferases to produce silencing of the gene and to stabilize DNA methylation status (Chen et al., 2003; Martinowich et al., 2003; Murgatroyd et al., 2009). Conversely, demethylation and removal of MBD proteins leads to increased gene activity (see Heim & Binder, 2012). Several studies in animal models and humans have now shown that ELS induces epigenetic alterations in stress-relevant genes that lead to changes in gene expression and, ultimately, a vulnerable neurobiological phenotype with increased risk for disorders.

In both rodents and humans, ELS has been associated with hypermethylation of DNA sequences in the gene encoding for the GR. In a rodent model, Weaver and colleagues (2004) observed increased DNA methylation in a neuron-specific promoter region of the GR gene in hippocampal tissue of offspring of mothers that exhibited

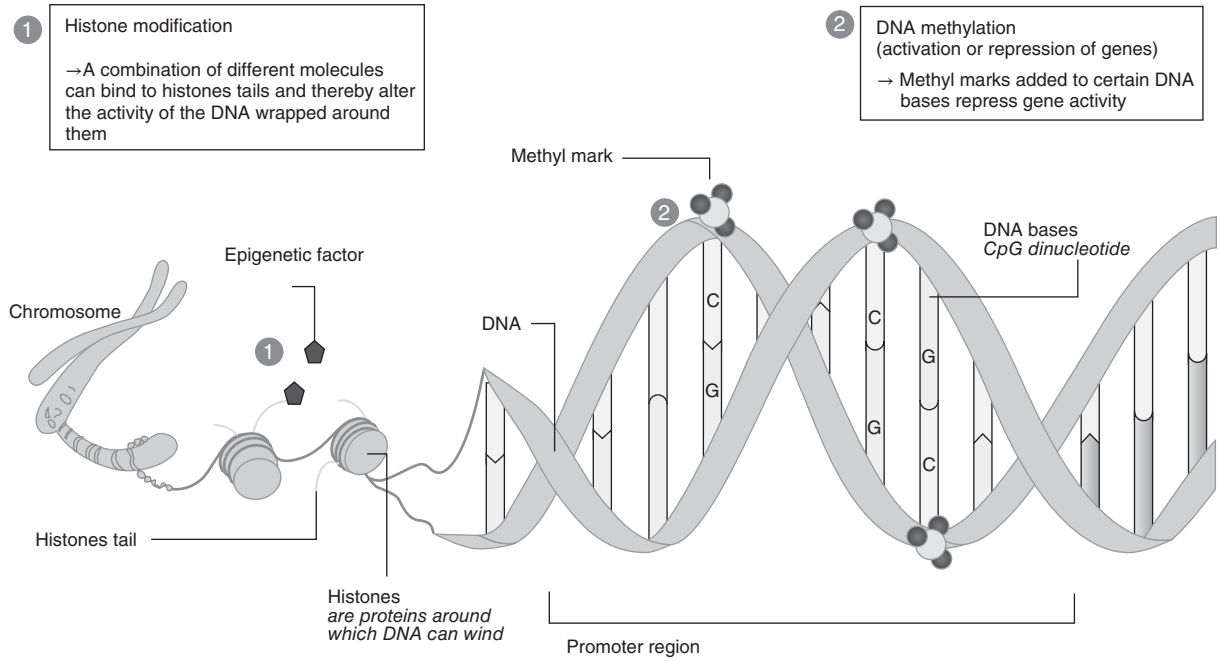

Figure 21.5 Principles of epigenetic programming. Two main epigenetic mechanisms involved in regulation of gene expression.

low maternal care behavior compared with offspring of mothers showing high maternal care behavior. This hypermethylation was associated with a decrease of NGFI-A transcription factor binding and decreased GR mRNA expression. In a postmortem study of suicide victims, reported histories of childhood abuse were associated with the same DNA hypermethylation in the GR gene in hippocampal tissue as well as decreases in NGFI-A binding and increases in GR mRNA expression (McGowan et al., 2009). Similar hypermethylation of the GR gene as a correlate of ELS was measured in leukocytes of healthy subjects (Tyrka, Price, Marsit, Walters, & Carpenter, 2012) as well as in patients with major depression or bipolar disorder (Perroud et al., 2014; Perroud et al., 2011). These findings of epigenetic silencing of the GR gene are in line with reports of long-term GR resistance and stress hormone system dysregulation following exposure to ELS.

Epigenetic changes have also been reported for other genes relevant to stress regulation in rodent models. Mice exposed to maternal separation exhibit hypomethylation of an enhancer region in the arginine vasopressin (AVP) locus, leading to increased binding of transcription factors and consequently an increase in AVP transcription and a lasting increase in AVP release (Murgatroyd et al., 2009). Similarly chronic social stress in adult animals has been shown to induce long-term hypomethylation in the promoter region of the gene encoding CRH, leading to an increase in CRH mRNA expression, but only in animals that display social avoidance (Elliott, Ezra-Nevo, Regev, Neufeld-Cohen, & Chen, 2010). Methylation changes have also been in the BDNF gene and were associated with altered BDNF mRNA expression in hippocampal and PFC tissue of rats exposed to stressed mothers who exhibited abusive behaviors (Roth, Lubin, Funk, & Sweatt, 2009). Whether these results translate to humans is unknown. Taken together, these results of epigenetic modification in CRH, AVP and BDNF genes are in line with dysregulation of the stress hormone system, neural changes, and risk for affective disorders after ELS.

These results focusing on methylation changes in single candidate genes were recently extended to investigate broader epigenetic changes. In rats exposed to low maternal care, altered methylation was reported for a larger region of the chromosome containing the GR gene, and within this larger region, the protocadherin gene family, which is implicated in synaptogenesis, showed the strongest association with exposure to low maternal care (McGowan et al., 2011). In humans, a genome-wide study of promoter methylation in hippocampal tissue of suicides revealed differential methylation of 362 genes in association with ELS, particularly genes involved in cellular or neural plasticity (Labonte et al., 2012). ELS-related differences in genome-wide methylation patterns are also seen in leukocytes from humans and are associated with changes

in gene expression (Mehta et al., 2013). Taken together, both, methylation and de-methylation of genes involved in regulating stress responses and neural plasticity have been reported as a consequence of ELS. The mechanism that underlies methylation changes might involve dissociation of MDB proteins from methylated DNA by phosphorylation, leading to removal of previously established DNA marks. Another potential mechanism involves glucocorticoid effects, as binding of GR to GREs in DNA leads to demethylation of CpGs around the GRE (see Heim & Binder, 2012).

A major advance in our understanding of the molecular mechanism mediating gene–environment interactions after ELS was recently provided by a seminal study by Klengel and colleagues that mapped a precise cascade of events that leads from ELS exposure to affective disorders via glucocorticoid-induced and genotype-directed epigenetic effects (Klengel et al., 2013). It was demonstrated in human leukocytes that a functional polymorphism altering chromatin interaction between the transcription start site and long range enhancers in the FKBP5 gene increases the risk of developing affective disorders in adulthood by allele-specific, ELS-dependent DNA demethylation in functional GREs of FKBP5. This demethylation was associated with increased stress-induced gene transcription and long-term dysregulation of the stress hormone system as well as a global impact on the function of immune cells and the structure of brain areas associated with stress regulation in risk allele carriers. Of note, FKBP5 demethylation in blood cells correlated with ELS, but not with current cortisol levels or adult trauma, suggesting that this epigenetic mark originated from childhood. To verify whether this finding that was obtained in peripheral leukocytes translates to neural cells and is indeed inducible by stress hormone elevations, in vitro experiments in human hippocampal progenitor cells were additionally performed. These experiments showed that a long-term demethylation of the same CpGs occurs after incubation of hippocampal progenitor cells with glucocorticoids, suggesting that human findings in leukocytes could extend to brain tissue and are dependent on GR activation. In addition, this demethylation was only seen in proliferating and differentiating neurons, but not in mature neurons, further evidencing that this epigenetic mark is a developmental event. Taken together, this study thus far provides the best evidence for a stress-induced molecular mechanism that translates ELS into risk for psychiatric disorders in genetically susceptible individuals. As the study clearly points to the existence of a sensitive period for this epigenetic effect, longitudinal studies in children are needed that map temporal trajectories of this molecular mechanism, which is essential for designing novel intervention strategies.

SUMMARY

We here provided a review of research concerning the relationship between exposure to adverse experiences during childhood and the risk for psychiatric disorders and medical diseases in later life. We have shown that ELS interacts with genetic factors to produce a neurobiological phenotype with changes in a connected circuitry of brain regions implicated in stress processing and emotion regulation. These changes likely lead to failure of this neural network to adapt or compensate in response to subsequent challenge, leading to exaggerated physiological responses to stress and failure of regulatory control, with impact on multiple organ systems and the immune system, as well as behavioral changes reminiscent of depression and anxiety disorders. The molecular mechanism that is at the core of the gene–environment interaction likely involves epigenetic programming of genes relevant to stress regulation with impact on gene expression, which ultimately underlies dysregulation of neurobiological stress systems and physiological and behavioral changes. Protective gene variants might not be susceptible to such programming. Psychosocial resilience factors and coping might buffer the effects of ELS through top-down regulation. There is reasonable foundation to believe that age at the time of ELS will critically interact with trajectories of brain regional development to produce variable outcomes (see Figure 21.6). These profound and stable changes induced by ELS are likely transmitted into the next generation.

FUTURE DIRECTIONS

While the here summarized research has provided major insights into the biological and molecular mechanisms that mediate the persistent effects of ELS on risk for a range of disorders, as well as the modification of this risk by gene–environment interactions, most human studies on the neurobiological effects of ELS are cross sectional or rely on retrospective self-reports of ELS in adult samples, not allowing for causal inferences. Cross sectional studies further do not allow for the identification of developmental trajectories of biological or behavioral changes over time, nor do they inform about sensitive periods for the effects of ELS. Available longitudinal studies in children were often started decades ago, and thus were not able

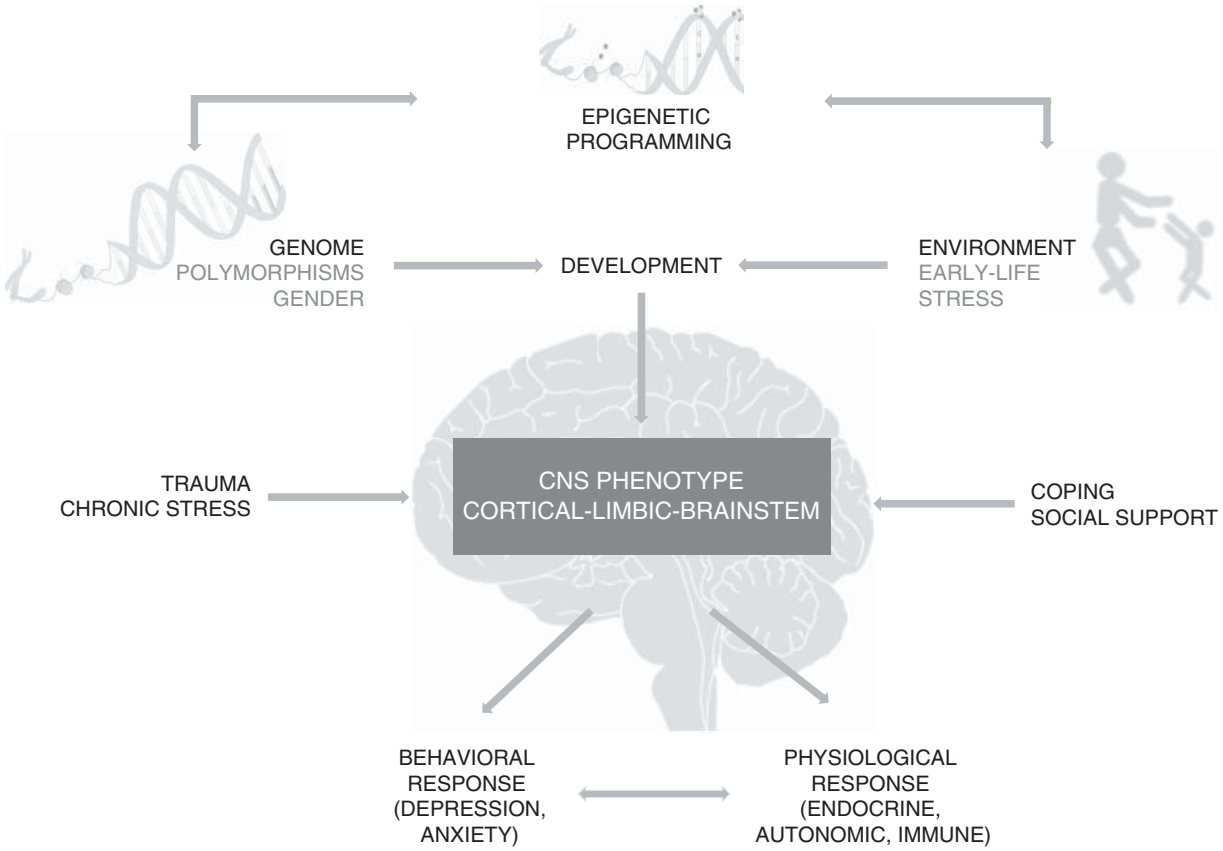

Figure 21.6 Vulnerability model. Genetic disposition and early-life stress interact via epigenetic programming to shape a vulnerable phenotype with changes in cortical–limbic–brainstem circuits. Upon additional stress or trauma exposure, maladaption in these circuits leads to increased endocrine–autonomic and behavioral–emotional responses. Social support and successful treatments may modify the stress responses system in different components. *Source:* Modified Ladd, C. O., Huot, R. L., Thrivikraman, K. V., Nemeroff, C. B., Meaney, M. J., & Plotsky, P. M. (2000). Long-term behavioral and neuroendocrine adaptations to adverse early experience. *Progress in Brain Research, 122*, 81–103.

to collect cutting-edge neurobiological or epigenetic data in the immediate aftermath of exposure to ELS or across development. Most studies, cross sectional or longitudinal, did not adopt a multisystem approach. Therefore, the implementation of longitudinal studies in children are urgently needed to understand the immediate processes of biological embedding of ELS over time, as well as their moderation by genotype, and that link these biological processes with symptom development. There is no doubt that ELS induces a fundamental change in stress systems at an early point in development, which programs these systems for life. Elucidating these immediate developmental events will provide insight into the early mechanisms that are responsible to produce this persistent and pronounced programming of stress systems and risk for stress-related disorders as well as its moderation by gene–environment interaction. In terms of gene–environment interactions after ELS and epigenetic embedding of ELS, genome-wide approaches will need to be applied, which will require large cohort studies.

TRANSLATIONAL IMPLICATIONS

There is a dire gap of translation between insights into the neurobiological and molecular mechanisms that link ELS exposure with long-term risk for clinical disorders and the use of this knowledge to develop new diagnostic markers and mechanism-based treatments. Understanding the precise mechanisms of biological embedding of ELS, as well as their moderation by genetic factors, will allow for the development of diagnostic markers that identify children at risk for developing psychopathological outcomes. In addition, such markers can identify children who might be susceptible to a specific intervention.

Precise knowledge of the mechanisms underlying the biological embedding of ELS will allow to develop completely novel and pathophysiology-based interventions that directly target these mechanisms to reverse or counteract biological changes after ELS and reduce or prevent disease risk. Understanding the temporal dynamics of biological embedding, including sensitive periods, may help to identify developmental time windows for specific interventions.

CONCLUSION

Taken together, the notion that ELS, in the context of genetic susceptibility, is a major risk factor for a range of disorders is widely accepted. Future research should elucidate the complex interplay of developmental trajectories, multiple genes, multiple environments, and molecular mechanisms in the relationship between ELS and clinical outcomes. Hopefully, such research will allow for designing novel and effective mechanism-based interventions that we can offer to children exposed to ELS, which might help reduce the adverse consequences of ELS and interrupt the transmission of ELS and its consequences across generations.

REFERENCES 870

Psychophysiological methods have been used throughout much of the history of modern psychopathology research. Measures of basal skin resistance were first used over 125 years ago in the laboratory of French neurologist Jean Charcot by Vigouroux (1879, 1888), who assessed differences in physiological arousal among various clinical groups. In 1904, Carl Jung reported a positive association between emotional responding to word stimuli and electrodermal reactivity (see Neumann & Blanton, 1970), foreshadowing later work linking skin conductance to state anxiety (e.g., Katkin, 1965). Soon thereafter, Eppinger and Hess (1910/1915) noted abnormally low resting heart rate among delinquents, a discovery that garnered considerable attention in the psychopathology literature for much of the next 100 years (see Lorber, 2004).

Psychophysiological research continues to burgeon in the 21st century. At present, two top-tier scientific journals (*Psychophysiology* and the *International Journal of Psychophysiology*) are devoted exclusively to measurement, assessment, and neurobiological mechanisms of psychophysiological phenomena. Many articles published in these journals address psychophysiological correlates of mental illness. Use of psychophysiological methods is also now common among those who publish in mainstream psychopathology journals.

Despite this popularity, psychophysiology has no universal definition. Although often considered a discipline in its own right (see, e.g., Berntson, Cacioppo, & Sarter, 2002), psychophysiology encompasses studies of phenomena that

[1]Color versions of Figure 22.9 is available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

cut across many areas of behavioral science, including health psychology (e.g., hypertension, insomnia; see Stoney & Lentino, 2000; Steptoe, 2007), forensic psychology (e.g., lie detection; see Iacono, 2007), social psychology (e.g., threat appraisal; see Tomaka, Blascovich, Kelsey, & Leitten, 1993), and psychopathology (e.g., delinquency, intentional self-injury, schizophrenia; see Beauchaine & Gatzke-Kopp, 2012; Edgar, Keller, Heller, & Miller, 2007; Levy, Sereno, Gooding, & O'Driscoll, 2010). These disciplines are characterized by different research questions, are born of different intellectual, philosophical, and research traditions, and often focus on different levels of analysis in terms of constructs (e.g., cognition, emotion, motivation), neurobiological systems (e.g., cortical, subcortical, peripheral), and social contexts (e.g., endogenous, exogenous, cultural). Nevertheless, psychophysiological methods are used quite fruitfully in each discipline.

Given this cross-disciplinary appeal, it is sometimes tempting to equate psychophysiology with a set of methods, such as electrocardiography, electroencephalography, and various brain imaging techniques, which can be used to identify biological bases of any human behavior. This conceptualization is potentially harmful, however, because it (1) encourages methods-driven training, research, and scholarship in which all psychological phenomena are studied in the same way and at the same level of analysis, depending on an individual's specific method of expertise (Sternberg, 2007), and (2) reinforces anachronistic reductionism in which 1:1 correspondences between psychological outcomes and physiological functions are assumed, which is rarely the case (see Berntson et al., 2002). Methods-driven research often impedes scientific progress, and is antithetical to modern multiple levels of analysis approaches to studying physiology-behavior-relations (e.g., Berntson & Cacioppo, 2004; Cicchetti, 2008). Thus, psychophysiological methods are best chosen based on specific research problems, and used in conjunction with other methods such as molecular genetics, behavior observation, self-reports, informant-reports, interviews, etc. (Beauchaine & Gatzke-Kopp, 2012; DeVries & Nelson, 2007; Sternberg, 2007). This is fully consistent with the developmental psychopathology perspective, outlined below.

In our view, psychophysiology is best defined as the study of (i.e., -ology) interactions between physiological systems (i.e., -physi-), and psychological states and traits (i.e., psycho-; see Fox, Hane, & Pérez-Edgar, 2006). Defined as such, psychophysiological methods can be especially useful in characterizing interactions between individual-level vulnerabilities and environmental risk factors in shaping maladaptive behavior. This is especially important for transactional models of psychopathology in which (1) specific biological vulnerabilities predispose individuals to mental illness, particularly in contexts of potentiating environmental risk; (2) vulnerabilities and risk factors span levels of analysis from genes, to intervening biological systems, to social contexts including families, neighborhoods, and cultures; and (3) causal influences on the development of psychopathology operate across these levels of analysis, sometimes changing in direction through both endogenous and exogenous mechanisms (see Beauchaine & Gatzke-Kopp, 2012; Mead, Beauchaine, & Shannon, 2010). Disentangling such processes is a primary objective of developmental psychopathology (Sroufe & Rutter, 1984).

THE DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE

Until late in the twentieth century, formulations of psychopathology were dominated by questions of nature versus nurture. The more longstanding belief was that mental illness derived from dysfunction located within individuals. This assumption pervades much of written history, and dates to works by Hippocrates. Galen, extending Hippocrates' writings, attributed temperamental traits including psychopathology to imbalances in four bodily humors. According to Galen, emotional volatility resulted from excess yellow bile, whereas melancholia resulted from excess black bile.

Other historically influential accounts of psychopathology—most notably Freud's psychoanalytic theory—traced causes of mental illness to environmental experience. Freud attributed psychopathology to intrapsychic conflicts among the id, ego, and superego. According to Freud, both the ego and superego derived their relative strength or weakness almost entirely from early experience.

Questions of nature versus nurture were largely irresolvable until the mid- to late-20th century because modern methodological and technological advances, including behavioral genetics (especially statistical modeling of twin registries), molecular genetics, psychophysiological data acquisition and analysis, and the computational power each depended on were not yet developed fully (see Beauchaine & Gatzke-Kopp, 2013). Even before most of these advances unfolded, however, forward-thinking psychopathologists were offering more sophisticated etiological models of mental illness, beginning with the *reaction range* concept from quantitative behavioral genetics. According to this notion, heritability sets upper and

lower bounds on psychological adjustment, but reactions to the environment dictate where within those bounds an individual functions. The reaction range concept was followed quickly by related *diathesis–stress* conceptualizations of schizophrenia, which specify how expression of genetic liability depends upon exposure to environmental risk (Gottesman, 1963; Gottesman & Shields, 1966; Meehl, 1962). The diathesis–stress framework ushered in a slow transition away from strict endogenous models of psychopathology, which focused almost exclusively on pathophysiological processes within individuals, and away from strict exogenous models of psychopathology, which focused almost exclusively on early adverse experiences (Cicchetti, 1984). Psychopathology could now be construed as the end product of interactions between genetic vulnerabilities (diatheses) and environmental risk factors (stressors).

These advances in technology, methodology, and conceptualization of mental illness laid the groundwork for the emergence of developmental psychopathology—a new discipline that extended gene–environment interaction models by focusing on *processes,* or *transactions* through which biological vulnerabilities and contextual risk factors interact to affect psychological adjustment. As defined by Sroufe and Rutter (1984), developmental psychopathology encompasses, " . . . study of the origins and course of individual patterns of behavioral maladaptation, whatever the age of onset, whatever the causes, whatever the transformation in behavioral manifestations, and however complex the course of the developmental pattern may be" (p. 18). As this definition implies, developmental psychopathologists are concerned with specifying alternative pathways to psychopathology (see, e.g., Cicchetti & Rogosch, 1996), both multifinal (i.e., How do similar vulnerabilities eventuate in different manifestations of psychopathology?) and equifinal (i.e., How do different vulnerabilities eventuate in similar manifestations of psychopathology?). Such specification requires studies of (1) individual-level vulnerabilities across levels of analysis (e.g., genetic, neural, psychophysiological), (2) environmental risk factors (e.g., family, peer network, neighborhood, culture), (3) biological vulnerability–environmental risk interactions across time, and (4) developmental continuities and discontinuities in behavior (see Beauchaine & McNulty, 2013; Rutter & Sroufe, 2000). Developmental psychopathology research transcends traditional disciplinary boundaries, including child clinical psychology, child and adolescent psychiatry, behavioral neuroscience, behavioral genetics, psychiatric genetics, etc., and has produced increasingly sophisticated transactional models of psychopathology that are largely unique to the discipline (e.g., Beauchaine, Klein, Crowell, Derbidge, & Gatzke-Kopp, 2009; Beauchaine & McNulty, 2013; Cicchetti & Toth, 1998; Crowell, Beauchaine, & Linehan, 2009; Dawson, 2008).

WHY USE PSYCHOPHYSIOLOGICAL METHODS IN DEVELOPMENTAL PSYCHOPATHOLOGY RESEARCH?

Psychophysiological methods have proven invaluable in advancing the developmental psychopathology research agenda (see Beauchaine & Gatzke-Kopp, 2012; Fox et al., 2006), and will likely continue to do so in upcoming years. As described below, autonomic psychophysiology has helped specify which children are most vulnerable to developing both internalizing (e.g., anxiety, depression) and externalizing (e.g., delinquency, substance abuse) disorders in contexts of liability and risk. For example, low electrodermal responding among 8–12-year-olds confers vulnerability to conduct problems in contexts of paternal antisocial behavior, whereas high electrodermal responding confers protection (Shannon, Beauchaine, Brenner, Neuhaus, & Gatzke-Kopp, 2007). Furthermore, children who exhibit high baseline heart rate variability are either fully or partly protected from adverse outcomes associated with exposure to maternal depression (e.g., Blandon, Calkins, Keane, & O'Brien, 2008), paternal antisociality (e.g., Shannon et al., 2007), parental drinking (e.g., El-Sheikh, 2005), and marital conflict/divorce (e.g., El-Sheikh, Harger, & Whitson, 2001; Katz & Gottman, 1995). Such findings provide obvious advantages for identifying children who are most in need of prevention and intervention programs (see Beauchaine, Neuhaus, Brenner, & Gatzke-Kopp, 2008; Beauchaine et al., 2013).

Psychophysiological measures may also provide information about psychological reactivity that cannot be gleaned from behavioral observation alone. For example, although high-functioning 6–7-year-old children with autism do not differ from their peers in behavioral responding to reward tasks, they exhibit more electrodermal reactivity, suggesting greater state anxiety (Faja, Murias, Beauchaine, & Dawson, 2013).

Relatedly, psychophysiological reactivity may provide information about psychological processes among individuals who cannot or will not provide reliable self-reports, such as infants and toddlers (e.g., Moore et al., 2009; Porges, Doussard-Roosevelt, Portales, & Greenspan, 1998), children and adolescents on the autism spectrum (e.g., Laeng, Sirois, & Gredebäck, 2012), and individuals who are motivated to deceive, such as those who wish to escape detection for committed crimes (e.g., Iacono, 2007).

Physiological measures are also used to detect psychological reactivity to stimuli that are not processed consciously. For example, phobic individuals produce elevated SCRs in response to masked phobia-related images compared with masked neutral and masked nonphobia-related images (Öhman & Soares, 1994). This highlights the need to explore psychopathology at different levels of analysis, including those that are not contingent on self-awareness, to better understand attentional and cognitive processes associated with symptom expression. Following from these and other considerations, some have advocated using psychophysiological measures to complement, and in some cases supplant, behavioral observation and self-report. Perhaps the best such example is lie detection (see Iacono, 2007), which continues to evolve despite lingering problems with both sensitivity and specificity in applied settings (e.g., Ben-Shakhar & Elaad, 2003).

In addition, autonomic psychophysiology sometimes provides prospective information about vulnerability to later psychopathology. For example, developmental increases from early to late childhood in respiratory sinus arrhythmia (RSA)—the component of heart rate variability associated with parasympathetic nervous system (PNS) function (Beauchaine, 2001; Porges, 1995, 2007), predict strong emotion regulation skills in adolescence. In contrast, stasis in RSA across development predicts later emotion dysregulation, which confers vulnerability to a range of adverse outcomes (see Beauchaine, 2015a; 2015b; Vasilev, Crowell, Beauchiane, Mead, & Gatzke-Kopp, 2009). In fact, although attenuated RSA is not observed among disruptive preschool children (Crowell et al., 2006), low baseline RSA and excessive RSA reactivity to emotion evocation are observed consistently among disruptive middle schoolers and adolescents, who do not exhibit normative developmental increases in PNS tone (Beauchaine, Katkin, Strassberg, & Snarr, 2001; Pang & Beauchaine, 2013). Importantly, aberrant patterns of RSA reactivity and deficiencies in emotion regulation appear to co-develop over time specifically in contexts of family coercion (Beauchaine, Gatzke-Kopp, & Mead, 2007; Beauchaine & Zalewski, 2015). This provides one example of how longitudinal relations between physiological vulnerabilities and environmental risk factors are often interactive and at times bidirectional (Crowell et al., 2013; Ford, Fraleigh, Albert, & Connor, 2010). As reviewed above, characterizing transactions between individual-level vulnerabilities and contextual risk factors is a primary objective of developmental psychopathology research.

In addition, psychophysiological measures can provide information about central nervous system processes that either cannot be measured noninvasively, or require measurement techniques that cannot be implemented with young children (see, e.g., Beauchaine & Gatzke-Kopp, 2012; Clark, Hasser, Kunze, Katz, & Kline, 2011; Porges, 2005, 2007; Thayer & Lane, 2000). As detailed below, for example, attenuated sympathetic nervous system (SNS)-linked cardiac reactivity to incentives may serve as a proxy for midbrain dopamine responding (see, e.g., Brenner & Beauchaine, 2011)—a core neural substrate of trait impulsivity, which is often expressed very early in life as attention-deficit/hyperactivity disorder (ADHD; see Gatzke-Kopp & Beauchaine, 2007; Neuhaus & Beauchaine, 2013; Sagvolden, Johansen, Aase, & Russell, 2005). Using a psychophysiological proxy for midbrain dopamine activity in very young children allows us to make inferences about central nervous system processes that otherwise could not be assessed until late childhood, adolescence, or in some cases adulthood. For example, although positron emission tomography (PET), the most direct noninvasive measure of neural function available,[2] is often used to evaluate midbrain dopamine function among adults with ADHD (e.g., Volkow, Fowler, Wang, Ding, & Gatley, 2002; Volkow et al., 2009), it is rarely used with children or adolescents given safety concerns associated with ingesting radioactive tracers (i.e., radionuclides). Alternatively, functional neuroimaging (fMRI) can be used to evaluate neural function without radioactivity. Either way, imaging protocols are difficult for very young children with ADHD to tolerate. Thus, when valid psychophysiological proxies for central nervous system function exist, they provide opportunities for scientific discovery that might otherwise be unavailable. We return to this important point later.

Finally, psychophysiological methods can sometimes be used to identify neurobiological vulnerabilities to psychopathology that cut across traditional diagnostic boundaries. Continuing with the aforementioned example, attenuated SNS-linked cardiac reactivity to incentives is observed among preschool children with ADHD and oppositional defiant disorder (ODD; Beauchaine et al., 2013; Crowell et al., 2006), middle schoolers with ADHD and conduct disorder (CD; Beauchaine et al., 2001), adolescents who are delinquent and aggressive (Beauchaine, Hong, & Marsh, 2008), and adolescents who

[2]PET provides the most direct index of neural function because radionuclides are designed to bind with specific receptors or transporters (in this case, dopamine transporters/receptors). In contrast, functional neuroimaging quantifies blood oxygen level, a less direct measure of neural function that is not specific to any particular neurotransmitter.

engage in later substance use (Brenner & Beauchaine, 2011). According to the *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (*DSM-5;* American Psychiatric Association, 2013), this list comprises no fewer than four assumedly distinct psychiatric syndromes (ADHD, ODD, CD, substance use disorder), despite evidence of shared etiology at genetic, psychophysiological, and neural levels of analysis (for reviews see Beauchaine & Gatzke-Kopp, 2012; Beauchaine & McNulty, 2013; Beauchaine, Shader, & Hinshaw, 2015; Gizer, Otto, & Ellingson, 2015). A major criticism of the *DSM* is its strict adherence to syndromal (i.e., symptom-based) diagnosis, even when neurobiological indicators suggest shared pathophysiologies (Beauchaine, Klein, Erickson, & Norris, 2013; Beauchaine & Marsh, 2006). In turn, when pathophysiology is ignored, etiological pathways to psychopathology are obscured (Preskorn & Baker, 2002), with adverse consequences for diagnosis, and for development of effective prevention and intervention programs (see Beauchaine, Neuhaus et al., 2008). This was a core contributing factor to the National Institute of Mental Health (NIMH) embarking on development of a new diagnostic system, the Research Domain Criteria (RDoC; Insel et al., 2010; Sanislow et al., 2010). The RDoC—a currently evolving dimensional approach to diagnosis—is based on *both* identifiable neurobiological processes and observable behavior (NIMH, 2015).[3]

DEFINITIONS, ASSUMPTIONS, AND TENETS OF PSYCHOPHYSIOLOGICAL RESEARCH

We now turn to general definitions, assumptions, and tenets of psychophysiological research. In recent years, many who would not have used psychophysiological measures in the past have begun doing so given hardware that is more affordable and readily implemented, and software that is largely automated. Although these advances make psychophysiological data collection more accessible and less labor-intensive, modern systems are also easier to use by those who do not have formal training in psychophysiology, and who may not be familiar with certain principles, assumptions, and limitations of the psychophysiological approach. Accordingly, below we outline a number of issues that should be considered when planning, executing, and interpreting psychophysiological experiments. We then turn our attention to uses of specific psychophysiological measures, before discussing various data analytic considerations.

Like any branch of science, psychophysiology has its own conceptual underpinnings and terminological conventions. Some of these are specific to particular methods (e.g., electro-cardiography, pupilometry), whereas others are more general, and should therefore be familiar to most anyone who conducts psychophysiological research. Thus, we provide discussion of several important terms and concepts below. We note however, that the scope of such issues is broad enough that several full-length texts have been devoted exclusively to psychophysiology (e.g., Andreassi, 2007; Cacioppo, Tassinary, & Berntson, 2007; Schmidt & Segalowitz, 2008; Stern, Ray, & Quigley, 2001). Readers are referred to these sources for more comprehensive coverage.

Tonic Versus Phasic Measures and Establishing Appropriate Baselines

By definition, tonic psychophysiological *activity* is assessed at rest, whereas phasic psychophysiological *reactivity* is computed as change from rest. Ideally, tonic measures are collected at the end of a movement- and stimulus-free quiet baseline condition, which must be long enough for an individual to achieve a wakeful resting state (Obrist, 1981). Such true baselines minimize effects of both exogenous (e.g., exposure to stressors before arrival at the lab, current lab conditions) and endogenous (e.g., individual differences in state anxiety) sources of error variance on estimates of both tonic and phasic psychophysiological function. This can be especially important in psychopathology research. For example, failure to collect true baseline heart rate from anxious participants may result in overestimates of tonic heart rate, which in turn translate into underestimates of phasic heart rate reactivity to stressors. This is likely to result in a Type II error (see Hastrup, 1986).

Quiet periods lasting 10–20 min or more may be required to achieve a true resting baseline (see Hastrup, 1986;

[3]This discussion may raise questions in some readers' minds about the distinction between biomarkers and endophenotypes, and the relative values of each in psychopathology research. Although space constraints preclude full consideration of these issues, biomarkers are usually defined by psychopathologists as endogenous, measurable characteristics that mark either risk for or manifestation of psychiatric illness. According to this definition, biomarkers need not be specific to any particular disorder as currently defined in the *DSM*. In contrast, endophenotypes are usually defined more restrictively, including specificity to a particular psychiatric disorder. As these definitions imply, psychophysiological variables can be biomarkers and/or endophenotypes. Interested readers are referred elsewhere for more comprehensive discussions (Beauchaine, 2009a; Gottesman & Gould, 2003; Gould & Gottesman, 2006).

Jennings, Kamarck, Stewart, Eddy, & Johnson, 1992). This has led some, especially those who conduct psychophysiological research with children, to use alternative conditions, such as vanilla baselines, when collecting tonic measures. With this approach, participants either watch a quiet, age-appropriate video (e.g., Sulik, Eisenberg, Silva, Spinrad, & Kupfer, 2013), or engage in minimally demanding tasks, such as color detection (Jennings et al., 1992). In developmental psychopathology research, use of vanilla baselines usually follows from one of two assumptions: (1) that young children, regardless of their level of functioning, cannot tolerate true baselines; or (2) that children with a particular trait being studied (e.g., impulsivity, emotion dysregulation), cannot tolerate true baselines (see, e.g., Gavin & Davies, 2008).

Although these assumptions should not be discounted, use of vanilla baselines may be quite problematic for some psychophysiological measures, such as heart rate and RSA. As will be discussed, RSA indexes ebbing and flowing of heart rate across the respiratory cycle. Low tonic RSA and excessive RSA reactivity to evocative stimuli are associated with emotion dysregulation—a hallmark of both internalizing and externalizing psychopathology (see below; Beauchaine, 2015a; 2015b; Beauchaine et al., 2007). Notably, however, even moderate levels of attention deployment, such as those elicited by vanilla baselines, reduce RSA somewhat among normal controls, but not among those with attention problems (see Beauchaine, 2001). In fact, RSA reactivity to lab tasks varies as a function of individual differences in both impulsivity and attention (e.g., Beauchaine et al., 2001). Thus, vanilla baselines may produce attention-induced confounds in comparisons of tonic and phasic responding between certain groups, such as externalizing males and controls.

Fortunately, even though 10–20-minute baselines are often preferred (Jennings et al., 1992), shorter intervals can be effective. In our own work, we regularly use 5 min resting baselines with children as young as age 4 years who have ADHD (see Beauchaine et al., 2013; Crowell et al., 2006). Our baselines consist of having children sit by themselves in a quiet room, facing a white wall, with no auditory or visual stimulation. Given the novelty of this situation, even preschool children with ADHD are able to sit almost movement-free for this length of time. Stillness is of course essential given the functional role of the ANS in supporting metabolic demands (see, e.g., Bush, Alkon, Obradović, Stamperdahl, & Boyce, 2011).

A final point regarding tonic versus phasic responding concerns consistent and specific use of terminology, which facilitates effective communication in any discipline. As noted already, tonic measures, by definition, are collected at baseline, whereas phasic measures, by definition, reflect change from baseline, regardless of the eliciting source of psychophysiological reactivity. When phasic measures are referred to as tonic measures, considerable confusion may result. For example, following publication of a highly influential paper on emotion regulation titled "Vagal Tone and the Physiological Regulation of Emotion (Porges, Doussard-Roosevelt, & Maiti, 1994), many subsequent papers appeared in the developmental and developmental psychopathology literatures in which the term vagal tone was used to refer broadly to any measure of RSA, whether tonic or phasic. As we have noted elsewhere (Beauchaine, 2001; 2015b), this is problematic for several reasons. For the discussion at hand, it is sufficient to state that tonic and phasic measures of RSA often have different external correlates and may reflect different physiological functions and should therefore be distinguished from one another for precise communication and indexing purposes.

Misinterpreting Baseline Measures

Failure to distinguish between tonic and phasic responding can also result in confusion regarding the neural underpinnings of, and individual differences in, baseline psychophysiological measures. For example, phasic changes in cardiac pre-ejection period (PEP), a systolic time interval spanning left ventricular depolarization and ejection of blood into the aorta (see below), are determined almost exclusively by SNS reactivity (Sherwood, Allen, Obrist, & Langer, 1986). In contrast, tonic PEP is determined by a host of additional factors, including preload, afterload, peripheral resistance, biomechanics, and pathophysiological processes (see, e.g., Sherwood et al., 1990). Accordingly, group differences between those with and without psychopathology in baseline PEP (e.g., Beauchaine et al., 2001) cannot be interpreted as deriving from sympathetic neural function. *At a minimum, any such conclusion requires assessment of phasic PEP reactivity*. This conclusion generalizes to most if not all psychophysiological processes. Nevertheless, it is quite common in the developmental and developmental psychopathology literatures to equate individual and group differences in baseline measures of autonomic activity with specific neural processes—a practice that is often unwarranted and potentially misleading.

Even phasic PEP responses, although initiated by the SNS, may be moderated by nonneural influences such as loading effects (see, e.g., Obrist, Light, James, & Strogatz, 1987). For this reason and others, we cannot assume

either (1) linear correspondences between neural reactivity and PEP change within individuals, or (2) equivalency in associations between neural reactivity and phasic PEP change across individuals. For example, a 10 ms change in PEP may correspond with more β-adrenergic neural reactivity in a person high in afterload than in a person low in afterload. Although this adds error variance to our measures, we are still on much stronger footing when making inferences about the neural underpinnings of phasic PEP reactivity than we are in making inferences about the autonomic underpinnings of tonic PEP. This conclusion also generalizes to most if not all psychophysiological processes.

The Law of Initial Values and Psychophysiological Reactivity

According to the law of initial values (LIV), relative magnitudes of phasic psychophysiological responding depend in part on preceding levels of tonic activity (Wilder, 1931, 1957). Wilder first articulated the LIV after noticing that changes in blood pressure following administration of both SNS agonists (e.g., adrenaline) and PNS antagonists (e.g., atropine)—both of which increase blood pressure—were smaller among those who exhibited higher resting values.

Debate over causes of the LIV has existed for years (see Furedy & Scher, 1989). Although LIV effects undoubtedly result in part from biomechanics (e.g., effects of maximum stroke volume on cardiac output), neural mechanisms (e.g., effects of the minimum refractory period on maximum heart rate), and their interactions, additional factors, including statistical artifacts, also play a role (see Berntson, Uchino, & Cacioppo, 1994). Furthermore, similar phenomena—often referred to as ceiling and floor effects—are common in other areas of research. For example, therapeutic gains among those in randomized clinical trials are often highly dependent on levels of baseline function (see, e.g., Vickers & Altman, 2001). Thus, across different areas of research, baseline values and subsequent change scores tend to covary negatively.

This covariation must be considered when we interpret both within-individual and between-groups psychophysiological research findings (Furedy & Scher, 1989). For example, if valid resting baselines are not obtained within individuals, subsequent change scores (baseline minus stimulus) will underestimate true psychophysiological reactivity. In between-groups research, unaccounted for differences at baseline may obscure important group differences in reactivity. As reviewed below, baseline differences in psychophysiological responding are observed between control participants and those with a host of psychiatric conditions. Since group differences in phasic responding are in part dependent on any such baseline differences, psychophysiological reactivity should not be evaluated without considering baseline responding.

Constructs Versus Measures

In psychology and most other branches of science, a *measure* is a quantifiable, directly observable variable. Measures are often referred to as *manifest indicators* in the psychometrics literature. In contrast, a *construct* is an unobservable, *latent variable* that must be inferred from manifest indicators (see, e.g., Nunnally & Bernstein, 1994). Almost all psychiatric diagnoses (e.g., depression, ADHD) represent latent variables (constructs), which are inferred from imperfect manifest indicators (measures) of clinical state (see Meehl, 1995). Importantly, measures may be specified at any of several levels of analysis, including genetic, hormonal, neural, behavioral, self-report, etc.

The distinction between constructs and measures, although often ignored in psychophysiology research, is no less important than it is in studies of psychopathology (see Strube & Newman, 2007). Vagal tone, for example, defined as resting parasympathetic efference from the brainstem to the heart (see Porges, 1995), is a *construct*. It is not observable directly, and can only be estimated noninvasively from indirect *measures* such as heart rate change following pharmacologic blockade, and quantification of RSA (see Berntson et al., 1997). In fact, RSA is only an accurate measure of vagal tone in specific contexts that include a valid resting baseline and tight respiratory control (see below; Grossman, 1992; Grossman, Karemaker, & Wieling, 1991; Ritz, 2009). The terms vagal tone (a construct) and RSA (a measure) should therefore not be used interchangeably, as they often are in the developmental and developmental psychopathology literatures. Although this particular example may seem harmless, it has produced considerable confusion in the literature about possible neural underpinnings of individual differences in RSA. More egregious examples of conflating constructs with measures also appear in the literature. In particular, low RSA is often equated with emotion dysregulation, when it is better construed as a biomarker of emotional lability. Emotion dysregulation itself is a psychological construct that can only be assessed with multiple measures collected across levels of analysis (e.g., self-report, behavior observation, informant report; see Cole, Hall, & Hajal, 2013).

Developmental Considerations

Finally, developmental changes in tonic and phasic psychophysiological responding are quite common, and occur through various mechanisms, including increased body size and associated alterations in cardiodynamics (e.g., Smulyan et al., 1998), age-related variation in physical fitness (e.g., Tulppo, Mäkikallio, Seppänen, Laukkanen, & Huikuri, 1998), maturation of frontal brain structures implicated in self-regulation and autonomic function (e.g., Gogtay et al., 2004), migration of neural control over behavior to different neural networks across development (Beauchaine & McNulty, 2013; Geier & Luna, 2009), age-dependent physiological changes (e.g., arterial hardening with older age; Mitchell et al., 2004), and psychological maturation (e.g., improved control over attention; e.g., Karatekin, 2004). Given this wide range of developmental effects, failure to model age is likely to introduce confounds and unwanted error variance into psychophysiological studies. Perhaps more importantly, understanding maturational effects and maturational failures is of direct interest to developmental psychopathologists (see Beauchaine & McNulty, 2013). Since no single longitudinal trajectory characterizes all autonomic constructs, we include descriptions addressing normative development in each section below. First, however, we provide a brief description of the autonomic nervous system (ANS).

THE AUTONOMIC NERVOUS SYSTEM

The ANS is a subdivision of the vertebrate nervous system that controls involuntary actions of body organs and certain tissues, including glands, extrastriatal muscles, and vasculature (see, e.g., Robertson, Biaggioni, Burnstock, & Low, 2004). Actions of the ANS are primarily reflexive, and occur in response to changing demands from the internal (visceral) and external environments. Under conditions of impending danger, for example, inhibitory parasympathetic effects on cardiac output are withdrawn and excitatory sympathetic effects are enhanced, which provides for rapid increases in blood flow and mobilization of energy to respond to the threat. Following escape or removal of threat, these responses are reversed, returning the ANS to its longer-term function of maintaining physiological homeostasis.

Based on both anatomical and functional distinctions, the ANS is typically parsed into sympathetic, parasympathetic, and enteric subdivisions, (Jänig, 2006). As alluded to already, a primary function of the SNS is to mobilize metabolic resources to cope with real or perceived threat. During fight-or-flight responding, the SNS (1) increases contractile force of the atria and ventricles, increasing blood flow and availability of oxygen to large muscle groups throughout the body; (2) elicits peripheral vasoconstriction, reducing blood supply to the extremities; (3) promotes bronchial dilation, improving respiratory efficiency; and (4) stimulates eccrine sweat gland secretion, improving grip of the palms and soles of the feet, among other effects.

The PNS also plays an important role in fight-or-flight responding through acute withdrawal of its inhibitory effects on dually innervated organs including the heart. This allows the SNS to exert excitatory effects unopposed. During periods of rest, however, the PNS serves primarily restorative functions by decreasing heart rate and contractility of the atria, promoting digestion, eliciting vasodilation, and stimulating bronchial contraction. Although the SNS and PNS often act in opposition to one another, they may also operate in coactive, coinhibitory, and uncoupled states, with important implications for health outcomes, including several that are linked to psychopathology, as described below (see Beauchaine, 2001, Beauchaine et al., 2007; Berntson, Cacioppo, & Quigley, 1991, 1993; Berntson, Cacioppo, Quigley, & Fabro, 1994; Berntson, Cacioppo, Binkley et al., 1994; Ondicova & Mravec, 2010; Thayer & Lane, 2000).

The third division of the ANS, the enteric nervous system (ENS), comprises an intrinsic, mesh-like network of neurons in the gastrointestinal tract. The ENS controls digestive processes and communicates with the CNS indirectly through sympathetic and parasympathetic innervation, but unlike the SNS and PNS, can also function independently of the CNS (Goyal & Hirano, 1996). In sections to follow, we focus exclusively on the SNS and PNS. Readers interested in learning more about the functions and neurodevelopment of the ENS are referred elsewhere (Gershon, 2008; Sasselli, Pachnis, & Burns, 2012).

The SNS and PNS are comprised of two populations of autonomic motor neurons, including (1) preganglionic neurons originating in the spinal cord or brain stem, and (2) postganglionic neurons synapsing with preganglionic neurons outside the CNS, which innervate target organs/tissues directly (see, e.g., Cramer & Darby, 2005). Cell bodies of preganglionic neurons in the SNS are located in the intermediate zone of thoracic and lumbar regions of the spinal cord, and form cholinergic synapses with postganglionic neurons located in chain formations on either side of or in front of the spinal cord (termed paravertebral ganglia and prevertebral ganglia, respectively). Synapses created

by postganglionic neurons and target organs/tissues are primarily noradrenergic, with some exceptions, including sweat glands, which are cholinergic (see below). Cell bodies of preganglionic PNS neurons are located in the sacral region of the spinal cord or the brainstem, where they exit through cranial nerves III, VII, IX, and X. The vagus (cranial nerve X) in particular subserves core regulatory functions, as described below, in its role mediating efferent and afferent neural traffic between target organs and CNS structures located in the medulla oblongata. Similar to the SNS, pre-postganglionic PNS synapses are cholinergic. Parasympathetic postganglionic neurons typically form cholinergic synapses with target organs and tissues, but sometimes use other neurotransmitters, including nitric oxide and vasoactive intestinal polypeptide. In both ANS branches, sensory neurons that originate from target organs provide feedback to the CNS, which modulates activity of autonomic motor ganglia. In fact, at least 80% of vagus neurons are afferent (i.e., originating in target organs and terminating in the CNS; see, e.g., Berthoud & Neuhuber, 2000). Combined, ganglia and sensory neurons provide infrastructure for motor and sensory communication between target organs/tissues and the CNS.

The ANS acts in concert with both the somatic nervous system (i.e., the skeletomotor system), which controls voluntary body movements, and neuroendocrine pathways, which regulate hormone release, to effect commands from the central nervous system (CNS). Coordination between the CNS and these peripheral systems enables organisms to respond to their external environments without compromising the integrity of internal body systems. For example, the ANS and the neuroendocrine system both contribute to the acute physiological stress response (PSR), a set of physiological and behavioral changes that occur following perception of psychological or physical threat. Neurophysiologically, the PSR is comprised of two primary components: (1) a quick-acting monoaminergic CNS response, which is initiated by the amygdala and serves to raise arousal and vigilance; and (2) short- and longer-lasting sympathetic and neuroendocrine responses involving systemic release of catecholamines and glucocorticoids (Rodrigues, LeDoux, & Sapolsky, 2009). During acute stress, epinephrine and norepinephrine are released from sympathetic nerve endings in the adrenal medulla, initiating a near-immediate response to threat, including accelerated breathing and heart rate (Carrasco & Van de Kar, 2003). In contrast, glucocorticoid release is regulated by a neural network including the paraventricular nucleus (PVN) of the hypothalamus, the pituitary gland, and the adrenal glands (i.e., the hypothalamic-pituitary-adrenal [HPA] axis). Primarily indirect limbic activation prompts secretion of corticotrophin-releasing hormone (CRH) in medial parvocellular neurons of the PVN, which then signals secretion of the adrenocorticotropic hormone (ACTH) in the anterior pituitary gland, which in turn stimulates release of glucocorticoids (primarily cortisol in humans) from the adrenal cortex (Jankord & Herman, 2008). Although autonomic reactivity and HPA axis responding are intricately co-regulated by the CNS, we do not discuss the structure or function of the HPA axis further, since it is covered in other chapters of this volume.

Importantly, CNS structures in the brainstem and elsewhere exert top-down effects on autonomic outflow, which accounts in part for effects of psychological factors such as subjective feelings of distress on autonomic function (de Morree, Szabó, Rutten, & Kop, 2013). Subcortical regions, including the paraventricular nucleus (PVN) and other nuclei of the hypothalamus, the periaqueductal gray of the midbrain, the central nucleus in the amygdala, the bed nucleus of the stria terminalis in the basal forebrain, and cortical regions, including the anterior cingulate, insular, and ventromedial prefrontal cortices, are implicated in coordination of autonomic, neuroendocrine, and somatomotor responses (e.g., Busnardo, Tavares, Resstel, Elias, & Correa, 2010; Dong & Swanson, 2006; Sullivan & Gratton, 1999). These regions either contain source nuclei that descend to SNS and/or PNS-specific structures in the brainstem or spinal cord (e.g., the nucleus ambiguus, the PVN via the dorsal longitudinal fasciculus) or provide input to regions that modulate autonomic neuronal activity (e.g., the septal nuclei, hippocampal, and amygdalar influences on the PVN via the medial forebrain bundle and other pathways). Although much remains to be learned about mechanisms that underlie neural influences on ANS functioning, psychological factors, such as stress, motivation, mood, and affective states, induce reliable changes in ANS activity and reactivity. Accordingly, measuring baseline ANS activity and ANS reactivity to certain experimental manipulations may inform our understanding of neural processes implicated in normal and pathological functioning. We now turn our attention to specific ANS constructs, how these are measured, and how inferences about psychopathology and its development may sometimes be gleaned from assessing ANS responding at baseline and in response to carefully chosen stimulus conditions.

CARDIOVASCULAR PSYCHOPHYSIOLOGY

Cardiovascular measures have a long history of use in psychopathology research. Although at one time most of this research was restricted to evaluation of heart rate (HR)

and HR reactivity, several additional cardiac variables are now routinely assessed. Some of these provide unique information that cannot be gleaned from measuring HR alone. Below we discuss some of these measures, beginning with HR itself.

Heart Rate

As noted already, HR has been used for decades to evaluate effects of various psychological phenomena—including those elicited by both endogenous states and exogenous stimuli—on autonomic function. Heart rate is easy to capture, and can be used in within-subjects, between-groups, and mixed experimental designs. Each cardiac cycle is characterized by rhythmic contractions and relaxations of the myocardium, which are induced by periodic patterns of electrical activity. Associated voltage changes are recorded with an electrocardiogram (ECG) to determine HR, which is typically measured in beats/min. The QRS complex, depicted in Figure 22.1, quantifies rapid depolarization of the left and right ventricles. The latency between peaks of the QRS complex (termed the R-R interval) can be digitized to the nearest ms (i.e., 1kHz., the current standard for most cardiac psychophysiology applications; see Berntson et al., 1997; Sherwood et al., 1990), and time series of contiguous R-R intervals can then be used to derive HR. Heart rate and related measures, such as heart period, are often used to index baseline cardiac function and event-related cardiac responses. In some contexts, measurement of heart period, or interbeat interval (IBI), offers advantages over HR, since heart period is related more linearly to autonomic control of the heart (Berntson, Cacioppo, & Quigley, 1995). In fact, use of HR may overestimate autonomic interactions on cardiac function, which can distort relations between psychological processes and autonomic functioning (Quigley & Berntson, 1996). Perhaps given its intuitive appeal, however, HR remains a more popular measure among many of those interested in physiology-behavior relations (see, e.g., Lorber, 2004).

Although the temporal sequence of electrical events underlying myocardial contraction is independent of neural and hormonal influences, both HR and the contractile force of heartbeats are determined by dynamic interactions among the SNS, the PNS, hormonal control, and several additional influences, including cardiovascular reflexes (e.g., the dive reflex), peripheral resistance, mean arterial pressure, and pathophysiological processes (for a more comprehensive account, see Berntson, Quigley, & Lozano, 2007). Acceleratory SNS activation is effected through β-1 adrenergic receptors located on the sinoatrial (SA) node. Since SNS innervation is excitatory, increased β-adrenergic activity produces HR increases (termed tachycardia), and stronger contractile force. In contrast, inhibitory PNS innervation is effected through the vagus nerve via cholinergic mechanisms, which slow HR (termed bradycardia). Heart rate is also affected by endogenous and exogenous factors that alter CNS and autonomic functioning, such as physical activity, psychological stress, medication use, etc. (see, e.g., Cacioppo, Uchino, & Berntson, 1994; Novak et al., 1993; Palatini, Benetos, & Julius, 2006).

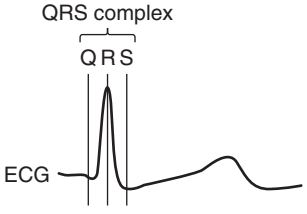

Figure 22.1 The QRS complex, as derived from a Lead III electrocardiogram (ECG).

Given this wide range of influences on cardiac function, determining specific sources of individual differences in HR and HR change is impossible without using measures that parse SNS, PNS, and other effects (see Berntson, Cacioppo, Quigley, & Fabro, 1994; Cacioppo et al., 1994). This is illustrated in the long history of research on autonomic function among aggressive and delinquent males. Collectively, these individuals exhibit low resting HR compared with their nonaggressive peers, a phenomenon described in the literature for over a century. For many decades, this low resting HR was attributed to excessive inhibitory vagal (PNS) efference to the heart, as outlined in the *vagatonia* hypothesis (Eppinger & Hess, 1910/1915). However, research conducted in our lab and others in which concurrent effects of SNS and PNS activation are evaluated indicates that males who engage in clinical levels of externalizing conduct exhibit *attenuated* PNS cardiac control, and that low resting HR likely results from deficient excitatory SNS effects (e.g., Beauchaine et al., 2001; Crowell et al., 2006; Mezzacappa et al., 1996). This demonstrates the value of parsing HR into its constituent autonomic components if we wish to better understand neural correlates of psychological phenomena including psychopathology (see Beauchaine, 2012; Beauchaine et al., 2007; El-Sheikh et al., 2009). We return to this point in later sections.

Autonomic Space

The decades-long assumption that low resting HR among externalizing males results from excessive PNS activation followed from what is often called the accentuated antagonism hypothesis of cardiovascular control. According to this hypothesis, which derived largely from research on

anesthetized dogs (e.g., Levy & Zieske, 1969), the SNS and PNS function reciprocally, with increased activity in one branch accompanied by decreased activity in the other. It is now widely recognized, however, that accentuated antagonism is an oversimplification, and that effects of the SNS and PNS on dually innervated organs such as the heart can be coupled or uncoupled based on environmental demands, psychological states and traits, and pathophysiological effects (Berntson, Cacioppo, & Quigley, 1991, 1993; Berntson, Cacioppo, Quigley, & Fabro, 1994; Berntson, Cacioppo, Binkley et al., 1994). Thus, ANS determinants of HR must be represented in two-dimensional autonomic space (see Figure 22.2), and HR cannot be used to surmise relative levels of SNS or PNS activation (see also Beauchaine, 2012; Paton, Boscan, Pickering, & Nalivaiko, 2005). As outlined below, the doctrine of autonomic space has major implications for developmental psychopathology research in which psychophysiological measures are used (see Beauchaine, 2001, 2009; Beauchaine et al., 2001; Boyce et al., 2001; Bubier & Drabick, 2008; El-Sheikh et al., 2009; Wolff, Wadsworth, Wilhelm, & Mauss, 2012).

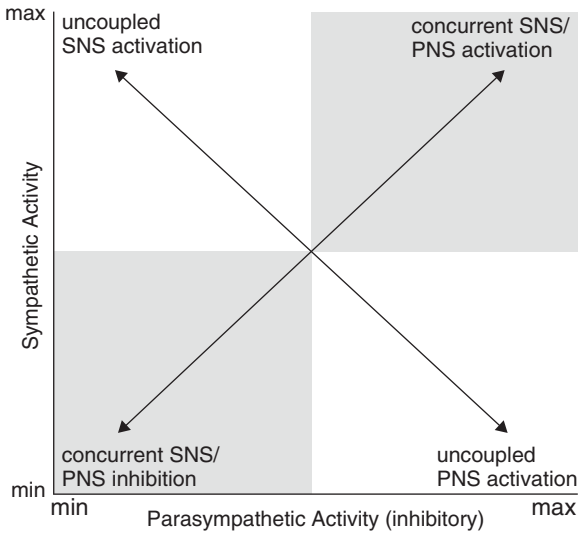

Figure 22.2 Two dimensions of autonomic space, with excitatory SNS activation represented on the y axis and inhibitory PNS activation represented on the x axis. Heart rate may be determined by coactive sympathetic and parasympathetic activity (concurrent SNS/PNS activation or concurrent SNS/PNS inhibition), or by uncoupled sympathetic/parasympathetic activity (SNS activation and PNS inhibition; SNS inhibition and PNS activation). As indicated in text, low resting HR among externalizing males appears to result from concurrent SNS and PNS inhibition (bottom left quadrant). *Source:* Adapted from Berntson, Cacioppo, Quigley, and Fabro (1994), Autonomic space and psychophysiological response. *Psychophysiology, 31*, 44–61

Links to Psychopathology

Despite these caveats, HR and HR change have long been used to render objective inferences about constructs such as overarousal among those high in trait anxiety (e.g., Rogeness, Cepeda, Macedo, Fischer, & Harris, 1990), biological vulnerability to antisocial personality disorder (e.g., Raine, Lencz, Bihrle, LaCasse, & Colletti, 2000), underarousal among externalizing children, adolescents, and adults (e.g., Dietrich et al., 2007), and sex differences in neurobiological risk for conduct problems (e.g., Beauchaine, Hong et al., 2008). As early as preschool, low resting heart rate is associated with aggressive behavior (Zahn-Waxler, Cole, Welsh, & Fox, 1995). In fact, low resting HR is the most replicable psychophysiological marker of externalizing behavior problems among males of all ages (Lorber, 2004; Raine, 2002). More recent work, however, reveals that SNS and PNS components of HR often correlate with different behavioral traits and affective states (see Beauchaine, 2001; Demaree & Everhart, 2004; Dietrich et al., 2007; Rogeness et al., 1990), even among those with externalizing disorders (Beauchaine et al., 2001, 2007; Beauchaine & Gatzke-Kopp, 2012).

Developmental Considerations

Median resting heart rate (HR) is 127 bts/min at birth, peaks at 145 bts/min at one month of age, and decreases to 113 beats/min by age 2 years (Fleming et al., 2011). Thereafter, HR declines at a more gradual yet steady rate to a median of 70 bts/min by age 18. Among healthy adults up to age 68, no further changes in resting HR or average ambulatory HR are observed (e.g., Kostis et al., 1982). However, both HR and HR reactivity are affected by cardiovascular conditions that are more prevalent in older age (e.g., Perret-Guillaume, Joly, & Benetos, 2009).

Reduced HR reactivity to psychosocial stressors is also observed across childhood (Matthews, Salomon, Kenyon, & Allen, 2002) and into old age (Kudielka, Buske-Kirschbaum, Hellhammer, & Kirschbaum, 2004). Furthermore, decreases in maximum HR during exercise are observed even among healthy aging individuals (e.g., Kostis et al., 1982). These developmental effects on HR and HR reactivity must be modeled explicitly if we wish to link trajectories in HR to psychological outcomes and reduce unwanted error variance in our longitudinal models (Burt & Obradović, 2013).

Choosing Appropriate Stimulus Conditions

As outlined previously, baseline HR should be acquired in a quiet, neutral setting after participants have acclimated

to the laboratory environment, and are relaxed and inactive (i.e., a true baseline). Multiple baseline recordings from different testing sessions are sometimes used to assess stability over time, or to reduce session-specific error variance by averaging (see Jennings et al., 1992).

As with any psychophysiological measure, HR reactivity is assessed by subtracting task-related HR from baseline HR. For some research questions, HR change in anticipation of threat or during study participation itself may be of interest (Burt & Obradović, 2013). However, it is more common in developmental research to evaluate HR reactivity to tasks that either elicit targeted emotions (e.g., empathy, exuberance), or induce attention deployment (e.g. Critchley et al., 2005; Lansink & Richards, 1997). Although no firm guidelines on stimulus duration exist, research with infants indicates that HR reactivity to 75 db acoustic stimuli follows an inverted U function across 2, 6, 10, 18, and 30 s stimulus durations, with maximum HR reactivity observed to stimuli of 10 s duration (Clifton, Graham, & Hatton, 1968).

Differences in HR reactivity following induction of specific emotions are subtle, but may nevertheless discriminate between emotions characterized by positive versus negative valence. For example, HR reactivity induced by negative emotional states lasts longer than HR reactivity induced by positive emotional states (Brosschot & Thayer, 2003). Moreover, larger HR responses are observed during presentation of sad and angry facial expressions than during presentations of happy facial expressions (Critchley et al., 2005). Such findings suggest that HR responses should not be collapsed across different types of emotion induction, unless the emotions are similar in valence.

Cardiac Pre-ejection Period

As noted already, cardiac PEP is a systolic time interval that spans the onset of left ventricular depolarization and ejection of blood into the aorta. Electrophysiologically, PEP is bounded by the ECG Q-wave, and the impedance-cardiographic (ICG) B-wave (Figure 22.3). Developed by the National Aeronautics and Space Administration (NASA) to evaluate cardiac function noninvasively (see Miller & Horvath, 1978), ICG captures systolic time intervals (e.g., PEP, left ventricular ejection time) and related cardiodynamic events (e.g., stroke volume, cardiac output) by measuring changes in impedance across the thorax (Sherwood et al., 1986). Since blood conducts electricity, changes in blood flow through the aorta can be estimated from the ICG signal via corresponding changes in thoracic impedance.

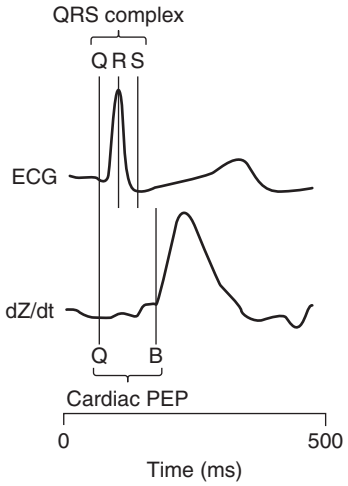

Figure 22.3 Electrocardiographic (top) and impedance cardiographic (bottom) recordings of one cardiac cycle. Time elapsed between the Q-wave of the QRS complex (top) and the B-wave of the ICG recording (bottom) represents cardiac pre-ejection period [PEP]). *Source:* Adapted from Sherwood Allen, Fahrenberg, Kelsey, Lovallo, and van Doornen (1990), Methodological guidelines for impedance cardiography. *Psychophysiology, 27*, 1–23.

Although resting PEP is determined by a variety of neural and mechanical factors and therefore suffers from interpretability concerns associated with almost all biomechanical processes, min-to-min evoked changes in PEP are determined almost exclusively by sympathetic (β-adrenergic) influences. Excitatory input from the SNS increases contractile force of the heart, elevates cardiac output, and produces shortened PEP latencies (Sherwood et al., 1986; see also Schächinger, Weinbacher, Kiss, Ritz, & Langewitz, 2001). However, because β-adrenergic effects on the heart operate through a second messenger system (adenylate cyclase), SNS-initiated changes in cardiac output following exogenous (e.g., threat) and endogenous (e.g., subjective distress) stimuli are delayed by about 20–30 s. Thus, unlike PNS influences, outlined below, SNS influences do not exert beat-to-beat control over cardiac reactivity. Cardiac PEP therefore provides less temporal resolution than some other measures of autonomic function described in this chapter. Nevertheless, it remains a valuable biomarker of certain emotional and motivational states, given appropriate stimulus conditions (see Beauchaine & Gatzke-Kopp, 2012; Brenner & Beauchaine, 2011; Brenner, Beauchaine, & Sylvers, 2005).

Most early work linking PEP reactivity to psychological states examined effects of stress on autonomic function. Some psychologically stressful laboratory conditions, particularly active coping tasks including public speaking and performance of mental arithmetic while being observed

by others, elicit PEP shortening, which indicates increased SNS activation (e.g., Berntson, Cacioppo, Binkley et al., 1994; Kelsey, Soderlund, & Arthur, 2004). Such stimulus conditions induce fear and anxiety, which mobilize the SNS to prepare for appropriate behavioral action (see Beauchaine, 2001; Brenner et al., 2005). A considerable body of research has also examined relations among PEP reactivity in the lab, PEP reactivity to everyday events, and cardiovascular health in different clinical groups (e.g., Nyklíček, Vorselaars, & Denollet, 2011).

Links to Psychopathology

Given its value as an index of SNS reactivity, and clear links between autonomic function and behavior problems among children, adolescents, and adults (e.g., Beauchaine, 2001; Beauchaine et al., 2001; Boyce et al., 2001), PEP has become a focal dependent variable in developmental psychopathology research (see Beauchaine & Gatzke-Kopp, 2012; Brenner & Beauchaine, 2011; Bubier & Drabick, 2008). We have used PEP reactivity with preschoolers (e.g., Beauchaine et al., 2013), middle-schoolers (e.g., Beauchaine et al., 2007), adolescents (Beauchaine et al., 2001), and young adults (Brenner et al., 2005) to evaluate reward-related processing and its associations with externalizing behavior disorders. As noted previously, under carefully selected stimulus conditions, PEP reactivity to monetary incentives serves as a peripheral biomarker of mesolimbic dopamine responding and associated individual differences in approach motivation (see Beauchaine & McNulty, 2013; Brenner et al., 2005; Brenner & Beauchaine, 2011). This assertion—that PEP reactivity *specifically* to incentives marks midbrain dopamine responding—follows from strong theoretical considerations and empirical associations. First, approach behaviors, which characterize reward-related processes, require energy mobilization, a function subserved by the SNS to meet metabolic demands. Second, changes in cardiac output required for behavioral approach are mediated by SNS-induced increases in the contractile force of the left ventricle (Sherwood et al., 1986). Third, dopamine modulates sympathetic function (Mannelli et al., 1999) and direct infusions of dopamine agonists into midbrain structures produce SNS-mediated increases in cardiac output (van den Buuse, 1998) that are similar to those observed when normal controls participate in reward tasks (see Brenner et al., 2005; Richter & Gendolla, 2009).

Compared with controls, males with ADHD, ODD, CD, and antisocial personality traits exhibit either diminished PEP reactivity to monetary incentives, or no PEP reactivity at all (for a review see Beauchaine & Gatzke-Kopp, 2012). This PEP nonreactivity parallels consistent neuroimaging results showing attenuated mesolimbic reactivity to reward among externalizing males (see, e.g., Durston, 2003; Rubia, 2011), and provides prospective prediction of substance use initiation and escalation among middle-schoolers (Brenner & Beauchaine, 2011).

The consistency of such findings has led our group and others to propose that deficient midbrain dopamine responding to reward—reflected in PEP under-reactivity during monetary incentive tasks—is a principal mechanism of behavioral impulsivity, a trait common to all externalizing conditions (see Beauchaine et al., 2009; Gatzke-Kopp, 2011; Gatzke-Kopp & Beauchaine, 2007; Sagvolden et al., 2005). Thus, consistent with sensation-seeking and central/autonomic underarousal theories (e.g., Castellanos-Ryan, Rubia, & Conrod, 2011; Gatzke-Kopp, Raine, Loeber, Stouthamer-Loeber, & Steinhauer, 2004), we have argued that those who exhibit impulse control problems engage in unrestrained reward-seeking behaviors to upregulate a chronically irritable/aversive mood state, the affective consequence of persistently low midbrain dopamine responding (see, e.g., Ashby, Isen, & Turken, 1999; Laakso et al., 2003).

The use of PEP to evaluate reward-related processing among externalizing preschoolers, middle-schoolers, adolescents, and adults exemplifies several of the advantages of psychophysiological research outlined previously. First, it provides for inexpensive, noninvasive estimation of central nervous system function. Many other noninvasive techniques such as functional neuroimaging and to a lesser extent EEG are costly, which limits their use and causes researchers to recruit small samples with low statistical power. Although several of our studies have involved neuroimaging (e.g., Gatzke-Kopp et al., 2009; Sauder, Beauchaine, Gatzke-Kopp, Shannon, & Aylward, 2012; Sauder, Derbidge, & Beauchaine, 2013; Shannon, Sauder, Beauchaine, & Gatzke-Kopp, 2009), by using cardiac psychophysiology we have extended our work on reward processing to larger externalizing samples, and to a broader age range than we could have otherwise assessed. In fact, it is difficult to imagine conducting neuroimaging studies with preschoolers, yet autonomic psychophysiology has enabled us to identify vulnerability among children as young as age four (Beauchaine et al., 2013; Crowell et al., 2006). In turn, early identification of vulnerability is of utmost importance if we wish to prevent progression along the externalizing spectrum as affected children mature (see Beauchaine, Hinshaw, & Pang, 2010; Beauchaine & McNulty, 2013; Beauchaine, Neuhaus et al., 2008).

Developmental Considerations

In our own work with typically developing individuals, we have found resting PEP values of 71.5 ms among preschoolers (mean age = 4.5 years), 99.3 ms among middle schoolers (mean age = 10.0 years), and 113.3 ms among young adults (age range = 18–24 years; see Brenner et al., 2005; Crowell et al., 2006; Marsh, Beauchaine, & Williams, 2008). Thus, resting PEP increases monotonically as a function of age through early adulthood, after which age-related changes are negligible (Uchino, Uno, Holt-Lunstad, & Flinders, 1999). Although developmental increases in resting PEP are also observed among externalizing samples, these individuals exhibit lengthened PEPs compared with controls at all ages.

Developmental trajectories in PEP reactivity are more difficult to ascertain, since different research labs have used different stimuli to evoke PEP responses. However, research using reward tasks in particular show no consistent differences across preschool, middle childhood, adolescence, and early adulthood (Beauchaine et al., 2001; Beauchaine, Hong et al., 2008; Brenner et al., 2005; Marsh et al., 2008). In contrast, Quigley and Stifter (2006) reported greater PEP reactivity among young adults than among preschoolers in response to a series of reaction time, emotion evocation, and interview tasks. This illustrates once again the importance of considering stimulus conditions in planning and interpreting psychophysiological experiments. Indeed, PEP reactivity appears to depend on a number of factors unrelated to chronological age, including task type and demographic variables, including sex and race (Matthews et al., 2002).

Choosing Appropriate Stimulus Conditions

It is important to reemphasize that the validity of peripheral markers of CNS processes is highly dependent on the choice of appropriate stimulus conditions. As we have described elsewhere (Brenner & Beauchaine, 2011), PEP reactivity should not be considered a marker of central dopamine responding under conditions other than reward. Although active coping tasks also induce PEP shortening (e.g., Kelsey et al., 2004), they do so through brain systems that subserve fear and anxiety—not behavioral approach (see, e.g., Pribram & McGuinness, 1975). Pre-ejection period reactivity during mental arithmetic therefore cannot be considered a marker of central dopamine responding. This illustrates why stimulus conditions must be considered carefully when formulating tasks designed to elicit specific patterns of neural activity if one wishes to interpret peripheral psychophysiological measures validly (see also Fortunato, Gatzke-Kopp, & Ram, 2013).

Because the ICG signal is sensitive to movement artifacts, respiratory artifacts, and other sources of noise, extracting a valid index of PEP requires that the ECG Q-wave and the ICG B-wave be ensemble averaged across multiple heart beats (see Kelsey & Guethlein, 1990; Sherwood et al., 1990). Similar to techniques used in event-related potential studies described elsewhere in this volume, ensemble averaging filters out noise contained in single heartbeats, and sums signal common across heartbeats. The minimum accepted duration for ensemble averaging is about 20 s, which captures roughly 25 cardiac cycles at normal adult HRs. Importantly, however, since SNS effects on cardiovascular function operate through a second messenger system, maximum PEP reactivity may lag up to 20 s poststimulus presentation. As a result, stimulus epochs should be considerably longer, and the first 20 s should be discarded for an accurate estimate of SNS reactivity.

Heart Rate Variability

Heart rate variability (HRV) refers to beat-to-beat changes in the time (ms) between successive R-R intervals derived from ECG recordings. This variability is determined by a number of factors, including diurnal influences, baroreceptor activation, tonic and phasic influences of the SNS and PNS, nonneural effects, and pathophysiological processes (see Beauchaine, 2001; Berntson et al., 1997; Porges, 1995; Ritz, 2009). The most basic measures of HRV include standard deviation of, coefficient of variance of, and mean successive difference in R-R intervals (see Allen, Chambers, & Towers, 2007; Berntson et al., 1997). These measures correlate highly with one another, and under certain conditions (see below), with vagal efference to the heart as determined by pharmacologic blockade (see Allen et al., 2007; Grossman, Van Beek, & Wientjes, 1990; Hayano et al., 1991). Associations with PNS activity/reactivity are a primary motivation for capturing HRV in psychopathology research, given consistent empirical links between deficient PNS responding and emotion dysregulation, which characterizes many clinical disorders (see Beauchaine, 2001; Beauchaine et al., 2007; Chambers & Allen, 2007; Dennis, Buss, & Hastings, 2012; Friedman, 2007; Obradović & Boyce, 2012; Rottenberg, 2007).

As reviewed previously, the SA node is innervated by both inhibitory PNS fibers from the vagus nerve and excitatory SNS fibers from thoracic spinal nerves. Thus, although SNS and PNS influences are primary determinants of HR and HRV, basic measures of HRV cannot be used to quantify parasympathetic contributions to

cardiac function, as is sometimes supposed (see Berntson, Cacioppo, & Quigley, 1991, 1993; Berntson, Cacioppo, Quigley, & Fabro, 1994; Berntson, Cacioppo, Binkley et al., 1994; Levy, 1988). Rather, to infer vagal activity/reactivity, more sophisticated processing of the ECG signal is required. This processing quantifies respiratory sinus arrhythmia (RSA), or the degree of ebbing and flowing of HR associated specifically with respiration (see Berntson et al., 1997; Porges, 1995). Inhibitory PNS efference slows HR during exhalation, whereas PNS withdrawal speeds HR during inhalation. This respiration-related periodicity in HR defines RSA, which is measured using either frequency domain or time domain methods (see Allen et al., 2007; Katona & Jih, 1975; McCabe, Yongue, Ackles, & Porges, 1985; Santucci et al., 2008; Thayer, Hansen, & Johnsen, 2010).

Frequency domain methods quantify the amount, or power of HRV within specific frequency bands, or windows (see Grossman, 1992). The most commonly used technique for capturing HRV in the frequency domain is spectral analysis, which decomposes the R-R time series into different components using fast-Fourier transformations or autoregressive techniques (see Akselrod et al., 1981; Beauchaine, 2001; Hayano et al., 1991; Thayer, 2002). Fast-Fourier transformations convert time-dependent phenomena into a spectral density function across all frequencies. The spectral density function can then be subdivided into specific frequency bands of interest (Figure 22.4). For example, depending on experiment-specific considerations, total spectral power in HRV might be subdivided into low frequency variability (below 0.04 Hz), mid frequency variability (0.04–0.15 Hz), and high frequency variability (above 0.15 Hz) components. At normal adult breathing rates, this high frequency component yields an estimate of RSA.

Provided that the high frequency band is defined to match the breathing rate of participants—a process called windowing—the estimate of RSA quantifies vagal efference to the heart (see Grossman, 1992; Grossman et al., 1991; Ritz, 2009). Yet breathing rates vary substantially both within and between individuals and samples. This can be especially problematic when ages of participants are dispersed widely, since children breathe at much higher frequencies than adults (see below). One approach used to deal with this problem is to have all participants breathe at the same rate, a process referred to as paced breathing. However, this method is artificial, is impractical for use with very young children, and cannot be used in naturalistic settings that require ambulatory assessment. Many researchers have therefore turned to autoregressive

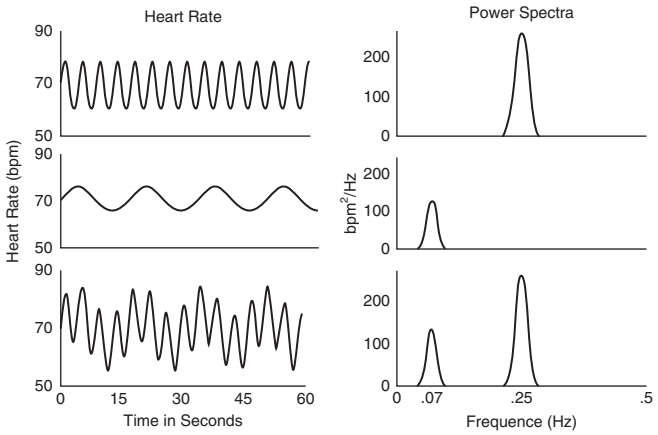

Figure 22.4 Fictitious heart rate signal (left) and associated power spectra (right). The top panels represent pure high-frequency variability (0.25 Hz), which is associated with RSA at normal breathing rates. The middle panels represent low-frequency variability (0.07 Hz), which arises from parasympathetic, sympathetic, and nonneural origin. The bottom panels represent the high- and low-frequency combined signal. Actual heart rate signals include spectral power at additional frequencies. *Source:* Adapted from Beauchaine (2001), Vagal tone, development, and Gray's motivational theory: Toward an integrated model of autonomic nervous system functioning in psychopathology. *Development and Psychopathology, 13*, 183–214.

techniques to circumvent the windowing problem (see Thayer, 2002; Thayer et al., 2010). These methods apply true components analysis to the IBI time series to determine empirically the appropriate breathing frequency for each participant (see Kay & Marple, 1981).

Certain time domain methods can also be used to address the windowing problem. Time domain methods estimate RSA directly from the IBI time series. Although basic metrics such as standard deviation of IBIs are necessarily computed in the time domain, these include all HRV—not only that associated with respiration (see Task Force of the European Society of Cardiology and the American Society of Pacing and Electrophysiology, 1996). Thus, time domain methods must also be chosen carefully if one wishes to extract high frequency HRV associated with respiration. One popular approach is the peak-to-valley method, in which differences between the shortest IBI during inhalation and the longest IBI during exhalation are averaged (Grossman, 1992; Grossman & Svebak, 1987; Grossman, Van Beek, & Wientjes, 1990). When using this approach, respiration data must be collected along with the IBI time series.

Much of the debate concerning control for respiration rate and/or tidal volume when estimating RSA concerns construct validity. Although it has long been assumed that

RSA indexes vagal efference to the heart (see Beauchaine, 2001), under certain conditions this may not be the case unless proper methods are used and/or controls are used (Grossman & Taylor, 2007; Ritz, 2009). It was also once thought that sympathetic influences on cardiac function predominate at low- to mid-frequency bands (Hayano et al., 1991), and that the low/high frequency ratio reflected autonomic balance between the SNS and PNS (e.g., Eckberg, 1997). However, more recent studies demonstrate quite clearly that considerable PNS influence exists in the low and mid frequencies (see Reyes del Paso, Langewitz, Mulder, van Roon, & Duschek, 2013). Thus, low frequency spectral power cannot be used to estimate SNS effects on the heart, and should not be substituted for PEP, which is well validated.

Links to Psychopathology

Although alternative measures of RSA do not correlate perfectly with one another, and do not always index vagal efference to the heart (construct validity), they may nevertheless serve as reliable markers of clinical state (predictive validity). Across many different measurement methods, low baseline RSA and excessive RSA reactivity (i.e., withdrawal) to emotion evocation are associated with internalizing and externalizing symptoms of psychopathology (see Beauchaine, 2001; 2012; 2015a; 2015b; Beauchaine & Thayer, in press; Porges, 2007; Vasilev et al., 2009), and with specific psychopathological conditions and traits, including anxiety (e.g., Hastings, Sullivan et al., 2008; Thayer, Friedman, & Borkovec, 1996), attention problems (see Rash & Aguirre-Camacho, 2012), autism (Neuhaus, Bernier, & Beauchaine, 2014; Patriquin, Scarpa, Friedman, & Porges; 2013), callousness (de Wied, van Boxtel, Matthys, & Meeus, 2012), conduct disorder (Beauchaine et al., 2001, 2007; Mezzacappa et al., 1996), depression (e.g., Rottenberg, 2007; Rottenberg, Salomon, Gross, & Gotlib, 2005; Rottenberg, Wilhelm, Gross, & Gotlib, 2002), nonsuicidal self-injury (Crowell et al., 2005), panic disorder (e.g., Asmundson & Stein, 1994), phobias (e.g., Ahs, Sollers, Furmark, Fredrikson, & Thayer, 2009), and trait hostility (Sloan et al., 1994), among others. Furthermore, concurrent internalizing and externalizing symptoms predict greater RSA withdrawal to emotion evocation than either internalizing or externalizing symptoms alone (Calkins, Graziano, & Keane, 2007; Pang & Beauchaine, 2013). In Figure 22.5 we present data on RSA reactivity to negative emotion induction collected from adolescent girls who engage in nonsuicidal self-injury (Crowell et al., 2005). Interestingly, this finding violates the law of initial values, since self-injuring adolescents

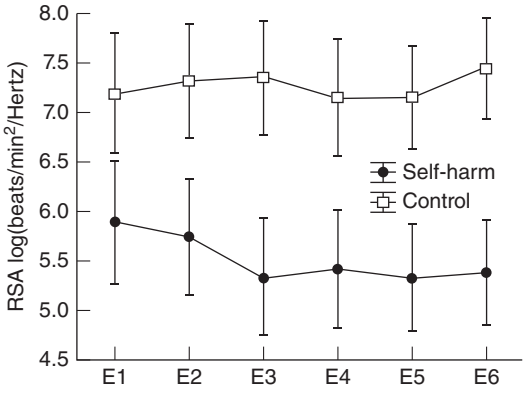

Figure 22.5 Respiratory sinus arrhythmia values (log[beats/min^2/Hz]) for control adolescent girls (open squares) and girls who engage in self harm (closed circles), across six 30 s epochs of negative mood induction during which participants watched a film clip of a young boy with his dying father. A significant main effect of group, and a significant Group × Epoch interaction were found, indicating lower RSA among those who engaged in self-harm, and progressively more RSA withdrawal across epochs for the self harm group, but not for controls. *Source:* From Crowell, Beauchaine, McCauley, Smith, Stevens, and Sylvers (2005), Psychological, autonomic, and serotonergic correlates of parasuicidal behavior in adolescent girls. *Development and Psychopathology, 17*, 1105–1127.

exhibited both lower RSA at baseline and more RSA reactivity to mood induction. Similar findings have emerged for many of the clinical conditions outlined previously.

All of these conditions are characterized by emotion dysregulation—the inability to effectively modulate affective states (see, e.g., Cole et al., 2013). As a result, one or more negative emotions (e.g., sadness, anxiety, rage) are experienced either too intensely or too enduringly to be adaptive (see Beauchaine et al., 2007). Although low baseline RSA and excessive RSA reactivity to emotion evocation mark this core emotion dysregulatory component of psychopathology (Beauchaine, 2001; 2015a; 2015b), specific manifestations (e.g., internalizing versus externalizing) are determined by interactions between emotion dysregulation, dysfunction in other neurobiological systems, and social determinants, some of which are discussed below (see Beauchaine et al., 2001; 2007; Beauchaine & Gatzke-Kopp, 2012; Chambers & Allen, 2007; El-Sheikh et al., 2009; Mead et al., 2010; Porges, 2007).

In contrast to consistent links between low baseline RSA, excessive RSA reactivity, and emotion dysregulation, high baseline RSA and moderate RSA withdrawal during attention demanding tasks are adaptive, and reflect strong regulatory capacity (e.g., Marcovitch et al., 2010; Richards, 1987). Children who exhibit high baseline RSA and either very little RSA withdrawal, or increased RSA to

emotion evocation, which is likely indicative of attention deployment (see Suess, Porges, & Plude, 1994), are either fully or partially protected from adverse outcomes often associated with exposure to maternal depression (e.g., Blandon et al., 2008), paternal antisociality (e.g., Shannon et al., 2007), parental drinking (e.g., El-Sheikh, 2005), and marital conflict/divorce (e.g., El-Sheikh et al., 2001; Katz & Gottman, 1995). Furthermore, studies of normative samples indicate consistent associations between resting RSA and several aspects of adaptive functioning in infancy, childhood, adolescence, and adulthood, including temperamental complaisance (Huffman et al., 1998), social competence, (e.g., Eisenberg et al., 2008) behavior regulation during social challenge tasks (e.g., Hastings, Nuselovici et al., 2008), attachment security (Diamond, Fagundes, & Butterworth, 2012), positive social interactions with partners (Diamond, Hicks, & Otter-Henderson, 2011), and empathy toward others who are in distress (e.g., Eisenberg et al., 1996; Liew et al., 2011). Thus, high baseline RSA and moderate RSA reactivity to emotionally evocative stimuli mark positive social adjustment and resilience in contexts of stress and adversity (see Beauchaine 2001).

Inconsistencies in the Developmental Versus Clinical Literatures?

A major objective of developmental psychopathology research is to juxtapose findings obtained from normative samples with findings obtained from clinical samples in efforts to (1) further our understanding of typical and atypical development, and (2) identify mechanisms through which certain individual differences, though not disordered themselves, render some children more vulnerable to developing psychopathology as they mature (see Beauchaine & McNulty, 2013; Cicchetti, 1984, 2006; Cicchetti & Rogosch, 1996; Sroufe, 1997; Sroufe & Rutter, 1984). By conducting these group comparisons across multiple levels of analysis (e.g., genetic, neural, autonomic, social), we seek to discover etiological and pathophysiological processes, specification of which is sometimes a precondition for effective intervention (e.g., Beauchaine & Gatzke-Kopp, 2012; Beauchaine, Neuhaus et al., 2008; Cicchetti, 2008; Cicchetti & Blender, 2004; Cicchetti & Dawson, 2002). Accordingly, when seemingly different neurodevelopmental processes characterize typical and atypical samples, understanding those differences should be a research priority.

In apparent contrast with findings described previously in which children, adolescents, and adults with clinical levels of conduct problems, delinquency, and related externalizing comportment exhibit excessive RSA withdrawal to emotion evocation (e.g., Beauchaine, Hong et al. 2008; Beauchaine et al., 2001, 2007; de Wied et al., 2012; Mezzacappa et al., 1996), in both normative and high risk samples, symptoms of externalizing behavior are often associated with either *less* RSA withdrawal during lab tasks, or no RSA withdrawal (e.g., Dietrich et al., 2007; Obradović, Bush, Stamperdahl, Adler, & Boyce, 2010). For example, Fortunato et al. (2013) reported less RSA reactivity during positive film clips among at-risk preschoolers who scored high on externalizing symptoms, and Hinnant and El-Sheikh (2009) reported a positive correspondence between externalizing symptoms and increases in RSA during problem solving among children in middle childhood. The consistency of divergent findings in clinical versus normative/high risk samples suggests that the discrepancy is not arbitrary, and cannot be explained away by failures to replicate (see Beauchaine, 2009b).

There are several possible explanations for these discrepant findings. One possibility is that different mechanisms of RSA-behavior relations exist at the extreme of externalizing scores than at the mode of the distribution. Even in high risk samples, few children meet clinical criteria for conduct problems. Thus, within such samples, most of the variance in correlations between RSA reactivity and externalizing behavior is determined by those who score <1 standard deviation above the mean on externalizing, where 84% of observed scores lie. In contrast, most of the clinical samples described previously either met criteria for conduct disorder or scored above the 95th percentile on conduct problems, aggression, delinquency, and so forth. If relations between RSA and externalizing behavior are different at extreme scores, any such difference will be swamped in normative samples by individual variation among those who score closer to the mean (see Beauchaine, 2009b). Notably, however, any such explanation requires specification of alternative mechanisms of RSA–behavior relations among normative versus clinical samples, for which there is no evidence to date.

A second, related explanation concerns the meaning of externalizing symptoms at different points of a normal distribution. Individual differences in externalizing scores are dispersed across the entire range of normal to extreme, and low to intermediate scores do not reflect problem behavior. As alluded to already, most of those who comprise both normative and high risk samples score within normal ranges of externalizing conduct. It makes little sense to suggest that an individual who scores $T = 60$ on the Child Behavior Checklist (Achenbach, & Edelbrock, 1991)—or one standard deviation above the population mean—is

exhibiting problematic behavior. On the contrary, externalizing scores in this range, which are by definition normal, are likely to reflect temperamental exuberance, positive affectivity, social competence, and adaptive engagement with the environment (see Degnan et al., 2011). These are the very traits that modest RSA withdrawal to emotion evocation and attention demanding tasks has been associated with in numerous studies, as described previously (Marcovitch et al., 2010; Richards, 1987; Suess et al., 1994). Thus, measures designed to assess psychopathology may not capture problematic behavior when used among individuals who score within normal ranges. Apparent associations between behavior problems and low RSA reactivity to behavioral challenge among normal and high risk samples may therefore be misinterpretaion.

A third possible explanation concerns differences in definitions of RSA used by developmentalists versus psychopathologists. In our work with clinical samples of adolescents, for example, we typically define (i.e., window) RSA as all spectral power > 0.15Hz (e.g., Beauchaine et al., 2001; Beauchaine, Hong et al., 2008; Crowell et al., 2005; Vasilev et al., 2009). This captures respiratory frequencies at and above 9 breaths per min. In contrast, it is common practice among those who work with developmentally normative and at-risk samples to set age-dependent upper limits when windowing RSA (e.g., Dietrich et al., 2007; Kennedy, Rubin, Hastings, & Maisel, 2004; Leary & Katz, 2004). Although appropriate windowing is important if one wishes to index vagal efference to the heart, upper limits can filter out variance in RSA from participants who breathe especially fast. Importantly, these individuals may be particularly vulnerable to developing psychopathology.

Finally, differences in stimulus conditions used by developmentalists versus psychopathologists must be considered. A core theme of this chapter is that the functions and CNS origins of psychophysiological responses cannot be inferred without considering the context within which the psychophysiological responses are evoked (see Beauchaine, 2012; Beauchaine & Gatzke-Kopp, 2012; Brenner & Beauchaine, 2011). Given its incredible complexity, the human brain is capable of far more variegated responding than the ANS. Yet because the ANS is the final common pathway between CNS responding and behavior, what may appear to be identical ANS response patterns are often initiated by very different neural systems and psychological reactions. As noted already, for example, although considerable evidence suggests that PEP reactivity to incentives marks midbrain dopamine responding, PEP reactivity to threat is driven by different neural systems. Thus, we cannot interpret PEP reactivity as an index of any single CNS process. Rather, as a marker of SNS reactivity, PEP shortening could reflect appetitive responding, fear, or stress reactivity, depending on stimulus conditions.

The same tenet applies to interpretations of RSA reactivity. Links between externalizing behavior and RSA reactivity have been evaluated across many stimulus conditions, including emotion evocation (e.g., Beauchaine et al., 2001), attention allocation (e.g., Suess et al., 1994), executive function (e.g., Marcovitch et al., 2010), and positive mood induction (e.g., Fortunato et al., 2013). In general, *externalizing behaviors are associated with excessive RSA withdrawal specifically during emotion evocation—not during other types of tasks*. This reflects the emotional lability/dysregulation component of conduct problems and related externalizing conditions (see Beauchaine et al., 2007, 2009; Beauchaine & Gatzke-Kopp, 2012). In contrast, *externalizing behaviors are associated with either less RSA withdrawal or increases in RSA during attention demanding, executive function, and problem solving tasks* (e.g., Dietrich et al., 2007; Hinnant & El-Sheikh, 2009; Obradović et al., 2010). This likely reflects attentional difficulties among these individuals (see also Beauchaine, 2001; Rash & Aguirre-Camacho, 2012).

Developmental Considerations

Among healthy individuals, time domain measures of baseline HRV increase linearly throughout infancy, childhood, and adolescence (e.g., Massin & von Bernuth, 1997; Silvetti, Drago, & Ragonese, 2001). For example, Silvetti et al. (2001) reported resting standard deviation of R-R interval values of 87, 133, 155, and 201 for 1–5-year-old, 6–10-year-old, 11–15-year-old, and 16–20-year-old females, respectively. Although slopes were not equivalent across sexes, a linear increase in HRV was also observed among males in the same age groupings (113, 154, 183, and 187), Linear increases in time domain measures of HRV should not be surprising given their dependence on respiratory frequency, which decreases substantially from childhood to adulthood (e.g., Fleming et al., 2011).

Frequency domain measures of RSA also increase with age, yet direct comparisons across broad time intervals are difficult given alternative metrics used to quantify spectral power by different labs and software programs (e.g., ln[beats/min^2/Hz] versus ms^2). Using the ln(beats/min^2/Hz) metric, we have reported resting RSA values of 6.73 among typically developing preschoolers (mean age = 4.5 years), and 7.20 among typically developing middle schoolers (mean age = 13.2 years; see Beauchaine et al., 2001; Crowell et al., 2006). After young adulthood, gradual

decreases in RSA are observed across the life span, although such decreases are moderated by physical fitness (Byrne, Fleg, Vaitkevicius, Wright, & Porges, 1996).

As noted previously, it is also important to define windows appropriately when estimating high frequency spectral power, which is used to extract RSA. To date, many researchers have used windows that are appropriate for infants or very young children across all age ranges in both cross sectional and longitudinal studies, which results in greater and greater misspecification of RSA as individuals mature. As alluded to before, accurate assessment of RSA depends on appropriate specification of respiration rate, which varies considerably across development (see Wallis, Healy, Undy, & Maconochie, 2005). In Table 22.1 we present expected respiration rates (at the 2–1/2 percentile, which captures most individuals) for children, ages 4–16 years. These values can be used to adjust windows when calculating RSA in the frequency domain.

Developmental changes in RSA reactivity are also difficult to evaluate given different stimulus conditions applied across labs and age groups. However, during emotion evocation tasks, we have found RSA reactivity values of −0.89 ln(beats/min^2/Hz) among typically developing preschoolers (mean age = 4.6), 0.02 ln(beats/min^2/Hz) among typically developing middle schoolers (mean age = 10.3), and −0.18 ln(beats/min^2/Hz) among typically developing adolescents (mean age = 13.2; Beauchaine et al., 2001; Crowell et al., 2006; Pang & Beauchaine, 2013). These data suggest that healthy control children become better able to regulate their physiological reactions to emotion evocation as they mature. In contrast, children with behavior problems become more reactive (see Pang & Beauchaine, 2013). Finally, older adults exhibit greater RSA reactivity to acute psychological stress than younger adults (Uchino et al., 1999).

TABLE 22.1 Respiration Rates (2–1/2 percentile) in Beats/Minute and Corresponding Hertz (cycles per second) for Appropriate Windowing of Frequency Domain Metrics of RSA

Age in years	Respiration rate[1] (beats/min)	Hertz
4	20	.33
5	19	.32
6	18	.30
7	17	.28
8	17	.28
9	16	.27
10	15	.25
11	14	.23
12	14	.23
13	13	.22
14	12	.20
15	12	.20
16	11	.18
adult	9	.15

[1]Respiration rates evaluated among 1,109 children, as reported by Wallis et al. (2005)

Choosing Appropriate Stimulus Conditions

In developmental and developmental psychopathology research with infants and children, RSA is often used as a peripheral index of attention allocation, emotion regulation, and social affiliative capacity (see, e.g., Beauchaine, 2001; Patriquin et al., 2013; Porges et al., 1994; Richards, 1985; Suess, et al., 1994). Linking RSA reactivity to these different constructs is fully appropriate when stimulus conditions are designed to evoke a matching psychological state. For example, to infer that RSA reactivity marks individual differences in empathic responding, RSA should be measured during an empathy-eliciting task (see, e.g., Liew et al., 2011). As we note earlier and elsewhere (Beauchaine, 2012), however, far too little attention has been paid to choosing appropriate stimulus conditions in psychophysiological research with children. This problem is especially evident in studies of RSA, where inferences are often extrapolated about psychological constructs (e.g., emotion regulation) from RSA reactivity collected during stimulus conditions that evoke psychological states that are only partly related.

In addition, even though the PNS exerts beat-to-beat control over HR, RSA cannot be measured on a second-to-second basis. Rather, to meet minimum assumptions of spectral analysis and related frequency domain techniques, at least 10 waveforms (respiratory cycles) must be subjected to fast-Fourier analysis (preferably more; see, e.g., Berntson et al., 1997). Thus, in research conducted with infants, who exhibit respiratory frequencies as high as 60 breaths/min, minimum epoch lengths as short as 15 s might be acceptable. In contrast, in research conducted with adults, who exhibit respiratory frequencies as low as 12 breaths/min, minimum epoch lengths may need to be 1 min or longer. Notably, however, stable estimates of RSA can also be extracted by averaging somewhat shorter epochs, an approach that may be advantageous when evaluating PNS reactivity. In our own research, we routinely examine trends in RSA reactivity during 3 min film clips by estimating spectral densities in successive 30 s epochs (e.g., Beauchaine et al., 2001; Crowell et al., 2005, 2006).

Finally, as with any psychophysiological measure, participant movement should be controlled carefully, since movement induces artifacts and increases measurement error by changing metabolic demands (see, e.g., Bush et al., 2011). Notably, however, minimal motor activity,

such as that involving hand movements to complete tasks, do not affect RSA or heart period appreciably (Porges et al., 2007).

ELECTRODERMAL ACTIVITY AND REACTIVITY

The term electrodermal activity (EDA) refers to both tonic and phasic responding of eccrine sweat glands, located primarily on the palms of the hands and soles of the feet, and innervated cholinergically by the SNS (see Uno, 1977; Vetrugno, Liguori, Cortelli, & Montagna, 2003). Eccrine sweat glands respond more strongly to emotion evocation than apocrine sweat glands, which more densely populate other parts of the body (Dawson, Schell, & Filion, 2007; Van Dooren, De Vries, & Janssen, 2012). Thus, assessing eccrine sweat gland activity and reactivity provides useful information about individual differences in emotional reactivity, and induction of certain psychological states, described below.

As noted already, measures of EDA were first used over 125 years ago by the French neurologist Jean Charcot, who discovered that tonic skin resistance differentiated between certain clinical populations (Vigouroux, 1879, 1888), and that phasic changes in skin resistance were evoked by sensory and psychological stimuli (Féré, 1888). Following from this early work, for many decades psychophysiologists continued to quantify EDA as *resistance* to current flow. This is accomplished by applying a small, constant current across the surface of the skin and measuring resistance to that current, usually in units of kilohm (kΩ) or megohm (MΩ). Since sweat conducts electricity, high skin resistance is associated with low sweat gland activity.

Although EDA has remained popular among psychophysiologists given its sensitivity to a wide range of experimental stimuli, its low cost, and its specificity as an index of SNS reactivity (see Uno, 1977; Vetrugno et al., 2003), it is no longer measured in units of skin resistance. Rather, contemporary measures of EDA index skin *conductance* by capturing current flow across the surface of the skin while voltage is held constant. Skin conductance is typically indexed in microsiemens (μS; $[1/\Omega] \times 10^{-6}$). Greater skin conductance results from increased sweat gland activity, and thus provides a more direct, linear index of eccrine sweat gland activity (Lykken & Venables, 1971). Changes in skin conductance that are not linked to any particular environmental stimulus or event are often referred to as nonspecific fluctuations (NSFs). In contrast, event-related skin changes in skin conductance (i.e., those that immediately follow a stimulus) are often called electrodermal responses (EDRs) or skin conductance responses (SCRs). Such event-related SCRs are elicited by a wide range of environmental stimuli of both positive and negative valence/hedonic value (see Dawson et al., 2007).

Recording EDA requires electrodes, electrode gels/pastes containing a conductive medium, signal conditioners/amplifiers, and appropriate software. The EDA signal can be collected in one of three ways, including (1) exosomatic recording using direct current (DC), (2) exosomatic recording using alternating current (AC), and (3) endosomatic recording (for a detailed discussion, see Boucsein et al., 2012). Across techniques, the EDR signal is very sensitive to measurement artifacts, which may arise from a number of influences (e.g., extraneous noise, signal drift across long testing sessions, hydration artifacts, etc.).

When using exosomatic recording with DC current, two silver–silver chloride (Ag/AgCl) electrodes are placed on either the distal phalanges or the thenar and hyper thenar eminences of the nondominant hand. This enables participants to use their dominant hand in experimental protocols without inducing movement artifacts into the EDR signal. Electrolyte gel or a sodium or potassium chloride paste is placed between the electrodes and the skin, and a small resistor is placed in series. A minute electrical current (e.g., 0.5 V) is then run between the electrodes. Exosomatic DC recording is the most commonly used method in psychophysiology research given the relative ease with which signals can be amplified and recorded.

One drawback to DC recording is electrode polarization, which results in voltage that runs counter to the applied voltage at the electrode-metal surface. Polarized electrodes reduce current flow, thereby inducing measurement error, which must be accounted for in quantifying EDA, particularly when tonic measures are computed. Unfortunately, polarization is not readily quantified, and may be induced nonlinearly as a function of applied voltage (Schaefer & Boucsein, 2000). However, some preventative measures can be taken to diminish polarization. For example, use of nonpolarizing (i.e., sintered) electrodes slows, but does not eliminate current flow reductions. Fowles et al. (1981) also recommend reversal of the DC current flow every 10–15 min during a single recording session to reduce polarization. Finally, polarization of electrodes can be eliminated almost entirely by use of AC rather than DC recording (since alternating current cyclically reverses polarity). Nevertheless, traditional DC recording remains more common in EDA research.

When using the third approach, endosomatic recording, no voltage or current is applied. Rather, a single electrode

is positioned on the palmar surface of the hand or sole of the foot and a reference electrode is placed on an inactive site, such as the forearm. Changes in potential are then compared at the active versus reference site. Although advantages of endosomatic EDA recording include its unobstrusiveness and its utility in identifying phasic responses, signals are not readily interpretable (see below), limiting its use in psychophysiological research.

The term EDA is used broadly to refer to tonic levels of skin conductance, and EDR is used to refer to phasic changes in skin conductance. These terms replace galvanic skin response and galvanic skin reflex, respectively, which are now considered to be anachronistic for two reasons (Boucsein, 1992). First, they imply erroneously that the skin-electrode interface behaves like a galvanic cell (a type of battery that generates current through chemical reactions). This does not reflect the exosomatic recording techniques that dominate the field today. Second, the term galvanic skin reflex suggests that responses cannot be elicited by cognitive or emotional processes since such responses are not reflexive. Accordingly, EDA and EDR are now preferred.

Whereas tonic activity captures basal skin conductance level (SCL), phasic reactivity captures moment-to-moment changes in skin conductance that occur either in response to identifiable stimuli (EDRs/SCRs), or in response to unidentifiable stimuli/internal events (nonspecific fluctuations [NSFs]). As this discussion implies, SCRs and NSFs are superimposed on SCL, and must therefore be decomposed mathematically from SCL when analyzing EDA data (see, e.g., Boucsein et al., 2012; Dawson et al., 2007). For exosomatic recordings, such transformations can be modeled offline using the EDA time course, which begins with 1–3 s nonresponse latency following stimulus onset (if a stimulus is presented), followed by a 1–3 s rise in skin conductance level, then a gradual decline/recovery period that may exceed 10 s (Figure 22.6; Dawson et al., 2007). For endosomatic recordings, the signal contains negative or positive responses that can follow mono-, bi-, and triphasic waveforms, and is thus subject to difficulties in terms of quantifying and interpreting the EDR signal (Christie, 1981).

Psychophysiologists are often interested in measuring the relative magnitude of SCRs, or the number of EDRs in a given time interval, since both capture SNS orienting and reactivity. In event-related designs, greater SCR amplitudes are observed when participants attribute more significance or self-relevance to a stimulus (Janes, 1982). In contrast, habituation can be quantified by reductions in EDR amplitudes across subsequent presentations of a stimulus (Martin & Rust, 1976). In addition, a number of other metrics may be of interest, including SCR latency (the time interval between stimulus presentation and an SCR), rise time (the time interval between stimulus presentation and peak SCR), recovery time (the time interval between peak SCR and full recovery of SCL amplitude),

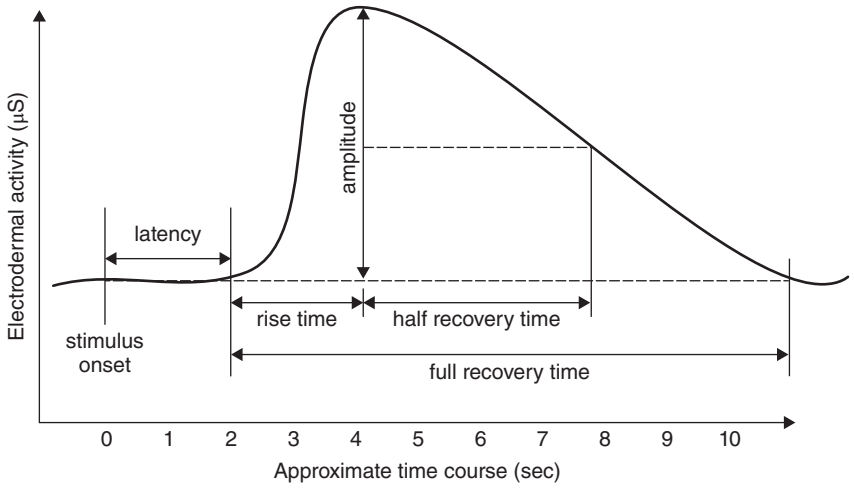

Figure 22.6 Prototypical post-stimulus skin conductance response (SCR). Note the 2–3 s latency period, followed by a steep rise in skin conductance and a much slower recovery to baseline. Both event-related SCRs and nonspecific fluctuations (NSFs) in skin conductance are superimposed on tonic skin conductance level (SCL), and are subject to sensitization and habituation effects. Although the time course of SCRs is often similar to that depicted here, considerable variability is observed, with lower amplitude responses exhibiting shorter recovery times, and higher amplitude responses exhibiting longer recovery times.

half-recovery time (the time interval between peak SCR and 50% recovery of SCL amplitude), number of trials to habituation, and stimulus-specific and nonspecific responding (see Dawson et al., 2007).

Although these measures are highly correlated with one another, some may index particular aspects of psychological functioning better than others. For example, following presentation of stimuli with high subjective significance, recovery time may be slowed more than amplitude is increased (Janes, 1982). In addition, although rise time and recovery time are correlated (Lockhart, 1972), rise time is associated with cardiac acceleration, whereas recovery time is not (Venables, Gartshore, & O'Riordan, 1980). For some populations, differences in responding across metrics may also have clinical implications. For example, antisocial males who exhibit better autonomic conditioning and faster EDR half-recovery time during midadolescence are partially protected from engaging in crime as adults (Raine, Venables, & Williams, 1996).

Links to Psychopathology

EDRs are elicited by a wide range of stimuli, including those that are cognitively demanding, novel, and evocative emotionally (Blanchette & Richards, 2012; Dindo & Fowles, 2008; Gao, Raine, Venables, Dawson, & Mednick, 2010a). Certain personality traits are also associated with individual differences in EDA (e.g., Yoshino, Kimura, Yoshida, Takahashi, & Nomura, 2005), and under appropriate stimulus conditions, patterns of EDA/EDR are associated with psychological vulnerabilities to psychopathology, including trait anxiety, impulsivity, and punishment insensitivity (see Beauchaine, 2001). For example, those high in trait anxiety exhibit greater EDA than controls (Katkin, 1965), and anxious individuals with alexithymia (difficulty identifying and expressing emotions) exhibit greater EDR amplitudes and slower recovery times to novelty than patients low in alexithymia (Rabavilas, 1987).

In contrast, males who are aggressive, and those with externalizing spectrum disorders including ADHD, CD, ASPD, and psychopathy—many of whom experience very little trait anxiety—exhibit attenuated EDA/EDR to a wide range of stimuli (see, e.g., Beauchaine et al., 2001, 2008; Chattopadhyay, Cooke, Toone, & Lader, 1980; Crowell et al., 2006; Giesen & Rollison, 1980; Hare, Frazelle, & Cox, 1978; Lorber, 2004). Such findings are observed in preschoolers, middle-schoolers, adolescents, and adults, and likely reflect a core neurobiological vulnerability to externalizing behavior. Satterfield and Dawson (1971) found that hyperactive children exhibit lower mean SCL, smaller stimulus-specific EDRs, and fewer and smaller NSFs than controls when listening to acoustic stimuli. When administered dopamine agonists, SCL and nonspecific EDRs become similar to those observed in typically developing children.

Children with ADHD also exhibit deficient SCRs during extinction of previously rewarded behaviors (Iaboni, Douglas, & Ditto, 1997), and boys with comorbid ADHD and CD show dampened EDRs, fewer NSFs, and habituate faster to experimental stimuli than controls (Beauchaine et al., 2001, 2008; Herpertz et al., 2001). This pattern of findings is similar to that observed among adults with antisocial personalities (e.g., Raine et al., 2000), and appears to reflect deficient inhibitory control over behavior (Beauchaine et al., 2015). Furthermore, lesions to the ventromedial prefrontal cortex (vmPFC) and the anterior cingulate gyrus—both of which are hypofunctional among psychopaths (Blair, 2008)—result in attenuated SCRs among adults (Tranel & Damasio, 1994). Finally, children and adolescents who exhibit diminished EDRs during fear conditioning are at risk for developing aggression as they mature (e.g., Fung Raine, Loeber, Lynam & Steinhauer, 2005; Gao, Raine, Venables, Dawson, & Mednick, 2010b). Taken together, consistent findings of hyper EDA/EDR among those high in trait anxiety and hypo EDA/EDR among those who are impulsive, aggressive, and low in trait anxiety indicate that EDA serves as reliable biomarker of vulnerability to both internalizing and externalizing spectrum conditions.

Abnormalities in EDA are also observed among those with schizophrenia, and among children with autism spectrum disorder (ASD). In fact, 40–50% of individuals with schizophrenia are classified as electrodermal nonresponders to innocuous but moderately intense stimuli that induce orienting responses in most participants (Bernstein, 1987). In contrast, 6–7-year-old children with ASD and normal intellectual functioning exhibit higher amplitude SCRs to reward feedback (Faja et al., 2013), but are less responsive to visual target stimuli compared to controls (van Engeland, Roelofs, Verbaten, & Slangen, 1991). However, consistent with the notion that autonomic measures usually capture individual differences in traits that cut across disorders, and rarely identify specific disorders as defined by our current diagnostic system (see above), SCR response amplitudes among those with ASD are correlated with internalizing symptoms, and with repetitive behaviors, particularly rituals and need for sameness.

In turn, repetitive behaviors have long been linked to high levels of anxiety in ASD populations, especially among high-functioning individuals (e.g., Gillott, Furniss, & Walter, 2001; Rodgers, Riby, Janes, Connolly, & McConachie, 2012). Thus, as in other populations, greater EDR is associated with anxiety among those with autism, and is not specific to the disorder.

Developmental Considerations

Although developmental changes are not observed in either SCL or NSFs from middle childhood through adulthood, evidence suggests greater EDA among preschoolers. For example, higher initial SCL and more NSFs are observed among 5-year-olds compared to 10-, 15-, 20-, and 25-year-olds (Venables & Mitchell, 1996). Other research groups have also reported stabilization of SCL beginning around age 6 (El-Sheikh, 2007; see also Shields, 1983).

The orienting response can be detected with electrodermal measures among children as young as age 3 months (Ingram & Fitzgerald, 1974). However, mature orienting (see below) does not appear until about age 3 years (Gao, Raine, Dawson, Venables, & Mednick, 2007; Tuvblad et al., 2012). Habituation effects emerge around age 4 years, and continue to increase into childhood (Gao et al., 2007). Like other psychophysiological responses, electrodermal orienting diminishes among older adults, yet habituation remains stable (Plouffe & Stelmack, 1984).

Evoked changes in EDA (i.e., EDRs) in response to external stimuli emerge in infancy around age 30 weeks (Storm, 2001), and are observed thereafter in children, adolescents, and adults (e.g., Cole, Zahn-Waxler, Fox, Usher, & Welsh, 1996; Fabes et al., 1994; McManis, Bradley, Berg, Cuthbert, & Lang, 2001). Such EDRs are observed to a wide range of stimuli, regardless of stimulus valence. Similar to findings associated with orienting, older adults (ages 70–80 years) show attenuated EDRs, especially to negative stimuli (Gavazzeni, Wiens, & Fischer, 2008).

Choosing Appropriate Stimulus Conditions

Perhaps more than any other psychophysiological measure, SCRs are evoked by a wide range of stimuli across sensory modalities (e.g., visual, auditory, tactile). Phasic SCRs are often used to quantify the *orienting response*, a coordinated set of actions across multiple physiological systems in response to novelty and/or changing environmental conditions. Orienting facilitates intake of information and preparedness for action through SNS activation and PNS withdrawal, among other mechanisms (see, e.g., Barry, MacDonald, De Blasio, Steiner, 2013; Porges, 1995). Skin conductance responses have long been used to assess both individual differences in orienting (e.g., Berggren, Öhman, & Fredrikson, 1977; Neary & Zuckerman, 1976), and effectiveness of experimental manipulations in inducing orienting (e.g., Dimberg & Öhman, 1983; McCarthy & Waters, 1997). Orienting responses are often evaluated using aversive auditory stimuli. Children with anxiety disorders produce larger EDRs to loud, abrupt sounds than controls, which reflects hypersensitivity to threat (Bakker, Tijssen, van der Meer, Koelman, & Boer, 2009). In contrast, many of those who are vulnerable to or affected by schizophrenia are under-responsive to orienting stimuli (e.g., Dawson & Nuechterlein, 1984; Gruzelier & Venables, 1972).

Skin conductance response amplitudes are also used to quantify *habituation*, or the tendency of physiological systems to decrease reactivity to a stimulus following repeated exposures (see, e.g., Lykken, Iacono, Haroian, Mc Gue, & Bouchard, 1988). Rates of habituation vary as a function of stimulus saliency (e.g., Öhman, Eriksson, Fredriksson, Hugdahl, & Olofsson, 1974), and faster habituation to punishment/extinction is often observed among impulsive individuals. For example, boys with comorbid ADHD and CD exhibit more rapid habituation to both orienting and aversive stimuli than controls (Herpertz et al., 2001), and less SCR reactivity to punishment/extinction (e.g., Iaboni et al., 1997).

Given the sensitivity of EDR to such a wide range of stimuli, careful attention must be given to experimental design and interpretation of results. Important considerations include the type of stimuli presented (including sensory modality and subjective significance of stimuli), presentation schedule (including sequencing and time intervals between and during stimulus presentations), number and order of different categories of stimuli in a single experiment (Boucsein et al., 2012), and instructions to participants. For example, participants who are instructed to ignore tones exhibit smaller amplitude SCRs and habituate faster than those who are told to attend to stimuli (Iacono & Lykken, 1983).

In general, since EDR is observed to such a wide range of stimuli, skin conductance is of limited value in distinguishing between emotions (see Johnsen, Thayer, & Hugdahl, 1995). Although some have reported differences in SCRs across certain emotions (e.g., higher amplitudes for anger and happiness than for fear, disgust, sadness, and surprise), such findings are not well replicated, and most emotions are indistinguishable using skin conductance alone (see Collet, Vernet-Maury, Delhomme, & Dittmar, 1997). Similar problems arise in research designed to

disentangle affective responses from potentially related but partly distinct processes such as orienting, attention, and goal-directed responses (Bradley, 2009). For example, stimuli of subjective significance elicit SCRs independent of associated emotional arousal level among adults (Dindo & Fowles, 2008), and independent of stimulus novelty and complexity in both normal children and children with psychopathology (van Engeland et al., 1991). Accordingly, manipulating the subjective significance of stimuli may render psychophysiological measures more sensitive to cognitive aspects of psychopathological phenomena, such as ruminative aspects of anxiety, than simply presenting stimuli that are novel or emotionally charged.

Psychological and physiological factors that are specific to participants themselves are also reflected in EDR, which may complicate interpretability. Such variables include skin hydration levels (Bundy & Mangan, 1979), individual differences in tonic electrodermal activity (Benedek & Kaernbach, 2010), age (Barontini, Lazzari, Levin, Armando, & Basso, 1997), medication/drug use (specifically substances with anticholingergic properties; e.g., Green, Nuechterlein, & Satz, 1989), and race (El-Sheikh, Keiley, & Hinnant, 2010; Janes, Worland, & Stern, 1976). For example, research shows consistently lower EDA among African Americans that among Whites. If race effects are not accounted for in psychophysiological research, incorrect conclusions may be drawn about EDA-behavior relations, especially if group comparisons are conducted across subsamples with different race distributions.

Characteristics of the physical environment during EDA recording should also be controlled to reduce their influence on eccrine secretion. For example, ambient temperature and humidity should be maintained and comfortable levels that do not induce hydration artifacts. Furthermore, given the sensitivity of EDA to both internal and external stimuli, preventative measures should be taken to diminish confounds and extraneous stimulation (e.g., noise). First, as outlined above, researchers should collect true resting baselines, even among children, to capture tonic SCL after habituation to the lab environment has occurred. Only then can reactivity to subsequent stimuli be assessed precisely. Many who conduct research with children use vanilla baselines in which soothing or mildly entertaining stimuli are presented (e.g., Jennings et al., 1992), under the assumption that children are either incapable of or will be disturbed by being left alone for 5–10 min—the minimum we recommend for obtaining a true baseline. However, in our own work with children as young as age 4 years—even those with severe ADHD—we have not found obtaining true baselines to be problematic (see, e.g., Beauchaine et al., 2013; Crowell et al., 2006). In addition, Boucsein et al. (2012) recommend affixing electrodes to the skin at a minimum of 5–10 min before recording to allow for better electrode-skin contact, and to provide time for the corneum to hydrate to similar levels across participants.

VULNERABILITY TO PSYCHOPATHOLOGY IN MULTIDIMENSIONAL AUTONOMIC SPACE

Thus far we have discussed only bivariate relations between vulnerability to psychopathology and psychophysiological responding. Well-replicated findings linking low resting heart rate to delinquency and aggression, blunted PEP reactivity during reward to externalizing spectrum disorders, electrodermal responding to trait and state anxiety, and RSA reactivity during mood induction to emotion dysregulation, are all examples of such bivariate associations. A growing body of research, however, has also examined vulnerability to psychopathology across multiple trait dimensions, using psychophysiological variables as biomarkers (see, e.g., Beauchaine et al., 2001; Beauchaine, Hong et al., 2008; Bubier & Drabick, 2008; Crowell et al., 2005, 2006; El-Sheikh et al., 2009; Gray, 1970; Shannon et al., 2007; Tranel, 1983). Extending research on psychopathology to multiple levels of analysis, including neurobiological systems implicated in behavior, mood, and emotion regulation, has important implications for our understanding of psychiatric comorbidity, resilience in the face of vulnerability, and both moderating and interactive effects of different neural systems on psychiatric adjustment (e.g., Beauchaine & McNulty, 2013; Beauchaine & Thayer, in press; Beauchaine et al., 2007; Cicchetti, 2008). Indeed, concurrent compromises in neurobiological systems underlying both appetitive and aversive responding are associated with worse behavioral outcomes than compromises in either system alone (e.g., Sauder et al., 2012). Understanding such interactive effects requires multidimensional models of psychopathology.

Two-Dimensional Models of Personality

Contemporary multidimensional models of psychopathology almost all include, at a minimum, separate axes for appetitive (e.g., behavioral activation, impulsivity, novelty seeking) and aversive (e.g., behavioral inhibition, trait anxiety, harm avoidance) behaviors (see Cloninger, Svrakic, & Przybeck, 1993; Gray, 1987; Gray & McNaughton, 2000;

McNaughton & Corr, 2004). These models follow from recognition that (1) those who fall at extremes along dimensions of approach behavior and avoidance behavior often suffer from functionally impairing levels of impulsivity and anxiety, respectively, and (2) individual differences in approach and avoidance motivation must be represented by separate axes since their neural underpinnings are structurally and functionally distinct (see, e.g., Gray & McNaughton, 2000).

The first two-dimensional model of personality, which was later modified to describe vulnerability to psychopathology, was published by Eysenck (1947; Eysenck & Eysenck, 1969). Eysenck's model included orthogonal dimensions of extraversion and neuroticism, which were later rotated by Gray (1970) to describe individual differences in motivated behavior, based on relative sensitivities of two phylogenetically old neural systems: the dopaminergically mediated mesolimbic (behavioral approach) system (BAS), which evolved to subserve appetitive func-tions, and the serotonergically mediated septo-hippocampal (behavioral inhibition) system (BIS), which evolved to subserve aversive functions (see Beauchaine, 2001; Fowles, 1980, 1988; Gray, 1987). Eysenck's two-dimensional model of personality and Gray's rotation appear in Figure 22.7.

In a highly influential Presidential Address to the Society for Psychophysiological Research, Fowles (1980) reviewed evidence that behavioral approach system activity could be indexed by HR acceleration to incentives, and behavioral inhibition system activity could be indexed by EDRs to mild punishment. He then noted that psychopaths demonstrate normal HR reactivity, behavioral approach, and active avoidance of threat, suggesting a functional BAS, but deficient EDR, passive avoidance learning, and extinction of previously rewarded behaviors, suggesting a dysfunctional BIS. Fowles (1988) later extended this motivational account of psychopathology to anxiety disorders, depression, mania, drug abuse, and schizophrenia.

After publication of Fowles' (1980, 1988) papers, Gray's (1970, 1987) reinforcement sensitivity (BIS/BAS) became a predominant organizing framework in psychophysiological research on psychopathology, including depression (e.g., Davidson, 2003; McFarland, Shankman, Tenke, Bruder, & Klein, 2006), anxiety (e.g., Colder & O'Connor, 2004) externalizing spectrum disorders (e.g., Beauchaine et al., 2001; Crowell et al., 2006), criminal offending, (e.g., Arnett & Newman, 2000), and schizophrenia (e.g., Scholten, van Honk, Aleman, & Kahn, 2006). At present, however, the popularity of reinforcement sensitivity theory in psychopathology research appears to be waning. Although this is likely stems from several factors, which we do not have space to review here (for discussions, see Brenner et al., 2005; Poythress et al., 2008), an especially important consideration is that strictly motivational models of psychopathology do not account for emotion dysregulation, which (1) characterizes many if not most forms of mental illness, (2) is mediated by different neural structures than either approach or avoidance tendencies, (3) tends to emerge later in development than individual differences in approach and avoidance behaviors, and (4) is less heritable than either approach or avoidance tendencies (see Beauchaine, 2001; 2015a; 2015b; Beauchaine & Gatzke-Kopp, 2012; Beauchaine & Thayer, in press; Beauchaine et al., 2007). Any multidimensional autonomic model of psychopathology should therefore include a peripheral index of emotion regulation/dysregulation.

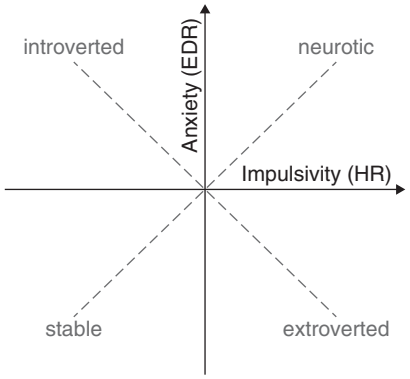

Figure 22.7 Gray's (1970, 1987) rotation (solid axes) of Eysenck and Eysenck's (1969) two-dimensional model of personality (hashed axes). Gray linked Eysenck's behavioral facets of personality to individual differences in susceptibility to reward cues (impulsivity) and punishment cues (anxiety). In doing so, he proposed specific neurobiological systems responsible for processing reward and removal of punishment (the behavioral approach system [BAS]) versus punishment and frustrative nonreward (the behavioral inhibition system [BIS]). Fowles (1980) noted that BAS activation could be indexed psychophysiologically by heart rate (HR) reactivity to incentives, whereas BIS activation could be indexed by electrodermal reactivity (EDR) to extinction/mild punishment. See text for further details. *Sources:* Adapted from Gray (1970), The psychophysiological basis of introversion-extraversion, *Behaviour Research and Therapy, 8*, 249–266; Gray (1987), Perspectives on anxiety and impulsivity: A commentary, *Journal of Research in Personality, 21*, 493–509; Eysenck & Eysenck (1969), *The structure and measurement of personality,* London, UK: Routledge & Kegan Paul; and Fowles (1980), The three arousal model: Implications of Gray's two-factor learning theory for heart rate, electrodermal activity, and psychopathy, *Psychophysiology, 17*, 87–104.

Vulnerability to Psychopathology in Three-Dimensional Autonomic Space

To address these concerns, we characterize vulnerability to psychopathology in three-dimensional autonomic space (Figure 22.8). Consistent with traditional motivational models, one of our axes represents trait impulsivity, assessed psychophysiologically as PEP reactivity to incentives, and a second represents trait anxiety, assessed psychophysiologically as EDR (either baseline NSFs or SCRs to mild punishment). However, we also include a third dimension, which represents emotion dysregulation, assessed psychophysiologically as RSA reactivity to emotion evocation (see Beauchaine, 2001; 2015a; 2015b). We have used this three-dimensional model as an organizing framework in our work on ANS-behavior relations among preschoolers with ADHD and ODD (e.g., Beauchaine et al., 2013; Crowell et al., 2006), middle schoolers with CD and depression (e.g., Marsh et al., 2008; Shannon et al., 2007; Vasilev et al., 2009), and adolescents who engage in self-harm (e.g., Crowell et al., 2005, 2013). Adding an emotion regulation dimension to traditional motivational models of psychopathology is important because many individuals who exhibit motivational vulnerability (i.e., high trait impulsivity or high trait anxiety) are protected from psychopathology if they have strong emotion regulation skills. For example, trait impulsivity, expressed early in life as ADHD, may only develop into more severe externalizing conduct if a child fails to develop strong emotion regulation capabilities, as reflected psychophysiologically in RSA (see Beauchaine et al., 2007; Beauchaine & McNulty, 2013).

OTHER PERIPHERAL MEASURES

Although cardiovascular and electrodermal measures are the most popular psychophysiological techniques in developmental, child psychopathology, and developmental psychopathology research, other methods can also be useful in addressing vulnerability–behavior relations, and other research questions discussed above. We now turn our attention to some of these alternative methods.

Startle and Prepulse Inhibition

The startle reflex is an ANS-mediated response that is elicited by abrupt presentations of intense stimuli. A variety of stimuli in auditory, tactile, vestibular, visual, and

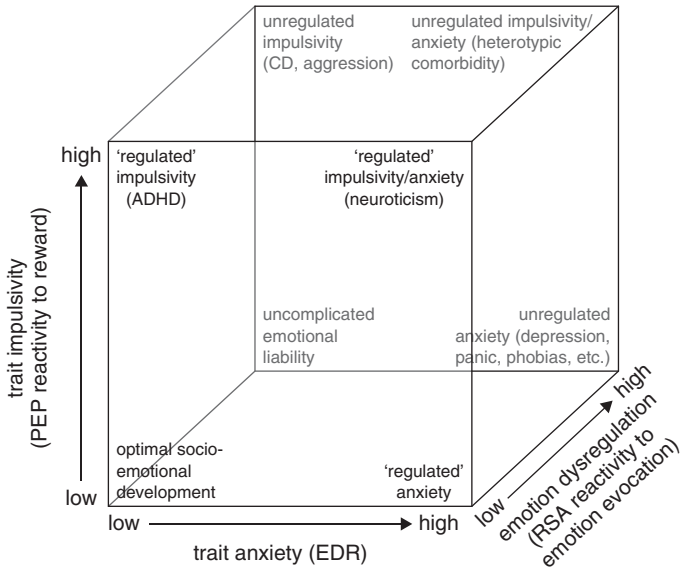

Figure 22.8 Three-dimensional representation of motivational and emotion regulational vulnerabilities to psychopathology. Trait impulsivity, assessed psychophysiologically as PEP reactivity to incentives, is depicted on the y axis. Trait anxiety, assessed psychophysiologically as EDR to extinction/punishment, is depicted on the x axis. Emotion dysregulation, assessed psychophysiologically as RSA reactivity to emotion evocation, is depicted on the z axis. Vulnerability to internalizing disorders is especially high when trait anxiety and emotion dysregulation co-occur, and vulnerability to externalizing disorders is especially high when trait impulsivity and emotion dysregulation co-occur. In contrast, vulnerability to internalizing and externalizing disorders may be offset by strong emotion regulation (see text). ADHD = attention-deficit/hyperactivity disorder. CD = conduct disorder. Heterotypic comorbidity = co-occurrence of internalizing and externalizing disorders.

olfactory modalities generate and/or contribute to startle responses among humans and other mammals (Cook, Davis, Hawk, Spence, & Gautier, 1992; Paschall & Davis, 2002; Yeomans, Li, Scott, & Frankland, 2002). Startle reflexes are produced by skeletomuscular contractions, which generate sudden, bilateral movements. These movements are most observable in the neck and shoulders, and in the eyeblink response. Other physiological changes, such as increases in blood pressure and heart rate, accompany the startle response (Holand, Girard, Laude, Meyer-Bisch, & Elghozi, 1999), and serve to prepare the body for defensive action. Startle responses are typically quantified by measuring skeletomuscular contractions following stimulus presentations. In humans, reflexive eyeblinks, generated by the orbicularis oculi muscle, are measured using electromyography (EMG; Berg & Balaban, 1999). Metrics of interest include signal magnitude (peak minus baseline), onset latency (interval to onset of response), and signal latency (interval between stimulus onset and peak response).

Startle modulation, that is, startle potentiation or inhibition, is quantified as the difference between startle elicited by a stimulus with and without the modulating stimulus/stimuli. Both the startle stimulus itself and modulating stimuli can be tested with varying intensities. Startle can be potentiated by pairing a startle-inducing stimulus, such as a loud sound, with aversive stimuli that either affect the senses directly (e.g., whiplash) or are psychological in nature (e.g., aversive visual stimuli). In contrast, startle can be diminished when an intense stimulus is presented immediately after a comparably weaker, nonstartling stimulus. The term prepulse inhibition (PPI), refers to this decrease in startle and is used to index *sensorimotor gating*, or the degree to which central inhibitory mechanisms regulate reflexive startle responses. The prepulse stimulus can be presented in the same or different sensory modality as the pulse, or startle stimulus.

Neural circuitry underlying acoustic startle is well characterized from animal research. Loud acoustic stimuli are initially processed by cochlear root neurons (CRNs) in the auditory nerve, which project to neurons in the nucleus reticularis pontis caudalis (PnC) that then synapse onto spinal motoneurons (Lee, López, Meloni, & Davis, 1996). Lesioning the CRNs or PnC eliminates the startle reflex, whereas lesions to other nearby structures, such as the ventrolateral lemniscus, suggest that these regions may be involved, but are not essential (Lee et al., 1996). The neural circuitry underlying PPI is more complex than the primary startle circuit described above. Brain areas implicated in PPI include limbic regions (e.g., hippocampus, basolateral amygdala, nucleus accumbens), the striato-pallidal circuit, thalamic and pontine nuclei, and the superior and inferior colliculi (Swerdlow, Geyer, & Braff, 2001).

Interest in startle responding derives in part from its sensitivity to modulatory effects of affective and attentional processes. Reflexive startle responses are exaggerated (i.e., potentiated) by aversive emotional cues (particularly fear-inducing stimuli), and suppressed by pleasant and otherwise appetitive stimuli (see Lang, Bradley, & Cuthbert, 1990). Potentiation and suppression of startle are effected through modulation of the PnC by the amygdala, which filters incoming information for emotional valence and self-relevance, among other functions (see, e.g., Paton, Belova, Morrison, & Salzman, 2006; Rosen, Hitchcock, Sananes, Misrendino, & Davis, 1991). Local microinjections of norepinephrine into the central nucleus of the amygdala potentiate the acoustic startle response, implicating the SNS in startle sensitization (Fendt, Koch, & Schnitzler, 1994). Furthermore, pharmacological blockade of the central nucleus of the amygdala eliminates fear-potentiated startle, but not light-enhanced startle, while preserving the baseline startle reflex (Davis, Falls, Campeau, & Kim, 1993; Walker & Davis, 1997). Consistent with these findings, systemic exposure to anxiolytics blocks startle potentiation to aversive cues in human subjects, but does not decrease overall startle magnitude (Patrick, Berthot, & Moore, 1996). Taken together, these findings suggest that the startle reflex and PPI may be especially useful for assessing fear-conditioning and vulnerability to certain forms of psychopathology that are characterized by excessive or insufficient experience of fear and anxiety.

Links to Psychopathology

Since startle responding is mediated by affective traits and modulated by affective stimuli, both the presence and magnitude of a response may provide insight into affective information processing. Infants as young as 5 months exhibit differential startle in response to acoustic stimuli when paired with positive versus negative visual stimuli (Balaban, 1995). However, such effects are inconsistent in developmental research (e.g. van Brakel, Muris, & Derks, 2006), and may reflect age differences of participants and paradigm heterogeneity between studies (Quevedo, Smith, Donzella, Schunk, & Gunnar, 2010; see below). Nevertheless, increased startle responding in both children and adolescents may mark vulnerability to later anxiety disorders (Grillon, Dierker, & Merikangas, 1998; Merikangas, Avenevoli, Dierker, & Grillon, 1999).

In contrast, reduced startle reflexes characterize child and adolescent samples who are hyporesponsive

to fear- and anxiety-provoking stimuli. For example, diminished acoustic startle is observed among preschoolers who were exposed to cocaine prenatally, which suggests impaired fear conditioning (Mayes, Grillon, Granger, & Schottenfeld, 1998). Similarly, children with disruptive behavior problems exhibit smaller acoustic startle reflexes than typical children when viewing unpleasant stimuli (Goozen, Snoek, Matthys, Rossum, & Engeland, 2004), and juvenile offenders show reduced startle blinks compared to nonoffenders. Even among offenders, conduct problems and psychopathic traits correlate negatively with startle response amplitudes (Syngelaki, Fairchild, Moore, Savage, & van Goozen, 2013).

Aberrant PPI is observed in certain clinical populations, including patients with schizophrenia, Tourette syndrome, and ADHD (e.g. Schulz-Juergensen, Thiemann, Gebhardt, Baumgarten-Walczak, & Eggert, 2014; Swerdlow et al., 2006; see Swerdlow & Neal, 2012). For example, children with ADHD exhibit diminished PPI, which improves following methylphenidate administration (Ashare et al., 2010; Hawk, Yartz, Pelham, & Lock, 2003, but see Schulz-Juergensen et al., 2014).

Developmental Considerations

Preschool-age children exhibit fully mature habituation of sensory-elicited startle, yet prepulse inhibition and facilitation of sensory-elicited startle does not emerge until around 8 years of age, which suggests a developmental lag between processing of a single stimulus and higher-order processing of multiple stimuli in relation to one another (see Ornitz, 1999). Prepulse modulation of startle, by definition, requires presentation of a prepulse stimulus, and differs from attention-modulated startle, which requires participants to actively wait for and attend to target stimuli. Although studies of the effects of attention on startle in pediatric samples are rare, attention may modulate responses more for infants and young children than adults (Ornitz, 1999). In contrast, affective modulation of startle under most conditions may be similar across the life span. For example, McManis et al. (2001) identified startle modulation using emotional images among children, adolescents, and adults. Similarly, Quevedo et al. (2010) reported comparable response patterns of emotion-modulated startle potentiation among 3-, 5-, 7-, 9-year-olds, and adults. However, 3- and 5-year-olds were less likely to respond to stimuli, and produced baseline startle of smaller magnitudes than adults (Quevedo et al., 2010). Additionally, both McManis et al. (2001) and Quevedo et al. (2010) identified significant sex effects, whereby female participants were more reactive to stimuli than male participants, independent of age (see also Kudielka et al., 2004). Furthermore, children between ages 9 and 12 years produce larger auditory-induced startle responses than adults when viewing unpleasant images for very short (60 ms) prepulse-pulse intervals (i.e., duration between onset of an image and an auditory tone), but adults produce larger startle responses for both pleasant and unpleasant images for prepulse-pulse intervals lasting 3500 and 5000 ms (Waters, Lipp, & Spence, 2005). Thus, some aspects of startle, such as attention-modulated responses, exhibit developmental effects that may be mediated by maturation of cortical-subcortical networks (Ornitz, 1999).

Choosing Appropriate Stimulus Conditions

Acoustic-related startle is well suited for laboratory settings given how readily and reliability it is produced. Acoustic startle requires a loud, sudden onset stimulus (typically 100 dB[A] SPL or more), and is evoked best by frequencies within the normal hearing range (Pilz, Schnitzler & Menne, 1987) and sounds that are registered in both ears concurrently (Li & Frost, 1996). In general, increasing the intensity of acoustic stimuli increases the associated magnitude, amplitude, and likelihood of inducing a response, and reduces onset latency (Blumenthal et al., 2005). Vestibular stimulation may also elicit startle responses, which can be modulated when paired with other stimuli, such as auditory tones (Blouin, Siegmund, & Inglis, 2007). Vestibular-evoked startle can be induced by rapid forward accelerations such as those used to test safety of passenger cars (Blouin, Inglis, & Siegmund, 2006). Similarly, tactile stressors, such as airpuffs to the eye and exposure to cold, can induce or moderate startle (Deuter et al., 2012; Hawk & Cook, 1997). Synchronous acoustic, vestibular, and/or tactile stimulation elicits the startle reflex more strongly than temporal summations of a single modality (Yeomans et al., 2002). Compared to other sensory modalities, startle resulting from olfactory and visual stimuli may be difficult to detect reliably in the absence of other sensory stimulation, and thus, are typically paired with other stimulus types to potentiate or diminish startle responses (e.g., Cook et al., 1992; Paschall & Davis, 2002; see Yeomans et al., 2002).

In experiments testing PPI, the lead interval, or the time between presentation of the prepulse and pulse may be varied depending on experimental objectives. Lead intervals of 30–500 ms typically yield PPI, whereas longer lead intervals often potentiate subsequent startle, known as

prepulse facilitation (Ashare et al., 2010). There is no gold standard for optimal prepulse intensity, although acoustic prepulses are typically quantified in terms of intensity above background noise. Importantly, stronger and more salient acoustic prepulses are generally associated with greater PPI (Braff, Geyer, & Swerdlow, 2001).

Since experiments that test the startle reflex typically involve presentation of aversive stimuli, such as distressing images or loud sounds, use of the startle paradigms for research on fear and anxiety may create ethical concerns, especially among certain pediatric populations such as those who suffer from PTSD and other anxiety disorders. Thus, although startle paradigms may be especially useful for studying state and trait anxiety, their utility must be weighed against potential risk to vulnerable participants.

Pupillometry

Since the eyes are an extension of the CNS, assessing certain aspects of ocular function may provide useful information about the physical and psychological integrity of an organism. In fact, ocular response patterns can be used to infer both voluntary and involuntary psychological processes related to attention, inhibitory control, emotional saliency, and social functioning (e.g., Hess & Polt, 1960; Klein & Foerster, 2001; Klin, Jones, Schultz, Volkmar, & Cohen, 2002; Wierda, van Rijn, Taatgen, & Martens, 2012).

The pupil, an opening in the center of the iris, allows light to enter the eye. Pupil diameter, which dictates how much light strikes the fovea and retina, is determined by tonic and phasic activity of two types of smooth muscles—radial muscles, which increase pupil size when stimulated, and sphincter muscles, which decrease pupil size when stimulated. Radial muscles are innervated by noradrenergic fibers of the SNS, whereas sphincter muscles are innervated by cholinergic fibers of the PNS. Thus, both sympathetic and parasympathetic efference determine pupil size, and measuring pupil size at rest and in response to changes in internal and external environmental conditions can be used to assess autonomic function. Although pupil size changes reflexively depending on ambient light conditions, pupillary responses are also evoked by mechanisms unrelated to visual perception, which may or may not be recognized consciously (see Laeng et al., 2012). Pupillary responses to psychological manipulations may therefore provide information that cannot be obtained from self-reports.

Pupillometry (PPM) refers to the measurement of pupil diameter, including constriction and dilation. This is accomplished using video recording and eye-tracking technologies. Of note, pupil dilation correlates with activation of noradrenergic fibers originating in the locus coeruleus, which supports use of PPM as an index of SNS function (Gilzenrat, Nieuwenhuis, Jepma, & Cohen, 2010; Koss, 1986). Pupil dilation is also associated with aspects of emotion and cognition, and therefore varies as a function of emotional saliency (e.g., Hess & Polt, 1960), task difficulty (e.g., Kahneman & Beatty, 1966), and attention deployment (e.g., Wierda et al., 2012). Under some circumstances, pupil dilation may more accurately track temporal aspects of attention effects than imaging methods such as EEG and fMRI (Siegle, Steinhauer, Stenger, Konecky, & Carter, 2003; Wierda et al., 2012).

Links to Psychopathology

Pupillometry has been used among a number of clinical populations. Although it has more limited use in typically developing pediatric samples, the technique has been used extensively among children, adolescents, and adults with ASD. Among children with autism, viewing others' faces is associated with pupillary constriction, in contrast to typical dilatory responses exhibited by mental-age and chronological-age matched controls (Anderson, Colombo, & Shaddy, 2006). In addition, reduced pupil size when viewing neutral faces, virtual faces, and objects differentiates children with autism from mental- and chronological-age matched controls with 72% accuracy, and may therefore serve as a marker for ASD (Martineau et al., 2011). Such findings may result from an imbalance between parasympathetic and sympathetic activity, a finding that has received some support based on neurochemical research in autism (Lam, Aman, & Arnold, 2006), and from studies using cardiac psychophysiology (e.g., Faja et al., 2013; Neuhaus, Bernier, & Beauchaine, 2015; Neuhaus et al., 2014; Patriquin et al., 2013).

Studies of pupil dilation indicate that anxious 9–13-year-olds exhibit prolonged responses to threatening stimuli, and invariant responses to different levels of threat compared to nonanxious controls (Price et al., 2013). In contrast, depressed children and adolescents exhibit reduced pupil dilation to negative words 9–12 s following stimulus presentation compared with controls, an effect that increases with greater symptom severity (Silk et al., 2007). Among adults with major depression, remission following cognitive therapy is associated with either (1) low baseline symptom severity, or (2) high baseline symptom severity, but low sustained pupillary responses to presentation of negative words, suggesting that PPM may be an effective means of predicting treatment response (Siegle, Steinhauer, Friedman, Thompson, & Thase, 2011).

Developmental Considerations

Developmental trajectories in pupillary responding are not well-studied. However, pupillometry and task performance data reveal that 10-year-olds perform similarly to adults on more basic tasks requiring attentional control and working memory, but struggle when performing more difficult cognitive tasks (Karatekin, 2004; Karatekin, Marcus & Couperus, 2007; Karatekin, Marcus, & White, 2007). In contrast, participants in mid- to late-pubescence may be more reactive to emotionally evocative and neutral words compared to pre-/early pubertal participants, as evidenced by greater peak pupil dilation to words, faster reaction times when reporting word valence, and greater recall of emotionally evocative words after task completion (Silk et al., 2009). Importantly, pubertal state—not age—accounts for such differences. Finally, both sympathetic and parasympathetic pupillary responses may diminish with advancing age in adulthood (Pfeifer et al., 1983; Van Gerven, Paas, Van Merriënboer, & Schmidt, 2004).

Choosing Appropriate Stimulus Conditions

As with other psychophysiological measures, both tonic and phasic pupillary responses are often assessed. In event-related designs, PPM may be used to index responses to a wide range of stimuli (most often emotionally salient images), and to evaluate cognitive processes relating to attention, executive load, and working memory. Constriction and dilation velocities are relatively fast, averaging just over 2 mm/sec in healthy samples (Boev et al., 2005). Thus, PPM can provide high temporal resolution if recordings are appropriately deconvolved (e.g., Wierda et al., 2012). However, because psychologically induced pupillary changes are comparatively smaller than light-induced changes, and rarely exceed 0.5 mm (Beatty & Lucero-Wagoner, 2000), it is important to use stimuli of enough saliency to produce detectable changes in pupil diameter, and to control for brightness level across stimulus conditions. As with most psychophysiological measures, PPM diminishes with habituation (Privitera, Renninger, Carney, Klein, & Aguilar, 2010), fatigue (Morad, Lemberg, Yofe, & Dagan, 2000), and age (Van Gerven et al., 2004), so care should also be taken to control for these effects if they are not of experimental interest.

Eye Tracking

Given the importance of social reciprocity in maintaining dyadic relationships (Back et al., 2011), variables such as gaze location and duration have long been of interest to behavioral scientists, including psychopathologists (e.g., Argyle & Dean, 1965). In early eye tracking research, eye movements and gaze location were inferred from either direct observation, or from coded videotapes of participants (e.g. LaFrance & Mayo, 1976). In contrast, contemporary eye-tracking devices record ocular movements with high temporal and spatial resolution. The most common eye-tracking method, video-oculography, involves illuminating the eye with an infrared or near-infrared light beam. A video camera is used to capture reflected images from the cornea and pupil of one or both eyes. The measure is first calibrated to each individual's ocular anatomy, based on the assumption that the reflection from the cornea is the brightest point on the reflected image, and the reflection from the pupil is the second brightest. By contrasting the relative position of these two reflected points, eye-tracking software identifies where an individual is gazing in real-time (Morimoto & Mimica, 2005).

Developed in the later part of the nineteenth century, early eye-tracking devices were quite invasive, requiring direct contact with the cornea of the eye, and motionless participants (Javal, 1878). Eye-tracking techniques became more precise with co-registration of corneal measurement and motion picture technology (see Mackworth & Mackworth, 1958). At present, participants may need to keep their head stationary (using a chin rest or bite board to provide more precise signals), or be able to move freely during recording, depending on the device being used. During free-moving recordings, many devices can be worn as goggles or contact lenses, with the obvious advantage of more naturalistic interaction with the environment.

An alternative to video-oculography, electrooculography, records eye movement and position by measuring the difference in electrical potential between two electrodes affixed to the surface of the skin on either side of the eye (Heide, Koenig, Trillenberg, Kömpf, & Zee, 1999). Notably, this approach is not well suited for evaluating variables such as gaze duration, fixation, or latency during social interactions or lab tasks. Rather, it is more commonly used to measure rapid eye movement (REM) in sleep research and is increasingly a method of interest for human-computer interfaces (e.g., Barea, Boquete, Rodriguez-Ascariz, Ortega, & López, 2010; Lopes, Tabachnik, Muller, Levison, & Bryan, 1983).

Three types of eye movements that occur while we are awake include *fixation* (maintaining gaze on a particular aspect of a visual scene), *saccades* (brief, rapid ocular movements observed while we scan a visual field), and *smooth pursuit* (slow ocular movements associated with tracking a moving stimulus; see Kowler, 2011). Both saccadic and smooth pursuit eye movements are involved in gaze

shifting, which allows large amounts of visual information to reach the fovea, and provides for detailed processing of the visual field (Lisberger, Morris, & Tychsen, 1987; see Henderson, 2003). Although smooth pursuit eye movements are largely voluntary, saccades can be initiated voluntarily (e.g., when targets are purposely attended to) or involuntarily (e.g., when targets suddenly appear and capture attention without conscious processing). Small, abrupt saccades observed during fixation cannot be controlled consciously.

Links to Psychopathology

Eye tracking dysfunction (ETD) is observed in several clinical disorders, including ADHD, conduct disorder, oppositional defiant disorder, Tourette syndrome, reading disorder, ASD, and schizophrenia (for a recent review see Rommelse, Van der Stigchel, & Sergeant, 2008). A voluminous literature links saccadic and smooth pursuit abnormalities in eye tracking to schizophrenia among adults (see Gooding & Basso, 2008; Levy et al., 2010; Mitropoulou et al., 2011). For example, both saccades toward anticipated targets and antisaccades made purposefully away from targets are disrupted in adults with schizophrenia (e.g., Barton, Pandita, Thakkar, Goff, & Manoach, 2008; Crawford, Haeger, Kennard, Reveley, & Henderson, 1995). In their recent meta-analysis, which assessed studies of ETD in schizophrenia conducted since 1993, O'Driscoll and Callahan (2008) determined that differences between patients and controls are most pronounced for global pursuit measures, or the extent to which eye position matches target positions. Specific measures that yield large effect sizes are maintenance gain, defined as the ratio of velocity of eye movement to that of target movement, and leading saccades, a subtype of anticipatory saccades that trace eye movements ahead of the target with small amplitudes (e.g., between 1–4 degrees; see Ross, Olincy, & Radant, 1999).

Importantly, recent research indicates that high error rates in antisaccade performance, an index of one's ability to consciously inhibit actions, can be identified in adolescents with an average age of psychosis onset as young as 13 years (Karatekin, Bingham, & White, 2010). Furthermore, adolescents who carry genetic risk for schizophrenia yet do not express the disorder exhibit increased corrective saccades compared with controls (Schreiber et al., 1997). Such findings suggest considerable promise for premorbid identification of vulnerable individuals, who can then be enrolled in preventive interventions, which may decrease risk for psychosis onset by as much as 65% across three years (McGorry et al., 2002). This is a clear example of the potential value of psychophysiological research in prevention and treatment of an extremely debilitating psychiatric condition (see also Beauchaine, 2009a; Beauchaine & Marsh, 2006; Beauchaine, Neuhaus et al., 2008).

Dysfunctional eye tracking in schizophrenia likely reflects aberrant neural processing of visual information, and compromised ability to anticipate the location of future visual stimuli (Chen, 2011; Levy et al., 2010). The neural substrates for these deficits include the middle temporal area (Chen et al., 2008), an extrastriate region involved in early motion perception, the parietal cortex (Wang, Brown, Dobkins, McDowell, & Clementz, 2010), particularly the ventral intraparietal area (Schlack, Hoffmann, & Bremmer, 2003), and the frontal eye fields (FEFs) of the PFC (McDowell et al., 2002). Both parietal regions and the FEFs are implicated in later-stage processing of motion.

Interestingly, acute nicotine administration improves eye acceleration during smooth pursuit initiation and reduces leading saccadic eye movements during visual tracking in both smoking and nonsmoking patients with schizophrenia, but has no effect on nonsmoking control participants (Avila, Sherr, Hong, Myers, & Thaker, 2003; Sherr et al., 2002). These results may suggest a role for nicotinic acetylcholine receptors in ETD, a conclusion supported by findings indicating that these receptors are hypofunctional in schizophrenia (Leonard et al., 1996). Nicotine may improve eye-tracking deficits via modulation of dopamine (DA) in the brainstem and midbrain. Nicotinic projections originating from the pedunculopontine tegmental nucleus agonize DA neurons in the superior colliculus, a structure implicated in eye movement control (Kobayashi & Isa, 2002). Importantly, effects of nicotine are not specific to eye movements. Nicotine administration improves sustained attention, psychomotor speed, and performance on other cognitive tasks among those with schizophrenia and other forms of pathology, including Alzheimer's disease and ADHD (Rezvani & Levin, 2001).

Eye tracking is also used extensively in research on ASD (e.g., Klin et al., 2002). An assumption of this research is that patterns of gaze shifting and fixation will provide insight into difficulties with social communication and reciprocity experienced by affected individuals. Using eye-tracking technology, Klin et al. (2002) determined that males with autism fixate less on the eye region and more on mouths, bodies, and objects when viewing social scenes compared to males who are not on the autism spectrum. Similarly, individuals with high functioning autism fixate more heavily on the mouth region and less on the eye region than controls when making judgments about facial

emotions (Spezio, Adolphs, Hurley, & Piven, 2007). Such visual fixation differences in autism are not identifiable in early infancy (Key & Stone, 2012; Young, Merin, Rogers, & Ozonoff, 2009) but emerge during the first 12 to 24 months of life (Rogers, 2009). Thus, individuals with ASD may acquire and use socially relevant information differently than typically developing individuals, and these divergent strategies may either help account for or in part cause social difficulties that characterize the spectrum. Consequently, social skills training for autism have begun to integrate eye gaze monitoring using eye-tracking technology (e.g., Lahiri, Bekele, Dohrmann, Warren, & Sarkar, 2013).

Developmental Considerations

Although peak velocity and duration of correct prosaccades is observed among 4–6-year-olds, preadolescents exhibit prolonged reaction times of prosaccades and antisaccades compared with adults (e.g., Klein & Feige, 2005; Munoz, Broughton, Goldring, & Armstrong, 1998; see Karatekin, 2007). Smooth-pursuit gain may develop through adolescence (e.g., Accardo, Pensiero, Da Pozzo, & Perissutti, 1995; Salman, Sharpe, Lillakas, Dennis, & Steinback, 2006; see Karatekin, 2007). Furthermore, implicit learning of a visual sequence matures by around age 8 to 10 years, whereas intentional learning continues to develop through adolescence (Karatekin, Marcus, & White, 2007). Evidence for differential processing of faces using eye tracking across age groups is limited and inconsistent (Marcus, 2005; Schwarzer, Huber & Dümmler, 2005) despite some findings of better facial recognition performance among adults than children (Marcus, 2005).

Choosing Appropriate Stimulus Conditions

In psychiatric research, smooth pursuit eye movements are often studied using a neutral stimulus that moves sigmoidally, although trapezoid and triangular target motion patterns are also used. Target speed (in degrees per s), amplitude, and number of stimulus cycles are sometimes varied depending on the experimental design, although no standardized protocol is used (Smyrnis, 2008). Since certain saccades, such as anticipatory and catch-up saccades, are also inherent to smooth pursuit tasks, both smooth pursuit and saccadic eye movements can be studied in a single paradigm. Antisaccades can also produce involuntary, prosaccades (saccades toward the target stimulus) and thus, both anti- and prosaccades can be used to index inhibitory control over the natural tendency to gaze towards a target (e.g., Klein & Foerster, 2001).

With the advent of mobile, high-precision eye-tracking technologies, much greater experimental flexibility is afforded. Eye movement patterns during passive viewing of faces or during dynamic social interactions, for example, can be quantified and compared within and between participants. Importantly, spontaneous gazing may need to be differentiated from instructed and task-specific behavior. For example, although individuals on the autism spectrum can fixate on the eyes of others in much the same way as controls when they are instructed specifically to do so, they exhibit large fixation differences when viewing faces freely (see above; Senju et al., 2009). Finally, use of mobile eye-tracking technologies is of considerable value in assessing social difficulties among those with autism, and in evaluating populations with eye movement deficits unrelated to social functioning, such as children with reading disorder (e.g., De Luca, Di Pace, Judica, Spinelli, & Zoccolotti, 1999).

Electromyography

Electromyography (EMG) is a technique used to measure electrical activity of muscles, both at rest and while contracting. To record from muscular tissue, electrode needles are inserted into skin directly above the muscles of interest. Electromyography is used in both experimental and clinical settings, primarily for evaluation of neural, muscular, or neuromuscular disorders. The technique is frequently used in nerve conduction studies, which determine the integrity and speed of nerve impulses. Electromyography can also be used to distinguish volitional motor activity, such as psychogenic jerking behavior, from avolitional motor activity, such as tics or myoclonus (involuntary muscle twitching). Electromyographic bursts less than 70 ms may indicate organic motor pathology, whereas prolonged and delayed responses involving coordination of multiple muscle groups suggest that movements are psychogenic (Kirsch & Mink, 2004).

Electromyography is also used to investigate facial mimicry and affective processing, and is particularly sensitive to emotional responding because it detects activity in facial muscles that cannot always be observed outwardly, and that may not be activated during conscious elicitation of facial expression (Tassinary & Cacioppo, 1992). Since unique patterns of facial muscle activity are induced when producing angry, happy, fearful, or sad faces, facial expressivity can be assessed using this technique (Deschamps, Schutte, Kenemans, Matthys, & Schutter, 2012; Ekman, Friesen, & Hagar, 2002). For example, spontaneous but not voluntary facial mimicry is compromised among adolescents and adults on the autism spectrum (McIntosh, Reichmann-Decker, Winkielman, & Wilbarger, 2006).

More recently, facial EMG has been co-registered with fMRI to simultaneously acquire neural and neuromuscular activity associated with particular affective states, enabling more sophisticated experimental designs (Heller, Greischar, Honor, Anderle, & Davidson, 2011).

Salivary Alpha-Amylase

Salivary alpha-amylase (sAA), an enzyme that aids digestion within the oral cavity, is increasingly regarded as a noninvasive marker of SNS responding to acute and chronic stress. This increasing popularity is most likely the result of readily available commercial assay kits and indications from pharmacologic blockade studies that sAA reflects individual differences in adrenergic activation (van Stegeren, Rohleder, Everaerd, & Wolf, 2006). Salivary alpha-amylase is also appealing because it can be assessed using the same salivary collection procedure used in cortisol research (as described elsewhere in this volume), without the equipment and expertise needed to collect impedance cardiographic and or electrodermal measures.

In contrast to free salivary cortisol, which is often used to assess HPA axis function, sAA is a putative index of sympathoadrenal medullar function, and therefore provides information about stress reactivity that cannot be assessed with cortisol alone (Nater & Rohleder, 2009; Nater et al., 2006). For example, following a social stressor, peak sAA and cortisol levels are correlated among control youth, but are uncorrelated among youth with a recent history of physical or sexual abuse or neglect (Gordis, Granger, Susman, & Trickett, 2008). Developmental fractionation of baseline sAA and baseline cortisol is also observed. Compared to young adults (ages 20–31 years) and older adults (ages 59–61), children (ages 6–10) display higher baseline sAA levels, but lower cortisol levels (Strahler, Mueller, Rosenloecher, Kirschbaum, & Rohleder, 2010). Finally, elevations in sAA following psychological stress are typical for adults, but are observed inconsistently among children (e.g., Strahler et al., 2010; Yim, Granger, & Quas, 2010).

Despite this increasing appeal of sAA as an index of sympathetic function, several limitations undermine its usefulness and interpretability. Perhaps most importantly, sAA levels are determined by both SNS and PNS activation, so it suffers from the same interpretability concerns as HR, outlined above. Indeed, sAA is released by the salivary glands, which have prominent PNS innervation (Proctor & Carpenter, 2007). Relatedly, sAA levels are influenced by salivary flow rate, which falls largely under PNS control. This may explain why coactivation of the SNS and PNS yields greater sAA secretion than SNS activation alone (Proctor & Carpenter, 2007). Furthermore, since the time-course of salivary outflow is much longer than the time course of any underlying SNS response, sAA has quite limited temporal resolution—a major limitation compared with impedance cardiographic and electrodermal measures. Finally, methodological issues, such the use of absorbent materials to collect saliva, stimulation of salivary release by chewing, and reliance on enzymatic activity to infer sAA concentration, may erode the validity and reliability of sAA measures (for review, see Bosch, Veerman, de Geus, & Proctor, 2011).

DATA ANALYTIC CONSIDERATIONS

Many data-analytic concerns arise when conducting psychophysiological research. Although some of these are specific to particular methods (e.g., ICG, EMG, etc.), others are more general, and should therefore be familiar to any developmental psychopathologist who uses psychophysiological measures. Several of these issues are presented below. We note, however, that our descriptions are brief. Readers who seek further information are referred to more comprehensive sources (e.g., Bach & Friston, 2012; Gratton, 2007; Jennings & Gianaros, 2007; Kristjansson, Kircher, & Webb, 2007; Strube & Newman, 2007).

Assessing Change in Developmental Versus Psychophysiological Research

Assessing intra-individual change is a fundamental objective of both developmental psychopathology and psychophysiology. As outlined above, developmental psychopathologists seek to characterize ontogenic processes that portend mental illness, which necessarily involves repeated assessments of psychiatric adjustment over time. In fact, longitudinal studies spanning many years and assessment waves are of particular value in mapping pathways of persistence toward and desistance away from psychopathology. In contrast, although psychophysiologists also evaluate change within individuals, they usually do so across much shorter time intervals, often spanning stimulus presentations of a few seconds to a few minutes. For this reason and others, developmentalists and psychophysiologists have arrived at very different approaches to assessing change. Understanding these alternative approaches is essential for developmental psychopathologists who use psychophysiological techniques.

Difference Scores in Developmental Psychology

Avoiding simple difference scores when assessing change is almost canonical in developmental psychology research (see Burt & Obradović, 2013; Rogosa, Brandt, & Zimowski, 1982). This follows from the observation that in some situations, the reliability of a difference score is much lower than the reliability of observed scores from which the difference score is derived (e.g., Lord, 1963). Low reliability creates a number of statistical problems that cannot be reviewed here. From a pragmatic standpoint, however, since low reliability attenuates correlations between measures, difference scores often underestimate associations between behavior change and important external correlates, resulting in Type II errors. This is an obvious problem in developmental psychopathology research, where links between psychiatric adjustment and longitudinal change in vulnerability and risk are primary foci.

Problems with reliability are amplified for certain types of measures (see Beauchaine, 2013). As outlined above, psychopathologists often deal with latent constructs, the causes of which cannot be observed directly (e.g., depression, anxiety, impulsivity), and must therefore be inferred from imperfect manifest indicators, such as observer impressions and teacher reports (Meehl, 1995; Nunnaly & Bernstein, 1994). Rating scales in particular carry halo effects and response biases that induce up to 50% measurement error into observed scores (Hoyt & Kerns, 1999). Moreover, reliabilities of change scores necessarily erode the longer the time interval between assessments given maturation and other developmental processes. Thus, even though difference scores yield an unbiased estimate of change, and may be adequate for use in many longitudinal research contexts (e.g., Rogosa & Willett, 1983), developmentalists favor alternative means of assessing change. These include analysis of residualized change scores, latent difference scores, and latent residual scores, among other approaches (for a review, see Burt & Obradović, 2013). All of these methods are intended to reduce measurement error.

Difference Scores in Psychophysiology

In contrast to a general proscription of difference scores in developmental psychology research, it is difficult to publish a paper in a psychophysiology journal without presenting and analyzing raw change scores (i.e., baseline minus task). Why this difference across literatures, and what are the implications for developmental psychopathology researchers who use psychophysiological measures? In addressing these questions, two important points stand out. First, most psychophysiological indices carry far less error than measures of psychological and psychiatric constructs. Current standards of quantification for most psychophysiological measures (e.g., RSA, PEP) call for 1 kHz resolution, which is far more precise than the resolution of Likert scales.[4] Although precision does not guarantee reliability, more precise measures of a construct yield higher reliabilities than less precise measures, given equivalent validity (for a discussion of the relationship between reliability and validity, see Sechrest, 1984). Second, many psychophysiological studies assess participants' reactions to stimuli in paradigms of very short duration. Thus, intervening maturational effects are of little if any concern. For these reasons, use of change scores in psychophysiological laboratory assessments is fully appropriate under most conditions.

Explicating reasons behind different approaches to assessing change in developmental psychology versus psychophysiology has important implications for research design. Avoiding difference scores and applying latent variable models in psychophysiology research—approaches that follow from the assumption that difference scores are always unreliable—would require recruitment of much larger samples than needed. Nevertheless, those who either (1) conduct research in which psychophysiological reactivity to lab tasks is assessed repeatedly across long time intervals (e.g., annually), or (2) use psychophysiological measures as one among several indicators of outcome, should consider latent variable alternatives (see Burt & Obradović, 2013). Other advantages of latent variable approaches to modeling psychophysiological data are beyond the scope of this chapter (see Bach & Friston, 2012; Lane, Franklin, & Curran, 2013).

Testing Interactions

A primary concern of developmental psychopathologists is to identify subgroups of children who are most likely to develop psychopathology in high risk contexts, so they can be enrolled in targeted prevention and intervention programs. Oftentimes, this involves determining whether psychophysiological responding marks either concurrent

[4]The term *precision* has been used in various ways in the history of psychometric theory and psychological measurement (see, e.g., Mellenbergh, 1996). Here we use the term to distinguish between scales of measurement, as described by Stevens (1946). Using Stevens's classification scheme, Likert scales carry ordinal precision, whereas most psychophysiological signals are processed with ratio precision.

or prospective differences in vulnerability among some children versus others (see, e.g., Beauchaine, Neuhaus et al., 2008; Brenner & Beauchaine, 2011). Making such determinations requires tests of statistical interaction effects (see Beauchaine, Webster-Stratton, & Reid, 2005). A statistical interaction, or moderating effect, occurs whenever the strength of association between two variables changes across levels of a third variable (see, e.g., Aiken & West, 1991). For example, Shannon et al. (2007) reported a positive association between paternal ASPD symptoms and offspring conduct problems for at-risk children and adolescents who scored high on resting RSA, but no such association for those who scored low on resting RSA. Most members of latter group scored high on conduct problems regardless of paternal antisocial behavior (see Figure 22.9). Thus, RSA *moderated* the effect of paternal ASPD on child conduct problems. Consistent with other research reviewed above, this suggests partial protection from psychopathology for children and adolescents who score high on baseline RSA (e.g., Blandon et al., 2008; El-Sheikh, 2005; El-Sheikh et al., 2001; Katz & Gottman, 1995).

As this brief discussion implies, interaction effects address a fundamental question in psychopathology research: Who is more vulnerable to developing mental illness? Like change scores, however, interactions are affected considerably by problems with reliability. In fact, since interaction terms are, by definition, the product of a predictor variable and a hypothesized moderator (paternal ASPD × offspring RSA in the previous example), measurement error inflates *multiplicatively*, with proportionate erosion of reliability. This is more problematic than unreliability of change scores, where error is at worst additive. Furthermore, error continues to be multiplied across each term in higher order interactions (e.g., three-way, four-way). In contrast to the situation with difference scores, however, unreliability of interaction terms has received almost no attention in the developmental psychology or psychophysiology literatures (see Beauchaine, 2009; Whisman & McClelland, 2005).

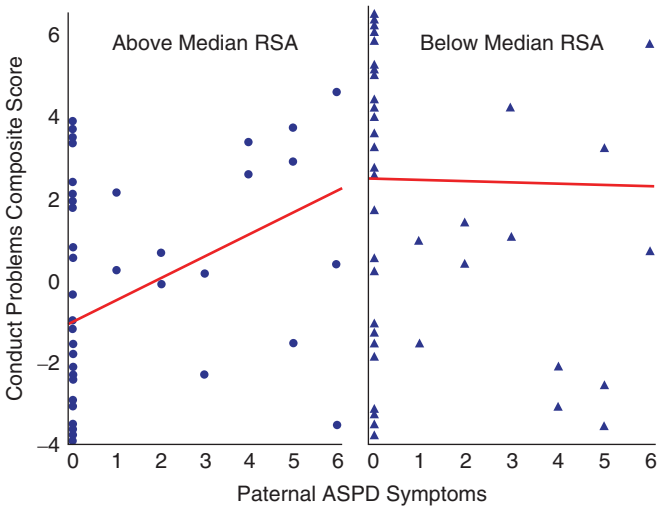

Figure 22.9 Relations between paternal ASPD symptoms and conduct problems for 180 high-risk children and adolescents who scored above and below the sample median on resting RSA. Since the relationship between paternal ASPD and child conduct problems differs as a function of baseline RSA, this represents a statistical interaction, or moderating effect. See footnote 1. *Source:* From Shannon Beauchaine, Brenner, Neuhaus, and Gatzke-Kopp (2007), Familial and temperamental predictors of resilience in children at risk for conduct disorder and depression, *Development and Psychopathology, 19*, 701–727.

As we have noted elsewhere, failure to consider reliability when testing interactions can result in both spurious findings that cannot be replicated (Type I errors), and failure to find important group differences in psychophysiology-psychopathology relations (Type II errors; see Beauchaine, 2009). The latter consequence is particularly unfortunate since the statistical power of interaction effects can (and should) be estimated in the planning stages of a study (see Whisman & McClelland, 2005). At present, many if not most studies in which statistical interaction effects are tested are underpowered because power analyses are conducted on main effects only. Since moderation effects are now routinely hypothesized in developmental psychophysiology research (e.g., El-Sheikh et al., 2009), more attention to reliability is essential.

Problems with Traditional Repeated Measures Analysis

Developmentalists and psychophysiologists alike assess outcomes across multiple time points. In large-scale longitudinal studies, this may involve repeated annual assessments of psychopathology across many years. In psychophysiology research, it is more likely to involve repeated administrations of a stimulus or stimuli within a single testing session. Still other studies involve mixed designs in which patterns of psychophysiological responding during lab tasks are collected across multiple longitudinal assessment points.

Traditionally, both developmentalists and psychophysiologists have analyzed such data using repeated measures analysis of variance (ANOVA). However, problems with repeated measures ANOVA are now well known. Most importantly, repeated measures ANOVA yields many false positives (Type I errors) when certain assumptions are violated and no statistical correction is used. Although such corrections are effective, repeated measures ANOVA

is also underpowered in many situations, which led Vasey and Thayer (1987) to recommend multivariate analysis of variance (MANOVA) as an alternative. At present, although ANOVA and MANOVA are still used, both developmentalists and psychophysiologists have turned increasingly to multilevel modeling (MLM) to analyze much of their data (see, e.g., Hoeksma & Koomen, 1992; Kristjansson et al., 2007).

Multilevel Modeling

Multilevel modeling is a regression-based technique in which separate regression equations are specified at every level of nesting in a data set. Initially, MLM was used in large-scale education research to disentangle variance in achievement scores that was attributable to individual children who were assessed repeatedly across time (Level 1), who were nested within classrooms (Level 2), which were nested within schools (Level 3). Since MLM divides total error variance into smaller components that are specific to each level of nesting, it is often more powerful than repeated measures ANOVA and MANOVA (see Raudenbush & Bryk, 2002; Raudenbush, Bryk, Cheong, Congdon, & Toit, 2011). Furthermore, MLM is not subject to several assumptions of ANOVA.

In most developmental and psychophysiological research, the first level of nesting in any MLM is a repeated measure. In such designs, an individual regression equation is first computed for each participant across the repeated measure at Level 1. The slope of this regression equation represents growth or decline in function. Predictors of growth can then be added to the Level 2 regression equation. For example, Figure 22.10 shows curvilinear growth in the probability of alcohol use across ages 7 to 15 years (Level 1), as predicted by individual differences in cardiac PEP reactivity to monetary incentives in the lab (Level 2) among 206 at-risk children and adolescents (Brenner & Beauchaine, 2011).

A second major advantage of MLM its ability to accommodate time-varying covariates. This enables researchers to determine, among other questions, whether intra-individual responses across levels of analysis (e.g., psychological, physiological) covary over time. For example, in our work addressing expressive and psychophysiological aspects of emotional responding among boys with conduct problems (Marsh et al., 2008), we evaluated time-linked correspondence of sad facial expressions and autonomic reactivity (Level 1) while boys with CD and controls (Level 2) watched an empathy-eliciting film. Although controls exhibited synchrony over time between sad facial expressions and autonomic function, as indexed by skin conductance, cardiac PEP, and RSA reactivity, boys with CD showed no correspondence between facial expressions and autonomic reactivity, even though they exhibited normal levels of facial sadness. This illustrates some of the increased flexibility that MLM affords over more traditional approaches to analyzing repeated measures.

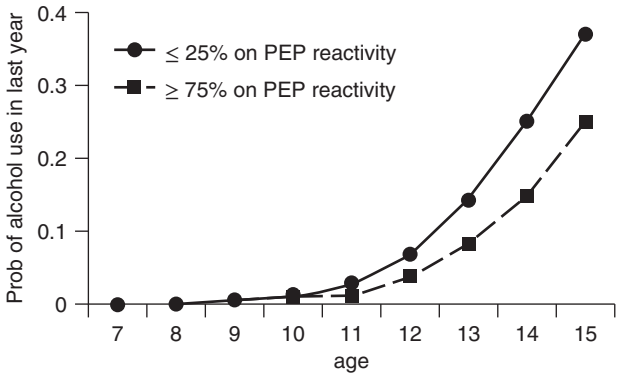

Figure 22.10 Probability of alcohol use in the past year as a function of age for at-risk participants scoring below the 25th percentile and above the 75th percentile on preejection period (PEP) reactivity to incentives ($n = 206$). Greater sympathetic nervous system responding is marked by PEP shortening (i.e., more PEP reactivity). *Source:* From Brenner and Beauchaine (2011), Cardiac pre-ejection period reactivity and psychiatric comorbidity prospectively predict substance use initiation among middle-schoolers: A pilot study, *Psychophysiology, 48*, 1587–1595.

FUTURE DIRECTIONS

In this chapter, we (1) outlined many of the technical intricacies involved in conducting developmentally sensitive psychophysiological research; (2) described the usefulness of psychophysiological methods in elucidating biological vulnerabilities to psychopathology; (3), considered how psychophysiological research can help us understand how such biological vulnerabilities interact with environmental adversity to promote development of psychopathology; (4) explained why psychophysiological biomarkers should be included in intervention research if we wish to identify mechanisms of treatment response and resistance; and (5) summarized certain methodological issues that should be considered when using psychophysiological measures. Along the way, we considered many challenging questions that have always faced developmental psychopathologists. For example, why are individuals differentially susceptible to environmental risk? What etiological mechanisms account for

comorbidities and continuities in psychopathology? Which mechanisms distinguish between those who exhibit developmentally limited forms of psychopathology versus those who traverse life-course persistent patterns? How can basic research better inform prevention and intervention? As we continue to pursue such questions, transdisciplinary and translational research—which developmental psychopathy was central in establishing (see, e.g., Beauchaine & Gatzke-Kopp, 2012; Cicchetti, 2008)—will be necessary as we build truly integrative developmental theories that bridge and combine existing and new methods and findings from behavioral neuroscience, behavioral and molecular genetics, psychophysiology, neuroimaging, and developmental, cognitive, social, and clinical psychology. Such objectives are fully consistent with the RDoC project of NIMH.

Combining psychophysiological and neuroimaging methods enables us to assess neural correlates of autonomic function, and resultant findings can help verify and refine existing theories about autonomic psychophysiology (see, e.g., Chang et al., 2013; Napadow et al., 2006), including psychophysiology-psychopathology relations (e.g., Ahs et al., 2009). For example, the theoretical underpinnings for RSA have been tested, upheld, and refined using multi-method approaches from psychophysiology, neuroimaging, and pharmacology (Thayer, Hansen, Saus-Rose, & Johnsen, 2009; see also Beauchaine & Thayer, in press). The neurovisceral integration perspective describes how top-down, inhibitory influences of the PFC on lower brain structures affect autonomic functioning and modify heart rate through vagal and sympathetic mechanisms (Thayer et al., 2009). More specifically, diminished PFC control over the central nucleus of the amygdala increases HR and reduces RSA through direct and indirect disinhibition of the medullary cardiovascular center (Thayer et al., 2009). By combining HRV with resting state fMRI, Chang et al. (2013) determined that fluctuations in high-frequency HRV are associated with greater functional connectivity from both the dorsal anterior cingulate cortex and amygdala to subcortical regions, including the brainstem, thalamus, and lateral hypothalamus, whereas low-frequency HRV is associated with greater functional connectivity from these two regions to the insula, temporoparietal junction, secondary visual areas, and the right dorsolateral PFC. Such findings elucidate the neural bases of vagally mediated tonic control of the heart. This understanding can be used to refine theoretical models linking tonic RSA to patterns of neural activation and behavioral performance on executive functioning tasks (e.g., Thayer et al., 2009).

Similarly, by combining HRV with measures of cerebral blood flow using PET, Lane et al. (2009) reported that activation of the medial PFC covaries with changes in high frequency HRV among healthy individuals when processing emotionally salient stimuli. Such findings provide novel information regarding relationships between patterns of neural responding and autonomic activity, and enable researchers to draw more precise conclusions about CNS functioning when using psychophysiological techniques in the absence of neuroimaging. For example, our knowledge of the functional nature of the medial PFC can aid in interpreting HRV data acquired during stimulus conditions that evoke affective processing. As stated in the introduction of this chapter, inferring CNS processes in situations where they cannot be observed directly (e.g., in naturalistic settings, among very young children) is a primary objective of psychophysiological research.

Another advantage of combining traditional psychophysiology with modern neuroimaging is the ability to capitalize on both the high temporal resolution afforded by peripheral psychophysiology and the high spatial resolution of MRI and PET, to provide both the when and where of psychological phenomena. For example, in a combined fMRI-EDA study that required participants to perform a difficult motor task, EDA time series recordings were transformed into model waveforms and used to model fMRI BOLD signal activation (MacIntosh, Mraz, McIlroy, & Graham, 2007). The rise-times at the start of each block were similar for the average EDA waveform and hemodynamic model, and both models mapped brain activation in regions implicated in motor activity, including the primary motor cortex, the primary somatosensory cortex, the cingulate gyrus, cerebellum, and putamen. However, the BOLD signal remained relatively constant within and between blocks, whereas peak-to-peak EDA amplitude attenuated within a given block and tended to decrease over successive blocks. This difference enabled an EDA-modeled early versus late block contrast, which revealed differential activation in the thalamus, cingulate gyrus, and insula that was undetectable using the hemodynamic response function, suggesting that this alternative to the hemodynamic response model uniquely captured time-varying effects related to practice and/or changes in attention. Future studies may also capitalize on similar, dual-method approaches to better identify relationships between neural activation and time-sensitive behavioral performance data and better account for individual differences in BOLD signal intensity.

Notably, there are also limitations in combining peripheral psychophysiology with MRI. For example,

impedance cardiography, which is required for evaluating SNS-mediated changes in cardiac function, is exceedingly difficult to perform simultaneously with MRI because the impedance signal is too weak to be detected in such a strong magnetic field. Second, as described throughout this chapter, it is critical that stimulus conditions are appropriately selected for the neurobiological conditions that one wants to assess (e.g., cardiac PEP for monetary incentives; RSA for emotion regulation) to draw valid conclusions about psychophysiological functioning. If a given psychophysiological measure does not index a particular psychological phenomenon under a specific set of stimulus conditions, identifying its neural correlates may be uninformative.

Finally, variables that evaluate interactions between the PNS and SNS often account for far more variance in a given outcome variable than those of single systems (e.g., Beauchaine, Gatzke-Kopp et al., 2013; El-Sheikh et al., 2009). Such variables are constructed by acquiring a measure of parasympathetic functioning, such as RSA, concurrently with that of sympathetic functioning, such as EDA, during or independent of imaging acquisition. As noted previously, however, greater statistical power is required to detect interactions than main effects since error for each main effect is multiplied together. Thus, to understand both the individual contribution of the PNS and SNS and how they interact with one another, future studies should include sample sizes that are sufficiently large to achieve sufficient statistical power.

An emerging area of study is psychophysiology within the context of behavioral and molecular genetics (see Beauchaine, 2015b; Beauchaine & Thayer, in press). Individuals undergo drastic physiological and psychological changes across the life span, following from dynamic transactions between genetic predispositions and environmental risk and protective factors. Psychophysiological measures are well positioned as intermediaries between genes and complex psychological and behavioral phenomena because they often index mutable biological processes. Using a developmental framework, the psychophysiological approach can track changes in ANS functions that are attributable primarily to endogenous factors (e.g., puberty; Silk et al., 2009) versus exogenous factors (e.g., experience of trauma; Blechert, Michael, Vriends, Margraf, & Wilhelm, 2007) and combinations of genetic predispositions and risk/protective factors associated with particular neural correlates and psychosocial outcomes (Bell & Deater-Deckard, 2007). Furthermore, behavioral genetics can improve our understanding of the etiological underpinnings of psychopathology by partialing out heritable factors from nonheritable factors. For example, the high degree of correlation between monozygotic versus dizygotic twins for smooth pursuit eye tracking, a well-characterized endophenotype for schizophrenia, suggests that proficiency in this domain has a strong heritable component (Katsanis, Taylor, Iacono, & Hammer, 2003), although its etiology remains opaque. Similarly, in a study in which fear extinction in PTSD was evaluated, EDA during extinction recall was greater for combat veterans with PTSD compared to both combat veterans without PTSD and their monozygotic twin without combat exposure or PTSD (Milad et al., 2008). This suggests sympathetic hyperresponsivity during extinction recall is engendered by combat trauma itself instead of serving as a genetic vulnerability to PTSD.

Consistent with the new NIMH RDoc initiative (Insel et al., 2010; Sanislow et al., 2010), developmental psychopathology has always incorporated data from genetic, neural, physiological, and behavioral levels of analysis in attempts to provide more comprehensive explanatory models than symptom-based, categorical classification systems afford (e.g., Cicchetti, 2008). One way to achieve this is by engaging in empirical pursuits that identify biomarkers and endophenotyes of maladaptive *traits* that span conventional diagnostic categories (e.g., impulsivity; emotion dysregulation; Beauchaine, 2009a; Beauchaine & Gatzke-Kopp, 2012). Such efforts can improve our understanding of the etiological mechanisms of psychopathology, including why and how seemingly different collections of symptoms stem from common etiologies (multifinality). By improving our understanding of etiology and how psychopathology develops and is maintained, we are better positioned to target mental illness directly for a given individual, and thus refine the ways we implement prevention and treatment strategies.

CONCLUSIONS

Peripheral psychophysiology has a long history of use in psychopathology research, and continues to be used by developmental psychopathologists as they construct truly ontogenic, transactional models of mental illness that span levels of analysis from genes, to intervening biological systems, to family contexts, to broader social systems. Although modern neuroimaging techniques such as EEG and fMRI, as described elsewhere in this volume, are now used routinely with child and adolescent samples, peripheral psychophysiological methods are still valuable tools for developmental psychopathologists who

seek to understand how individual attributes interact with contextual risk factors to promote psychopathology among vulnerable individuals. When used in well designed experiments with appropriate stimulus conditions, proper consideration of maturational and developmental processes, and carefully planned data analysis, peripheral psychophysiology is an important component of a broader network of methods spanning molecular genetics, neuroimaging, behavioral genetics, behavior observation, dyadic interaction analysis, and sociometrics. All of these approaches—and others—will be needed as we build a more comprehensive understanding of developing psychopathology in the twenty-first century.

INTRODUCTION

Schizophrenia is a severe mental illness afflicting about 1 percent of the population (Cannon, 1996; McGrath, Saha, Chant, & Welham, 2008; van Os & Kapur, 2009). Its characteristic symptoms include hallucinations, delusions, disorganized speech and thought, grossly disorganized behavior or catatonia, and abnormalities in emotional expression and motivation along with chronicity and poor functioning (APA, 2013; Tandon et al., 2013). Throughout most of the twentieth century, our understanding of the origins and developmental course of this disorder was substantially influenced by Emil Kraepelin, who proposed that schizophrenia is a neurodegenerative brain disorder similar in natural history to Alzheimer's disease, but with onset in early adult life (Kraepelin, 1918). More recently however, there has been a major shift toward a neurodevelopmental model of schizophrenia, which posits that the neural underpinnings of the disorder arise during early central nervous system development that are subsequently exacerbated during cerebral maturation in adolescence and early adulthood (Figure 23.1; Cannon, 1997, 2008; Lewis & Levitt, 2002; Rapoport, Addington, Frangou, & Psych, 2005; Weinberger, 1987).

Several lines of evidence support the early neurodevelopmental viewpoint. Numerous prospective studies have revealed associations between obstetric events, particularly those involving fetal hypoxia and infection, and elevated risk for schizophrenia, thus implicating early adverse events as contributing to the development of the disorder (Brown, 2011; Cannon, Rosso, Bearden, Sanchez, & Hadley, 1999). Recent advances in genomics have also shed light on the involvement of rare genetic mutations (copy number variants) as well as additive effects of common genetic variants in the etiology of schizophrenia (Malhotra & Sebat, 2012; Owen, Williams, & O'Donovan, 2009).

[1]Color versions of Figures 23.1–23.3 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

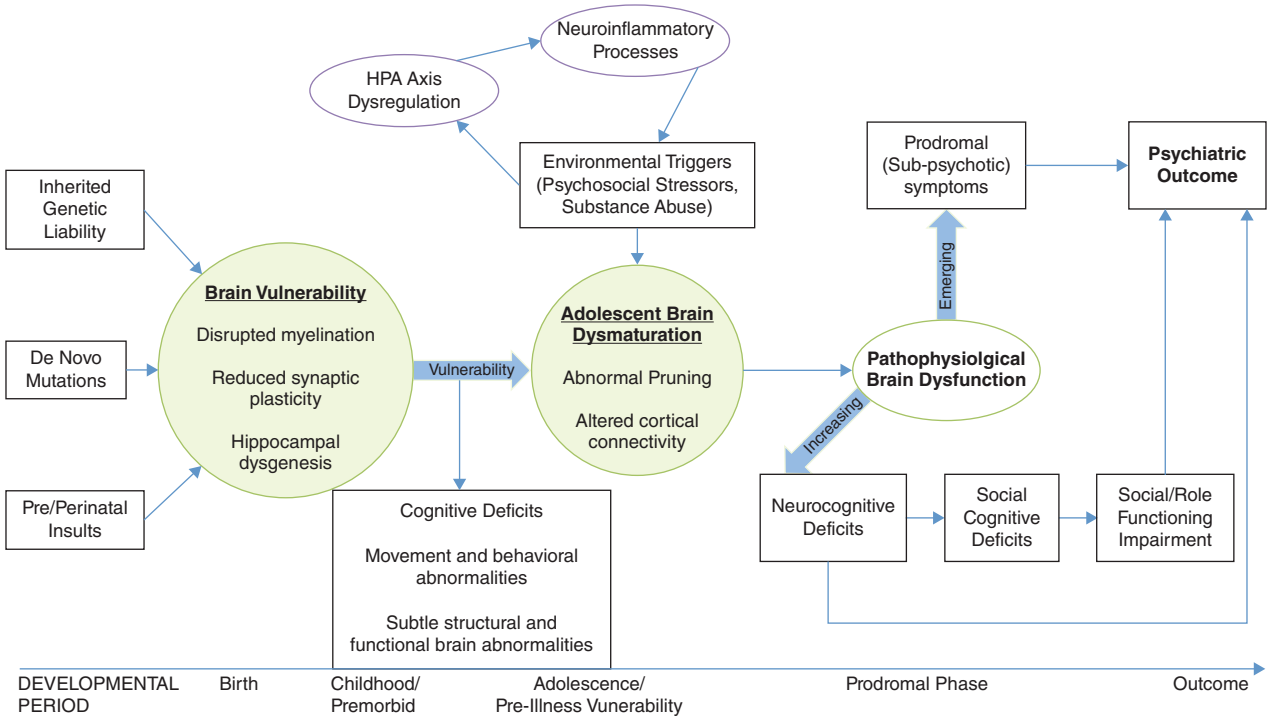

Figure 23.1 Early and late neurodevelopmental abnormalities in schizophrenia. Conceptual model of the hypothesized relationship of vulnerability-related and progressive neuroanatomic abnormalities to the development of neurocognitive and functional impairment in the early phases of psychosis. See footnote 1.

Furthermore, the presence of subtle deficits in cognition and behavior during childhood among individuals who ultimately develop schizophrenia as adults suggests that brain compromise is present long before acute illness onset (Agnew-Blais & Seidman, 2012; Bearden et al., 2000; Cannon, Rosso, et al., 2000; Reichenberg et al., 2010; Rosso, Bearden, et al., 2000; Seidman et al., 2013).

Despite these indications that multiple liability markers for schizophrenia emerge during early brain development, formal diagnostic symptoms and signs of the disorder do not typically manifest until the late adolescent period. Indeed, there is a remarkable consistency in age-at-onset distributions for schizophrenia in diverse cultures around the world, implicating the late adolescent/early adult period as the peak period of risk for onset (Gogtay, Vyas, Testa, Wood, & Pantelis, 2011; Jablensky et al., 1992; Paus, Keshavan, & Giedd, 2008). Adolescence represents a period of active brain development, during which increases in neuronal efficiency are accompanied by a reduction (i.e., pruning) of excess synapses and by myelination of axonal connections in regions critical for higher order cognition, particularly the prefrontal cortex (Huttenlocher, 1979; Petanjek et al., 2011), and these processes during adolescent brain development may play a role in the pathogenesis of schizophrenia (Feinberg, 1990; Hoffman & McGlashan, 1997; P. D. McGorry, 2011). Interestingly, some structural magnetic resonance imaging (MRI) studies have observed progressive gray matter reductions in first-episode patients with schizophrenia (Andreasen et al., 2011; Asami, Bouix, Whitford, & Shenton, 2012; Witthaus, Kaufmann, Bohner, & Özgürdal, 2009) and in individuals at clinical high risk, particularly in those who subsequently convert to psychosis (Brent, Thermenos, Keshavan, & Seidman, 2013; Sun et al., 2009; Witthaus et al., 2009). The sources of this progression require further investigation, but it may reflect a disruption of mechanisms underlying synaptic pruning. Such processes may be overly aggressive in individuals predisposed to developing schizophrenia (e.g., due to a disease-related defect in synaptic plasticity mechanisms), or may be normal but interact with previously existing brain vulnerability in winnowing neuronal connectivity to below some hypothetically critical threshold. Ascertaining individuals who are initially showing symptoms consistent with a high risk for imminent onset of psychosis (i.e., prodromal patients) and following them over time is necessary to characterize the course of neurobiological change among those who develop full-blown psychosis and to elucidate predictors of this outcome (Cannon et al., 2003).

This chapter reviews and evaluates evidence bearing on the relative contributions of early (i.e., genetic and pre/perinatal) and late (i.e., adolescent) neurodevelopmental influences to the etiology and pathogenesis of schizophrenia. We first describe briefly the various neural disturbances that have been detected in schizophrenia, followed by a review of the research supporting both early developmental vulnerability factors and later developmental influences on frank illness onset. These studies provide a useful framework for hypothesis generation concerning the timing of onset and course of brain abnormalities in schizophrenia. Certain brain abnormalities in schizophrenia appear to be reflective of an inherited vulnerability state and are thus likely to emerge prior to illness onset and be fairly stable after their initial appearance, while other abnormalities are unique to (or more severe in) individuals who manifest the illness phenotype and may thus first appear or significantly progress and worsen as one moves beyond an inherited vulnerability state to a fully symptomatic state. We then investigate potential causal mechanisms that may influence the timing of frank illness onset, including neurobiological effects of stress as well as genetic and hormonal influences on synaptic pruning. The principal conclusions that can be reached from this review are that: 1) the case for involvement of early neurodevelopmental influences in the etiology and pathogenesis of schizophrenia is consistent and compelling, including evidence from human epidemiological studies, prospective studies of birth cohorts and samples at risk, post-mortem neuropathology studies, experimental studies using animal models and molecular and behavioral genetics studies; and 2) the case for involvement of later neurodevelopmental processes, as elucidated by neurobiological studies of the prodromal phase and early-onset psychosis, suggests that such processes appear likely to influence the onset and timing of diagnostic symptoms and signs. These processes may include stressful events, potentially inducing a cascade of neuroinflammatory processes leading to accelerated synaptic pruning and consequent gray matter loss. We conclude this chapter with an updated version of the neurodevelopmental hypothesis of schizophrenia, specifying a number of ways particular sets of early and late influences might interact in determining the timing of onset and course of the disorder, and finally with a set of key future directions for the field.

BRAIN ABNORMALITIES IN SCHIZOPHRENIA

The use of noninvasive neuroimaging technologies has facilitated significant progress in the characterization of brain abnormalities in schizophrenia. Disturbances in prefrontal and temporo-limbic systems and their inter-connections appear particularly prominent in the disorder (Cohen & Servan-Schreiber, 1992; Grace, Moore, & O'Donnell, 1998; Gray, Feldon, Rawlins, & Hemsley, 1991). At the structural-anatomical level, patients with schizophrenia show a variety of volumetric changes throughout the brain, including reduced cortical, hippocampal, and thalamic volumes and increased sulcal and ventricular volumes; recent meta-analyses indicate that there is a relatively greater degree of reduction in frontal and temporal cortical volumes compared with posterior cortical volumes (Bora et al., 2011; Olabi et al., 2011; Shepherd, Laurens, Matheson, Carr, & Green, 2012; Vita, De Peri, Deste, & Sacchetti, 2012).

Post-mortem evidence of decreased prefrontal cortical thickness without a reduction in the number of cell bodies (Selemon, Rajkowska, & Goldman-Rakic, 1995, 1998) suggests that a reduction of interneuronal neuropil underlies these *in vivo* MRI findings of cortical gray matter reduction in schizophrenia (Selemon & Goldman-Rakic, 1999), a prediction that has been confirmed by observations of reduced dendritic spine density on prefrontal cortical pyramidal neurons (Broadbelt, Byne, & Jones, 2002; Glantz & Lewis, 2000; Harrison & Weinberger, 2004). This pattern implies a disruption in cellular plasticity mechanisms rather than neuronal degeneration *per se*. This interpretation is also supported by the lack of gliosis, or scarring associated with degeneration of cortical neurons, in the brains of patients with schizophrenia which would be expected to result from an active neurodegenerative process (Bogerts et al., 1993; Roberts & Harrison, 2000). These post-mortem findings were more recently replicated in a study that also found reduced dendritic spines on pyramidal cells involved in corticocortical connectivity after controlling for effects of age and postmortem interval, with the greatest reduction in temporal and frontal association cortex (Garey, 2010). These authors reiterated that this appears to be due to reduced neuropil, given that the number and position of neurons remain unaffected. By examining the glial subtypes independently, the authors also found an increase of microglia in the frontal and temporal cortices. The increase is postulated to result from perinatal damage and persist into adulthood as a method of neuroprotection, again suggesting a neurodevelopmental process. Additionally, this interpretation is supported by findings of cellular positioning abnormalities consistent with disturbances of neuronal migration during gestation (Akbarian et al., 1993; Arnold, Hyman, Van Hoesen, & Damasio, 1991; Falkai, Schneider-Axmann, & Honer, 2000; Jakob &

Beckmann, 1986; Ross, Margolis, Reading, Pletnikov, & Coyle, 2006). In particular, individuals with schizophrenia have demonstrated dysfunction of neocortical networks, which may be attributable to improper cell migration and corresponding faulty arrangement of inhibitory neurons (Sultan, Brown, & Shi, 2013). While these latter findings clearly imply that risk factors for schizophrenia are operative *in utero*, the role of cellular positioning abnormalities in the pathophysiology of schizophrenia and their relationship to the gross morphological findings such as gray matter reduction is not yet known.

Further support for involvement of a developmental rather than degenerative process is provided by research addressing the well-documented role of GABA and glutamate in schizophrenia (Coyle, 2006; Marsman, Heuvel, et al., 2013). Typical cortical development involves the formation and organization of layers of both excitatory (glutaminergic) neurons and inhibitory (GABAergic) interneurons that in turn have long- and short-distance projections thoughout the brain. Early disruption to these complicated processes and cellular signals (e.g., via glutamatergic and GABAergic cell migration) is postulated to result in abnormal development of the specific connections neccesary for proper functional networks, leading to disorders such as schizophrenia (Sultan et al., 2013). In particular, both glutamatergic and GABAergic neurons synapse onto the spines of pyramidal cells, potentially explaining the reduced dendritic spine density and gray matter volume highlighted previously (Garey, 2010), the compromised neurotransmission/cortical connectivity of these cells (Lewis, 2000), and reported deficits in glutamate and GABA receptors (Anticevic et al., 2013; Krystal & Moghaddam, 2010). These developmental aberrations are further reflected in work demonstrating that patients with schizophrenia evidence faster rates of glutamate reduction with age compared with healthy controls (Marsman, Mandl, et al., 2013).

The consequences of these structural and cellular abnormalities in schizophrenia appear to manifest as a wide variety of clinical signs, cognitive impairments and alterations in brain function. For example, Gur et al. (1998) found associations between structural brain changes and clinical presentation during the first two years of illness such that reductions in frontal and temporal lobe volume were associated with less improvement in negative symptoms and hallucinations in first episode adult patients, even when controlling for medication dose and compliance. This pattern of findings has been similarly reported by Sporn and colleagues (2003), Ho et al. (2003), and DeLisi, Sakuma, Ge, and Kushner (1998), among others. However, somewhat counter-intuitively Gur et al. also reported greater *improvement* with regard to delusions, and Sporn et al. found greater clinical improvement associated with a higher rate of gray matter reduction. The investigators proposed that this inverse relation may be reflective of a process by which diseased tissue is removed through compensatory pruning (Gur et al., 1998; Sporn et al., 2003). In other words, it may be that the brain's normative process of synaptic elimination results in the removal of deviant neural connections, thus leading to clinical improvement.

Cognitive performance and functional neuroimaging research have also identified behavioral and brain activation abnormalities corresponding to these structural alterations. Patients with schizophrenia have been found to show performance deficits on nearly all measures of neurocognitive functioning (Kahn & Keefe, 2013). Against this background of generalized deficit, working memory, attention, abstraction, episodic learning and memory, and language functions appear to be particularly severely affected (Cannon, Huttunen, et al., 2000; Reichenberg & Harvey, 2007; Saykin, Shtasel, Gur, & Kester, 1994). These findings have been corroborated by evidence of abnormal physiologic activity (i.e., altered blood flow) in prefrontal and temporal lobe regions in patients with schizophrenia during performance of tests assessing these same domains of functioning (Callicott et al., 1998; Ragland et al., 2012; Ranganath, Minzenberg, & Ragland, 2008; Wolf et al., 2007; Yurgelun-Todd et al., 1996). Dorsolateral prefrontal cortex (DLPFC) function in particular may be compromised early in the developmental course of psychosis (Weinberger et al., 2001; Molina et al., 2005); these abnormalities may be due to relatively localized neuropil reduction in this brain region (Selemon, Mrzljak, Kleinman, Herman, & Goldman-Rakic, 2003).

Abnormalities in neural connectivity between brain regions are also proposed to play a fundamental role in schizophrenia (Friston & Frith, 1995; Karlsgodt et al., 2008). Functional connectivity, defined as the statistical association between spatially distributed neurophysiological time series (Friston, 2004), is one method that allows for evaluation of integrated networks of activation across multiple brain regions. Patients with schizophrenia show decreased cortical network efficiency across the whole brain as measured by various functional connectivity network metrics (e.g., small-worldness, which represents the degree to which topographically separate regions are linked through relatively few connections) (Alexander-Bloch, Lambiotte, Roberts, & Giedd, 2012; Bullmore & Sporns, 2009; Lynall et al., 2010).

Patients with schizophrenia demonstrate patterns of both over- and under-connectivity during task performance (Haut et al., in press; Quidé, Morris, Shepherd, Rowland, & Green, 2013; Wolf et al., 2009) and within intrinsic networks active during rest (Alonso-Solís et al., 2012; Camchong, MacDonald, Bell, Mueller, & Lim, 2011; Zhou et al., 2007). In particular, there appears to be reduced functional integration in cortical connectivity with frontal regions, including frontotemporal (Lawrie et al., 2002), frontoparietal (J. J. Kim et al., 2003), frontostriatal (Koch et al., 2008), and frontothalamic circuits (Anticevic et al., 2013), as well as local prefrontal cortical circuits (Cole, Anticevic, Repovs, & Barch, 2011). On the other hand, patients with schizophrenia show increases in thalamic connectivity with sensory motor regions (Anticevic et al., 2013) and within regions of the default mode network, which is more active during rest (Whitfield-Gabrieli et al., 2009). These altered connectivity patterns appear to have functional implications, as disrupted functional connectivity has been associated with clinical symptom severity and cognitive performance (Cole et al., 2011; Garrity et al., 2007; Rotarska-Jagiela et al., 2010). Disrupted connectivity has also been associated with overall and negative symptom severity in recent onset, antipsychotic naïve schizophrenia patients (Lui et al., 2009), indicating that these abnormalities are not due to effects of treatment chronicity or long-term effects of illness. Furthermore, diffusion tensor imaging (DTI), which allows for the measurement of the integrity of white matter tracts, suggests structural correlates to these findings of disrupted functional connectivity in schizophrenia. These structural connectivity abnormalities appear particularly prominent in tracts connecting the frontal lobe with the thalamus, cingulate gyrus, hippocampus, temporal and occipital lobe (Ellison-Wright & Bullmore, 2009).

THE CASE FOR INVOLVEMENT OF GENETIC AND EARLY NEURODEVELOPMENTAL PROCESSES IN SCHIZOPHRENIA

The Genetic Architecture of Schizophrenia

Given the substantial body of evidence indicating very high heritability of schizophrenia (~80–85%) (Cardno et al., 1999; McGuffin, Farmer, & Gottesman, 1984), it should be possible to identify specific genes that underlie these disturbances. Nevertheless, until recently, genetic findings in schizophrenia were notoriously inconsistent and difficult to replicate. With the advent of ever-larger genome-wide association studies (GWAS) and increasingly sophisticated technology for the detection of small copy number variants (CNVs), the field of schizophrenia genetics has been rapidly advancing on two fronts, leading to substantial progress in our understanding of the genetic architecture of this complex disorder. In particular, recent studies support the notion that the high heritability of schizophrenia reflects a combination of relatively common alleles of small effect, and some rare alleles with relatively large effects (Owen et al., 2009).

Common Sequence Variation

Genetic variation can involve differences in DNA sequence, as well as changes in chromosome structure (Thapar & Cooper, 2013). Single nucleotide polymorphisms (SNPs) are common DNA sequence variations of individual nucleotides that are frequently observed in the population (>1%). SNP variation is typically investigated through genetic association studies. These studies originally investigated allelic variation within single candidate genes, but the advent of high-throughput genotyping methods has enabled interrogation of the entire human genome with increasing numbers of genetic markers (Mulle, 2012). The first genome-wide association studies (GWAS) of schizophrenia (in samples of up to 7,000 individuals) did not reveal any risk loci reaching genome-wide significance, suggesting that there are no common risk alleles of large or moderate effects size (O'Donovan et al., 2008; Sullivan et al., 2008). Researchers from the International Schizophrenia Consortium then tested an alternate hypothesis: specifically, that schizophrenia is due to an aggregation of multiple risk alleles at thousands of loci (i.e., a polygenic inheritance model) (Purcell et al., 2009), as originally postulated by Gottesman and Shields (1967). This study revealed that, indeed, common polygenic variation may accounts for as much as one-third of the total variation in schizophrenia risk; and further, that this liability is substantially shared with bipolar disorder, but is largely *not* shared with several nonpsychiatric diseases. This kind of highly polygenic model suggests that genetically influenced variation in brain development and function may create a diathesis for severe mental illness. Recently, a large, multi-stage GWAS involving over 13,000 schizophrenia cases and 18,000 controls identified 22 genetic loci that reach the threshold for genome-wide significance, one of which was also significantly associated with bipolar disorder (Ripke et al., 2013). Several of the significant SNPs were in genes involved in calcium signaling, implicating disruption of neuronal calcium signaling in the pathophysiology of schizophrenia. Calcium channels

have fundamental importance in synaptic plasticity and in learning and memory functions (Woodside, Borroni, Hammonds, & Teyler, 2004).

Structural Variation

In the past decade, copy number variation (CNV) has been established as a major source of human genetic variation (Iafrate et al., 2004). These submicroscopic variations (<500 kb in size) arise by *de novo* mutation in the individual or in recent ancestry (Malhotra & Sebat, 2012) and appear to play a key role in multiple complex neuropsychiatric diseases, particularly autism and schizophrenia, as well as other disorders of neurodevelopmental origin such as epilepsy and intellectual disability (Gill, 2012; Mulle, 2012; Owen, 2012). Certain CNVs have now been shown to be incontrovertibly associated with schizophrenia, and provided some of the first evidence for a role of rare chromosomal rearrangements in disease pathogenesis (Tam, Redon, Carter, & Grant, 2009). In particular, 25 to 30% of adults with 22q11.2 Deletion Syndrome (Velocardiofacial/DiGeorge Syndrome; 22q11DS) develop schizophrenia, making 22q11DS one of the greatest known risk factors for schizophrenia identified to date (Murphy, Jones, & Owen, 1999; Schreiner, Lazaro, Jalbrzikowski, & Bearden, 2013) and the only known recurrent CNV responsible for introducting new cases of schizophrenia into the population (Karayiorgou, Simon, & Gogos, 2010). This disorder also involves cardiac and craniofacial anomalies, marked deficits in visuospatial cognition, and elevated rates of other psychiatric disorders in childhood including autism spectrum disorders, anxiety disorder, and attention deficit disorder (Schneider et al., 2014). However, psychosis appears to be the most specific association with this mutation. In most diagnosed cases, the syndrome results from a 3 megabase (Mb) *de novo* deletion. This particular region of the genome is thought to be highly susceptible to chromosomal rearrangement due to the groups of low copy repeat sequences flanking the deletion breakpoints, which may cause misalignment due to high sequence homology (Shaffer & Lupski, 2000).

The greatly increased risk for psychosis in this syndrome suggests that a gene or genes within the 22q11.2 locus may contribute to schizophrenia susceptibility in the broader population. Support for this notion is provided by genetic linkage and association studies implicating genes within the 22q11 region in schizophrenia (i.e., proline dehydrogenase (*PRODH*), catechol-*O*-methyltransferase (*COMT*), *ZDHHC8*, G-protein-coupled receptor kinase (*GRK3*), *GNB1L*, and the micro-RNA processing gene *DGCR8* (Mukai et al., 2004; Paterlini et al., 2005; Williams et al., 2007), as well as suggestive findings in GWA studies for genes within this locus (Purcell et al., 2009), and the finding that mice heterozygously deleted for some of the genes in this region have sensorimotor gating and memory impairments similar to those observed in schizophrenia (Karayiorgou et al., 2010). As such, individuals with this syndrome may have genetically determined differences in brain anatomy that predispose to schizophrenia (Van Amelsvoort et al., 2004), although currently the mechanism for the development of schizophrenia in individuals with this syndrome is not known.

Recent large-scale association studies have additionally revealed three novel schizophrenia-associated recurrent CNV loci at chromosomes 1q21.1, 15q13.3, and 15q11.2 (Tam et al., 2009). Although these rearrangements were extremely rare events, occurring in just 0.1% to 0.55% of schizophrenia cases, estimated odds ratios for association of schizophrenia with these regions were high (~2.7 – 18) (Stefansson et al., 2008; J. L. Stone et al., 2008). Several highly plausible schizophrenia candidate genes are located within these regions. In particular, the 15q11.2 CNV partially overlaps with the Prader-Willi Syndrome locus and contains the cytoplasmic FMR1 interacting protein 1 isoform (*CYFIP1*) gene, which plays a role in synaptic plasticity and brain development. Also of interest, the *CHRNA7* (alpha7 nicotinic receptor) gene is a schizophrenia candidate gene that is targeted by neuregulin1-erbB signaling to axons for surface expression in sensory neurons (Hancock, Canetta, Role, & Talmage, 2008).

While CNVs thus appear to play an important role in schizophrenia risk, aside from 22q11DS the specific CNV regions that have been implicated are often extremely rare, sometimes even unique, events. Nevertheless, there appears to be some convergence of the biological pathways affected by these structural rearrangements. Notably, one common characteristic is the involvement of proteins related to synaptic development and functions (Walsh et al., 2008; Xu et al., 2008). These biological functions have also been implicated by GWAS findings, as discussed above. Thus, convergent evidence from studies of both common and rare genetic variation suggests that genes involved with neurodevelopmental processes including cell migration and proliferation, axonal outgrowth, myelination, and synaptogenesis are implicated in schizophrenia.

Liability-Related Versus Disease-Specific Brain Abnormalities

Given the strong genetic contributions to schizophrenia and the well-documented neuroanatomic abnormalities

associated with the illness, liability to disease may be reflected at the level of neural abnormalities in clinically unaffected relatives. As such, a question of major importance is whether some of the brain abnormalities associated with schizophrenia are shared by the nonpsychotic first-degree relatives of these patients. Such a pattern would be expected to occur given the complexity of the inheritance of the disorder, in which multiple genes of small effect and a nontrivial environmental component appear to aggregate to increase risk for phenotypic expression (Purcell et al., 2009). That is, many first-degree relatives of schizophrenia patients would be expected to carry a subset of the vulnerability genes in a predisposing configuration but remain clinically unaffected. Understanding the effects on these nonaffected relatives and other individuals with genetic high risk (GHR) is an important way to differentiate genetically and familial-based vulnerability or predisposing factors from individual environmental causes, disease process specific effects or associated but noncausal features.

Neurocognitive Findings in Genetic High-Risk Cohorts

Many studies have demonstrated that unaffected biological relatives of patients with schizophrenia display qualitatively similar, but quantitatively milder, neuropsychological impairments when compared with normal controls, even after accounting for substance abuse and other psychiatric diagnoses (Cannon, Huttunen, et al., 2000; Park, Holzman, & Goldman-Rakic, 1995). Healthy relatives of patients with schizophrenia exhibit patterns of deficits similar to patients on verbal memory performance (Toulopoulou, Rabe-Hesketh, King, Murray, & Morris, 2003) as well as frontal lobe functions (Staal, Hijman, Hulshoff Pol, & Kahn, 2000) including spatial working memory (Glahn et al., 2003), attention (Michie et al., 2000), and language (Cannon & Marco, 1994; Snitz, MacDonald, & Carter, 2006). A recent meta-analysis found global cognitive function (as assessed by measures of IQ) to be the most strongly affected in individuals at GHR, with additional moderate effects in more specific domains such as declarative memory, working memory and attention (Agnew-Blais & Seidman, 2012). Additionally, Faraone, Seidman, Kremen, Toomey, Pepple, and Tsuang (2000) found that relatives from multiplex families (as defined by two or more first degree relatives with schizophrenia) had significantly lower scores on measures of estimated intelligence and verbal and visual recall than relatives from simplex families (one relative). These shared cognitive impairments account for a significant portion of overall genetic risk for psychosis (Toulopoulou et al., 2010). Such findings support the view that cognitive deficits are reflective of a diathesis for schizophrenia and may serve as an indicator of genetic vulnerability to the disorder, rather than resulting from the disease process or pharmacological intervention.

Genetically Mediated Structural Neuroanatomic Anomalies

Findings of neuroanatomic abnormalities among unaffected relatives of patients with schizophrenia may also be reflective of underlying genetic influences. Evidence from structural MRI studies of healthy relatives of patients with schizophrenia has revealed global volumetric deficits (Cannon et al., 1998) and ventricular enlargement (Reveley, Reveley, Clifford, & Murray, 1982), as well as more specific structural anomalies. Reduced gray matter volume has also been found among unaffected relatives outside the period of risk for developing psychosis (Seidman et al., 1997; Seidman et al., 1999; Suddath, Christison, Torrey, Casanova, & Weinberger, 1990), indicating that these volumetric reductions may be a stable vulnerability factor. Recent comprehensive reviews of the literature indicate that individuals at GHR show consistent gray matter deficits within temporal lobe regions (particularly the hippocampus) and that reduced prefrontal cortical volume or thickness was the most consistent finding across studies, implicating reduced hippocampal and PFC volume as potential risk factors for schizophrenia (Thermenos et al., 2013).

Neurophysiologic Alterations and Functional Dysconnectivity in Genetic High-Risk Cohorts

Functional neuroimaging techniques have also been used in those at genetic risk for schizophrenia to identify neural systems that might be especially vulnerable to the genetic factors that influence psychosis risk. Early research found that children of mothers with schizophrenia show decreased dorsolateral prefrontal and inferior parietal lobe activity during working memory tasks, similar but attenuated compared with the degree of hypoactivation found in patients with schizophrenia (Keshavan et al., 2002). Siblings of individuals with schizophrenia also show altered patterns of neural activity in prefrontal and parietal regions (Brahmbhatt, Haut, Csernansky, & Barch, 2006). Reduced activity in medial prefrontal, thalamic and cerebellar regions was found during an executive functioning task involving verbal initiation in those at genetic risk of schizophrenia (Whalley, 2004), suggesting that GHR individuals are less able than healthy controls to appropriately recruit these regions with increasing task demands. Furthermore, using a technique known as

cerebral perfusion, which involves quantifying the flow of radioactively tagged blood to brain regions, Blackwood et al. (1999) found reduced perfusion during verbal memory in inferior prefrontal regions and the anterior cingulate, as well as increased perfusion in subcortical regions. These results highlight metabolic dysfunction in those regions even among those identified as GHR, though to a lesser extent than clinically affected individuals.

On the other hand, studies demonstrating reduced frontal activation in patients with schizophrenia as well as GHR were often confounded by lower levels of performance compared with controls. Indeed, when controlling for performance accuracy GHR individuals show *hyperactivation* in DLPFC and ventrolateral prefrontal cortex (VLPFC) during working memory tasks (Callicott et al., 2003; Seidman et al., 2006), as well as increased anterior cingulate and thalamic activity (Thermenos et al., 2004). Furthermore, symptomatic adult GHR subjects show hyperactivation in the spatial working memory network (Choi et al., 2012), as do adolescent offspring of schizophrenia patients (Diwadkar et al., 2012). These patterns of hyperactivation are intermediate to those typically observed in patients with schizophrenia and do not appear to be specific to working memory related functions, as nonpsychotic siblings also demonstrate increased right middle frontal and precentral gyrus activity during facial emotional processing (Li et al., 2012). Right PFC hyperactivity in GHR individuals has also been shown during performance on a language task (Li et al., 2007) and during declarative memory encoding (Bonner-Jackson, Csernansky, & Barch, 2007; Whyte et al., 2006). It is speculated that these observed patterns of hyperactivity are indicative of cortical inefficiency (Callicott et al., 2000; Schlösser et al., 2008) or a compensatory response (Tan et al., 2006), similar to that found in patients with recent-onset schizophrenia.

Genetic liability for psychosis is also associated with reduced neural activity in subcortical regions such as the hippocampus, which is critically involved in learning and memory, and the striatum (Callicott et al., 2003; Thermenos et al., 2004), which plays an important role in response to reward (Delgado, 2007) and motivation (Shohamy, 2011). GHR individuals demonstrate a failure to activate the striatum during inhibition of saccades (Raemaekers, Ramsey, Vink, van den Heuvel, & Kahn, 2006), similar to what has previously been reported in patients with schizophrenia, as well as reduced amygdala activation to negative mood induction (Habel et al., 2004). Collectively, these findings suggest that structural and functional neural abnormalities—particularly in prefrontal and medial temporal brain regions critical for working and declarative memory processes and emotional processing—may reflect a genetic diathesis to schizophrenia.

Additionally, studies of cortical networks at rest have shown atypical functional connectivity in individuals predisposed to the development of psychosis that are similar to patterns identified in patients with schizophrenia but represent more circumscribed dysfunction. In particular, while patients with schizophrenia showed widespread dysregulation of functional connectivity between the striatum and other cortical regions, unaffected relatives demonstrated reduced connectivity between the dorsal striatum and dorsal, medial, and lateral prefrontal cortex and hyperconnectivity between the ventral striatum and orbitofrontal and insular regions (Fornito et al., 2013), which the authors speculate may be reflective of the roles those networks play in cognition and salience, respectively. Furthermore, while patients with schizophrenia demonstrated unique alterations in cerebellar and frontotemporal networks (which were not observed in their clinically unaffected relatives), relatives did share decreased network connectivity in frontooccipital and frontal/thalamic/basal ganglia networks and increased connectivity in sensorimotor networks (Khadka et al., 2013). Alterations in functional connectivity shared between schizophrenia patients and relatives are present both at rest and across different task conditions, supporting the notion that these are stable alterations reflecting genetic liability (Repovs & Barch, 2012). In addition, altered thalamo-cortical connectivity was found to be stronger in GHR individuals showing subthreshold psychotic symptoms than those who were asymptomatic (Dauvermann et al., 2013). These findings are notable given that the thalamus is a central relay station in the brain thought to integrate cortical and subcortical functions (Haber & Mcfarland, 2001), which computational modeling suggests may be critically involved in the development of acute psychotic symptoms (Lisman, Pi, Zhang, & Otmakhova, 2010).

Overall, these functional neuroimaging findings suggest that individuals at genetic risk for psychosis show abnormalities in brain activity that may reflect inherited neural vulnerability factors rather than disease-specific effects. Across studies, and similar to patients with established psychosis, GHR individuals show inefficient prefrontal and reduced subcortical activity (MacDonald, Thermenos, Barch, & Seidman, 2009), as well as disrupted cortical connectivity betweeen frontal, striatal and thalamic regions. Although patients with established illness generally show more extensive neural abnormalities relative to GHR

subjects, the shared abnormalities must be prospectively investigated over time to determine their predictive value for emergence of psychotic illness.

Twin Studies

Neurocognitive and neuroimaging studies of twins discordant for schizophrenia allow for further clarification of genetic and nongenetic contributions to the brain abnormalities associated with the illness. Because healthy monozygotic (MZ) and dizygotic (DZ) cotwins of patients with schizophrenia differ by a ratio of 2:1 with regard to genetic liability for the disease, it becomes possible to test whether the degree of cognitive or neuroanatomical deficit increases with genetic proximity to a proband. Further, because discordant MZ cotwins are 100% genetically identical, any abnormalities that are unique to or more severe in the affected compared with unaffected cotwins are likely to be nongenetic in origin. A study of an epidemiologically ascertained sample of Finnish twins revealed that impaired performance on tests of spatial working memory and structural abnormalities in prefrontal brain regions varied in a dose-dependent fashion with degree of genetic loading for schizophrenia. Specifically, MZ unaffected cotwins were significantly more impaired than DZ unaffected cotwins, who in turn were significantly impaired compared with control subjects (Glahn et al., 2003). Decreased white matter volume has also been found in twin pairs discordant for schizophrenia (Hulshoff Pol et al., 2004), indicating that these abnormalities are likely reflective of genetic vulnerability factors. Subcortical structures including the hippocampus (van Erp et al., 2004) and thalamus (Ettinger et al., 2007) also show intermediate genetic effects such that unaffected cotwins show reduced volumes relative to controls but to a lesser extent than probands. Unaffected twins also demonstrate abnormalities in functional activation intermediate to probands, suggesting that cortical activation inefficiency may also be a partially heritable component of the disorder (Karlsgodt et al., 2007).

In contrast, deficits in long-term memory and anatomical changes in the hippocampus and adjacent temporal cortex were specifically more pronounced in patients with schizophrenia compared with their own healthy MZ cotwins (Cannon, Huttunen, et al., 2000). Furthermore, while verbal memory was impaired in both patients and cotwins, greater behavioral impairment and unique reductions in hippocampal volume in probands suggests structural compromise due to nongenetic factors (van Erp et al., 2008). Similarly, a study of monozygotic twin pairs discordant for schizophrenia found relatively reduced gray matter volume in the affected twin in brain regions including the insula, superior/medial frontal gyrus, cingulate, superior temporal gyrus and paracentral lobule (Borgwardt et al., 2010). Taken together, these studies generally indicate more widespread or pronounced gray matter decreases in the affected cotwins (Hulshoff Pol et al., 2004), suggesting that nongenetic, disease-related factors are likely to be more involved in these abnormalities.

The Role of Prenatal and Perinatal Complications in the Development of Schizophrenia

In addition to genetically influenced neurodevelopmental factors, early environmental factors are also proposed to play a role in the etiology of schizophrenia. Environmental exposures, including infections, nutritional deficits, and neurotoxins, are known causes of neuropsychiatric disorders, and are potent disruptors of brain development which have also been shown to contribute to increased risk for schizophrenia later in life (Brown, 2011). Prenatal and perinatal complications, particularly those associated with fetal hypoxia, appear to be particularly robustly associated with increased risk for schizophrenia. Fetal hypoxia appears as a risk factor in a larger proportion of the cases (30–40%) than all forms of pregnancy complications (including viral exposure) and signs of fetal maldevelopment (Cannon, 1997; Fatemi & Folsom, 2009).

Complications associated with fetal hypoxia are also of interest because fetal oxygen deprivation represents a plausible mechanism for explaining much of the structural pathology of the brain detected in neuroimaging studies of adult patients with schizophrenia. For example, in a Finnish birth cohort, a history of fetal hypoxia was associated with significant reductions in gray matter density in both prefrontal and temporal lobe regions among patients with schizophrenia and their healthy siblings, but not in controls at low genetic risk for the disorder, and more so in the patients than in their siblings (Cannon, van Erp, & Glahn, 2002). This pattern appears to be consistent with a genotype-environment interaction, in which hypoxia-related obstetric complications represent random environmental events, which may add to or multiply the risk for phenotypic expression of schizophrenia when they occur in a genetically vulnerable individual. Schmidt-Kastner and colleagues (2006) suggest that susceptibility genes for schizophrenia were more likely to be expressed in the cerebrovasculature or regulated by hypoxia than randomly selected genes, and rates of interaction between some of these hypoxia-related genes and obstetric complications were found to be increased in patients with schizophrenia (Nicodemus et al., 2008).

The hippocampus in particular is acutely vulnerable to hypoxic-ischemic damage (Gonzalez-Rodriguez, Xiong, Li, & Zhou, 2014; Zola & Squire, 2001). Among monozygotic twins discordant for schizophrenia, relatively small hippocampi in the ill twin were significantly related to labor and delivery complications and to prolonged labor, both risk factors associated with fetal oxygen deprivation (McNeil, Cantor-Graae, & Weinberger, 2000). We have previously found that schizophrenia probands who experienced fetal hypoxia have smaller hippocampal volumes than those who did not, a difference not noted among unaffected siblings and healthy comparison subjects (van Erp et al., 2002). Moreover, hippocampal volume differences occurred in a stepwise fashion with increasing genetic load for schizophrenia, suggesting that, in patients with schizophrenia spectrum disorders, hippocampal volume is influenced in part by schizophrenia susceptibility genes, as well as an interaction of these genes with fetal hypoxia.

At the cellular level, the neural sequelae of hypoxia vary in severity from alterations in neurite outgrowth to neuronal cell death (Nyakas, Buwalda, & Luiten, 1996). In the former case, immature neurons may survive the hypoxic insult but still have a compromised elaboration of synaptic interconnections (Nyakas et al., 1996). Evidence from animal studies indicates that sublethal hypoxia results in global dysynchrony in brain maturation programs due to profound loss of coordinated regulation of neuronal gene transcription (Curristin et al., 2002). Specifically, in a mouse model chronic sublethal hypoxia resulted in up-regulation of genes subserving presynaptic function, and suppression of genes involved with synaptic maturation, postsynaptic function, and neural transmission. Genes involved in myelination, glial maturation and cytoskeletal organization were also affected, leading to retardation of synapse formation and reduction of cytoskeletal systems needed to form neuritic processes and synaptic structures. In addition, fetal hypoxia leads to up-regulation of stress and hypoxia response pathways, which may further slow neuronal maturation. Intriguing findings come from a rat model of schizophrenia, in which direct lesions of the hippocampus early in life were found to produce deficits in prepulse inhibition, enhanced sensitivity to stress, and differential response to amphetamine, all of which do not become apparent until the postpubertal period (Lipska & Weinberger, 2002). Further, these investigators found that even transient inactivation of the ventral hippocampus during a critical period of development may be sufficient to disrupt normal maturation of the prefrontal cortex and trigger behavioral changes comparable to those observed in animals with permanent excitotoxic hippocampal lesions (Lipska & Weinberger, 2002). Supportive data in humans comes from the Philadelphia Collaborative Perinatal Project (Cannon, Yolken, Buka, & Torrey, 2008), which found a differential response to fetal hypoxia, involving differential reduction of the neurotrophic factor BDNF in cord blood, in cases versus controls.

Evidence for Cognitive, Motor, and Behavioral Impairment in Infancy and Childhood

Central to the neurodevelopmental hypothesis of schizophrenia (Fatemi & Folsom, 2009; D. A. Lewis & Levitt, 2002; Weinberger, 1987) is the identification of developmental anomalies preceding overt clinical symptoms of schizophrenia. Retrospective studies, as well as high-risk studies of the offspring of parents with schizophrenia, have consistently demonstrated the existence of cognitive impairment and behavioral and neurobiologic abnormalities long before the onset of schizophrenia. Such studies offer substantial evidence that such early events may be less quiescent and more functionally apparent than was previously believed. Although the majority of patients with schizophrenia show no signs of outright psychotic symptomatology until adolescence or early adulthood, there is substantial evidence that the pathologic processes that predispose to the disorder are evident earlier in life in more subtle forms.

In the domain of cognitive development, a meta-analysis of the high-risk literature (Aylward, Walker, & Bettes, 1984) revealed that preschizophrenic children showed deficits on standard IQ tests compared with matched groups of peers or siblings who did not develop psychiatric illness, and these deficits were shown to predict an early onset, poor prognosis form of the illness. Early receptive (Cannon, Jones, & Murray, 2002) and expressive (Bearden et al., 2000) language abnormalities are also a robust finding among retrospective studies of individuals with schizophrenia. Similarly, first-generation longitudinal high-risk studies initiated in the early 1960s and 1970s, some of which have followed children of parents with schizophrenia from birth onwards, have consistently found these high-risk children to perform more poorly on neuropsychological measures, across a variety of cognitive domains, relative to children of parents with no psychiatric history (Keshavan, Diwadkar, Montrose, Rajarethinam, & Sweeney, 2005) particularly measures requiring integrated information-processing (e.g., Niendam et al., 2003). These impairments appear early in development, prior to overt behavioral signs of illness (e.g., Cornblatt,

Lenzenweger, Dworkin, & Erlenmeyer-Kimling, 1992; Erlenmeyer-Kimling & Cornblatt, 1987) and have high specificity and moderate sensitivity for predicting serious behavioral disturbances, including social impairment and behavioral problems, emerging in high-risk subjects during midadolescence (Cornblatt & Erlenmeyer-Kimling, 1985).

Neurologic and motor abnormalities have also been identified in children vulnerable to schizophrenia (Marcus, Auerbach, Wilkinson, & Burack, 1981; Mednick & Schulsinger, 1964), the severity of which is associated with adult psychiatric status (Fish, 1987). Longitudinal follow-up of infants studied as part of the Jerusalem Infant Development Study revealed that the neurobehavioral deficits displayed in infancy by offspring of schizophrenic parents persisted over time, and the children who had developed schizophrenia spectrum diagnoses by adolescence demonstrated poor neurobehavioral functioning across the developmental periods studied (Hans et al., 1999). A study of home movies obtained from families in which one child later developed schizophrenia indicated that preschizophrenic children had significantly more neuromotor abnormalities and less developed motor skills than both their healthy siblings and individuals who later developed affective disorder (Walker, Savoie, & Davis, 1994). These findings have been confirmed in general-population studies, which find that delayed gross motor milestones are predictive of psychosis outcome (Crow, Done, & Sacker, 1995; Isohanni et al., 2001; Jones, Rodgers, Murray, & Marmot, 1994). Moreover, in young adolescent Danish children who were videotaped while eating lunch at school, those who subsequently developed schizophrenia (particularly boys) evidenced differences on measures of sociability and general neuromotor functioning relative to children who developed other psychiatric disorders, or no disorder (Schiffman et al., 2004). Delayed motor development during infancy and impaired motor coordination during childhood consistently discriminate between individuals at high and low genetic risk for schizophrenia, suggesting that early motor deviance may be a marker of genetic liability (Egan et al., 2001). Consistent with this interpretation, in the Philadelphia cohort of the National Collaborative Perinatal Project (NCPP), we found that deviance on motor coordination measures at age 7 was associated with both adult schizophrenia and unaffected sibling status, suggesting that a co-familial (and perhaps genetic) factor underlies motor coordination deficits in schizophrenia (Rosso, Bearden, et al., 2000). In addition, adolescents with schizotypal personality disorder have been reported to have elevated rates of involuntary movements relative to non-ill comparison subjects and adolescents with other personality disorders, further supporting the notion that certain motor abnormalities may reflect a genetic vulnerability to schizophrenia (Koning et al., 2011; Walker, Diforio, & Baum, 1999).

Second-generation high-risk studies such as the Edinburgh High Risk study have focused on prospective ascertainment of premorbid risk indicators, and on following genetically at-risk individuals through the critical adolescent period, to disentangle genetic liability factors from those associated with disease onset (Johnstone, Russell, Harrison, & Lawrie, 2003). This study has been highly informative regarding clinical and neuroimaging markers, which are identifiable years before actual illness onset in genetically at-risk individuals. In particular, high-risk adolescents and young adults in this cohort exhibited significantly lower IQ at baseline relative to controls (Byrne, Hodges, Grant, Owens, & Johnstone, 1999), and those who experienced an increase in psychotic symptoms exhibited an apparent decline in IQ and memory over two-year followup (Cosway et al., 2000), suggesting that onset of psychosis may coincide with a decline in cognitive function. Additionally, neuroimaging studies in this cohort suggest that the progression from genetic vulnerability to overt psychosis may be preceded by structural and functional changes in the temporal lobe (Lawrie, McIntosh, Hall, Owens, & Johnstone, 2008).

While these studies have been instrumental in revealing a relationship between genetic liability to schizophrenia and early forms of impairment, such findings may not be generalizable given that only 5 to 10 percent of patients with schizophrenia have a parent with schizophrenia. Further, because offspring in most high-risk samples have not passed through the period of elevated risk for onset of schizophrenia, and those that have include only a small number of participants who ultimately develop psychotic disorder, there is limited data on the degree to which early deficits predict adult schizophrenia in such samples. Thus, population-based cohorts are necessary to determine which precursors, or combination thereof, represent true risk factors for schizophrenia. Three such studies, conducted in England (Jones et al., 1994), Sweden (David, Malmberg, Brandt, Allebeck, & Lewis, 1997), and the United States (Cannon, Bearden, et al., 2000), have showed a linear trend of increased risk for schizophrenia across decreasing levels of cognitive performance. Moreover, at age 7, children who would later go on to develop schizophrenia demonstrated lower academic achievement, verbal ability and attention/working memory relative to children who did not develop a psychotic illness (Seidman et al., 2013).

The bulk of the evidence suggests that, against a background of longstanding cognitive deficit compared with the general population, additional decline may occur prior to illness onset (Woodberry, Giuliano, & Seidman, 2008). For example, a study of Israeli military draftees found that draftees who eventually developed schizophrenia showed a measurable decline in cognitive performance that began about 2 years prior to illness onset, concomitant with impaired social functioning that became progressively worse during the course of late adolescence (Davidson et al., 1999). Using a prospective population cohort design, Reichenberg et al. (2010) demonstrated patterns of cognitive impairment indicative of both longstanding cognitive deficits and increasing cognitive lag in children who would go on to develop schizophrenia. Specifically, children who would later develop schizophrenia demonstrated early, stable deficits in verbal and visual knowledge, reasoning, and conceptualization whereas they demonstrated increasing deficits (developmental lag) on attention and visuo-spatial problem solving abilites, with greater cognitive impairment in the subset who also had known familial risk.

There is also evidence of early behavioral problems displayed by individuals who ultimately develop schizophrenia, albeit with considerable variation. Retrospective and prospective population-based cohort studies have consistently documented the existence of abnormalities in premorbid social development in preschizophrenic individuals, ranging from solitary play preference at age 4 to social anxiety, withdrawal, and acting-out behavior in adolescence (Jones et al., 1994). Studies of childhood films have additionally revealed affective abnormalities in preschizophrenic children, with increases in negative facial expression as early as age 1 (Walker, Grimes, Davis, & Smith, 1993), suggesting that vulnerability to schizophrenia may be associated more generally with difficult infant temperament (Walker, Lewine, & Neumann, 1996). In a prospective longitudinal study of a Philadelphia birth cohort, social maladjustment at age 7 was a significant predictor of adult schizophrenia (Bearden et al., 2000). Moreover, rates of deviant behaviors (e.g., echolalia, meaningless laughter, and stereotyped behaviors) at age 4 and 7 were significantly elevated in both preschizophrenic children and their unaffected siblings, suggesting that such problems may indicate genotypic susceptibility to the disorder, or shared early environmental influences.

Both high-risk (Keshavan et al., 2005) and population-based studies (Cannon et al., 1999) have found that the presence of multiple premorbid indicators, across domains of functioning, are associated with an elevated risk for schizophrenia, over and above single risk factors. Similarly, the Dunedin New Zealand Health and Development Study observed that persistent, multidimensional impairment in early childhood was predictive of psychotic symptoms in childhood and adulthood (Cannon et al., 2002). Whereas emotional problems and interpersonal difficulties were present in children who later developed psychotic, mood, or anxiety disorders, significant impairments in neuromotor, receptive language, and cognitive development were unique to children later diagnosed with schizophreniform disorder. This study also provides some of the first evidence of continuity of psychotic symptoms over the life span: self-reported delusional beliefs and hallucinatory experiences at age 11 predicted a 16-fold increase in risk for schizophreniform disorder (but not mood disorder) at age 26 (Poulton et al., 2000). Such investigations are critical for the delineation of compelling risk factors that may increase positive predictive value in the identification of young people at risk for schizophrenia.

Not surprisingly, emerging evidence suggests that functional impairment during adolescence may have more predictive value in the identification of young people at high risk for schizophrenia than that attained in studies of childhood functioning (Davidson et al., 1999; Keshavan et al., 2005). Because of this, epidemiologic studies of schizophrenia risk have begun to move forward in the illness, progressing from stages that clearly precede clinical signs of the disorder to those more proximal to the onset of psychosis.

THE CASE FOR INVOLVEMENT OF LATER NEURODEVELOPMENTAL PROCESSES IN SCHIZOPHRENIA

By definition, a substantial decline in role functioning and a severe disruption in integrated cognitive and emotional processing occurs around the time of onset of schizophrenia during late adolescence and early adulthood. In view of this pattern, it is tempting to postulate that there are brain changes in addition to those instantiated through early neurodevelopmental influences that occur proximally to the onset of psychosis, thus acting as triggers for this functional decline and psychotic symptom expression (Figure 23.1). As noted previously, the most well established disease-related deficits in schizophrenia involve frontal and temporal lobe structures, abnormalities of which have been linked to the occurrence of hypoxia-associated birth complications among individuals with schizophrenia. Nevertheless, as we shall see, additional progressive deficits in these brain structures appear

to characterize the period proximal to illness onset. While there is debate regarding the interpretation of longitudinal MRI studies, as the reported rates of annualized gray matter decline seem unsustainably high (Weinberger & McClure, 2002), emerging evidence suggests that rates of decline in gray matter may level off with age, distinct from the course of atrophy typically associated with neurodegenerative disorders (Mathalon, Rapoport, Davis, & Krystal, 2003). The question then becomes, if these disease–related deficits are present to some degree from early in life, what mechanisms cause them to further deteriorate in adolescence/early adulthood, and are these mechanisms primary or secondary to the emergence of psychosis?

Clinical High-Risk Studies and Early Detection

With the shift in focus from an early neurodevelopmental model of schizophrenia to increasing interest in more proximal developmental risk factors, a new research strategy has emerged and gathered considerable support. Building on traditional high-risk approaches, the so-called clinical high-risk (CHR) paradigm (Yung & McGorry, 1996; Yung et al., 1998) goes beyond indicators of genetic vulnerability to focus on clinical features that are believed to reflect heightened vulnerability for imminent onset of psychosis. A central goal in CHR research is to prospectively follow a well-characterized group of putatively prodromal individuals through the period of conversion to gain a deeper understanding of the progression of clinical, biological, and neurocognitive changes that characterize the onset of overt illness. Such studies may enhance our understanding of the pathophysiology of psychotic illness, and allow for the discrimination of the schizophrenia prodrome from that of other conditions (e.g., affective psychosis), thus informing early treatment strategies. Finally, results of CHR research may aid in identifying late risk factors for the transition into psychosis, as well as protective factors or interventions that may alleviate, delay, or possibly prevent the onset of psychotic illness (Cannon et al., 2003; Yung et al., 2003).

Developmentally, the prodrome or CHR state can be viewed as the transition between the premorbid and psychotic stages of illness (Cornblatt, Lencz, & Obuchowski, 2002; Yung & McGorry, 1996). Retrospective studies indicate that the first indication of deterioration occurs within 3 to 5 years of onset and consists of a constellation of gradually developing, low-grade psychiatric symptoms and signs, including reduced concentration (attention), decreased drive and motivation (anergia), depressed mood, sleep disturbance, anxiety, social withdrawal, suspiciousness, deterioration in role functioning, and irritability. These symptoms are followed by gradual emergence of transient psychotic symptoms, including hallucinations, delusions, or disorganized speech. Full-blown schizophrenia is considered to have evolved when CHR behavioral features have been present continuously for at least six months, and psychotic symptoms have persisted continuously for at least 1 month (APA, 1994).

Over the past decade, investigators have identified three putative prodromal syndromes that map onto the developmental sequence described above. Criteria for these syndromes currently focus on three groups of individuals: 1) those who are experiencing attenuated positive psychotic symptoms that have emerged or worsened in the past year, 2) those who describe brief and intermittent periods of frank psychotic symptoms with recent onset, and 3) those with familial risk for a psychotic disorder, and who have experienced a significant decline in functioning in the past year. Operational definitions for these syndromes differ slightly across research programs, but are largely comparable.

Early studies using these criteria found that 22 to 54% of treatment-seeking individuals ascertained in a putatively prodromal state will convert to full-blown psychotic disorder within two years (McGlashan, Miller, & Woods, 2001; P. D. McGorry, Yung, & Phillips, 2003; Yung & McGorry, 1996). However, larger and more recent studies have typically found lower rates of conversion to overt psychosis among those initially ascertained in a CHR state, ranging from 20 to 35% over a 2-year period (Cannon, Cornblatt, & McGorry, 2007). Additionally, while some recent work suggests a decelerating rate of conversion over longer follow-up periods (Cannon, 2008), a much wider range of rates of conversion (9–76%) has been reported across several studies when the follow-up period has been expanded to a 9-year period (review: Cannon, Cadenhead, et al., 2008). The reasons for this are not entirely clear, but some investigators have speculated that it may be due to various assessment measures capturing different stages of developing illness compared with others, as well as to possible effects of early intervention following CHR identification. Regardless, rates of psychosis in these samples far surpass those in the population in general. Thus, these studies continue to offer the unique opportunity to identify behavioral and neurobiological markers most predictive of schizophrenia outcome, and, by extension, to develop interventions that may be implemented prior to onset of the full-blown disorder. At the same time, given that the majority of these at-risk individuals will not develop psychosis, it is critical to improve our predictive criteria so that preventive treatments can be offered to those who need them most.

Results thus far have identified several baseline clinical variables that appear to be predictive of conversion to psychosis, over and above prodromal criteria alone. Specifically, findings from the Melbourne Prodromal Study (Yung et al., 2003) suggest that poor functioning, prolonged duration of untreated prodromal symptoms (>900 days), high overall level of psychopathology, subthreshold psychotic symptoms, depression severity, as well as clinically significant avolition and anxiety were all predictive of conversion to psychosis in their prodromal sample. Strikingly, 87% of those participants who had four or more of these risk factors converted to psychosis within 6 months after study entry. In a multisite study in the United States, Cannon et al. (2008) found that five baseline features contributed uniquely to prediction of psychosis: genetic risk for schizophrenia with recent functional decline, more severe unusual thought content and suspicion/paranoia, greater social impairment, and a history of substance abuse. Prediction algorithms, which combined two or three of these variables, greatly increased in positive predictive power (i.e., 68–80%) relative to prodromal criteria alone, suggesting that prospective ascertainment of individuals at risk for psychosis is indeed possible. The use of more sensitive and specific prediction algorithms is critical for minimizing exposure of false-positive cases to potential stigma or adverse events; moving toward individualized prediction algorithms is an ultimate goal of this area of research, which has clear public health benefits.

Along these lines, investigators have also explored neuropsychological changes associated with conversion to psychosis. Seidman et al. (2010) compared typically developing individuals to GHR and CHR cohorts. Results revealed significant differences in general neuropsychological functioning among the CHR group compared with healthy controls, with greater degree of baseline impairment in those who subsequently converted. In particular, verbal learning, processing speed, and verbal memory were most impaired in CHR youth, with the latter most sensitively predicting rapid transition to psychosis. Other studies investigating neurocognitive predictors of overt psychosis have similarly found impairments in the above areas and in measures of attention among the CHR group (Keefe et al., 2006; Lin et al., 2011; Niendam et al., 2006), and have demonstrated that verbal episodic memory performance of those who subsequently convert more closely resembles the performance of schizophrenic patients relative to those who do not, suggesting it may be useful as a predictive factor (Eastvold, Heaton, & Cadenhead, 2007). Another recent study found that a combination of neurocognitive factors (e.g., executive functioning, theory of mind, and visual and working memory) provided the best predictive model of psychosis conversion (Kim et al., 2011).

Associated Neuroanatomical Changes in CHR Patients

Longitudinal prospective studies during the early stages of illness can deepen our understanding of late processes underlying onset of schizophrenia, as these patients have had minimal exposure to potential confounding factors, such as pharmacological agents and chronicity (Bagary et al., 2003) and structural brain changes associated with schizophrenia appear to be at their peak intensity during the initial stage of illness (Gur et al., 1998; Kasai et al., 2003). Pantelis and colleagues (Pantelis, Velakoulis, et al., 2003) reported baseline differences in regional grey-matter volume between CHR participants who subsequently developed a psychotic illness versus those who did not. Specifically, those who developed psychosis had less gray matter *at baseline* in the right medial temporal, lateral temporal, and inferior frontal cortex, and in the cingulate cortex bilaterally. Longitudinal follow-up indicated that CHR individuals who developed psychosis showed additional gray matter reduction in the left parahippocampal, fusiform, orbitofrontal and cerebellar cortices, and the cingulate gyri, whereas longitudinal changes were restricted to the cerebellum in those who did not become psychotic. Additional research in CHR samples has also revealed reduced hippocampal and amygdala-hippocampal complex volumes, smaller thalami, and several morphological abnormalities, including cingulate and paracingulate folding patterns (review: Pantelis et al., 2005). More recently, a pattern of progressive brain tissue loss has been reported in CHR samples that appears more pronounced in individuals who subsequently convert to psychosis. Longitudinal anatomical MRI studies have shown greater cortical gray matter volume loss or contraction in CHR patients who convert, especially in prefrontal and temporal lobe regions, compared with individuals who do not convert to psychosis during the follow-up period (Sun et al., 2009; Takahashi et al., 2009). This pattern of results mimics that found in first-episode schizophrenia and appears to be an exaggeration of the pattern of prefrontal contraction seen during cortical maturation, suggesting that late developmental deviations may play a role in the onset of psychosis (Sun et al., 2008), see Figure 23.2.

However, this body of work has not fully addressed potential confounds including duration of prodromal symptoms and effects of antipsychotic medication, which are often prescribed to patients who develop psychosis before post-conversion imaging scans take place. Therefore,

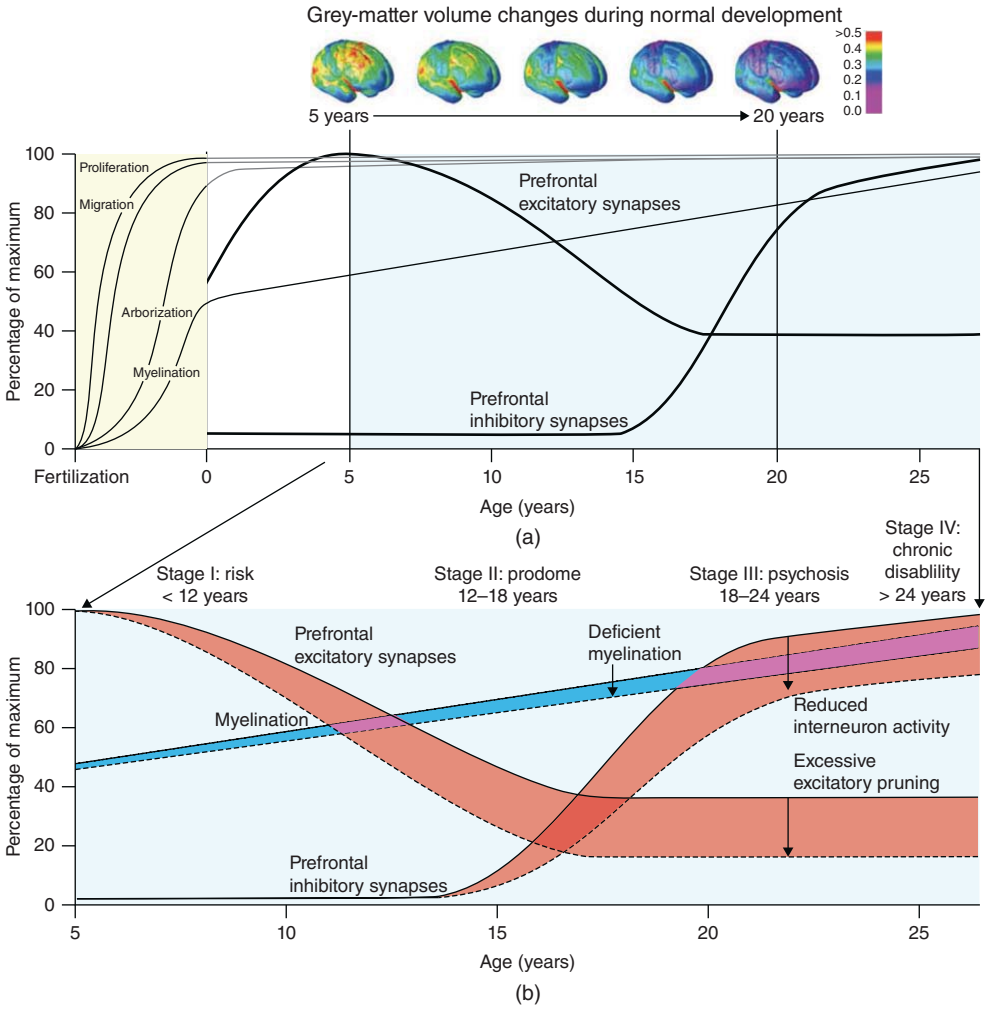

Figure 23.2 Neurodevelopmental model of schizophrenia. (a) Normal cortical development involves proliferation, migration, arborization (circuit formation) and myelination, with the first two processes occurring mostly during prenatal life and the latter two continuing up to about age 20. The combined effects of synaptic pruning and myelin deposition are theorized to account for the progressive gray matter loss observed in in vivo longitudinal neuroimaging studies. Underlying the overall reduction, local changes are far more complex. Data from human and nonhuman primate brain indicate increases in inhibitory, with concomitant decreases in excitatory synaptic strength occurring differentially in prefrontal cortical regions throughout adolescence and early adulthood, during the period of prodromal symptom development and emergence of psychosis. (b) The trajectory in children developing schizophrenia could include reduced elaboration of inhibitory pathways and excessive pruning of excitatory pathways leading to altered excitatory–inhibitory balance in the prefrontal cortex. Reduced myelination would alter connectivity. Although some data support each of these possible neurodevelopmental mechanisms for schizophrenia, none has been proven to cause the syndrome. Detection of prodromal neurodevelopmental changes could permit early intervention with potential prevention or preemption of psychosis. See footnote 1. *Source:* Figure reprinted with permission from Insel 2010.

a recent multisite longitudinal study examined rates of gray matter reductions in prefrontal, temporal, and parahippocampal regions among medicated and unmedicated converters, nonconverters, and healthy control participants (Cannon et al., 2015). Results replicated previous findings of steeper rates of gray matter loss in frontal regions, concomitant with third ventricle enlargement, among converters compared with nonconverters and healthy controls. Further, this study demonstrated identical gray matter changes in unmedicated converters, suggesting that such structural changes are not related to exposure to antipsychotic medications. The duration of the prodrome also appeared to play a role, as shorter periods of prodromal symptoms among converters (regardless of medication exposure) were marked by steeper reductions in prefrontal cortical thickness and greater ventricle expansion

compared with converters with longer prodromal symptom duration, nonconverters and healthy controls.

Diffusion tensor imaging studies probing white matter organization have also identified disrupted patterns of development in CHR patients. For example, Karlsgodt et al. (2009) found reduced FA in working memory-related tracts (e.g., superior longitudinal fasciculus) that predicted declines in social and role functioning, as well as a failure of CHR patients to demonstrate age-appropriate FA increases in several white matter tracts. As white matter volume typically increases in adolescence due to increasing myelination, especially within the frontal lobes and hippocampus (Paus, Collins, Evans, Leonard, & Pike, 2001), evidence for a disrupted developmental trajectory during this period further supports the role of later neurodevelopmental processes in the onset of psychosis.

Functional Brain Abnormalities in CHR Patients

Functional neuroimaging techniques (including fMRI, MRS, and PET) have been used to investigate the neurophysiologic correlates of the reported neurocognitive deficits (Brewer et al., 2006; Niendam et al., 2006) that precede the onset of psychosis. There is now an emerging literature indicating that neurocognitive abnormalities in CHR subjects are often qualitatively similar to those found in individuals who have developed schizophrenia, with functional activation patterns intermediate between schizophrenia patients and controls (Broome et al., 2009; Fusar-Poli et al., 2007). Exploration of the functional abnormalities that precede the development of overt psychotic symptom onset can help to identify early pathophysiological changes that may be potential targets for early treatment to prevent or ameliorate psychosis onset.

Abnormal prefrontal activation during cognitive tasks has been found in the CHR phases of psychosis (Fusar-Poli et al., 2007) and a recent meta-analysis found evidence for consistent reductions in neural activation across tasks utilizing multiple modalities in the medial frontal gyrus, superior frontal gyrus and anterior cingulate and in the left inferior frontal gyrus (Fusar-Poli, 2012). Prefrontal dysfunction during working memory and episodic memory tasks has been found in CHR individuals (Allen et al., 2011; Broome et al., 2010; Broome et al., 2009) and is related to striatal dopamine functioning (Fusar-Poli, Howes, et al., 2011). These deficits mirror reductions in DLPFC activity found in individuals with first-episode or untreated schizophrenia during working memory (Mendrek et al., 2004), executive functioning tasks utilizing context processing (Barch et al., 2001; MacDonald et al., 2005) and planning (Rasser et al., 2005) and that have been shown to be associated with patient symptoms (MacDonald et al., 2005; Snitz et al., 2005).

While DLPFC hypoactivation is one of the most consistent functional abnormalities identified in CHR patients, a number of other cortical regions have been implicated in psychosis risk showing hyperactivation. Studies of working memory performance have found increased activity in other prefrontal cortical regions such as VLPFC as well as other medial and inferior prefrontal regions in CHR samples (Fusar-Poli, Broome, Woolley, et al., 2011; Pauly et al., 2010). CHR individuals also show increased activation across frontal and temporal regions implicated in language processing that are associated with symptoms and functioning (Sabb et al., 2010) and increased inferior frontal gyrus activation during verbal fluency is associated with elevated striatal dopamine function (Fusar-Poli, Howes, et al., 2011). Increased prefrontal cortical activation during a verbal fluency task was also found in high-risk subjects who subsequently converted in contrast to subjects who did not go on to develop psychosis (Allen et al., 2012). During a theory of mind task, CHR subjects show more activation than both controls and established schizophrenia patients in the inferior frontal gyrus and multiple regions surrounding the temporal-parietal junction (Brüne et al., 2011). Increased inferior frontal gyrus activation has also been shown in at-risk individuals when inhibiting self-perspective taking (van der Meer, Groenewold, Pijnenborg, & Aleman, 2013). As discussed earlier, the evidence for increased prefrontal activation relative to controls has been hypothesized to reflect cortical inefficiency (Callicott et al., 2000; Schlösser et al., 2008) or a compensatory response (Tan et al., 2006). Individuals with recent-onset schizophrenia also demonstrate increased VLPFC activity in conjunction with reduced DLPFC activity during working memory maintenance and manipulation (Tan, Choo, Fones, & Chee, 2005), and a recent meta-analysis (Smieskova, Fusar-Poli, Allen, & Bendfeldt, 2010) noted evidence for decreased prefrontal activation and potentially compensatory increased activation in connected brain areas, similar to a pattern found in a meta-analysis of fMRI studies of schizophrenia patients (Minzenberg, Laird, Thelen, Carter, & Glahn, 2009).

Increasing severity of prefrontal cortical functional abnormalities are also found as disease chronicity increases. For example, Morey et al. (2005) found a decreasing pattern of activation in frontal regions of the brain in the anterior cingulate, middle frontal gyrus, and inferior frontal gyrus during a visual oddball task between controls, CHR individuals, individuals with early schizophrenia and those with chronic schizophrenia. Studies such as these suggest

that prefrontal function is impaired prior to the onset of a full psychosis episode and may represent a vulnerability marker or an early sign of disease development. Furthermore, normalization of prefrontal activation is related to improvement in severity of positive symptoms in CHR individuals (Fusar-Poli, Broome, Matthiasson, et al., 2011). These differences in functional activation may be related to the patterns of gray matter loss previously described (Fusar-Poli, Broome, Woolley, et al., 2011) but functional alterations in the inferior frontal gyrus and insula have been shown to remain following correction for group differences in gray matter volume (Smieskova et al., 2011).

Studies of psychosis risk samples also frequently implicate medial temporal lobe regions such as the hippocampus and parahippocampal cortex. In addition to structural abnormalities in high-risk individuals in these regions (Pantelis, Velakoulis, et al., 2003), parahippocampal dysfunction was found during verbal memory performance in CHR patients (Allen et al., 2011) and a spatial working memory task produced reduced activation in right middle temporal gyrus (Fusar-Poli et al., 2010). In addition to prefrontal and temporal lobe activation abnormalities, fMRI has implicated many other cortical regions in the development of psychosis. CHR samples have also been shown to demonstrate altered cortical functioning in parietal, occipital, and basal ganglia regions (Broome et al., 2010; Sabb et al., 2010) and decreased insula activity during negative mood induction (Pauly et al., 2010). Furthermore, CHR individuals who transition to psychosis also show reduced middle frontal gyrus (Marjoram et al., 2006) and reduced posterior cingulate gyrus activation (Brüne et al., 2011) at baseline during theory of mind tasks, as well as a failure to increase lingual gyrus activation with increasing task difficulty (Whalley et al., 2006) relative to those who do not transition to psychosis.

Functional Connectivity Abnormalities in CHR Patients

Additionally, there is increasing evidence that alterations in the networks underlying the integration of multiple brain areas may be associated with the development of psychosis (Andreasen, Paradiso, & O'Leary, 1998; Frith, 2005; Honey et al., 2005). Resting state fMRI, which probes the functional connectivity networks inherent in the brain during wakeful rest, has shown that CHR subjects show increased connectivity within the default mode network (DMN) as well as decreased anti-correlation between default regions and task-positive networks (Shim, Oh, Jung, Jang, & Choi, 2010), indicating less differentiation between these networks. Activation within the DMN (Raichle et al., 2001) may represent self-referential (Gusnard, Akbudak, Shulman, & Raichle, 2001) or spontaneous thought, and is also implicated in social cognition (Buckner, Andrews-Hanna, & Schacter, 2008). These results are similar to those found in established psychosis (Whitfield-Gabrieli et al., 2009; Zhou et al., 2008), and are associated with symptom severity (Shim et al., 2010; Sorg et al., 2013). Furthermore, CHR individuals demonstrate a pattern of thalamic overconnecitivty with sensory-motor regions and underconnectivity with prefrontal regions that is more pronounced in individuals who subsequently convert to psychosis (Anticevic et al., in submission) and is similar to thalamic dysconnecitivity found in patients with schizophrenia (Anticevic et al., 2013).

In addition to abnormal functional networks at rest, analyses of functional connectivity during task performance have identified a number of atypical patterns in individuals at risk for developing psychosis. Complementing the evidence for altered regional activation in prefrontal and temporal lobe regions, disruptions of frontal and temporal task-related networks have been implicated in psychosis vulnerability (Fusar-Poli et al., 2007). Altered activation in the superior temporal gyrus as well as disrupted frontotemporal connectivity was also shown during a working memory task, such that CHR individuals show superior temporal gyrus activation and functional coupling to middle frontal gyrus intermediate to the deactivation and negative coupling of controls and the activation and positive coupling of recent-onset psychosis (Crossley et al., 2009). Interactions between frontal and parietal brain regions show progressively less working memory modulation between control, CHR, and first-episode psychosis, suggesting alterations in functional integration preceding psychosis onset that may also be modulated by antipsychotic treatment (Schmidt et al., 2013). Functional connectivity during an episodic memory task is also reduced between medial temporal lobe regions and stimulus processing regions in both CHR and first-episode patients (Haut et al., in press). Taken together, these functional activation and connectivity studies suggest that individuals exhibiting clinical signs of psychosis risk also demonstrate functional abnormalities in prefrontal, temporal, and subcortical regions that are attenuated but qualitatively similar to those found in patients with schizophrenia. Many of these abnormalities are also more pronounced in CHR who develop a psychotic disorder prior to the onset of frank psychotic symptoms and thus may be reflective of both clinical state and risk for subsequent conversion to psychosis.

Effects of Early Intervention

Targeted early intervention for CHR youth shows some promising results. A recent review of randomized clinical trials to date revealed lower rates of conversion to psychosis among those receiving specialized treatment (11%) compared with treatment as usual or control (no treatment) groups (31.6%) after one year of intervention (Preti & Cella, 2010). For example, family-focused psychoeducation for CHR youth has demonstrated improvements in positive symptoms and social/role functioning (O'Brien et al., 2007), leading to the development and current implementation of a more extensive randomized-controlled trial for family-focused therapy (Schlosser et al., 2012). Similarly, several lines of research have demonstrated the benefits of cognitive behavioral therapy (CBT) for delaying or preventing psychosis onset (review: Okuzawa et al., 2014), including a meta-analysis that suggested intensive CBT leads to at least a 50 percent reduction in the rate of conversion to psychosis (Hutton & Taylor, 2014).

Early-Onset Schizophrenia

Another burgeoning research strategy has focused on early-onset schizophrenia (EOS), a potentially more neurodevelopmentally severe form of illness, which may therefore be uniquely informative regarding mechanisms underlying late developmental processes. EOS is sometimes further subcategorized into adolescent-onset (AOS) and childhood-onset schizophrenia (COS), both of which are particularly virulent and chronic forms of schizophrenia. AOS is typically defined as emergence prior to age 18, in contrast with childhood-onset (COS) for which the disorder is present before the age of 12 (Kumperscak, 2011). Unlike the transitory CHR stage, EOS is characterized by fully psychotic levels of symptomatology, with diagnostic criteria that are identical to that of the adult-onset disorder (Kumperscak, 2011; Thomsen, 1996). Both of these disorders are relatively rare: only 0.1 to 1 percent of all schizophrenic disorders occur before the age of 10, 4 percent before the age of 15, and 10 percent between the ages of 16–20 (Kumperscak, 2011). EOS is associated with poor prognosis across symptomatology and functioning domains (Vyas & Gogtay, 2012), and characterized by more severe cognitive deficits, particularly in the areas of working memory and attention, as well as greater genetic loading relative to the adult-onset form of illness (Frangou, 2010; Rajji, Ismail, & Mulsant, 2009; Zabala et al., 2010). This model may therefore provide greater insight into the abnormalities associated with the disorder, while simultaneously allowing for investigations of the effects of adolescent development on symptom emergence.

Neuropsychological Changes in EOS

Age of onset is a source of heterogeneity in neurocognitive functioning; earlier onset typically yields more significant impairment across multiple domains (Basso, Nasrallah, Olson, & Bornstein, 1997; Collinson et al., 2003). For example, Basso et al. (1997) compared adolescent-onset and adult-onset patients with chronic schizophrenia, and showed that patients with adolescent-onset performed significantly less well than did patients with adult-onset schizophrenia, particularly on memory and executive function tasks. Pantelis and colleagues (2003) hypothesized that brain functions that typically develop during the peak period of risk will be most impaired among patients with schizophrenia. Supporting this point, they found that working memory, a skill that develops throughout adolescence and peaks at age 20 was more compromised among adolescents and young adults with schizophrenia than was set-shifting, a cognitive function that purportedly emerges earlier in development. Finally, a recent meta-analysis of the relationship between cognition and age at onset concluded that individuals with EOS had significantly larger deficits than those with adult first-episode schizophrenia in the areas of arithmetic, executive function, processing speed, verbal memory, and global IQ (Rajji et al., 2009).

Associated Neuroanatomical Changes in EOS

Several lines of evidence suggest that developmental anomalies associated with schizophrenia may vary depending on the developmental stage of the individual at illness onset (Brewer et al., 2003; Mathalon et al., 2003; Mehler & Warnke, 2002); thus, longitudinal studies of EOS may be particularly informative in this regard. The NIMH study of childhood-onset schizophrenia has been instrumental in shedding light on the ways age of onset may interact with normative developmental processes during early disease progression. Thompson et al. (2001) analyzed repeated high-resolution MRI brain scans of adolescent patients with early-onset schizophrenia, discovering a dynamic pattern of gray matter loss that began in the parietal region and progressed forward to the temporal and frontal cortices. The final pattern of loss was consistent with cross-sectional studies of adults with schizophrenia showing a relatively greater degree of reduction in frontal and temporal cortical volumes. Up to 5 percent annual loss was noted in bilateral parietal, temporal, and motor regions and rates of loss were faster for younger patients, demonstrating a nonlinear effect (Thompson et al., 2001).

Further reports from the NIMH study have revealed deviant patterns of development in the corpus callosum and the cerebellum among patients with COS (Keller, Castellanos, et al., 2003; Keller, Jeffries, et al., 2003), sugggesting developmental disruptions to interhemispheric communication and cognitive function superimposed over typical brain development. Notably, there appears to be diagnostic specificity to this pattern of progressive gray matter loss: for children and adolescents with transient psychotic symptoms that did not meet criteria for schizophrenia, gray matter reduction over time did not differ from that observed in healthy comparison subjects (Gogtay et al., 2003). These patients provide a valuable comparison group to the child-onset schizophrenia patients because they had a similar level of cognitive functioning and had received a similar course of treatment with antipsychotic medication, indicating that these brain changes are intrinsic to the illness and do not result from medication exposure. In addition, the unaffected siblings of these childhood-onset schizophrenia patients were found to have smaller total brain volume and reduced total, frontal, and parietal gray matter volume compared with healthy controls (Gogtay et al., 2003), suggesting a genetically influenced pattern of neuroanatomic abnormalities. However, observed gray matter abnormalities in siblings may be an age-dependent endophenotype, as longitudinal follow-up indicated that these deficits normalized by the typical age of onset of schizophrenia. These deficit reductions correlated with overall functioning at the final scan, suggesting a relationship between degree of neural plasticity and outcome for siblings that did not develop the illness (Gogtay et al., 2007).

Other longitudinal studies of EOS patients have highlighted decreased gray matter volume loss in the prefrontal cortex only, as well as smaller thalamic and increased CSF volumes, though sample size was limited (Arango et al., 2008; Moreno et al., 2005). Another small longitudinal study failed to find progressive reduction in gray matter volume (James, Javaloyes, James, & Smith, 2002), except in the posterior inferior vermis among male participants (James, James, Smith, & Javaloyes, 2004). Here, the authors speculated that their negative findings may have reflected a leveling off of gray matter loss in late adolescence, as was found in the NIMH study (Sporn et al., 2003). Thus, replication remains critical in this population to determine if the degree of progressive gray matter loss found in the NIMH study is specific to COS, or if similar patterns will be seen among adolescent-onset patients as they go through the same period of development.

Further research is also necessary to better understanding age-related differences in brain development in early psychosis. While some longitudinal prospective studies of adult first-episode patients have revealed broad changes in whole brain volume with no detectable progression in specific regions (e.g., temporal or frontal lobe structures) (Cahn et al., 2002; DeLisi et al., 1997; Pantelis, Yucel, et al., 2003), other studies of adults have revealed similar patterns of change to those seen in patients with COS, but of a much smaller magnitude (Gur et al., 1998). One study of adolescents and adults with recent-onset schizophrenia showed progressive decreases in gray matter volume in the left superior temporal gyrus during the first 1.5 years following initial hospitalization, followed by a leveling off of cortical loss (Kasai et al., 2003). These results were not observed in a control group of individuals with first-episode affective psychosis (e.g., mania), suggesting that the observed grey matter deficits may result from an early, schizophrenia-specific progressive process in the temporal region. Notably, gray matter loss specific to superior temporal regions was also associated with increasing psychotic symptom severity over time in 22q11DS patients, suggesting some convergent abnormalities associated with symptom emergence (Jalbrzikowski & Bearden, 2011).

Diffusion tensor imaging studies have revealed reduced white matter integrity (i.e., decreased FA values) in the pyramidal and corticopontine tracts, superior thalamic and optic radiations, corpus callosum, and arcuate fasciculus (Douaud et al., 2007), and in parietal and cerebellar regions in patients with AOS (Kyriakopoulos, Vyas, Barker, Chitnis, & Frangou, 2008). Furthermore, Douaud et al. found that the observed FA reductions were correlated with gray matter deficits in superior temporal, inferior parietal, and motor regions. Reduced FA in AOS patients was also observed in the left superior and inferior longitudinal fasciculi (Clark et al., 2012; Douaud et al., 2007), tracts implicated in working memory. These findings suggest that abnormal patterns of myelination or axonal organization may underlie cognitive deficits associated with schizophrenia.

Adolescent-onset schizophrenia has also been associated with several morphological abnormalities, such as enlarged cavum septi pellucidi (deviated membrane separating left and right lateral ventricles) and reduced gyral folding in the left anterior cingulate cortex, which are in accordance with chronic (adult) schizophrenia literature (Pantelis et al., 2005). Decreased overall cortical thickness and abnormal gyral and sulcal curvature indices have also been reported among AOS individuals compared with controls, even after covarying for age and gender (Janssen

et al., 2009; White, Andreasen, Nopoulos, & Magnotta, 2003). In related analyses, patients evidenced smaller sulcal width in the frontal, parietal, and temporal lobes, and reduced gyral thickness in the temporal lobe (White et al., 2003). Given that sulcal and gyral patterning is essentially fixed early in life, these kinds of anomalies may be markers of subtle neurodevelopmental disturbance (Pantelis et al., 2005). Additionally, regional cortical thinning has been identified in several areas including the bilateral precuneus, left insula, and right operculum (Voets et al., 2008), brain structures that are critically involved in memory, visuospatial processing, emotion, and global cognitive functioning. Of note, however, several of these structural anomalies have also been observed in other disorders such as autism, therefore perhaps representing a more nonspecific neurodevelopmental vulnerability (Pantelis et al., 2005). Further, the structural anomalies reported in AOS do not entirely converge with those from studies of adult-onset patients; this may be due to true structural neuroanatomic differences as a function of age at onset, but the relatively small sample sizes and heterogeneous methodologies of these cross sectional AOS studies precludes any firm conclusions. Prospective studies involving direct comparison of early and later-onset cohorts are needed to better understand the way age at onset impacts the developmental trajectory of the illness.

Associated Functional Changes and Deficits in EOS

Related anomalies in EOS samples compared with age-matched controls have also been revealed via functional neuroimaging, notably in the domains of emotion processing and working memory. For example, EOS patients show greater difficulty discriminating sad, angry, and fearful faces, with related aberrations in neural activity in regions such as the fusiform and occipital gyri and cuneus, regions important for emotion processing and regulation and visual processing (Seiferth et al., 2008). EOS patients have also demonstrated increased activation in orbitofrontal and medial frontal regions, key areas involved in emotion processing, during a negative valence induction and verbal working memory task, indicating impaired emotion-cognition interactions (Pauly et al., 2008).

Additional studies utilizing visuospatial and verbal working memory tasks have revealed both abnormal patterns of neural activity in several regions (e.g., ventrolateral prefrontal cortex, anterior cingulate cortex) and disrupted functional connectivity within working memory networks in EOS patients relative to healthy controls (Thormodsen et al., 2011; White, Hongwanishkul, & Schmidt, 2011; White, Schmidt, Kim, & Calhoun, 2011). Taken together, results suggest that EOS patients evidence abnormal functioning in attentional control and working memory circuitry, and perhaps develop atypical cognitive compensatory responses to increasing task-based performance demands. Event-related potential designs have further suggested that EOS individuals have deficits in early visual processing that may contribute to such working memory impairments, particularly in information encoding (Haenschel et al., 2007).

Synthesis: Neuroimaging Evidence for Involvement of Later Neurodevelopmental Processes

Overall, these results suggest that individuals at risk for developing psychosis show abnormalities in cognition, neuroanatomy and functional activity prior to the onset of primary psychotic symptoms, which appear to be attenuated but similar to those found in early psychosis. In addition, those CHR individuals who go on to convert to psychosis show more pronounced baseline deficits.

A cautionary note is warranted, however, as many of the functional imaging studies done to-date are cross-sectional comparing some combination of high-risk, first-episode and control individuals. Even those with clinical follow-up rarely report on neural activation changes within individuals before and after conversion to psychosis. This highlights the need for more longitudinal studies to follow the dynamic changes in functional activity and connectivity that precede transition to psychosis. Further study is additionally warranted to determine if the degree of progressive gray matter reduction and other morphological abnormalities found among adolescent patients with childhood-onset schizophrenia is specific to this severe variant of the disorder, or if a similar pattern can be detected among adolescent-onset patients as they go through the same period of development.

Magnetic Resonance Spectroscopy Studies

Despite the evidence suggesting the importance of adolescent neural maturational processes in the onset of schizophrenia, direct measures of abnormal neuronal growth and degeneration processes are difficult to quantify in vivo. Nuclear magnetic resonance spectroscopy (MRS) offers a method of assessing brain phospholipid and energy metabolism that corresponds to developmental neuronal changes. This methodology allows a noninvasive investigation of human brain development and is well suited to identifying abnormalities in synaptic pruning that may occur in adolescence (Pettegrew, Klunk, Panchalingam,

McClure, & Stanley, 2000). Two MRS techniques that are currently utilized in schizophrenia research are phosphorus magnetic resonance spectroscopy (^{31}P-MRS) and proton magnetic resonance spectroscopy (^{1}H-MRS). In vivo ^{31}P-magnetic resonance spectroscopy examines indirect indicators of cell membrane synthesis and degradation in addition to measures of energy metabolism (Ross & Michaelis, 1994). ^{31}P-MRS studies have identified alterations of membrane phospholipid metabolites in the frontal cortex of first-episode, neuroleptic naïve schizophrenia subjects, compared with matched controls (Keshavan, Pettegrew, Panchalingam, & Kaplan, 1991; Pettegrew, Keshavan, Panchalingam, & Strychor, 1991; Williamson, Pelz, Merskey, & Morrison, 1991), suggesting decreased synthesis and increased breakdown of membrane phospholipids in recent-onset schizophrenia patients. This pattern resembles an exaggerated form of the changes observed in normal aging (Pettegrew & Minshew, 1992). Such findings may reflect an increase in membrane phospholipid turnover, perhaps because of an accelerated synaptic pruning process during late childhood and early adolescence (Keshavan, Stanley, Montrose, Minshew, & Pettegrew, 2003).

To further address this neurodevelopmental perspective, Stanley et al. (1995) used ^{31}P-MRS to examine phospholipid synthesis in the DLPFC in 11 drug-naïve, 8 newly diagnosed and medicated, and 10 medicated and chronic patients with schizophrenia. Decreased phospholipid synthesis was observed in all three groups, which implies lower levels of cell membrane synthesis at all stages of the disorder. Additionally, there was an increased level of phospholipid breakdown in the drug-naïve group, suggesting that earlier stages of schizophrenia may be characterized by increased breakdown of cell membranes. At the level of structural neuroanatomy, these metabolic changes may correspond to increased gray matter volume loss in the early stages of illness. Abnormalities in phospholipid metabolism have also been observed in the DLPFC of high-risk adolescents (Keshavan et al., 2003; Rzanny et al., 2003), suggesting a pattern of increased membrane turnover at illness onset with a continued pattern of membrane abnormalities throughout the course of the disorder (Berger et al., 2002).

^{1}H-magnetic resonance spectroscopy also provides indirect measures of metabolites related to neuronal and glial energy metabolism as well as phopholipid metabolism (Ross & Michaelis, 1994). Of the metabolites examined in ^{1}H-MRS, *N*-acetylaspartate (NAA) is primarily seen as an index of neuronal integrity (Keshavan, Stanley, & Pettegrew, 2000) that can be used to identify neurons and their dendritic and axonal extensions and is mostly concentrated in pyramidal neurons. NAA increases during the course of normal development until the adolescent period, when there is a decrease associated with pruning of superfluous neuronal connections; however, this decrease is less drastic than the sharp decrease in NAA that is seen in neurodegenerative diseases (Moore, Slovis, & Chugani, 1998). Choline includes metabolites that are involved in the synthesis of myelin and cell membrane metabolism (Ross & Michaelis, 1994) and creatine (Cr) is defined as a general marker of energy metabolism (Passe, Charles, Rajagopalan, & Krishnan, 1995). The observation of decreased levels of NAA or a decreased NAA/Cr ratio is believed to indicate some form of neuronal loss, such as synaptic pruning or neuronal dysfunction, while increased levels of choline or an increased choline/Cr ratio signals deafferentiation (Ross & Michaelis, 1994). Glutamine is primarily found within glial cells; decreased levels of this metabolite are thought to represent neuronal loss, dysfunction, or deafferentiation (Ross & Michaelis, 1994).

Studies of ^{1}H-MRS in schizophrenia have consistently reported reduced NAA levels in the hippocampus, mesial temporal lobe and the frontal lobe, including the DLPFC, in both adult (Bertolino & Weinberger, 1999; Steel et al., 2001) and child-onset schizophrenic patients (Bertolino et al., 1998). Significant reductions in NAA/Cr ratios have been found in these regions in both chronic schizophrenia patients (Bertolino et al., 1996; Yamasue et al., 2002; Yurgelun-Todd et al., 1996) and neuroleptic-naïve first episode patients (Cecil et al., 1998) and in children with schizophrenia spectrum disorders (Brooks et al., 1998). Supporting the idea that NAA/Cr ratio may mark genetic vulnerability to schizophrenia, Callicott et al. (1998) showed a decreased NAA/Cr ratio in the hippocampi of both schizophrenic patients and their unaffected siblings when compared with healthy controls. Moreover, Keshavan and colleagues (1997) found that offspring of parents with schizophrenia showed a reduced NAA/choline ratio in the anterior cingulate region when compared with healthy controls. Studies of neuroleptic-naive patients with schizophrenia (Bartha et al., 1997; Theberge et al., 2002), as well as nonill offspring of parents with schizophrenia (Tibbo, Hanstock, Valiakalayil, & Allen, 2004) have also revealed increased glutamate/glutamine levels in the medial frontal cortex, anterior cingulate and thalamus, signaling possible dysfunction of glutamate in the pathogenesis of schizophrenia.

Similar to adults with schizophrenia, temporal gray matter deficits in high-risk, medication-naïve patients were found to be dose-dependently correlated with abnormal

glutamate function in corresponding regions (Stone et al., 2009). Similar glutamatergic deficits have been observed in the thalamus, and appear to be associated with altered neural activity during verbal cognitive demands (Fusar-Poli, Stone, Broome, & al, 2011). However, increases in glutamate in the dorsal caudate (de la Fuente-Sandoval et al., 2011), anterior cingulate and medial frontal cortex (Fusar-Poli, McGuire, & Borgwardt, 2012) have also been noted, suggesting nonuniform dysfunction. Nevertheless, these findings suggest the possibility for early psychopharmacological intervention targeting the glutamate system.

Thus, while these studies demonstrate that altered NAA levels in frontal and temporal regions are associated with risk for schizophrenia, it is not yet clear how anomalies in brain metabolites highlighted by MRS techniques correspond to brain volumetric changes and abnormalities of cellular migration in schizophrenia. Some researchers have also suggested that findings of decreased frontal NAA ratios may be related to effects of long-term antipsychotic treatment (Bustillo et al., 2001; Bustillo et al., 2002). Future refinements in MRS methodology offer the promise of more detailed exploration of neurogenesis and the processes of myelination, synaptic pruning, and gliosis in living human subjects.

POTENTIAL CAUSAL MECHANISMS

The Role of Stressful Life Events and Their Neurobiological Effects

We have described the role of prenatal stress as an early occurring factor previously in this chapter, and now turn our attention to the potential moderating role of psychosocial stress as a late factor in adolescence and adulthood (Figure 23.1). Diathesis-stress models of schizophrenia suggest that environmental stress may interact with genetic vulnerability in triggering the onset of psychotic symptoms and exacerbating symptoms during the course of the disorder. A 1985 review of the behavioral literature regarding the role of psychosocial stress in schizophrenia concluded that evidence for a causal role was weak, while some findings pointed to a potential role of stress in activating symptoms in previously diagnosed psychotic patients (Tennant, 1985). Additional research since that time has continued to support these conclusions, with the addition of a more complex understanding of the neurobiological effects of stress on the central nervous system.

Several studies have examined the temporal relationship between stressful life events and symptom severity, pointing to a role for environmental stressors in psychotic symptom exacerbation and relapse. In a landmark study, retrospective assessments indicated that independent life events (those life events judged *not* to be due to the mental illness) were more likely to occur in the three weeks prior to onset of a psychotic episode in schizophrenia patients than in a similar period of time for nonpsychiatric control participants (Brown & Birley, 1968). This sample included first-episode and more chronic patients, all of whom had a rapid increase in symptoms prior to episode onset. The authors calculated that onset was brought forward by 10 weeks, on average, for these patients, thus providing the first evidence for the triggering hypothesis (Birley & Brown, 1970; Brown & Birley, 1968). This theory proposes that an underlying biological vulnerability causes psychosis, while environmental stress, may trigger the precise timing of onset.

In a review of the behavioral literature on stress and schizophrenia, Norman and Malla (1993) examined 23 studies that retrospectively assessed life events prior to psychotic onset or relapse (only three assessed first-episode patients) and reported that seventy-seven percent of the studies showed significant evidence that higher stress levels were associated with more severe symptoms within schizophrenic samples. However, none of the studies that compared schizophrenia patients to control subjects with other psychiatric disorders showed higher rates of life events for the schizophrenia patients compared with patients with other psychiatric disorders, suggesting that schizophrenia patients may be more vulnerable to the effects of stress, but do not necessarily experience more stressful events (Norman & Malla, 1993). More recent work found that recent-onset patients with schizophrenia assessed longitudinally endorse lower rates of negative and positive life events than healthy adults. Of note, of the events they did report, patients with schizophrenia rated events as less controllable and endorsed having fewer or less effective coping strategies, suggesting lower self-efficacy (Horan et al., 2005). This underreporting of life events may be due to the withdrawal of recent-onset schizophrenia patients from social activities or interactions, particularly if they believe themselves to be less capable of coping with stress or change. Regardless, the observed higher reactivity to events compared with healthy controls has been replicated and is proposed to be a driving predictor of increases in psychotic symptoms (Docherty, St-Hilaire, Aakre, & Seghers, 2009).

Although the measurement of independent events attempts to control for the effect of illness in creating life stress, the direction of causality is not yet clear: life events

could exacerbate symptoms, and increased symptoms could increase the level of stressful events in a patient's life. Additionally, psychosocial stress may not have a unique effect on psychotic symptoms, as life events have also been linked to an increase in mood symptoms in patients with schizophrenia (Ventura, Nuechterlein, Subotnik, Hardesty, & Mintz, 2000) and patients with purely affective disorders (Brown & Harris, 1978). Life stress is thought to exacerbate psychiatric symptoms across a variety of mental disorders, and may also exacerbate immune system functioning and the symptoms of physical illness in diseases such as diabetes, cardiovascular disease, and cancers (Cohen & Herbert, 1996; Spiegel & Kato, 1996; Strike & Steptoe, 2004).

High-risk paradigms examining the link between stress and symptoms may shed some additional light on this matter. Cullen et al. (2014) examined the effects of stress on children at high risk for developing schizophrenia. These children either had a family history of the disorder or showed several prodromal features (e.g., subclinical psychotic symptoms, poor functioning, speech/motor abnormalities). Results indicated that both groups reported more frequent exposure to negative life events and daily stressors, as well as greater corresponding stress, compared with typically developing children. *Post hoc* analyses further revealed correlations between daily stressors and current psychopathology. These results were replicated in another high-risk cohort of adolescents with schizotypal personality disorder (Tessner, Mittal, & Walker, 2011); the authors found greater rates of undesirable life events and greater associated distress compared with those with no personality disorders. Reported negative life events also correlated with current prodromal symptoms and predicted future increases in positive prodromal symptoms over one year. Therefore, results from both studies suggest that the experience of and reactions to environmental stressors are associated with vulnerability to psychosis.

A hypothetical neurochemical mechanism linking the stress system to symptoms of schizophrenia is altered activity of the hypothalamic-pituitary-adrenal (HPA) axis. The cascade of hormones in response to stress proceeds through the HPA pathway as cells in the periventricular nucleus of the hypothalamus secrete corticotropin-releasing hormone, which increases adrenocorticotropic hormone secretion by the pituitary gland, which stimulates the adrenal gland to release glucocorticoids, which then feedback via glucocorticoid receptors in the hippocampus to dampen the system once the stressor has passed (see Figure 23.3).

Elevated levels of cortisol may exacerbate symptoms through a neurotoxic effect on the hippocampus (McEwen & Seeman, 1999), and by ultimately increasing dopaminergic activity in the prefrontal cortex (Walker & Diforio, 1997). In animal models, prolonged stress has been shown to result in a dysregulated negative feedback circuit, whereby damaged hippocampi fail to correctly modulate HPA axis activity (Sapolsky, Uno, Rebert, & Finch, 1990). On the basis of animal models, some have argued that stress also increases glutamate in both the prefrontal cortex (PFC) and the hippocampus, which can also result in altered dopamine levels (Moghaddam, 2002). The increase in PFC glutamate, as opposed to the hippocampus, does not appear to be dependent on glucocorticoids, and therefore, may represent a second pathway that is activated as part of the brain's fast response to stress, which occurs prior to and during the stress response via the HPA

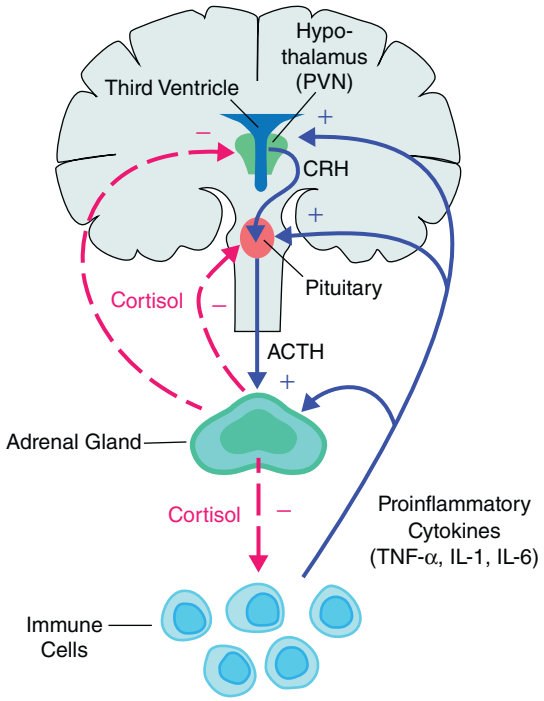

Figure 23.3 Bidirectional communication between the immune system and HPA axis. Pro-inflammatory cytokines, such as TNF-α, IL-1, and IL-6, stimulate glucocorticoid release by acting at all three levels of the HPA axis (solid blue lines). In turn, glucocorticoids negatively feedback on the immune system to suppress the further synthesis and release of proinflammatory cytokines (dashed red line). In addition, glucocorticoids regulate their own production through negative feedback on the upper levels of the HPA axis, including corticotropin-releasing hormone (CRH) in the paraventricular nucleus (PVN) of the hypothalamus and adrenocorticotropin (ACTH) in the anterior pituitary (dashed red lines). See footnote 1. *Source:* Reprinted with modifications from M. N. Silverman, B. D. Pearce, & A. H. Miller, Cytokines and HPA axis regulation, in *Cytokines and Mental Health*, ed. Z. Kronfol, pp. 85–122, Norwell, MA: Kluwer, 2003.

axis (Lowy, Gault, & Yamamoto, 1993; Moghaddam, Bolinao, Stein-Behrens, & Sapolsky, 1994). Although a review of basic research on stress in animal models as related to schizophrenia is outside the scope of this chapter (see Corcoran et al., 2003, for a review), this type of research has vastly increased our understanding of the body's complex stress response and its effects on the mind and brain.

Studies of patients with schizophrenia have primarily utilized cortisol assays to assess HPA axis integrity. A recent comprehensive review of this literature (Walker, Mittal, & Tessner, 2008) reached several important conclusions: (1) HPA activity indices are elevated in a substantial proportion of patients with psychotic illness, including medication naïve and first-episode patients; (2) antipsychotic agents tend to reduce cortisol, with more pronounced reductions in those who respond to treatment, whereas agents that increase dopamine levels or exacerbate psychotic symptoms increase cortisol levels; (3) glucocorticoid receptors appear to be downregulated in individuals with schizophrenia, suggesting there may be reduced negative feedback on the HPA axis; and (4) reduced hippocampal volume, which is related to hypercortisolemia, is a consistently reported neuroanatomic abnormality in schizophrenia. Moreover, cortisol levels and hippocampal/amygdala volumes have also been independently shown to be predicted by a combination of stress-system genetic profiles (e.g., HPA axis-related genes) and early stressful life events among children with depression, highlighting the developmental link between neuroanatomical changes and stress-related genes and environmental factors (Pagliaccio et al., 2014).

In a prodromal sample, individuals at clinical high risk of developing psychosis demonstrated higher levels of cortisol than healthy controls. In addition, higher levels of cortisol within this cohort were associated with greater symptom severity and subsequent conversion to a psychotic disorder (Walker et al., 2013). Adolescents with schizotypal personality disorder have also been shown to have higher levels of salivary cortisol than adolescents with other personality disorders and normal controls, especially at the first sample of the day (Weinstein, Diforio, Schiffman, Walker, & Bonsall, 1999). At present, the direction of causality regarding elevated cortisol and HPA axis dysregulation is unclear. That is, heightened cortisol may be the consequence of developing subthreshold psychotic-like symptoms, or it may play a role in triggering or exacerbating symptoms. Alternatively, biological stress systems could trigger the expression of symptoms in vulnerable individuals. Longitudinal studies involving densely spaced assessments proximal to the time of illness onset are critical to help disentangle these multiple possibilities.

Genetic and Hormonal Regulation of Synaptic Pruning

In addition to the role of hormones in mediating stress response, hormones are likely to play a key role in adolescent brain maturation (Walker & Bollini, 2002). Gonadal and adrenal hormones have been shown to affect structural development, as well as immediate functional properties, of the brain. While some of the behavioral influences exerted by these hormones are short-term nongenomic effects, mediated by receptors on the surface of neurons, steroid hormones also affect later gene expression via intracellular hormonal receptors in neurons (McEwen, 1994; Watson & Gametchu, 1999). Animal research has demonstrated that hormones can trigger gene expression relevant to postpubertal neuromaturational processes (Ojeda & Ma, 1999). For example, estrogen-induced cyclic synaptogenesis has been observed in the adult rat hippocampus (McEwen, 1994). These genomic effects of hormones involve changes in the expression of messenger RNA that codes for specific proteins that, in turn, play a role in receptor density, reuptake, and neurotransmitter synthesis. These proteins can also trigger the expression of genes that impact neuronal survival (govern maturational processes such as proliferation and elimination of neurons). Thus, structural plasticity is an important aspect of steroid hormone action in the developing nervous system (McEwen, 1994). There is now extensive evidence from animal models indicating that steroid hormones affect brain organization during adolescence (Vigil et al., 2011), and recent studies show similar effects in humans (Peper, Hulshoff Pol, Crone, & van Honk, 2011). While the role of genomic hormonal effects in triggering onset of schizophrenia is purely speculative, some investigators have hypothesized that hormonal changes during adolescence, especially of the reproductive steroids, may trigger the expression of faulty genes, possibly affecting synaptic pruning or myelination (Amateau & McCarthy, 2002). This is supported by observations that age-related gray matter volume reductions during adolescence in healthy males might be steeper than those of healthy females (De Bellis et al., 2001). One mechanism by which rising hormone levels in adolescence may trigger expression of a latent genetic predisposition to schizophrenia is through dysregulation of the HPA axis. It is also possible that early hippocampal insult (i.e., due to prenatal complications) may increase the likelihood that a latent genetic predisposition to schizophrenia will be expressed in adolescence (Walker & Bollini, 2002). Thus,

early environmental insult may alter gonadal hormone expression; alternatively, effects of hormones may alter the nature of the early insult (Andersen, 2003).

Inflammation and Immune Factors

Inflammation and the activation of immune cells in the brain (e.g., microglia) has also been suggested to play a role in the development and symptomatology of schizophrenia (Monji, Kato, & Kanba, 2009; Watanabe, Someya, & Nawa, 2010). Increased levels of proinflammatory cytokines have been consistently found in patients with established illness (Potvin et al., 2008), and are associated with positive symptoms and overall symptom severity (Dimitrov et al., 2013). Meta-analysis suggests that some cytokines appear to show transient, state-related increases in conjunction with symptom exacerbation, whereas others show more consistent alterations (Miller, Buckley, Seabolt, Mellor, & Kirkpatrick, 2011). Antipsychotics are also known to produce anti-inflammatory effects (Tourjman et al., 2013). Another marker of inflammation, S100B, has been found to be elevated in unmedicated patients with schizophrenia and decreases with antipsychotic treatment (Zhang et al., 2010).

In addition to the evidence for increased inflammation subsequent to illness onset, recent studies suggest a potential role in disease pathophysiology. Patients with schizophrenia and their relatives have increased incidence of autoimmune disorders (Benros, Mortensen, & Eaton, 2012) and genome-wide studies have shown an association between schizophrenia and genes associated with regulating immune function and inflammation (Jia, Wang, Meltzer, & Zhao, 2010; Stefansson et al., 2009). Furthermore, abnormal expression of immune-related genes has been found in post-mortem studies of schizophrenia patients (Saetre et al., 2007), particularly in the prefrontal cortex (Arion, Unger, Lewis, Levitt, & Mirnics, 2007). Inflammatory cytokines may also play a role in the relationship between maternal viral infections and increased subsequent schizophrenia risk, as many viral infections do not cross the placenta (Ashdown et al., 2005; Deverman & Patterson, 2009). The effects of these prenatal infections may lead to immune cells in the brain that are more responsive to subsequent infection even into adulthood (Bland et al., 2010) and may have wide-ranging effects on cognition and brain morphology (Miller, Culpepper, Rapaport, & Buckley, 2013).

The relationship between schizophrenia and immune/neuroinflammation needs further clarification. For example, it remains uncertain whether inflammatory increases are the primary cause of the associated symptom increases or co-occur in response to other pathological processes. As such, the CNS immune response may prove either neuroprotective or detrimental. However, initial indications that pro-inflammatory cytokines may inhibit neurogenesis in the hippocampus (Liu et al., 2006) and disrupt synaptogenesis (Stellwagen & Malenka, 2006) suggest that these processes may exacerbate cognitive deficits or prolong acute psychotic episodes. Targeting these inflammatory cytokines or microglial activation has been suggested as a possible novel therapeutic target for treatment development (Mansur et al., 2012; Monji et al., 2013). In addition, recent multi-site longitudinal work has investigated blood-based biological correlates of a psychosis high-risk state (Perkins et al., 2015). An extensive algorithm selected 15 plasma analytes of inflammation, oxidative stress, metabolism, and hormonal status that significantly differentiated clinical high-risk individuals who later developed psychosis from clinical high-risk individuals who did not develop psychosis, as well as from unaffected control participants. The majority of the identified analytes were immunomodulatory (i.e., cytokines and proteins involved in inflammation modulation, particularly within the HPA), suggesting a potential blood biomarker of psychosis based on indicators of oxidative stress, immune system dysfunction, altered HPA function, and their interactions. Higher levels of these proinflammatory analytes at baseline evaluation have also been shown to strongly predict increased rates of gray matter loss in the prefrontal cortex among CHR converters (Cannon et al., 2015), highlighting the link between inflammation and neuroanatomic changes associated with psychosis onset and emphasizing the need for more research into the developmental order of these effects.

Interactions Between Early and Late Risk Factors

Theories regarding the development of psychotic symptomatology in the adolescent period must also account for findings of early childhood abnormalities in patients with schizophrenia (Walker & Bollini, 2002). Keshavan and colleagues (Keshavan, 1999; Keshavan & Hogarty, 1999) proposed that schizophrenia arises from both an early brain abnormality and late maturational processes of brain development interacting with adverse biochemical and psychosocial factors during adolescence and early adulthood. That is, prenatal or early postnatal factors (genetic or environmental) produce anomalous neural connectivity, resulting in premorbid impairment. Subsequently, during adolescence, the onset of prodromal or

fully psychotic symptoms may result from excessive elimination of synapses and secondarily, phasic dopaminergic overactivity (see Figure 23.2). Because normal ingrowth of dopamine fibers occurs during the late adolescent period (Benes, 1997), other investigators have hypothesized that developmental changes in dopamine levels may drive the onset of positive symptoms of schizophrenia during the adolescent period, thereby moderating the expression of congenital neuropathology in vulnerable individuals (Walker et al., 2008; Weinberger, 1995).

Such a progressive developmental pathophysiology of the illness during adolescence may result from several factors working singly, or in combination. First, genetic factors may predispose to excess synaptic elimination, increased neuronal apoptosis (i.e., programmed cell death), decreased cell somal size, or a combination of these processes during adolescence. Such changes might result from altered expression of genes that are critical for neurodevelopmental processes (Nawa, Takahashi, & Patterson, 2000; Olney & Farber, 1995), or altered dynamics of dopaminergic and GABAergic neurotransmitter systems (Costa et al., 2001). Second, hormonal changes, especially of the reproductive steroids, could modulate brain maturational processes such as synaptic pruning or myelination (Amateau & McCarthy, 2002). Third, psychosocial environmental factors might play a significant role as well. It is well established that environmental enrichment leads to increased spine density and dendritic arborization (Globus, Rosenzweig, Bennett, & Diamond, 1973; Lewis, 2004). Likewise, environmental deprivation or stress can lead to the opposite, i.e., an increased fall-out of synapses or neurons, and decreased neuronal viability. Synaptic plasticity mechanisms (e.g., long-term potentiation (LTP) and long-term depression (LTD)) are critical for sculpting the nervous system (Whitt, Petrus, & Lee, 2014). LTP and LTD can be elicited by activating N-methyl-d-aspartate-type glutamate receptors (NMDARs) (Lüscher & Malenka, 2012), and evidence from both animal models and human studies implicates NMDAR dysfunction in both symptoms of schizophrenia and disease progression (Gao & Snyder, 2013). Thus, one appealing hypothesis regarding schizophrenia pathogenesis is that genetically mediated hypofunction of NMDA receptors, and consequent weakening of these NMDA-dependent mechanisms of synaptic plasticity lead to an overabundance of weak synapses during adolescence that thus become targets for over-pruning.

Additionally, findings linking gray matter reductions and other gross morphological changes in schizophrenia to fetal hypoxia (Cannon, van Erp, Rosso, et al., 2002) suggest another possible mechanism by which such early influences interact with later maturational changes in influencing the timing of onset of schizophrenia. Importantly, fetal hypoxia has been associated with earlier onset forms of the disorder (Cannon, Rosso, et al., 2000; Rosso, Cannon, et al., 2000; Verdoux et al., 1997), suggesting that the presence of this risk factor may in some manner predispose to an earlier age at onset. The neural sequelae of hypoxia vary in severity from alterations in neurite outgrowth to neuronal cell death (Nyakas et al., 1996). In the former case, immature neurons may survive the hypoxic insult but still have a compromised elaboration of synaptic interconnections (Nyakas et al., 1996). Studies in fetal sheep have shown that hypoxia secondary to chronic placental insufficiency is associated with reduced cortical thickness and increased cortical neuronal density, without any observable neuronal loss (Rees et al., 1998). The pattern of morphologic changes associated with hypoxia in studies of schizophrenia is thus compatible with an animal model of chronic fetal hypoxia and with the observed cellular pathology in schizophrenic patients. In this context, processes associated with cortical synaptic pruning during late adolescence and early adulthood (Feinberg, 1982; Keshavan, Anderson, & Pettegrew, 1994) might interact with the earlier hypoxia-related effects in lowering interneuronal connectivity to below a threshold critical for integrated cognitive activity, leading to further behavioral deterioration at that time.

Thus, current models offer promising hypotheses regarding mechanisms by which processes associated with postpubertal brain development might interact with earlier compromises of the brain in predisposing to schizophrenia. Nevertheless, theories as to why adolescence represents a time of increased risk for schizophrenia onset remain speculative. It may be that heterogeneity in the course and outcome of schizophrenia is a function of the interaction of early brain pathology with normal or abnormal developmental factors occurring throughout life, up until the time when the illness commences (Pantelis, Yucel, et al., 2003). Findings of accelerated gray matter loss proximal to the time of illness onset may reflect aberrant maturational processes during adolescence, or may reflect an interaction of early neurodevelopmental anomalies with adolescent maturational processes. Whatever the cause, recent studies that follow patients longitudinally through the prodromal phase into the first episode of illness do provide evidence for progressive structural changes during this time period. The role of later environmental stressors, and how they may impact upon an already vulnerable individual, warrants further investigation in both naturalistic human studies and via experimental animal models.

SUMMARY AND CONCLUSIONS

According to the original neurodevelopmental hypothesis of schizophrenia, the disorder results from a set of basic biological errors that occur early in life and lead to a combination of structural, functional, or biochemical anomalies in the developing brain. This model of schizophrenia has been highly influential, and has moved the field substantially forward by focusing attention on early developmental deviation in individuals who develop the illness in adulthood. Specifically, in the area of epidemiology, this model has led to the investigation of early signs of functional compromise in individuals destined to develop schizophrenia in adulthood, and the interaction of specific obstetric complications with genetic factors in the etiology of psychotic illness. Convergent evidence from neuropathological investigations indicates patterns of neuronal displacement consistent with a neurodevelopmental origin.

However, a major limitation of this model is that it does not account for the delay in onset of the disorder. Why is it that the full-blown diagnosis of schizophrenia so typically manifests during the late adolescent/early adult period? Taken together with recent evidence of neuroanatomic change during the early phase of illness, it seems likely that additional factors active during this time period play a role in the disease process.

Recent advances in our understanding of processes that occur proximal to onset call for an update to the neurodevelopmental model. It is important to keep in mind that progressive anatomic changes do not preclude the existence of a neurodevelopmental insult in schizophrenia, as an inherited neurodevelopmental abnormality may also have progressive features (Mathalon et al., 2003). Here we have outlined a model in which some neurocognitive and neuroanatomical abnormalities reflect genetic trait markers, others are environmentally mediated, and the development of frank psychosis may involve a third, partially overlapping series of structural and functional changes. Theorists have focused on two sources of influences that might account for neuronal disruption proximal to the time of onset of illness, one of which is pruning-related plasticity processes that occur as a normative aspect of brain development during adolescence, and the other of which is stress-related and other hormonal changes that may have neurotoxic effects in pathways implicated in the pathophysiology of schizophrenia. In regard to the former, certain schizophrenia-related factors (e.g., genes that predipose to disrupted synaptic plasticity or neuroinflammatory processes) may disrupt the regulation of regressive brain maturational events at this time. However, it is also possible that there is nothing intrinsically wrong with these later maturational brain processes in individuals predisposed to schizophrenia, but these processes nevertheless participate in determining the timing of onset of functional deterioration and psychotic symptom formation by reducing the reserve of interneuronal connectivity to below some hypothetically critical threshold (Hoffman & McGlashan, 1997).

Brain maturational processes during adolescence are thought to underlie the development of a number of cognitive abilities, including working memory, reasoning, planning, and problem solving, that are critical for adaptive life functioning during adulthood. The specific mechanisms underlying the development of these functions are not well understood, but are likely to involve a complex interplay of genetic and nongenetic factors regulating the brain maturational processes active at that time, including synaptic pruning and myelination. Identifying the determinants and developmental course of these processes and their relationships to the phenotypic expression of adaptive cognitive functions is a critical step in the development of strategies to enhance these abilities in the population and to prevent their disability in complex neuropsychiatric diseases such as schizophrenia. The question of whether brain abnormalities in schizophrenia are static versus dynamic has been a critical issue for the field to resolve; and indeed, over the past decade some consensus has emerged that progressive neural changes do occur around the time of disease onset (Pantelis et al., 2005).

Nevertheless, it has yet to be resolved whether this process results from a failure of normal development due to a fixed early insult, a failure in an ongoing maturational process such as synaptic pruning, a degenerative process from a stage achieved through normal development, or some combination of these factors (Cannon et al., 2003). A deeper understanding of normal neurodevelopmental events is clearly critical for elucidating the potentially abnormal pathophysiological processes at work in schizophrenia.

Increasingly sophisticated in vivo neuroimaging methodologies currently offer researchers the possibility of investigating these neurobiological processes as they unfold. However, it is not yet known whether such alterations are causally relevant to onset, or merely epiphenomena of other neurodevelopmental processes at work. In this regard, the functional significance of volumetric reduction noted in longitudinal MRI studies is a paramount question. As such changes do not appear to be accompanied by neurodegenerative processes at the cellular level, it is possible they may reflect short-term

physiological variability or plasticity that does not signify ongoing deterioration.

A second, related issue is the differentiation of risk factors that are causal, and could thus represent potentially important therapeutic targets, compared with markers of vulnerability that may identify those at greatest risk, but are merely epiphenomena that do not necessarily impact the later course of illness. The identification of causal risk factors, such as particular neurocognitive deficits or brain abnormalities, has obvious implications both for research and for the development of new treatments that may improve the quality of life for individuals suffering from the disorder, and is thus a primary goal of current clinical high-risk research.

From a developmental perspective, the unfolding of the clinical disorder is a long-term process, involving multiple developmental phases, different types of risk factors, and the understanding that psychosis is in no way an inevitable outcome (Cornblatt et al., 2002). A better understanding of the developmental trajectory of neurobiological processes in schizophrenia will inform early intervention strategies as to the most vulnerable brain functions or structures, as well as the stages of the illness most amenable to treatment (Pantelis, Yucel, et al., 2003). Such intervention strategies offer promise that the functional deterioration related to onset of the clinical disorder may be delayed, attenuated, or ultimately prevented altogether.

FUTURE DIRECTIONS

Moving Forward: Mechanistic Studies in Earlier Phases of Illness

It is clear from literature summarized above that the first few years of psychosis represent a critical period in that many patients show substantial cognitive and social deterioration which has extremely detrimental effects upon long-term success in functioning independently. Nevertheless, because current mental health care practices are largely reactive rather than proactive in nature, and because the public is poorly educated about the nature and early signs of mental illness, there is often a substantial delay before young people with onset of psychotic symptoms are evaluated and treated psychiatrically (Cannon et al., 2003; Yung et al., 2003). Consistent findings indicating poorer treatment response and functional impairment given longer duration of untreated psychosis (Norman & Malla, 1993) argue for a new approach attempting to ascertain at-risk individuals before the onset of schizophrenia and to provide interventions designed to stave off illness progression and to improve functioning and long-term outcome. Indeed, over the past 20 years there has been a paradigm shift, which has enabled identification of the earliest clinical signs of psychosis, thus allowing for the possibility of preemptive interventions (McGorry, 2013). Neurobiological biomarkers may enhance our ability to predict risk at an individual level, a key step toward personalized medicine in the mental health arena.

A better understanding of the neurodevelopmental trajectory in high-risk individuals who develop schizophrenia, compared with those who do not, will allow researchers to elucidate the temporal and spatial pattern of neural and behavioral changes associated with the emergence of prodromal and psychotic symptoms. Recent longitudinal studies investigating these processes have begun to provide important evidence validating the early prodromal phases as critical periods for testing the effectiveness of primary preventive intervention programs, and may suggest strategies for the development of novel preventive treatments that can correct or compensate for the specific neurodevelopmental and psychological changes associated with the formation of psychotic symptoms during late adolescence and early adulthood. In addition, improved understanding of the neurodevelopmental trajectory preceding onset of psychosis may help to identify biomarkers present earlier in development, leading to an improved mechanistic understanding of the disease pathophysiology. Youth experiencing prodromal symptoms are likely already impacted by the disrupted neurodevelopmental processes, but earlier detection may prevent further functional deterioration, as well as amelioration of already present symptoms.

Of particular importance is determining the relative timing and contribution of the various genetic, early developmental and later developmental factors described in this chapter. For example, there is a recent expansion of research focused on understanding the pathophysiology of schizophrenia as altered connectivity within the brain. Early implications are that some but not all of the deficits precede psychosis onset, but current research is very limited. As such, it is currently unknown how the anatomical changes and connectivity alterations found in those who develop psychosis relate to particular genetic variations or environmental influences. Additional functional and structural connectivity studies are needed to clarify what alterations are present early in development, which develop more proximal to the onset of symptoms, and which appear concurrently with onset or as part of further deterioration in the active disease state. In addition, longitudinal studies of high-risk individuals are needed to determine if the progressive anatomical changes highlighted earlier are also

reflective of altered structural and functional connectivity patterns, and if these appear sequentially or concurrently. Finally, as noted above, further research is needed to differentiate which neurological differences are causal risk factors versus those that are more likely epiphenomena that are markers of the disorder but do not represent direct causal pathways.

On the other hand, it may also prove beneficial to expand outcomes research beyond psychosis incidence to functional disability and other outcomes in high-risk individuals overall (Cannon, 2008). While one important goal of research in the early phases of illness is understanding the neurodevelopmental processes underlying conversion to psychosis and developing interventions to reduce the incidence of psychosis, many individuals with clinical risk who do not develop frank psychosis remain symptomatic and functionally impaired (Addington et al., 2011). This suggests that the neurodevelopmental phenomenon addressed by high-risk studies expands beyond that of risk of psychosis onset to risk of long-term social and occupational impairments. A better understanding of the factors that predispose an individual showing risk symptoms to recover versus maintain a symptomatic state is needed.

Understanding Epigenetic, Epistasis, and Gene Environment Contributions

As described in this chapter, the understanding of genetic contributions to the development of schizophrenia through DNA structural and sequence variation has advanced considerably in recent years. These findings implicate a number of neurodevelopmental processes including cell migration and proliferation, axonal outgrowth, myelination and synaptogenesis, as well as neuronal cellular functioning mechanisms (e.g., calcium channels). Importantly, a recent large scale GWAS (~37,000 cases and 113,000 controls) identified 108 genome-wide significance risk loci for schizophrenia including genes involved in glutamatergic neurotransmission and immune function (Schizophrenia Working Group of the Psychiatric Genomics, 2014). At the same time, effect sizes for these risk variants are quite small, and current genetic models explain only part of the known heritability, suggesting the need for continued genetic exploration utilizing sophisticated statistical techniques in conjunction with GWAS for gene discovery (Lee et al., 2012). In addition, epigenetic variation, epistasis, and gene-environment interactions are important avenues for future research.

Epigenetic influences, changes in gene activity that are not caused directly by the DNA sequence but that produce long-term alterations in the transcription of genes, have been suggested to play an important role in the expressions of genes contributing to the pathophysiology and developmental of psychosis (Dempster, Viana, Pidsley, & Mill, 2012; Labrie, Pai, & Petronis, 2012). Epigenetic processes including methylation (Dempster et al., 2011; Mill et al., 2008) and histone modification (Tang, Dean, & Thomas, 2011) show altered profiles in individuals with psychosis (Halene, Peter, & Akbarian, 2014). Epigenetic alterations are often associated with prenatal (Maćkowiak, Bator, Latusz, Mordalska, & Wędzony, 2014) and postnatal (Zhang et al., 2010) environmental factors, suggesting an explanatory role in the neurodevelopmental processes underlying schizophrenia. However, examination of these effects is complicated by the potential for differential expression in different tissue types and confounds of using postmortem samples from the brain. During the process of cellular differentiation in fetal development, cells shift from pluripotent stem cells to specific tissue types and expression/epigenetic alterations may differ between tissues. Further research is necessary to determine the relationship of more accessible peripheral tissues (e.g., blood) to neuronal expression (Heijmans & Mill, 2012).

In addition to the differential effects of different levels of individual gene expression, the interaction of genes with each other is an important avenue for future study into neurodevelopmental influences on psychosis. Epistasis, when the action of one or more genes depends on the action of other modifier genes, can produce complex interactions between different combinations of genes. These interactions between genes may lead to nonadditive effects (both suppressive and enhancing), which can therefore complicate more traditional methods of gene discovery. For example, genetic variation in AKT1 was found to increase risk for schizophrenia when combined with risk alleles for COMT and BDNF but not alone (Tan et al., 2012). Similarly, multiple interactions have been found between genes associated with neurodevelopmental processes and schizophrenia risk that predict structural brain changes (Andreasen et al., 2011). As with epigenetic influences discussed above, epistatic effects likely account for some of the missing heritability and so continued research into the interactions between different gene actions will allow for clarification of the underlying pathophysiological processes.

In addition to genetic expression patterns and gene-gene interactions, the interaction between genetic factors and environmental risk factors is also an important avenue for future research. As discussed previously, understanding of the impact of environmental factors such as prenatal

hypoxia, stress, and inflammation on gene expression is in its infancy. For example, many candidate genes for schizophrenia susceptibility have been shown to be regulated by hypoxia (Schmidt-Kastner et al., 2006) and obstetric complications show greater behavioral impacts in individuals with genetic susceptibility (Forsyth et al., 2013). There are many additional environmental factors that increase the incidence of schizophrenia (Brown, 2011; van Os, Kenis, & Rutten, 2010); however, their mechanisms of action and interaction with particular genes are not known. These epigenetic, epistasis and gene-environment interactions likely work in concert to produce the pathophysiological processes that influence the development of schizophrenia and more research is needed to understand their complex relationships.

Improving Treatment and Interventions for Schizophrenia

Despite major advances in neuroscience, drug discovery and pharmacogenomics, the treatments currently available for schizophrenia have only limited effectiveness. In addition, current medications have significant side effects and do not appear to impact the neurodevelopmental alterations in individuals prior to psychosis onset, suggesting limited prophylactic utility (Amminger & McGorry, 2012; McGorry et al., 2002). Taken together, this suggests that the currently available pharmaceutical treatments do not fully address the causal mechanisms of psychosis and are likely most effective at treating some of the associated affects of the underlying pathophysiology. Currently, the antipsychotic medications primarily used to treat psychosis rely on modulation of dopamine receptors, particularly the dopamine D2 receptor (Kapur & Mamo, 2003). However, improved understanding of the neurodevelopmental mechanisms underlying schizophrenia may provide additional targets for treatment and prevention. For example, the role of glutamate and GABA (Agnew-Blais & Seidman, 2012; Coyle, 2006; Krystal & Moghaddam, 2010) discussed previously suggest that future pharmacotherapy may prove more effective by targeting these symptoms. Similarly, the white matter alterations noted in schizophrenia and high-risk patients have suggested a potential role for myelination disruption in the onset of psychosis. Levels of nervonic acid, a component of the myelin sheath, at baseline predict rate of conversion and supplementation with omega-3 fatty acids has been found to reduce rates of conversion in preliminary studies (Amminger & McGorry, 2012). Future studies based on a mechanistic understanding of schizophrenia pathophysiology are essential for identifying novel targets for intervention.

Existing diagnoses rely on symptoms so far removed from drug targets that discovery of new treatments is almost always serendipitous. Development of rational pharmacotherapies for schizophrenia may be aided by more discrete definitions of pathological phenotypes to replace currently defined syndromal targets. Conventional diagnostic phenotypes are marked by such heterogeneity and overlap that genomic analyses using current syndrome definitions are questionable. Defining new phenotypes of the disorder at a neural-systems level, with links to drug mechanisms-of-action and patterns of gene expression, could yield dramatic advances in neuropsychiatric therapeutics, like those that resulted from the identification of neuropathological and neurochemical targets in Parkinson's disease (Fiandaca & Bankiewicz, 2010). A focus on endophenotypes expressed across multiple syndromes and species, examined using a multidisciplinary approach that capitalizes upon convergent technologies from molecular to behavioral, will likely accelerate the discovery of new treatments.

In particular, cognitive abnormalities, known to be a core feature of schizophrenia, offer quantitative phenotypes for genomic studies and clinical trials, and provide strong bridging relations to informative neural systems models. Measurement of cognitive constructs is highly scalable, enabling phenotype assessments to be conducted with the high throughput necessary for adequately powered genomic association studies and multi-center clinical trials. For example, a recent study of cognitive remediation in schizophrenia found improvement in reality monitoring with cognitive training, which correlated with increased medial prefrontal cortical activity (Subramaniam et al., 2012)

Notably, technological advances are making it increasingly feasible to screen populations on a large scale to identify at-risk individuals at an early age. At the same time, these advances (such as web- or smart-phone based applications) can greatly improve access to cognitive training programs or other therapies that can be administered remotely. Combining such methods with in vitro models of disease may open revolutionary prospects for both pathophysiological modeling and avenues for new interventions.

Translational Implications

Human-Induced Pluripotent Stem Cells

The recent discovery that fibroblasts (skin cells) can be reprogrammed into a pluripotent state and subsequently differentiated into neural progenitor cells and neurons has

great potential to lead to the discovery of molecular and cellular defects that may be critical to disease pathogenesis (Brennand & Gage, 2011; Dolmetsch & Geschwind, 2011). Recent studies of major mutational models of autism such as Timothy syndrome have led to some remarkable new findings of cellular phenotypes that can be rescued with pharmacologic agents that specifically target the observed cellular defects (Paşca et al., 2011).

The human-induced pluripotent stem cell (hiPSC) approach appears very well suited to the study of neurodevelopmental disorders, but there are still many questions and limitations to this approach (Rapoport, Giedd, & Gogtay, 2012). Heterogeneity within and across populations and lack of standardization of protocols are major challenges in the field. Nevertheless, investigation of neuronal developmental phenotypes in hiPSC-derived neurons from patients with schizophrenia may be highly informative. Recently, Brennand et al. (2011) reprogrammed fibroblasts from four patients with schizophrenia into hiPSCs and subsequently differentiated them into neurons. The hiPSC-derived neurons from schizophrenia patients showed diminished neuronal connectivity as well as decreased neurite number, PSD95-protein levels and glutamate receptor expression. These findings are consistent with post-mortem data and animal models indicating reduced dendritic arborization in schizophrenia (Selemon & Goldman-Rakic, 1999). Intriguingly, reduced neuronal connectivity in the hiPSC was rescued by treatment of the cells with an antipsychotic.

Conducting these cellular assays on a larger scale and linking them to variability in phenotypic expression, as well as validating them against *in vivo* neuroimaging data from the same patients, are key next steps. Additionally, investigating hiPSC models in the context of homogeneous genetic subtypes of psychosis such as individuals with 22q11.2 deletions will likely increase the robustness of the cellular phenotypes detected and reduce heterogeneity.

Cross-Disorder Neural Endophenotypes

The investigation of biologically based endophenotypes—quantitative traits or markers proposed to represent more direct expressions of underlying genes—may yield far more informative results than studies of aggregate psychiatric phenotypes (Gottesman & Gould, 2003). As such, an endophenotype-based approach is likely to aid in unraveling the complexity of transmission of complex mental disorders like schizophrenia. Combining information across multiple levels of phenotypic expression, with modeling of the neural systems that support these functions, can advance definitions of phenotypes that will be useful in developing more effective treatments.

With revisions to our current diagnostic classification system (DSM-V; APA, 2013) underway, it is critical that scientific evidence be better utilized in its development. Several investigators in the field have highlighted the need to increasingly strive for classification that more closely represents expression of underlying biologic systems (Merikangas & Risch, 2003). This principle is embodied in the National Institute of Mental Health's new Research Domain Criteria (RDoC) initiative, the goal of which is to develop a research classification system for mental disorders based upon fundamental biobehavioral dimensions that may cut across current heterogeneous categories of psychiatric disorder (Casey et al., 2013). For example, while schizophrenia and bipolar disorder have traditionally been viewed as distinct disorders, recent work from the Psychiatric Genomics Consortium (Lee et al., 2013) has revealed a high degree of genetic correlation between schizophrenia and bipolar disorder, consistent with prior findings from linkage and association studies indicating substantial familial co-aggregation and overlap in the genomic regions associated with these two disorders. Elucidating the specific genetic and neural mechanisms influencing susceptibility to and expression of these illnesses, and explaining the nature of the overlap between them, is critical to understanding the necessary and sufficient conditions for overt psychosis and to the development of more effective treatment and prevention strategies.

INTRODUCTION

The concept of an endophenotype was adapted from insect genetics (John & Lewis, 1966) and introduced to psychiatric genetics in the early 1970s by Gottesman and Shields (Gottesman & Shields, 1972; Gottesman & Shields, 1973; Gottesman & Shields, 1982). At that time, the molecular genetics of psychiatric disorder was barely even a fantasy, and the considerable intellectual debate over the ethics of studying genetics of mental illness and cognition (i.e., intelligence in particular) dominated the discussion (Gould, 1981, 1996). Nevertheless, after a long dormant period, and changes in the zeitgeist, interest in a genetic approach grew remarkably strong, with a dramatic acceleration of endophenotype studies in the last decade or two (Braff et al., 2008) (see Figure 24.1).

The interest in and conceptualization of endophenotypes extends beyond schizophrenia, to bipolar disorder (Hasler et al., 2006), attention-deficit/hyperactivity disorder (ADHD) (Doyle et al., 2005a; Doyle et al., 2005b) and other psychiatric disorders (Gottesman & Gould, 2003; Gottesman & Hanson, 2005). In fact, the approach is applicable to any disorder, whether psychiatric or other medical (such as diabetes, heart disease, etc.); however, in this chapter, we will largely limit the focus to schizophrenia, which has developed a voluminous literature on endophenotypes in the past two decades (Braff & Freedman, 2002; Braff et al., 2007; Gottesman & Gould, 2003; Tsuang, et al., 1993).

What then, is an endophenotype? Most researchers agree on a number of core principles. Most essential is that endophenotypes are measures that are quantitative and often laboratory based, and may not be observed directly within a standard clinical framework (in which symptoms predominate, at least in psychiatry). Thus, measures like eye-tracking, working memory measures of cognition, prefrontal function measures using functional magnetic resonance imaging (fMRI), or gamma oscillation measures of event related potentials (ERPs) are just a few examples of potential endophenotypes that may show certain characteristics but currently do not play specific roles in the current diagnostic criteria for disorders. Further, endophenotypes are conceptualized as important heritable links between genetic variation and the disorder itself. In theory, endophenotypes can occur based purely on genetic factors, or can emerge as a result of interactions with non-genetic factors (e.g., perinatal complications, stress etc.).

Gottesman and colleagues proposed that endophenotypes would have genetic etiologies that were simpler

TABLE 24.1 Proposed criteria for endophenotypes

Endophenotypes are related to the illness
Endophenotypes are heritable
Endophenotypes are present in all phases of the illness, though their expression may vary by developmental phase, age, gender, phase of illness, treatment or other environmental or co-morbid conditions
Endophenotypes are present at higher rates in the ill relatives of ill patients, compared with healthy relatives of ill patients
Endophenotypes occur in unaffected biological relatives at higher rates than they do in the general population
Endophenotypes are quantitative traits that can be measured reliably and are associated more with the particular illness than they are with other disorders

Source: Adapted from Gottesman and Gould, 2003, and Lenzenweger, 2013.

than those of the clinical illness. Though this has not been borne out clearly yet (Flint & Munafo, 2007), proof of this hypothesis may reflect the need to identify endophenotypes that are closer to their underlying genetic etiologies than those thus far identified (Glahn et al., 2014). This view is consistent with the likelihood that clinical diagnostic symptoms in psychiatry are relatively distal effects arising from pleiotropic genes with small effect sizes (Meyer-Lindenberg & Wienberger, 2006). This, in turn, reflects the likelihood that observable effects, though heritable, represent cumulative effects of multiple genes, with their attendant complex genetic architectures (Almasy, 2003; Glahn et al., 2014; Munafo & Flint, 2011). The more directly endophenotypes reflect the genes that produced them, however, the simpler the underlying genetic architecture may be. It also follows from this view that these more proximal expressions of genetic effects would be less amenable to direct observation than more complex distal clinical symptoms (Gottesman & Gould, 2003).

Gottesman and colleagues (Gottesman & Gould, 2003; Gould & Gottesman, 2006; Hasler et al., 2006; Lenzenweger, 2013) proposed several criteria for the identification of endophenotypes in schizophrenia. The criteria listed below were adapted from these sources (Gottesman & Gould, 2003; Lenzenweger, 2013) and listed in Table 24.1. In short, the criteria require that the deficits: 1) occur in association with the illness; 2) are trait-like and largely stable and largely independent of the influences of clinical state; 3) show heritability; 4) co-segregate with the illness; 5) occur at a higher frequency (and usually lesser severity) in biological relatives, especially first-degree relatives, than in control groups drawn from the general population, and 6) are quantitative traits that can be measured reliably and are associated more with the particular illness than they are with other disorders.

Braff and colleagues suggested that endophenotypes may represent a subset of a broader category of biological markers or vulnerability markers, largely associated with genes, whereas the broader category of markers can arise from the environment or some multifactorial process (Braff et al., 2007). Lenzenweger, in a review of similarities and differences between endophenotypes, intermediate phenotypes and biomarkers, emphasized this distinction as well, noting that biomarkers, unlike endophenotypes, need not be subject to genetic influences (Lenzenweger, 2013). Similarly, biomarkers need not co-segregate with the illness within families, which is another critical distinction with the endophenotype concept (Glahn et al., 2014; Lenzenweger, 2013). Definitions and uses of the term biomarker vary considerably, particularly compared with Gottesman and colleague's proposed definition of an endophenotype (Iacono, 1983; Miller & Rockstroh, 2013). Because biomarkers may not be subject to illness-related genetic influence, they may comprise a correlate of an illness-related process, rather than a mediator of an illness-related process (Kendler & Neale, 2010). Despite these differences, there is a general consensus that endophenotypes and biomarkers are related concepts, with endophenotypes forming a subset of biomarkers that are mediated by the same genetic etiologies that produce susceptibility to the illness (Glahn et al., 2012; Glahn et al., 2014; Lenzenweger, 2013; Miller & Rockstroh, 2013).

Intermediate phenotype (Meyer-Lindenberg & Wienberger, 2006; Rasetti & Weinberger, 2011) is another concept that is related to endophenotype. Weinberger and colleagues described intermediate phenotypes as heritable traits on a trajectory that extends from genetic etiology to clinical illness. The term has gained traction and is often used interchangeably with endophenotypes, if not as

frequently. Glahn et al. pointed out that a PubMed search using the term endophenotype listed 2111 publications between 1972 and August, 2013, while intermediate phenotype listed 700 (Glahn et al., 2014). As Lenzenweger and others (Miller & Rockstroh, 2013) have pointed out, however, the concept is ambiguous in several respects, such as the meaning of intermediate, and has been used in substantially different ways. For example, Insel and Cuthbert suggested that intermediate phenotypes were most appropriate for personality or other clinical clusters of symptoms (Insel & Cuthbert, 2009). Ambiguity in the concept is increased further by using a term that already has a formal meaning in genetics that is related to partial dominance (Lenzenweger, 2013). Notably, heritable intermediate phenotypes may be conceptually identical to endophenotypes (Lenzenweger, 2013; White & Gottesman, 2012).

A key issue related to the concepts of trait and stability is the role of development and age, and the impact of psychotropic medications. For example, with regard to the latter, neurocognitive measures can vary somewhat with illness exacerbations and remissions, as well as with medication status. Spohn and Strauss (1989) reviewed the literature and showed that neuroleptic treatment is associated with limited normalization on many psychological measures, whereas anticholinergic treatments appear to disrupt some aspects of memory. The core cognitive deficits remained, however, to greater or lesser degrees (Spohn & Strauss, 1989). Thus, stability is relative. Another issue, more related to the intrinsic development of the illness, is exemplified by the evolution of brain structural changes. In this situation, a preexisting deficit in the volume of prefrontal cortex (PFC), found in children at familial (genetic) high risk (FHR) for schizophrenia (Thermenos et al., 2013), shows further reduction in volume as the individual passes through a period of high risk into a first episode of schizophrenia (McIntosh et al., 2011). We will take up later what is known about the genetic basis of the PFC structural abnormality, but there is evidence for a genetic origin and evolution (Gulsuner et al., 2013). This changing picture poses many questions about the possibly varied genetic basis of different phases of illness, and whether PFC volume or thickness could be a useful endophenotype. In any case, age, development and stage of illness are important factors in considering the conceptualization and utility of endophenotypes.

Taking this conceptualization of endophenotypes as a starting point, we may now ask where they fit in an etiological model of schizophrenia. Figure 24.2 shows a model that helps to provide a context for the role of endophenotypes. We hypothesize that the combination of

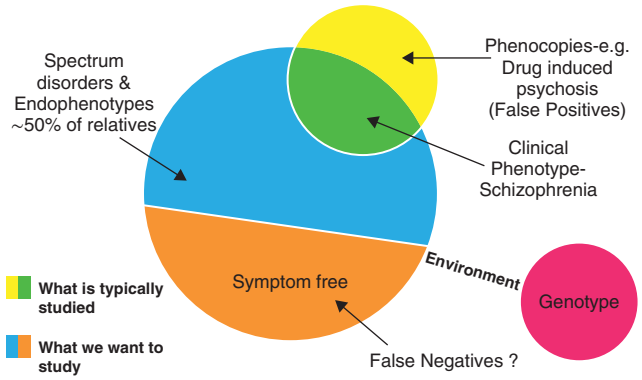

Figure 24.2 Model of genetic and phenotypic heterogeneity. See footnote 1. *Source:* Adapted with permission from Tsuang, Gilbertson and Faraone, 1991.

genotype (the circle to the right) and environment produces a range of possible outcomes (the large circle), only a small portion of which are captured by a clinical diagnosis of schizophrenia (the smaller circle intersecting with the larger one). Moreover, some portion of diagnosed individuals will be similar phenotypically, but will reflect false positive cases (e.g., people with schizophrenia-like brain disorders). The bottom portion of the larger circle contains unaffected individuals, which may also contain false negative cases, to an unknown extent. The upper portion of the larger circle contains the space between unaffected individuals and those with valid diagnoses of schizophrenia. This area contains individuals with less severe, schizophrenia spectrum diagnoses, and validly diagnosed schizophrenia itself. Endophenotypes are hypothesized to occur in this area, whether or not they occur in association with a recognized spectrum condition (e.g., schizotypal personality disorder). To the extent that new endophenotypes are identified, portions of the area at the bottom that are now classified as unaffected, may be reclassified into the area occupied by spectrum conditions/endophenotypes.

GENETICS OF SCHIZOPHRENIA: CURRENT STATUS AND APPLICATION TO ENDOPHENOTYPES

Although the idea of genetic contributions to schizophrenia is well-accepted and compelling (Allan et al., 2008; Craddock et al., 2009; Gottesman & Hanson, 2005; Harrison & Weinberger, 2005), until recently, the identity of genes that increase susceptibility to the disorder, and especially the biological mechanisms by which they act, have been largely unknown. Even with the recent flood of genetic associations with schizophrenia (Ruderfer et al.,

2013; Smoller et al., 2013) the findings only account for a small percentage of the etiological variance, which leaves mechanistic understanding in an early stage (Chen, 2013; Greenwood et al., 2011; Greenwood et al., 2013). Moreover, the genes being discovered as associated with schizophrenia may not be specific to schizophrenia, and may reflect susceptibilities to other disorders such as bipolar disorder or autism (Smoller et al., 2013). Nevertheless, the recent findings of 108 susceptibility loci in people with schizophrenia, including genes for brain development and immunity, has solidified the genetic foundation for schizophrenia (Schizophrenia Working Group of the Psychiatric Genomics Consortium, 2014).

Understanding how genetic determinants of schizophrenia modulate liability for schizophrenia-spectrum conditions requires considering the idea that schizophrenia is broader than the DSM or ICD syndromes that are required for diagnosis (Tsuang et al., 2000). This can influence our thinking in a number of directions. On the one hand, it draws attention to the idea that schizophrenia and affective psychoses are on a continuum, and that this continuous dimension can be measured (Keshavan et al., 2011). On the other hand is the idea that conditions milder than schizophrenia such as schizotypal personality are on a continuum with schizophrenia, and manifest milder versions of some of the abnormal traits. The importance of identifying endophenotypes (Gottesman & Gould, 2003; White & Gottesman, 2012) reflects a growing awareness that multidimensional expressions of psychiatric disorders can advance the search for underlying etiological or modulatory factors (Allan et al., 2008; Allen et al., 2009; Chan & Gottesman, 2008; Eack et al., in press; Gottesman & Gould, 2003; Gur et al., 2007a; Turetsky et al., 2007). Moreover, endophenotypes may be more specific and amenable to objective measurement than diagnostic symptoms (Braff & Freedman, 2002; Braff et al., 2007; Gottesman & Gould, 2003), and are heritable, as noted above (Greenwood et al., 2007; Greenwood et al., 2013; Husted et al., 2009). While the underlying genetic etiology of many putative endophenotypes have turned out to be quite complex themselves (Flint & Munafo, 2007), these features all support the usefulness of endophenotypes in genetic studies (Braff & Freedman, 2002; Braff et al., 2007; Faraone et al., 1995a; Faraone et al., 2003; Faraone et al., 1995b; Gottesman & Gould, 2003; Gottesman & Shields, 1972; Seidman & Wencel, 2003; Tsuang, 1994; Tsuang et al., 2000; White & Gottesman, 2012).

At the time the concept of endophenotypes gained currency, the field of molecular genetics was in its infancy and the field of psychiatric genetics was based largely on the well-known genetic epidemiology that schizophrenia and other psychiatric disorders ran in families, and that the pattern of transmission was not consistent with a single major gene (Faraone & Tsuang, 1985; Gottesman & Shields, 1967). Family studies of parent-child and sib-pairs contributed to the well-known increase of a roughly 10-fold increase in the rate of schizophrenia when a first-degree relative had the illness (Gottesman, 1991; Tsuang et al., 1999a). This increased by an additional two or three fold with two first-degree relatives (such as a parent and a sibling with schizophrenia) or another 4–5 fold when a sibling was a monozygotic identical twin, sharing identical DNA. Schizophrenia was known to be highly heritable (approximately 81% on average) (Sullivan et al., 2003) and a genetically heterogeneous disorder (McClellan & King, 2010). This state of affairs existed mainly into the 1990s, when it became clear that a sole focus on DNA was insufficient to explain the role of genetics, and a focus on RNA and proteins was emerging (Glatt et al., 2011). More recently, as very large samples have begun to demonstrate as many as 100+ genes (of small effect) to be associated with schizophrenia (Ruderfer et al., 2013), the field has become much more complex. For example, a recent development is the identification of rare gene-disrupting copy number variants (CNVs) that contribute significantly to schizophrenia (Walsh et al., 2008), as well as other neurodevelopmental illnesses like autistic spectrum disorder. CNVs that disrupt genes involved with signaling, synaptic plasticity, and neurodevelopmental processes may be especially important for schizophrenia (Gulsuner et al., 2013; Kirov et al., 2012; Walsh et al., 2008).

These latter findings on brain neurodevelopment are consistent with the longstanding belief that endophenotypes for schizophrenia are presumed to derive mainly from the central nervous system (CNS). This is a very large terrain and thus we limit our scope in this chapter to focus on two important classes of endophenotypes that reflect the CNS: neuropsychological and structural neuroimaging endophenotypes. Even within the world of neuroimaging, which is quite broad, this review will focus on structural neuroimaging using magnetic resonance imaging (MRI). In addition to their relationships to underlying neurobiological etiologies, neuropsychological and structural neuroimaging share other common features. Both, for example, involve measures that are amenable to objective definition and measurement, both have been studied intensively and are amenable to quantitative analyses such as meta-analyses, and both have been discussed conceptually as furthering our understanding of the liability to develop schizophrenia (Fusar-Poli et al., 2011; Seidman et al., 2004;

Stone & Giuliano, 2013; Thermenos et al., 2013; White & Gottesman, 2012). This review will highlight representative findings in both of these areas. We will emphasize the utility of proposed MRI and neuropsychological endophenotypes in the context of key conceptual features that includes their association with schizophrenia, their appearance in unaffected biological relatives, their heritability and their trait-like characteristics—that is, their relatively stable appearance during all phases of the illness. By stability we do not mean that a characteristic is invariant. Rather, we mean that the characteristic is always present to some extent, and that the influence of clinical state on the trait is relatively modest compared with its typical appearance during more clinically quiescent periods.

NEUROPSYCHOLOGICAL ENDOPHENOTYPES

Are Cognitive Deficits a Central Part of the Disorder?

Some investigators proposed that cognition should be added to the diagnostic criteria for schizophrenia (Kahn & Keefe, 2013), although this option has critics (Heckers, 2013) and was not heeded in the recent deliberations by the Psychosis subcommittee of the DSM-V revision (American Psychiatric Association, 2013). Nevertheless, there is a broad consensus that cognition, including neurocognition and social cognition, is one of the key elements of the illness (Elvevåg & Goldberg, 2000; Seidman, 1983). This recognition, and the need to have a standardized neurocognitive assessment for treatment trials of cognition, led directly to the development of the Measurement and Treatment Research to Improve Cognition in Schizophrenia Consensus Cognitive Battery (MATRICS–CCB) (Kern et al., 2008; Nuechterlein et al., 2008) and other brief, standardized batteries. Moreover, quantitative studies over the last 15 years demonstrate significant cognitive impairment across a broad range of cognitive domains (Aleman et al., 1999; Heinrichs, 2005; Heinrichs & Zakzanis, 1998). Cognitive deficits are associated with both impaired quality of life and with poor functional outcomes (Green, 1996; Green & Braff, 2001; Green et al., 2000; Mesholam-Gately et al., 2009; Nuechterlein et al., 2012). They are largely stable and severe from the first episode of psychosis to the chronic period and present in all phases of the illness (Heinrichs & Zakzanis, 1998; Mesholam-Gately et al., 2009). Thus, we share the belief of many in the field, that neuropsychological deficits are both hallmarks and core features of dysfunction in schizophrenia (Heinrichs, 2005). Nevertheless, several unresolved issues are also discussed below.

Are Cognitive Deficits Found in All Persons with Schizophrenia?

A separate but related question, and one that is more difficult to answer, is whether all individuals with schizophrenia have a neurocognitive disorder. All of the studies in this area, including those studying high IQ individuals with schizophrenia (Gray et al., 2013; Kremen et al., 2001; MacCabe et al., 2012), conclude that either the vast majority have neurocognitive deficits (Allen et al., 2003; Kremen et al., 2000; Kremen et al., 2001; Palmer et al., 1997) or that all do (Keefe et al., 2005; Wilk et al., 2005). Nevertheless, there are some methodological constraints that lead to caution about concluding this: while some of these studies find a modest subgroup of 25% or fewer of the sample that seem unimpaired, most of the samples are drawn from chronically ill patients who are more likely to be impaired, and none of these studies has assessed individuals at multiple time points to clarify whether the deficits are present at all time points. Despite these caveats, it appears that the vast majority has some form of cognitive impairment, which may vary by severity and type (Kremen et al., 2004; Seidman et al., 1992). Thus, from the point of view of endophenotype criteria (Gottesman & Gould, 2003), neurocognitive deficit meets the first criteria for an endophenotype—it is a core part of the illness.

Is There One Central Cognitive Deficit or Multiple Deficits?

This issue has been an area of debate for 20 years since Blanchard and Neale's paper describing a generalized cognitive deficit in schizophrenia (Blanchard & Neale, 1994). This point of view challenges the idea of deficits in many neurocognitive areas proposed by some (Seidman et al., 1992), or the primacy of executive function (prefrontal) deficits suggested by others (Goldberg et al., 1987; Levin, 1984; Seidman, 1983). This issue has been studied from a number of perspectives, and we will conclude that the answer is both—that there is evidence for a generalized deficit and that this cuts across many domains of cognition. On the other hand, there is also evidence that some deficits cannot solely be explained by the generalized deficit and thus, there are specific as well as generalized deficits.

This section focuses on general neuropsychological deficits first, and then takes up particular cognitive domains. We will focus on representative areas that are both impaired and well studied: overall cognitive abilities, learning and memory, attention, and executive functions (EFs). We will also emphasize specific representative tests/variables within each domain to identify the most valid endophenotype candidates.

Broad/Generalized Deficits

The notion of broad or more generalized deficits can be viewed in at least two ways. One is to consider single measures that are presumed to assess generalized functioning, such as Full Scale IQ scores derived from Wechsler intelligence tests. Impairments in broad measures of cognition, however, occur often in the context of broad neuropsychological impairments across many domains in schizophrenia (Hill et al., 2013; Seidman, 1997; Seidman et al., 1992). A recent meta-analysis that included 100 studies published between 2006 and 2011 showed, for example, that patients with schizophrenia performed worse than controls on all cognitive tests and domains assessed, though particularly in processing speed and episodic memory (Schaefer et al., 2013). This raises the question of whether separable cognitive deficits really occur, or whether they reflect a more generalized deficit that is evident in whichever cognitive domain is assessed. These choices are not mutually exclusive, however, as recent studies reveal both general and more specific cognitive deficits in schizophrenia (Dickinson et al., 2004; Nuechterlein et al., 2004; Wang et al., 2010). We will focus on IQ scores as a general measure of overall cognitive function because they are relatively discrete measures that can be assessed and compared more easily across studies.

Aylward et al. showed in a 1984 meta-analysis that overall cognitive ability as measured by IQ scores in subjects who subsequently developed schizophrenia or related disorders, was lower than in comparison samples. The effect size (Cohen's *d*) was small to medium (–0.43). Later, Woodberry et al. (2008) performed a meta-analysis on 18 studies in which children or teenagers subsequently developed schizophrenia, schizoaffective disorder, or schizophreniform disorder, using more recent diagnostic criteria. Consistent with Aylward et al., these subjects showed lower overall cognitive abilities, as measured by IQ scores in the premorbid period, with a moderate effect size relative to healthy controls ($d = -0.54$). This effect size is about half the magnitude of the IQ deficit in schizophrenia (Heinrichs & Zakzanis, 1998), which shows that a substantial portion of the deficit appears premorbidly. Sorenson et al. (2010) also showed that children 10–13 years old who later developed a disorder in the schizophrenia spectrum had lower IQ scores compared with a group who did not develop a psychiatric disorder. Clearly, IQ is affected premorbidly.

Mesholam-Gately et al. (2009) included data from 47 studies in a meta-analysis of first-episode schizophrenia. They showed medium to large deficits across 10 neuropsychological domains (effect sizes from $d = -0.64$ to -1.20), including an overall cognitive domain ($d = -0.91$) that was composed mainly of IQ tests. They also found that the magnitude and extent of cognitive deficits at the first episode was similar to the level of deficits observed in chronic schizophrenia (Heinrichs, 2005; Heinrichs & Zakzanis, 1998), further demonstrating the stability of these deficits.

Nonpsychotic relatives of patients with schizophrenia also show stable, cognitive deficits (Faraone et al., 1999; Kremen & Hoff, 2004; Sitskoorn, Aleman, Ebisch, Appels, & Kahn, 2004; Snitz, MacDonald, & Carter, 2006). A meta-analysis that assessed 43 neuropsychological test scores from 58 studies showed smaller differences from control subjects than generally occur with patients (Snitz et al., 2006). Differences in overall cognitive ability, using the Wechsler Adult Intelligence Scale-Revised (WAIS-R), however, were significant, with a small effect size ($d = 0.31$). Consistent with the studies of adults is the result from a recent quantitative review of 28 studies of young nonpsychotic relatives under the age of 30 (and as young as age 7) that demonstrated that the largest impairment (presumably associated with genetic risk) was in IQ (Agnew-Blais & Seidman, 2013). While this could be a function of better psychometric features (e.g., higher reliability of IQ than other tests) and larger subject samples, which yielded more reliable estimates than many individual tests, it still supports the general deficit idea. Thus, this general impairment is found at all ages studied so far, in the premorbid period and in those at genetic risk for schizophrenia based on family history. It is also observed in the so-called prodromal, clinical high risk period (Giuliano et al., 2012) in which IQ deficits were again prominent.

A meta-analysis of IQ showed moderate levels of heritability (0.48) (Devlin et al., 1997). A few studies that assessed the heritability of IQ in schizophrenia also showed significant findings. One of these demonstrated small to moderate heritabilities (0.31–0.62) for neuropsychological measures in 17 multiplex Canadian families, with the highest heritability shown by IQ (0.64–0.74; the estimates varied slightly depending on which statistical model was used) (Husted et al., 2009). The concurrent and significant heritabilities for IQ and for other neuropsychological measures raise a question about whether broader measures such as IQ are independent from cognitive abilities that are conceptualized more narrowly (e.g., working memory or mental flexibility). Relevant to this point, Aukes and colleagues studied schizophrenia patients and their relatives in 25 multigenerational Dutch families and showed, for example, that a significant genetic correlation accounted for 76% of the variance between measures of spatial working memory and IQ (Aukes et al.,

2009). Owens et al. showed significant genetic correlations between measures of semantic and phonemic fluency, initiation and mental flexibility (i.e., EFs) and IQ (Owens et al., 2011), and Goldberg et al. showed significant genetic correlations between the Letter-Number Sequencing Test (i.e., working memory) and IQ (Goldberg et al., 2013). Toulopoulou et al. used twin and family data to show that shared genetic effects accounted for most of the variance in significant phenotypic correlations obtained between measures of intelligence and schizophrenia (89%), and between measures of immediate and delayed recall and schizophrenia (72% and 86%, respectively) (Toulopoulou et al., 2010). These findings provide support for the view that the same genes that contribute to the phenotypic expression of intelligence also contribute to the phenotypic expression of measures in other cognitive domains. For comparison, representative heritability scores are listed in Table 24.2 for IQ and other cognitive domains. Representative studies included in the table were published in the last 20 years, and included both twin and family studies. In addition, reviews or meta-analyses were included, with multiple results listed as ranges of heritabilities. PubMed search terms included heritability, schizophrenia, neurocognition, cognition, neuropsychology, memory, attention, executive function, and intelligence.

Although in one sense, these genetic correlations provide support for the use of these cognitive domains as endophenotypes, they also raise the question of the extent to which separable cognitive deficits actually occur in schizophrenia. An alternative possibility is that cognitive deficits reflect more generalized or widespread deficits that become salient in whichever cognitive domain is assessed (Goldberg et al., 2011). In a series of studies that assessed the issue, Dickinson and colleagues showed that much of the variance in cognitive performances that were attributable to diagnoses of schizophrenia were related to a single, common factor. In one of these studies, 47% of the variance in cognitive performance was attributable to a schizophrenia diagnosis, and 65% of that was attributable to a single, common factor (Dickinson et al., 2004). They showed in a subsequent study that 63.6% of the diagnosis-related variance derived from a common factor, with much smaller percentages attributable to performance in other cognitive domains, such as verbal memory (13.8%) and processing speed (9.1%) (Dickinson et al., 2008). Moreover, the same group demonstrated that schizophrenia patients showed higher correlations between composite scores of neuropsychological functions in a study of confirmatory factor analysis compared with healthy controls, consistent with the hypothesis that

TABLE 24.2 Heritabilities of Selected Neuropsychological Functions in Healthy Subjects and in Subjects with Schizophrenia

Study	Cognitive Domain	Subjects		Heritability (h^2 Intraclass Correlation or Risch's Lambda)

patients demonstrated a more generalized cognitive ability (or deficit) than controls (Dickinson et al., 2006). Consistent with these findings, a more recent study demonstrated both common and specific variance in a cognitive test battery that was related to functional deficits in schizophrenia (Sheffield et al., 2013).

Nevertheless, evidence for broad generalized deficits and evidence for more specific cognitive deficits do not necessarily conflict with each other, as both general and more specific cognitive deficits in schizophrenia occur simultaneously (Dickinson et al., 2004; Nuechterlein et al., 2004; Wang et al., 2010). Moreover, significant and even severe neuropsychological deficits can be shown in individuals with high IQ (Seidman, 1990), and thus the two levels of analysis are not isomorphic at the individual patient level. Similarly, the presence of one or more common cognitive factors does not mean that eventual treatments would affect all dimensions of cognition equally. Neuropsychological test performance in healthy control samples is often variable (Binder et al., 2009; Wechsler, 1997) and subject to dissociation in focal lesion cases (e.g., the patient H.M. developed profound temporal lobe amnesia following surgery for epilepsy, but retained intact immediate memory and above-average overall cognitive abilities (Squire & Shimamura, 1996)). Similarly, cognitive dysfunction is also likely to be dissociable, with potential treatments for schizophrenia influencing some dimensions of cognition more effectively than others.

In the effort to develop the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) Cognitive Consensus Battery (MCCB), evidence for separable cognitive factors was obtained through factor analytic and other empirical studies (Nuechterlein et al., 2004). Seven distinct, replicated dimensions of cognitive dysfunction in schizophrenia were identified, including: Speed of Processing, Attention/Vigilance, Working Memory, Verbal Learning and Memory, Visual Learning and Memory, Reasoning and Problem Solving, and Verbal Comprehension. Verbal Comprehension was excluded because it was considered less likely than the other dimensions to change with treatment, while Social Cognition was added because of growing interest in it, and because of a more general interest in understanding how changes in cognition affect other functional domains. We discuss some of these specific domains below.

Narrower/More Specific Deficits

Learning and Memory. Deficits in memory are among the most consistent and severe neuropsychological deficits in schizophrenia (Aleman et al., 1999; Cirillo & Seidman, 2003; Heinrichs, 2005; Heinrichs & Zakzanis, 1998; Seidman et al., 1992). Performance on learning and memory endophenotypes usually refer to performance on tests of learning and memory that assess the abilities to learn, retain and retrieve specified information. Most studies focus on the retention of facts or conscious, personally-experienced episodes, often called 'declarative' memory (Squire & Zola-Morgan, 1991). Its association with the illness is robust. Effect sizes versus appropriate comparison populations are typically large, in the 1.0–1.5 standard deviations range (Aleman et al., 1999; Cirillo & Seidman, 2003; Gold, 2004; Heinrichs, 2005; Heinrichs & Zakzanis, 1998; Stone & Hsi, 2011). Deficits in declarative (DM) are thus associated closely with schizophrenia spectrum conditions.

Deficits in DM are also stable. They occur at different phases of the disorder, including prior to the prodrome and prior to frank psychosis, and after remission from psychotic symptoms (Cirillo & Seidman, 2003; Hill et al., 2004; Joyce, 2005; Kravariti et al., 2003; Roofeh et al., 2006; Turetsky et al., 2002; Tuulio-Henriksson et al., 2004; Woodberry et al., 2008). Mesholam-Gately et al. showed a large effect size ($d = -1.20$) for an Immediate Verbal Memory composite score in their meta-analysis at the time of the first episode, and even larger effect sizes for specific test measures (Mesholam-Gately et al., 2009). These included $d = -1.47$ for immediate recall of short stories on the Wechsler Memory Scale (WMS) Logical Memory Test, and $d = -1.34$ for the total number of words recalled correctly over the course of learning 5 trials on the California Verbal Learning Test (CVLT). One of the largest evaluations of this same measure of learning on the CVLT-II was performed at seven sites as part of the first phase of the Consortium on the Genetics of Schizophrenia (COGS-1), with 509 control subjects, 309 subjects with schizophrenia, 449 sibling relatives and 232 parent relatives (Stone et al., 2011). The effect size for subjects with schizophrenia was again large (e.g., $d = -1.20$ for controls versus schizophrenia probands on the total correct responses for the 5 learning trials), consistent with the results obtained by Mesholam-Gately et al. in 2009.

Deficits in DM occur independently of deficits in overall cognitive ability (Tuulio-Henriksson et al., 2004), are mainly independent of clinical state (Cirillo & Seidman, 2003), and are largest in the learning/encoding stage (Cirillo & Seidman, 2003; Stone & Hsi, 2011), with milder deficits evident in rates of forgetting and in recognition, similar quantitatively to that observed in other conditions with mild medial temporal lobe damage (Gold et al., 1995;

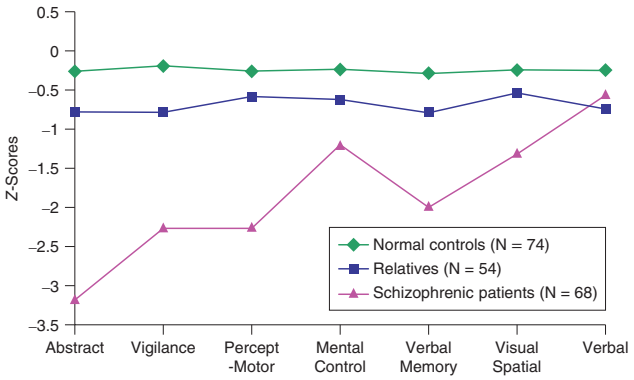

Figure 24.3 Neuropsychological profiles in patients with schizophrenia, first-degree relatives, and normal controls with a mean age in their early 40s. See footnote 1. *Source:* Adapted from Faraone et al., 1995. Reprinted with permission.

Seidman et al., 1998). Moreover, DM deficits prior to treatment show they were not produced by antipsychotic medications, which, in fact, may improve them modestly (Keefe et al., 2006b; Thornton et al., 2006).

Non-psychotic biological relatives of individuals with schizophrenia also show impaired encoding on DM, but the deficits are milder (no more than half of the effect observed in patients), and most often, do not involve abnormally high rates of forgetting (Agnew-Blais & Seidman, 2013; Faraone et al., 1995b; Faraone et al., 1999; Faraone et al., 2000; Gur et al., 2007a; Kremen & Hoff, 2004; Skelley et al., 2008; Stone et al., 2011; Stone & Hsi, 2011) (see Figure 24.3). The qualitative similarity of DM deficits in relatives to those that occur in patients adds to the view that impairments in DM reflect intrinsic features of the disorder (i.e., endophenotypes) rather than secondary phenomena related to effects of medication, psychosis, or other cognitive dysfunctions.

Until recently, most studies of DM in schizophrenia focused on verbal memory. Earlier (Seidman et al., 2003a; Tracy et al., 2001; Tuulio-Henriksson et al., 2003) and more recent studies (Cestari et al., 2013; Scala et al., 2013), however, show visual memory deficits in both schizophrenia patients and in non-psychotic relatives that are similar to those observed in verbal declarative memory. There is too limited a database to conclude that the deficits are equivalent in the two modalities, and such a conclusion would also require tests matched on difficulty to be equivalently impaired, a standard not yet observed. Nevertheless, visual memory deficit is present and significant.

Memory in healthy adults is moderately heritable (Bouchard, 1998; Finkel et al., 1995a), with heritability estimates that range generally between 30% and 60% (Papassotiropoulos & de Quervain, 2011). Deficits in DM in schizophrenia are similarly heritable. As noted above, for example, Husted et al., assessed heritability of several neuropsychological functions, and IQ (Husted et al., 2009). Immediate recall on the WMS Logical Memory Test was among the measures that showed significant heritability (0.40–0.49). Wang et al. showed that performance on the Logical Memory Test was the most heritable neuropsychological measure assessed (0.34) in a sample of first-episode, drug naïve, Han Chinese patients with schizophrenia and their siblings and parents, in relation to controls (Wang et al., 2010). Calkins et al. assessed the heritability of several neuropsychological functions in African-American probands with schizophrenia or schizoaffective disorder, their biological relatives, and in control subjects (Calkins et al., 2010). They showed significant heritability for several composite neuropsychological functions, including verbal memory (about 0.50). Performance on this verbal memory composite also showed significant heritability (0.66) in a previous multiplex, family study of schizophrenia from the same group (Gur et al., 2007b). Greenwood et al. demonstrated significant heritability for CVLT-II performance (0.25) in the COGS study, which included subjects with schizophrenia or schizoaffective disorder, depressed, and their biological siblings and parents (Greenwood et al., 2007; Greenwood et al., 2011).

Attention. Deficits in attention have long been considered central features of schizophrenia, and are among the most extensively studied (Calkins et al., 2010; Cornblatt & Keilp, 1994; Gur et al., 2007b; Kraepelin, 1919; Kremen et al., 1992; Nuechterlein, 1983; Nuechterlein & Dawson, 1984; Seidman et al., 2012). Several overlapping dimensions of attention are impaired. These include, among others: 1) attention span, which refers to the extent of information that can be held in mind; 2) selective attention, which refers to an ability to focus on particular stimuli; 3) cognitive control of attention, which refers to the abilities to organize and direct attention in relation to task demands; and 4) sustained attention and concentration, which refer to the abilities to sustain focus over time, sometimes in the presence of interfering or prepotent stimuli. Many of these aspects of attention are impaired in schizophrenia. Heinrichs and Zakzanis showed medium to large deficits in their meta-analysis of 22 measures derived from 204 studies (Heinrichs & Zakzanis, 1998), for example, including medium-sized deficits in auditory attention span (d = 0.62) and large deficits in measures of sustained attention (d = 1.18). More recently, Heinrichs also showed a large effect size (of over 1.0) for deficits in sustained attention (Heinrichs, 2005).

In their meta-analysis of first-episode psychosis in schizophrenia, Mesholam-Gately et al. (2009) organized putative attention measures into three composite subdomains. In the first of these, tests of attention also emphasized processing speed and produced an Attention: Processing Speed composite score that showed a large deficit compared with controls ($d = -0.96$). A second dimension of attention was assessed with an Attention: Vigilance subdomain that included scores from computerized continuous performance tests (e.g., omission errors, commission errors, and d'). This composite demonstrated a medium effect size versus control subjects ($d = -0.72$). The third subdomain emphasized working memory, which refers to the abilities to both hold information in mind consciously and manipulate it to solve problems or make decisions. The type of tests that comprise the Attention: Working Memory subdomain, which will also be considered in the next section (EFs), showed a medium to large effect sized deficit relative to control subjects (−0.79). The division of attentional components was based on cognitive science (Posner & Petersen, 1990), as well as factor analytic studies of clinical neuropsychological measures of attention (Kremen et al., 1992; Mirsky et al., 1991).

Different dimensions of attention overlap with each other to varying degrees, and with other neuropsychological deficits. Cohen et al., for example, showed that cognitive control of attention was closely related to mechanisms involved in the representation and maintenance of contextual information needed for the efficient selection of task-appropriate actions (i.e., working memory) (Cohen et al., 1999). The overlap between cognitive dimensions of function or dysfunction again raise questions about the prominence of general cognitive deficits in schizophrenia, as opposed to more specific deficits. Consistent with other recent findings, however (Dickinson et al., 2004; Wang et al., 2010), Nuechterlein et al., in their review of 13 factor analytic studies, also demonstrated support for separate cognitive deficits, including a separate attention/vigilance factor that focused on sustained, focused attention (Gur et al., 2007a; Nuechterlein et al., 2004).

Progress in defining and validating deficits in sustained attention separate from other, related cognitive dysfunction, together with consistent evidence of medium to large deficits, has contributed to a focus on sustained attention or vigilance as an endophenotype in schizophrenia (Chen & Faraone, 2000; Cornblatt & Keilp, 1994). Continuous performance tests (CPT) (Rosvold et al., 1956), a family of adaptable procedures, are the most widely utilized measures to assess sustained attention (Gur et al., 2007a). While different versions of the test are differentially sensitive to related cognitive dysfunctions (e.g., in working memory or perceptual processing) in schizophrenia, even simpler versions show consistent, medium to large deficits in vigilance, in most studies (Birkett et al., 2007; Mesholam-Gately et al., 2009; Pukrop & Klosterkotter, 2010). In a recent study, Seidman et al., developed an auditory CPT battery that allowed for manipulations of cognitive load and level of interference (Seidman et al., 2012), and showed substantially larger effect sizes for schizophrenia patient versus control comparisons on auditory working memory + interference ($d = 1.5$) than simple auditory vigilance ($d = 1.1$).

Performance stability has been demonstrated for several versions of CPTs. Among these, the degraded stimulus CPT and the CPT, Identical Pairs (CPT-IP) version, showed good reliability across sites, nationally and internationally (Cornblatt et al., 1988; Gur et al., 2007a). Deficits in these tests occur in medication naive subjects and in subjects taking antipsychotic medications (Finkelstein et al., 1997; Keefe et al., 2007b), and they occur in different stages of illness (Bhojraj et al., 2010a; Keefe et al., 2006a; Nuechterlein et al., 1992).

Like their ill relatives, nonpsychotic biological relatives of individuals with schizophrenia also show deficits in CPTs (Gur et al., 2007a; Kremen & Hoff, 2004). Snitz et al. showed small to medium effect sizes for several variables (Snitz et al., 2006). Among these, a quantitative measure of the ability to distinguish target from nontarget stimuli (d') showed a medium deficit in the CPT., Identical Pairs version ($d = -0.53$), as did false alarm responses ($d = -0.54$). Recent large studies using the Penn Battery version of the CPT have also demonstrated significant deficits in nonpsychotic relatives (Calkins et al., 2010; Gur et al., 2007b). Nonpsychotic relatives show smaller deficits on simpler versions of CPTs, rather than on more complex versions that contain higher loads of working memory, interference and/or perceptual processing (Kremen & Hoff, 2004), but still show significant impairments in vigilance with minimal working memory and perceptual processing loads (Birkett et al., 2007). In Seidman's auditory CPT study described earlier, relatives showed deficits in the small to medium range ($d = 0.4$ to 0.5) when interference was maximized (Seidman et al., 2012).

A growing literature shows that performance deficits in attention are significantly heritable. Cornblatt et al. showed heritabilities for the CPT, Identical Pairs version, of 0.39 (using digits as verbal stimuli) and 0.49 (using shapes as visual, nonverbal stimuli) in healthy families (Cornblatt et al., 1988). Chen et al. showed heritabilities of 0.48 to 0.62 in relatives of patients with schizophrenia

(Chen et al., 1998). Greenwood demonstrated a significant level of heritability for the degraded stimulus version of the CPT (0.38) in the COGS-1 study (Greenwood et al., 2007), while Gur et al. and Calkins et al. showed significant heritability using the Penn Battery CPT (0.50 and 0.40, respectively) (Calkins et al., 2010; Gur et al., 2007b). Interestingly, a recent study that assessed heritability for performance in tests of attention that did not utilize CPT tests did not show significant levels of heritability (Wang et al., 2010), which further validates the use of CPTs as endophenotypes.

Executive Function. Executive functions (EFs) refer to a family of cognitive abilities that include, among others, the acquisition, organization, maintenance, transformation, updating and retrieval of information, and also its protection from interference. These properties underlie and contribute to many adaptive cognitive and functional activities, such as learning, problem solving, fluency, processing speed, mental persistence, and resistance to interference. Like the other cognitive domains reviewed in this discussion, EFs are involved in the normal performance of many cognitive tasks. Also similar to the other cognitive domains reviewed in this section, EFs are often robustly impaired in schizophrenia (Bhojraj et al., 2010a; Egan et al., 2001; Gur et al., 2007a; Gur et al., 2007b; Kremen & Hoff, 2004; Seidman et al., 1992; Seidman et al., 1995), but separable from other cognitive abilities (Nuechterlein et al., 2004) in at least some dimensions.

Many studies documented deficits in EF in schizophrenia. Among several that quantified the magnitude of the dysfunctions, Heinrichs et al. used an EF composite score based on performance on the Wisconsin Card Sorting Test (WCST), which showed a large deficit ($d = 0.95$) compared with control subjects. Heinrichs also showed deficits with large effect sizes in a 2005 meta-analysis for performance on the WCST and on tests of verbal fluency (both > 1.0). Mesholam-Gately et al. also used an EF composite based on WCST function in their meta-analysis of first episode schizophrenia and showed a large deficit ($d = -0.83$). Other aspects of EF have also shown significant deficits. Lee and Park, for example, showed small to medium deficits in visual-nonverbal ($d = -0.46$) and in verbal ($d = -0.45$) working memory tasks. Wang et al. showed medium to large effect-sized deficits ($d = -0.73$ to -1.33) for prospective memory tasks (i.e., remembering to carry out intended actions) (Wang et al., 2009).

Despite the large deficits shown in individuals with schizophrenia for several measures of EF, some do not have equal potential as endophenotypes. Deficits on the WCST, for example, though large and studied extensively, may have limited value as an endophenotype. Heritability studies for WCST performance have been inconsistent, with several studies failing to show significant heritability estimates in schizophrenia families (Gur et al., 2007b). Kremen et al. performed the largest adult twin study to date on the heritability of the WCST., using the Vietnam Era Twin Registry sample, and failed to show either significant heritability or monozygotic–dizygotic differences (Kremen et al., 2007). Several factors probably contribute to inconsistent WCST heritability levels in the context of large deficits in performance, including the multifactorial complexity of the test and a multitude of cognitive factors that contribute to performance (Kremen et al., 2007).

Working memory tests provide another paradigm that emphasizes EF, has been studied extensively in schizophrenia (Lee & Park, 2005), and are more promising as endophenotypes. There are two broad classes of working memory studies. As noted above, the first one emphasizes vigilance and the transient maintenance of information (e.g., WAIS-IV Digit Span Forward). The second class involves vigilance and maintenance of information as well, but it also involves the manipulation of information (e.g., WAIS IV Letter-Number Span). It is the second type of working memory task that emphasizes EFs, and which will be considered here in more detail as a putative endophenotype for schizophrenia. This paradigm also corresponds to the more complex working memory tasks referred to in the Attention section, above (Mesholam-Gately et al., 2009).

Effect sizes for all working memory paradigms considered together (Lee & Park, 2005) are smaller than they are for the cognitive endophenotypes reviewed above in overall cognitive ability, verbal declarative memory, and sustained attention. More complex paradigms with larger EF deficits, however, often demonstrate large effect sizes (Gur et al., 2007b). This point was demonstrated, for example, in a recent, large COGS study that compared performance on simple and more complex verbal working memory paradigms in schizophrenia probands, their relatives, and control subjects (Horan et al., 2008). Effect sizes for the probands versus controls were large ($d = -0.94$) for the more executive paradigm, and were medium ($d = -0.54$) for the simpler paradigm that emphasized maintenance.

Deficits in working memory show other features similar to the strong endophenotype candidates discussed above. These include stability. Deficits in working memory are present at all stages of the illness (Gur et al., 2007a; Heaton et al., 2001; Keefe et al., 2006a; Lee & Park, 2005; Mesholam-Gately et al., 2009), are present with and without antipsychotic medication (Barch et al., 2001; Keefe

et al., 2007a), and are not secondary to clinical symptoms of schizophrenia (Heaton et al., 2001).

Non-psychotic relatives of patients with schizophrenia show smaller but significant deficits in working memory. Snitz et al. showed, for example, small ($d = -0.27$, digit span, backward condition) to medium ($d = -0.55$, spatial delayed response tasks–accuracy) effects sizes (Snitz et al., 2006). Like patients with schizophrenia, working memory tasks that emphasize EFs show greater effect size decrements in relatives. Conklin et al. showed, for example, that effect size increased from a digit span forward ($d = -0.43$) to a digit span backward ($d = -0.56$) to a letter–number span ($d = -0.66$) paradigm (Conklin et al., 2005). Horan et al. showed similar findings, with a larger effect size in a letter–number span paradigm that required reordering ($d = -0.36$) than a letter–number span that did not require reordering ($d = -0.22$) (Horan et al., 2008).

Performance on working memory tasks shows significant heritability in both healthy subjects (0.43–0.49) (Ando et al., 2001; Hansell et al., 2005) and in families with schizophrenia (0.36–0.42) (Tuulio-Henriksson et al., 2002). Recent studies by Husted et al. (2009), Calkins et al. (2010), and Greenwood et al. (2007) provide additional evidence for heritability of working memory performance in schizophrenia families (0.32–0.50) (cf. Table 24.2).

Summary. Taken together, the studies in this section provide strong overall support for the view that both general and specific cognitive deficits are core features of schizophrenia that are significant in magnitude, occur in all phases of the illness to varying degrees, are evident to milder degrees in nonpsychotic relatives compared with controls, and are heritable. This evidence implicates overall general intellectual abilities, but also more specific abilities in attention, learning and memory, and executive function as endophenotypes for schizophrenia.

NEUROIMAGING OF BRAIN STRUCTURE ENDOPHENOTYPES

Schizophrenia was originally proposed as a neurobehavioral disorder over a century ago (Bleuler, 1911/1950; Kraepelin, 1919). The conceptualization has been confirmed through a massive neuroimaging and postmortem literature (Harrison, 1999; Shenton et al., 2001) that is well beyond the scope of the current chapter. Instead, we have chosen to limit the focus to structural neuroimaging, and thus to exclude functional neuroimaging, in part because a structural magnetic resonance imaging (MRI) scan does not involve a task that could be subject to many confounds. It does not exclude the possibility of confounds or moderators to structural scans, such as type of magnet, field strength, technician reliability, head position, software used to measure structural features such as freesurfer, voxel-based morphometry, or manual segmentation and parcellation, reliability of measurement, etc. All of these are indeed factors that can create noise that could interfere with the signal of brain abnormality and yield differences across studies. Nevertheless, given these caveats, structural scans by their nature are more likely to measure trait characteristics. Moreover, there is now enough of a literature on brain structure in first-degree relatives of persons with schizophrenia, and in individuals at clinical high risk (CHR) or prodromal periods, that we concluded that the best MRI yield for this review would come from structural studies.

Brain Abnormalities in Patients with Schizophrenia and Their Relatives: Structural Magnetic Resonance Imaging (sMRI)

The study of abnormal psychobiological endophenotypes in patients with schizophrenia and their unaffected (nonpsychotic) first degree relatives has developed considerably over the past 40 years since the initial computer tomography (CT) scans were introduced (Johnstone et al., 1976). These include, among others, psychophysiological endophenotypes such as P50, prepulse inhibition, oculomotor abnormalities and other sensory gating paradigms (Turetsky et al., 2007), and a variety of structural, functional, and metabolic neuroimaging paradigms.

A vast literature of in vivo neuroimaging studies beginning in the late 1970s with CT scans (Johnstone et al., 1976; Weinberger et al., 1979a, 1979b) show compelling evidence for structural brain abnormalities in schizophrenia (Bogerts, 1993; Harrison, 1999; McCarley et al., 1999; Ren et al., 2013; Roiz-Santianez et al., 2013; Seidman et al., 2004; Shenton et al., 1997; Thermenos et al., 2013). Despite heterogeneous patient samples, methodologies, and imaging technologies, neuroimaging studies consistently implicate a variety of abnormalities in brain structure. Moreover, meta-analyses (Boos et al., 2007) and reviews comprised primarily of adult relatives indicate that these nonpsychotic and unmedicated siblings, offspring, and parents had elevated rates of brain structural abnormalities (Seidman et al., 2003b; Seidman et al., 2004). Moreover, these findings are consistent with and extend the much older pneumoencephalography and CT studies that demonstrated brain structural abnormalities in schizophrenia (Seidman, 1983).

The effects are generally milder in relatives than in patients, and less widespread than in the patients where the abnormalities had a more diffuse nature. Similar to the case for cognitive abnormalities, neuroimaging abnormalities do not occur in all relatives. Also similar to the case for many psychiatric and neurological disorders and syndromes, there is no one discrete brain region or circuit that is consistently abnormal in schizophrenia. Nevertheless, abnormalities such as ventricular enlargement (especially including the third and lateral ventricles) are among the most robust and extensively replicated findings in any domain of biological research on schizophrenia (Seidman et al., 2003b; Shenton et al., 2001). While structural abnormalities are widespread (Fusar-Poli et al., 2011; Honea et al., 2005; Ren et al., 2013; Thermenos et al., 2013), it is of considerable interest that many brain structures that show abnormalities in schizophrenia include or are related to limbic system structures that are involved in the regulation of emotion and declarative memory, which are often markedly impaired in schizophrenia (Cirillo & Seidman, 2003; Papez, 1937; Stone & Hsi, 2011).

Structural brain abnormalities share other important endophenotypic features with cognition that facilitates the study of critical questions related to the development and expression of schizophrenia, as noted earlier in this chapter. One of these is that like cognition in typically developing individuals and in schizophrenia, brain structure in typically developing individuals (Peper et al., 2007) and in schizophrenia (Boos et al., 2007; Moran et al., 2013) reflects significant genetic influence.

Another similarity is a shared notion of stability, which, as we noted above, is used here to refer to the invariance of the presence of the abnormality, rather than to an invariance of its particular expression. This is important conceptually and clinically because different brain abnormalities may be related to different features of the illness, may develop in different brain regions at different times, and may change in expression over time (Olabi et al., 2011; Seidman et al., 2003b; Vita et al., 2012). These features are thus relevant to the question of which brain abnormalities are necessary or specific for the development of psychosis, which may be addressed, in part, through cross sectional studies of nonpsychotic relatives of patients with schizophrenia (Seidman et al., 2003b, 2004; Thermenos et al., 2013). Related to this point is the question of when structural brain changes develop and under what specifiable environmental conditions? This point also underlies a growing number of recent prodromal studies that seeks to identify changes in brain structure or function in high-risk (HR) subjects that are proximal to the development of psychosis (Borgwardt et al., 2008; Fusar-Poli et al., 2011, 2012). Moreover, recent evidence of continued changes in brain structure following the development of psychosis suggests that brain changes in schizophrenia may be progressive (Olabi et al., 2011; Vita et al., 2012).

One recent trend has been to study younger relatives up to about age 30. This has the advantage of being able to assess whether brain abnormalities are present in childhood, and whether they evolve over time, particularly during the HR period of adolescence, and whether they might be useful for prediction of psychosis. In part this focus has been spurred by the same reasoning that motivates CHR studies of youth, which is the goal of understanding the pathophysiology of psychosis and its prediction. In a recent review, we found that many neuroimaging studies of young relatives reported findings in multiple brain regions (Thermenos et al., 2013). In that paper, we abbreviated the names of the 12 research groups that produced structural MRI data to make them easier to refer to (on p. 609). We will use the same convention here for simplicity. They are named along with the author most often identified with their papers: Canada High Risk Study (Canada HRS; Tibbo/Allen), Edinburgh High Risk Study (Edinburgh HRS; Lawrie/Johnstone), German High Risk Study (German HRS; Schreiber), Harvard Adolescent High Risk Study (Harvard Adolescent HRS; Seidman), Harvard Language and Risk High Risk Study (Harvard Language HRS; DeLisi), India High Risk Study (India HRS; Venkatasubramanian), Iowa High Risk Study (Iowa HRS; Ho), Korea High Risk Study (Korea HRS; Kwon), New York University High Risk Study (NYU HRS; DeLisi), NIMH High Risk Study (NIMH HRS; Gogtay/Rapoport), Pittsburgh/Detroit High Risk Study (Pittsburgh/Detroit HRS; Keshavan), University of North Carolina High Risk Study (UNC HRS; Belger), Turkey High Risk Study (Turkey HRS; Sismanlar), and the Washington University of St. Louis High Risk Study (Washington University HRS; Csernansky). Note that the evolving phases of the NIMH study lead us to incorporate two data sets (first authors were Gogtay/Mattai).

This review demonstrated that most of the studies were cross sectional, with only a few using longitudinal designs. When multiple studies were published by the same group at different time points. Thermenos et al. (2013) emphasized the conclusions from the studies with the larger and later samples. It should be noted that studies vary considerably in their method of MRI analysis, with a diversity of methods and software used for morphometry (e.g., manual vs. automatic segmentation, manual parcellation, voxel-based morphometry [VBM]) and statistical

analysis (e.g., corrections for multiple comparisons across the whole brain vs. regions of interest [ROI], multivariate pattern analyses at the level of single subjects; Zarogianni et al., 2013). Thus, the conclusions drawn may be less robust than those for neuropsychological measures that are standardized and, in essence, simpler to measure.

Brain Morphology (Gray Matter: Volume, Cortical Thickness, and Shape) as Depicted in Cross Sectional Studies

Overall Brain Size

This measure is often unreported in schizophrenia patients and in relatives, yet it could be a good general measure, similar to overall IQ. Smaller overall brain volumes in schizophrenia than matched controls but not in bipolar disorder vs. controls was first reported by Ward et al. (1996) and Hoge et al. (1999). The reductions in schizophrenia were modest, roughly 1–2%. A recent study that assessed patients with either schizophrenia or schizophreniform disorder, showed significant decreases of 1.30% and 1.12% respectively (Crespo-Facorro et al., 2009). A recent meta-analysis also showed smaller whole brain volumes (De Peri et al., 2012), thus it appears that a small but reliable difference exists in patients with schizophrenia. The picture in nonpsychotic relatives is mixed and based on far fewer studies. The Pittsburgh/Detroit HRS (Keshavan et al., 2002b; Rajarethinam et al., 2007) and the NIMH HRS (Gogtay et al., 2003) reported lower intracranial volumes, while the Edinburgh HRS., Turkey HRS., and Harvard Adolescent HRS did not.

Total Cortex

Similar to overall brain size, measures of total cortex are often not the focus of sMRI investigations, mainly for the same reason—the focus has been on identifying specific, abnormal neural circuits. Nevertheless, numerous studies reported reductions in particular regions make clear that cortical reductions occur in schizophrenia (Bora et al., 2011; Crespo-Facorro et al., 2009; Honea et al., 2005; Palaniyappan et al., 2012; Ren et al., 2013). Recently, the Bipolar-Schizophrenia Network on Intermediate Phenotypes (B-SNIP), a large consortium study reported widespread cortical reductions in subjects with either *DSM-IV* (American Psychiatric Association, 1994) schizophrenia or schizoaffective disorder compared with healthy controls, and were also more substantial than those observed in subjects with bipolar I disorder with psychosis (Ivleva et al., 2013). A selective review of papers published between 2001 and 2008 showed reductions in cortical gray matter volumes in all regions of interest except for the caudate nucleus, which often enlarges due to effects of antipsychotic medications (Levitt et al., 2010). The same review concluded that these cortical decreases did not differ between first-episode and chronic samples, indicating that they were largely present at the onset of psychosis rather than mainly occurring secondary to chronicity. Moreover, reductions were particularly prominent in cortical regions (e.g., frontal and temporal lobes) that are related to higher cognitive and to emotional processing.

In addition to reduced cortical volumes, subjects with schizophrenia show widespread cortical thinning compared with controls and to patients with bipolar I disorder (Jung et al., 2011; Rimol et al., 2010). In one study that reported simultaneous analyses of cortical volume, thickness and area, most volume reductions were associated with cortical thinning, with more circumscribed reductions in cortical areas (Rimol et al., 2012).

Compared with healthy control subjects, a prodromal group showed significant cortical thinning as well, though not as extensive as that demonstrated by a schizophrenia sample (Jung et al., 2011). Similarly, a study from the Edinburgh HRS showed multiple areas of cortical thinning in first episode patients, including the superior frontal, medial parietal, and lateral occipital regions, but only showed thinning in the left middle temporal gyrus in the HR group (Sprooten et al., 2013). This HR sample included 17 subjects who later developed schizophrenia. Notably, the observed thinning in the left middle temporal gyrus in these subjects was not predictive of their later conversion to psychosis. In this regard, these HR subjects who later developed psychosis did not differ from HR subjects who did not develop psychosis. However, a separate study of this group over the course of 8 years showed that as they became prodromal and developed increasing symptom severity, they showed additional volume reductions (McIntosh et al., 2011), as reported earlier. Taken together, these findings underscore the point that some volume abnormalities are evident earlier in development than others and are less predictive of clinical outcome, while others develop in closer association to the onset of schizophrenia, and are more closely related to its development.

Other findings with nonpsychotic relatives are mixed. In the B-SNIP study, nonpsychotic relatives of subjects with schizophrenia or schizoaffective disorder did not show total cortex gray matter volume reductions. Similarly, the Pittsburgh/Detroit HRS did not report overall differences in total cortical thickness or surface area (Prasad et al., 2010a). In contrast, the Washington University HRS

(Calabrese et al., 2008) and the NIMH HRS (Gogtay et al., 2003) reported an overall smaller total cerebral volume in HR compared with controls.

Lobes in the Cortex

Prefrontal (PFC). Smaller PFC volumes, thickness or surface areas are well-replicated in schizophrenia, and often show relatively significant cortical volume reductions in superior, middle, or inferior frontal regions (Bora et al., 2011; Honea et al., 2005; Ivleva et al., 2013; Levitt et al., 2010; Ohtani et al., 2013; Palaniyappan et al., 2012; Ren et al., 2013; Xiao et al., 2013). Cortical thinning is also evident in these regions (Jung et al., 2011; Rimol et al., 2010; Schultz et al., 2010), as is other diverse cellular pathology involving both neurons and glia (Goldman-Rakic, 1994; Selemon & Rajkowska, 2003). Nevertheless, the large size of the PFC, coupled with its dense networks of connections and functional and anatomical heterogeneity, also contributes to conflicting sMRI findings. A recent study that used 3T imaging and reliable manual parcellation in an attempt to improve the accuracy of PFC volume measurements confirmed reductions in chronic schizophrenia patients in the left superior frontal, bilateral middle frontal and bilateral inferior frontal gyri (Ohtani et al., 2013).

A recent meta-analysis that included clinical HR (i.e., prodromal) subjects showed reductions in the left medial and the right middle frontal gyrus, and in the right inferior frontal gyrus in subjects who developed psychosis subsequently (Fusar-Poli et al., 2011). Frontal regions were also smaller bilaterally in a recent prodromal sample ($n = 182$) compared with control subjects, and did not show additional changes in a subgroup ($n = 48$) that subsequently developed psychosis (Mechelli et al., 2011). More studies are needed to determine the central changes in the CHR phase of illness.

A study from the Washington University HRS that also used a manual parcellation procedure showed smaller middle and inferior frontal gyri in schizophrenia subjects, but only smaller inferior gyri in the nonpsychotic HR subjects (Harms et al., 2010). This finding thus showed an intermediate level of abnormality in the HR group. Similarly, the Harvard Adolescent HRS reported smaller medial frontal gyri and frontal poles (Rosso et al., 2010), and the NYU HRS showed smaller right inferior frontal gyri in the HR subjects (Li et al., 2012a). The Turkey HRS showed only a nonsignificant reduction in PFC volume, but also reported on a relatively small sample (23 HR and 26 control subjects) and restricted age range (8 to 15 years old) (Sismanlar et al., 2010).

A few HR studies reported language-related cortical abnormalities. The Pittsburgh/Detroit HRS reported a smaller left pars triangularis, a reversal of pars triangularis asymmetry (Bhojraj et al., 2009), and smaller areas in the frontal-parietal lobes (Prasad et al., 2009). The Harvard Language HRS reported a smaller left pars triangularis and right pars orbitalis, and a reversal of orbitalis lateralization (Francis et al., 2012). The NYU HRS study did not find significant changes in the laterality index in language areas in the HR group (Li et al., 2012b).

Multiple HR studies demonstrated differences in cortical thinning from controls, though they varied somewhat in the nature and extent of the abnormalities. Among these, the Korea HRS showed significant thinning bilaterally in the ventromedial PFC and frontal poles (Byun et al., 2012). The NIMH HRS showed significant thinning in the left PFC in the HR group (Gogtay et al., 2007), in a larger follow-up study of an earlier report (Gogtay et al., 2003). An independent study from the same group using the same procedures as they did in their 2007 study showed bilateral PFC (and left temporal) thinning in a sample of HR subjects who were 5 to 26 years old (Mattai et al., 2011b). It should be noted that brain abnormalities in subjects in this sample, however, normalized with age, with few abnormalities remaining by the age of 17. In this context, a recent report from the Edinburgh HRS that showed superior gyrus frontal lobe thinning in first-episode subjects with schizophrenia showed thinning only in the left middle temporal gyrus in the HR group (Sprooten et al., 2013). Other studies that have shown widespread decreases in cortical thickness in schizophrenia patients in frontal and temporal cortices have not found any significant differences from controls in nonpsychotic relatives (Borgwardt et al., 2008; Goldman et al., 2009). While the great majority of studies showing abnormalities in cortical area or thickness report thinning in schizophrenia, one HRS (NYU) showed increased cortical thickness and cortical areas in the HR group (Li et al., 2012a).

These studies of PFC abnormalities in cortical volumes or cortical thinning thus show a range of relationships between subjects with schizophrenia and relatives, including milder or more restricted PFC abnormalities in relatives (Harms et al., 2010), different abnormalities in nonpsychotic relatives compared with schizophrenia patients (Sprooten et al., 2013) and a lack of abnormalities in relatives compared with patients, at least at certain developmental stages (Mattai et al., 2011b). These similarities in patterns show support for alterations in brain regions as endophenotypes, but the differences between patients and relatives are consistent with patterns reported

in other brain regions (Xiao et al., 2013), and with the view that brain abnormalities in schizophrenia subjects at least partly reflect the expression of illness rather than only the liability to develop it (Goldman et al., 2009). Nevertheless, PFC reductions in clinical HR subjects who are not yet psychotic (Fusar-Poli et al., 2011; Mechelli et al., 2011) highlight a need to integrate findings among different types of HR subjects.

Temporal Cortex. Structural abnormalities in temporal cortex are well established in schizophrenia (Bogerts, 1993; McCarley et al., 1999; Seidman et al., 2003b; Shenton et al., 2001). Similar to findings obtained in studies of PFC, they are also frequently prominent (Bora et al., 2011; Honea et al., 2005; Ivleva et al., 2013; Levitt et al., 2010; Palaniyappan et al., 2012) and conceptualized as key areas in the etiology of schizophrenia (Bogerts, 1993, 1997; Crow, 1990). Earlier reports of abnormalities focused on the superior temporal gyrus (McCarley et al., 1999; Shenton et al., 2001), but now include the middle and inferior temporal gyri as well (Hu et al., 2013; Kuroki et al., 2006; Tang et al., 2012; Xiao et al., 2013). Cortical thinning is also evident in these regions (Jung et al., 2011; Ratnanather et al., 2013; Rimol et al., 2010; Schultz et al., 2010), including in the planum temporale (Ratnanather et al., 2013), and also abnormal lateralization (Hu et al., 2013; Ratnanather et al., 2013).

In a recent study that examined both first-episode subjects with schizophrenia and their unaffected siblings (Hu et al., 2013), the schizophrenia subjects showed bilaterally lower volumes in the middle and superior temporal gyri. The unaffected siblings showed a subset of these abnormalities, with smaller volumes in the left middle temporal gyrus. The Pittsburgh/Detroit HRS reported bilaterally smaller superior temporal gyri in nonpsychotic relatives (Rajarethinam et al., 2004), that were not observed in the Harvard Language HRS (Francis et al., 2012). In a subsequent larger study, the Pittsburgh/Detroit HRS showed a smaller right Heschl's gyrus, and increased Heschl's gyrus L>R asymmetry in the HR group (Bhojraj et al., 2009). Subsequent studies also showed bilaterally smaller temporal cortices in a study of default mode processing (Bhojraj et al., 2010b), and smaller, thinner superior temporal gyri (in auditory association cortex), especially in males (Bhojraj et al., 2011).

The Korea HRS and the NIMH HRS both demonstrated bilateral temporal lobe cortical thinning in the HR groups (Byun et al., 2012; Gogtay et al., 2007). A subsequent NIMH study showed reduced cortical thickness in the left temporal lobe in HR (Mattai et al., 2011b), replicating their earlier study (Gogtay et al., 2007). The Turkey HRS study reported a nonsignificant reduction in whole temporal lobe volume (Sismanlar et al., 2010), while the NYU HRS study found increased cortical thickness in the right superior temporal gyrus (Li et al., 2012a).

Fusar-Poli et al. reported reduced volumes in the superior temporal gyrus in their meta-analysis that remained significant following the development of psychosis in a subgroup of subjects (Fusar-Poli et al., 2011). A recent study of preprodromal children aged 9 to 12 years old who showed multiple antecedents of schizophrenia (including psychotic-like experiences in some of the children) reported decreased volumes in the right middle temporal gyrus and increased volumes in the left superior-middle temporal gyri (Cullen et al., 2013). These temporal lobe abnormalities were evident whether or not the children endorsed symptoms of psychosis.

Parietal Cortex. Volume reductions in parietal cortices are reported in schizophrenia frequently (Borgwardt et al., 2008; Honea et al., 2005; Ivleva et al., 2013; Levitt et al., 2010; Olabi et al., 2011; Palaniyappan & Liddle, 2012; Sprooten et al., 2013; Yildiz et al., 2011), though abnormalities do not appear as prominent as those in frontal or temporal lobes (Honea et al., 2005; Ivleva et al., 2013). Nevertheless, similar types of neuropathology in parietal cortex, such as cortical thinning, occur in schizophrenia (Palaniyappan & Liddle, 2012; Rimol et al., 2010) and in prodromal subjects (Jung et al., 2011). Moreover the supramarginal gyrus, which is one of two subregions of the inferior parietal lobule, showed morphometric abnormalities compared with controls that were not evident in the angular gyrus, which is the other subregion. The abnormalities included reduced gyrification (especially in the left hemisphere) and cortical thinning (Palaniyappan & Liddle, 2012). Both subregions showed reduced volumes. Evidence of parietal volume reductions in early onset schizophrenia and significant correlations between right superior parietal volume and age of illness onset (Burke et al., 2008) contribute to the view that some forms of schizophrenia may start in the parietal lobe and then progress to the temporal and frontal lobes (Yildiz et al., 2011).

HR studies have also implicated the parietal lobes. Among these, in the Pittsburgh/Detroit HRS, HR subjects had smaller right supramarginal and angular gyri than controls (Bhojraj et al., 2009). They also showed attenuation of supramarginal and angular gyrus asymmetries, (Bhojraj et al., 2009), and increases in curvature and parietal cortical thinning (Prasad et al., 2010a). The NIMH HRS also reported parietal volume reductions

(Gogtay et al., 2003, 2007). A second, independent NIMH HRS also reported parietal cortical thinning although these findings lost statistical significance as the subjects reached adolescence (Mattai et al., 2011b). The NYU HRS study was the only study to reveal statistically larger cortical thickness in HR, in the right angular gyrus (Li et al., 2012a). Abnormalities in the supramarginal and the angular gyri were not obtained in the Harvard Language HRS (Francis et al., 2012).

Occipital Cortex. Lowered occipital cortical volumes have been shown in schizophrenia (Ivleva et al., 2013), as has cortical thinning (Rimol et al., 2010). Moreover, a recent multivariate study of gray matter abnormalities in schizophrenia identified one of two components as including the posterior occipital lobe (Turner et al., 2012).

The Korea HRS reported cortical thinning in the occipital cortex (Byun et al., 2012). In contrast, the NYU HRS study reported increased occipital cortical thickness in HR (Li et al., 2012a). Occipital differences in cortical volume, surface area, or thickness were not observed in the Pittsburgh/Detroit, Edinburgh, NIMH, Iowa, or Harvard Adolescent HRS.

Ventricles

Ventricular enlargement is prominent in schizophrenia, as demonstrated by several meta-analyses (Arnone et al., 2009; De Peri et al., 2012; Sayo et al., 2012; Wright et al., 2000) and many previous CT and pneumoencephalographic studies (Johnstone et al., 1976; Weinberger et al., 1979a, 1981). One recent meta-analysis included 72 MRI studies (Sayo et al., 2012) that showed a significantly increased ventricular brain ratio with a mean effect size of 0.65. Another recent study that evaluated brain abnormalities in first-episode schizophrenia and bipolar disorder showed lateral ventricular enlargement in 45 studies compared with controls (De Peri et al., 2012).

Somewhat in contrast, effects in nonpsychotic relatives are mixed. The Pittsburgh/Detroit HRS reported an enlarged third ventricle (Keshavan et al., 1997a), as did the Edinburgh HRS (Lawrie et al., 2001). However, neither the Edinburgh nor the NYU HRS (DeLisi et al., 2006) showed significant differences from controls in lateral ventricular volumes. In general, similarities and differences in brain volumes between patients and relatives at least partially reflect the influence of psychosis (Palaniyappan et al., 2012).

Cingulate Cortex

Anterior. Several studies show abnormalities in the anterior cingulate cortex (ACC). A meta-analysis of seven MRI studies showed significantly reduced volumes in patients with schizophrenia, compared with healthy control subjects (Baiano et al., 2007). A meta-regression analysis in the same study showed that reductions in volume were related to slice thickness but not to age or gender. Another meta-analysis using 31 studies also showed significantly reduced volumes in the ACC compared with healthy control subjects (Glahn et al., 2008). Bora et al. showed reduced volumes in the ACC that were related particularly to chronicity, negative symptoms and male sex (Bora et al., 2011). By contrast, Calabrese et al. did not find volume reductions in the ACC (Calabrese et al., 2008). Another study that did find volume reductions, however, also showed that greater duration of illness and severity of positive symptoms correlated significantly with reduced ACC volumes, but not with posterior cingulate volumes (Wang et al., 2007).

Findings from family HR studies are mixed. Smaller ACC density reductions in nonpsychotic relatives were reported by the Edinburgh HRS (Job et al., 2003) using VBM, but not more recently when the same group used a more surface-based analysis (FreeSurfer) (Sprooten et al., 2013). The Pittsburgh/Detroit HRS (Diwadkar et al., 2006) reported reduced ACC volumes, although the subjects had schizotypal features that may have made them more like a prodromal group. Cortical thinning was reported by the Korea HRS in the right anterior cingulate and the left paracingulate cortices (Byun et al., 2012). As noted already for schizophrenia patients, the Washington University HRS did not find significant differences in volume, surface area, or thickness (Calabrese et al., 2008).

A recent study of 14 prodromal subjects, 34 first-episode subjects, and 51 healthy controls showed significant gray matter reductions in the left ACC in the first-episode subjects compared with the healthy controls (Nakamura et al., 2013). The prodromal group did not differ significantly from either of the other groups, however. These findings may reflect the small sample size to some extent or the method of ascertainment, as several (though not all) HR studies also reported volume reductions. Results from another study of prodromal subjects showed reduced cortical thickness in the ACC (and other regions) compared with healthy controls (Jung et al., 2011). They showed less severe reductions in thickness, which were also less widespread, than those observed in patients with schizophrenia.

Posterior. Jung et al. (2011) showed reductions in cortical thickness in the posterior cingulate. The Washington University HRS reported reductions in the posterior cingulate

in schizophrenia patients (Calabrese et al., 2008), but the significance of the finding was related to whole cerebral volume reductions, and was lost when cerebral volume was utilized as a covariate. In a larger study by the same group (Wang et al., 2007), significant reductions in posterior (and anterior) cingulate volumes remained after effects of whole cerebral volumes were accounted for.

The Washington HRS reported decreased volumes in the posterior cingulate in nonpsychotic siblings that were of similar magnitudes to the reductions they reported for patients with schizophrenia (Calabrese et al., 2008), but which also reflected the effects of cerebral volume, as noted. The Korea HRS reported significant cortical thinning in the left posterior cingulate (Byun et al., 2012).

Hippocampus

As described previously, medial temporal lobe abnormalities occur frequently in schizophrenia (Glahn et al., 2008; Honea et al., 2005, 2008; Ivleva et al., 2013; Nelson et al., 1998; Seidman et al., 2003b; Stone & Seidman, 2008; Wright et al., 2000), which often include the hippocampus. One of the relatively few studies that did not show reduced hippocampal volumes in patients attributed their findings to methodological limitations (Honea et al., 2008), as the same group showed hippocampal volume decreases in another analysis that utilized subcortical segmentation (Goldman et al., 2008). More recently, a study that compared manual tracing methods with a semiautomated parcellation method (FreeSurfer) in schizophrenia and schizoaffective subjects showed bilateral reductions in hippocampal volumes using both methods (Arnold et al., 2014). Another recent study that also showed bilateral reductions in hippocampal volumes demonstrated further that smaller volumes were related to poorer cognitive performance after controlling for age, gender, education, and Positive and Negative Syndrome Scale (PANSS) scores (Guo et al., 2014). Notably, a longitudinal study of child-onset schizophrenia showed stable reductions of hippocampal volume between the ages of 10 and 29 compared with control subjects, while the trajectories of the volumes did not change (Mattai et al., 2011a).

Numerous studies show smaller hippocampal volumes in nonpsychotic relatives of patients with schizophrenia (Boos et al., 2007; Moran et al., 2013), though not all show it (Boos et al., 2012; Honea et al., 2008). Several early HR studies that assessed the amygdala-hippocampal complex prior to the development of segmentation procedures that could differentiate the hippocampus and amygdala, showed smaller volumes in HR youth (Keshavan et al., 1997b, 2002a; Lawrie et al., 1999; Schreiber et al., 1999). Similarly, recent studies also showed bilaterally smaller hippocampal volumes (Ho & Magnotta, 2010; Sismanlar et al., 2010), and shape differences (Ho & Magnotta, 2010). In contrast, the UNC HRS reported smaller hippocampal volumes but the findings did not remain significant when they were corrected for brain volume (Dougherty et al., 2012). Moreover, the NIMH study that reported stable volume reductions in childhood-onset schizophrenia did not show differences between nonpsychotic siblings and controls (Mattai et al., 2011a).

Summary of Representative Cross Sectional Studies

At the broadest level, we can conclude that brain structure is an endophenotype for schizophrenia. Structural deficits are associated with schizophrenia, are state independent, and are generally more prevalent among the relatives than in healthy controls. Many structures have been found to be abnormal but the consistency of findings and the relatively small number of studies suggests to us that currently the most robust findings are for PFC and hippocampus across patients and relatives. Although there are fewer studies, a growing literature highlights the importance of cortical thinning in both patients and relatives.

Longitudinal Studies

There is substantial evidence of longitudinal brain structure alterations in schizophrenia, usually demonstrated from the first episode of psychosis onward throughout the first 5 years of illness (Asami et al., 2012; Hulshoff Pol & Kahn, 2008; Olabi et al., 2011; Vita et al., 2012). It is now also apparent that the structural alterations become progressively more pronounced over time even earlier, in the prodromal, CHR period, thus beginning before the first episode of psychosis has been initiated. Comparisons of structural brain alterations in CHR compared with controls have shown progressive loss of gray matter in orbital PFC (Borgwardt et al., 2008; Pantelis et al., 2003), superior temporal cortex (Borgwardt et al., 2008; Takahashi et al., 2009), ACC, parahippocampus, fusiform cortex (Pantelis et al., 2003), and insula (Takahashi et al., 2009). Moreover, structural changes in CHR who convert to psychosis compared with those who do not demonstrate evidence for significantly greater reductions over time in PFC (Dazzan et al., 2012) and temporal cortex (Takahashi et al., 2009).

The literature is more limited and a bit mixed in the family HR studies that evaluated change in brain structure over time. Three studies have carried out longitudinal analyses: the Edinburgh, Pittsburgh/Detroit and the NIMH HRS. The Edinburgh HRS is the one completed study that has a large enough sample size followed

longitudinally, including a relatively large sample of HR who later developed schizophrenia, to begin to hypothesize a pattern (McIntosh et al., 2011). The HR group when taken together showed significant reductions over time compared with controls in whole brain volume, left and right temporal lobe, and left frontal lobe volume. Over time, the left and right PFC showed significant reduction in those who developed schizophrenia, and this tissue loss was significantly greater than in the other HR groups who did not go on to develop schizophrenia. These data, as well as the aforementioned observation that PFC volume is smaller at the baseline assessment, indicates that it is a risk factor for schizophrenia, and is a central focus of brain changes as the illness develops.

In the Pittsburgh/Detroit HRS, while longitudinal one year follow-up scans of HR showed reductions in surface area in the total cortex, bilateral inferior frontal cortex and occipital cortex (Prasad et al., 2010b), the small number of individuals who transitioned to psychosis thus far is too small to draw any conclusions. In the NIMH study headed by Gogtay and Rapoport, a number of baseline differences were observed, consistent with other studies (i.e., smaller cortex including PFC, temporal and parietal cortices in two independent samples (Gogtay et al., 2007; Mattai et al., 2011b). However, there were trajectory differences compared with the other studies, in that most differences between controls and HR siblings normalized by ages 17–20, and no differences between groups remained significant at the last assessment point in both samples. The differences across these three studies highlight sampling differences in their designs. For example, the Edinburgh HRS sampled teenagers from families with at least two ill cases, the Pittsburgh/Detroit HRS sampled offspring, and the NIMH study sampled well siblings of cases of childhood schizophrenia.

The longitudinal studies highlight the challenge of using imaging measures as endophenotypes, especially based on data from HR studies. Nevertheless, perhaps the most robust measures to date are PFC volume or thickness, followed by hippocampal volume, and it is likely that this active area of research will yield more findings in the coming years.

Heritability of and Susceptibility Genes in Neuropsychological and Structural Brain Traits

Heritability in Brain Abnormalities

Our review confirms the familial nature of abnormalities in brain volumes in schizophrenia families. While not all abnormalities in relatives are identical to those in patients, owing to effects of psychosis (Palaniyappan et al., 2012), stage of development, environmental factors and gender, among other factors (Geoffroy et al., 2013; Kaymaz & van Os, 2009), volume abnormalities in specific brain regions in patients with schizophrenia are accompanied frequently by reductions in the same regions in their biological relatives. Moreover, similar to the case for cognitive abilities in healthy individuals (Bouchard, 1998; Finkel et al., 1995a, 1995b; Papassotiropoulos & de Quervain, 2011), brain volumes in healthy individuals are heritable (Kaymaz & van Os, 2009; Peper et al., 2007). This discussion focuses somewhat more on heritability of brain abnormalities than on heritability of cognitive functions, which were reviewed above in relation to a more discrete number of cognitive domains. Representative heritabilities in schizophrenia are shown in Table 24.3. As with the representative heritabilities for selected cognitive domains listed in Table 24.2, heritabilities for selected brain regions are listed in Table 24.3. Studies listed in the table were published in the last 20 years, and focused on twins or families with schizophrenia. PubMed search terms again included schizophrenia and heritability, and brain volume, and MRI.

Similar brain abnormalities in nonpsychotic relatives provide evidence for co-segregation of the abnormalities in schizophrenia families (Seidman et al., 2002). From an endophenotype perspective, however, it is also important to demonstrate that abnormalities are related to the risk for schizophrenia (i.e., they share genetic variance with the disorder and show a genetic, also called a phenotypic, correlation). Family and especially twin studies have been particularly useful in this regard, both in assessing heritability (and in estimating the extent of shared and unique environmental factors), and in showing the extent to which they are related to overlapping genetic effects. Representative family and twin studies show that group differences in brain volume are often, though not always, associated with evidence for heritability. Family studies include Honea et al. (2008), for example, who showed gray matter volume reductions in schizophrenia patients in temporal, frontal and parietal cortices but did not show significant genetic correlations (using intraclass correlations, ICC) between patients and siblings in left medial frontal gyrus, left superior temporal gyrus, and left insula. Patients and their siblings did show significant ICCs (and heritability) for hippocampal volumes, however, which did not show group differences between patients and either controls or siblings. Goldman et al. (2008) also used a family design and showed widespread subcortical and cortical reductions or increases in patients, including the hippocampus. Although nonpsychotic relatives did not show significant volume differences compared with controls for any region, strong

TABLE 24.3 Heritabilities of Selected Brain Regions in Healthy Subjects and in Subjects with Schizophrenia[1]

[1]Refers to heritable influence on volume loss in a 5-year longitudinal design.

evidence for genetic influence on volume reductions was obtained for the cortex and the hippocampus, as measured by ICCs and Risch's lambda. Turner et al. (2012) analyzed two separate datasets with patients and controls, one of which also included nonpsychotic siblings. Evidence for schizophrenia-related genetic influence was obtained for volumetric abnormalities in medial and inferior frontal lobe, temporal lobe, and posterior occipital lobe.

Several twin studies also show evidence of heritability in brain volume abnormalities, which is related to schizophrenia. Consistent with other family study findings, twin pairs who are discordant for schizophrenia often show greater volume abnormalities in the affected member of the pair (Rijsdijk et al., 2005). In one study that compared monozygotic and dizygotic twin pairs who were discordant for schizophrenia (or for bipolar disorder) with healthy control twin pairs, significant genetic correlations were obtained between schizophrenia and thinner parahippocampus, thinner right orbitofrontal cortex, thicker right parietal cortex, thicker temporoparietal cortex, and thicker superior motor cortex (Hulshoff Pol et al., 2012). Notably, greater environmental liability was associated with thinner right medial occipital cortex. The same group followed brain volume changes in monozygotic and dizygotic twins who were discordant for schizophrenia, in comparison to healthy controls, for 5 years (Brans et al., 2008). In that period, significant decreases in volume occurred in whole brain and in the frontal and temporal lobes in patients and in their nonpsychotic twins. Significant genetic correlations between liability for schizophrenia and changes in brain volume reflected significant genetic effects on these correlations, as shown by heritabilities of 66% for whole brain, 76% for frontal lobe, and 79% for temporal lobe.

Van Haren et al. (2012) reported findings from the largest twin study to date to relate brain volumes in schizophrenia to their relative genetic and environmental contributions. This study included 684 subjects, including concordant and discordant monozygotic and dizygotic twin pairs, and control twins. Data were collected at five sites by the Schizophrenia Twins and Relatives (STAR) consortium. The results showed smaller volumes for several brain regions in subjects with schizophrenia, and also smaller white matter and a larger third ventricle. Significant heritabilities were obtained for most of the brain volumes assessed. In one instance, 77% of the smaller cerebral volume in schizophrenia subjects was attributable to genetic factors that contributed to both the smaller volume and to the liability for developing schizophrenia. Similarly, 94% of the reduction in cerebral white matter was attributable to genetic factors, and 83% of the enlargement of the third ventricle was attributable to genetic factors. It is important to note, however, that these large heritabilities do not mean, for example, that 77% of the variability in cerebral volume is accounted for by genetic factors that increase liability for schizophrenia. The actual correlation between schizophrenia and volume size was −.22, which explains 4.8% of the total variance in cerebral volume. This is still a significant portion of the variance, and one

that highlights the importance of genetic factors in the neurodevelopmental factors underlying brain development and function.

Heritabilities for brain abnormalities are often comparable to heritabilities for cognitive functions, though both vary considerably depending on the particular brain region or cognitive function. The study by Husted et al. (2009), for example, assessed heritability for 13 cognitive measures in a multiplex family design and found intelligence (IQ) to have the highest value (64–74%). Heritabilities of the other measures ranged from 31 to 62%. In another example, Toulopoulou et al. (2007) used a twin design to assess heritabilities of intelligence, working memory, processing speed, perceptual organization, and verbal comprehension (Toulopoulou et al., 2007). Significant genetic influences affected all cognitive domains, but shared genetic variance accounted for 92% of the covariance between liability to schizophrenia, and intelligence. In the COGS heritability study described earlier (Greenwood et al., 2007), all cognitive measures proposed as endophenotypes showed significant heritabilities that ranged from 25% (California Verbal Learning Test–Second Edition) to 55% (Spatial Processing, from the Penn Battery).

Schizophrenia Susceptibility Genes

The demonstration that at least some disease-related changes in cognition and in brain structure are influenced by common genetic processes is a step closer to understanding both the genetic etiology of schizophrenia, and the biological trajectories involved that create the liability. In parallel with attempts to identify possible endophenotypes that are associated with the illness, appear in nonpsychotic relatives, show stability and are heritable are attempts to identify their underlying genetic architecture. This includes the identification of chromosomal regions that may harbor individual genes, and attempts to identify candidate genes themselves.

Models of the genetic transmission of schizophrenia have long emphasized the importance of additive genetic effects of genes that individually exert small or moderate effects (Faraone & Tsuang, 1985; Gottesman & Shields, 1967; Tsuang et al., 1999a). These small effects contributed to the difficulties in the late 1980s and early 1990s in replicating findings in genetic linkage studies (Tsuang et al., 1999a). The situation improved somewhat with the development of large and often international collaborative studies to increase sample size and statistical power, which, in turn, increased positive findings and replications of those findings (Baron, 2001). The search for susceptibility genes still remained mired, however, by a variety of factors such as continued difficulties in finding pleiotropic genes of small effect, polygenic inheritance, environmental factors, and heterogeneity, among others. The increasing utilization of putative endophenotypes and the decreasing reliance on clinical symptoms alone improved the situation further by identifying potential biological substrates that underlie schizophrenia. These developments influenced a movement toward studies to identify or test candidate genes, including genome-wide association studies (GWAS), which are useful in detecting associations to common alleles (Greenwood et al., 2013).

Several recent studies reported associations of single nucleotide polymorphisms (SNPs) with measures of cognition. Simons et al. (2013) studied 152 SNPs in 43 candidate genes in patients with schizophrenia and healthy comparison subjects. The patients showed 13 significant associations between the SNPs and cognitive functions assessed with a battery of tests, which were located in DRD1, DRD3, SLC6A3, BDNF, FGF2, SLC18A2, FKBP5, and DNMT3B. Greenwood et al. (2013) reported a genome-wide linkage analysis that included 10 cognitive endophenotypes (including an antisaccade task, which has a cognitive component) that they already showed to be heritable (Greenwood et al., 2007). One region showed genome-wide significance (antisaccade task) on chromosome 3p14, and another region almost showed genome-wide significance on 1p36 (Emotion Recognition from the Penn battery). Nine other regions showed suggestive linkage. In a separate study, Greenwood et al. related these endophenotypes to 94 functionally relevant candidate genes for schizophrenia and found that 38 of them were associated with at least one endophenotype to schizophrenia (Greenwood et al., 2012). Moreover, 11 genes showed evidence of pleiotropy, with associations to three or more endophenotypes (including ERBB4 and NRG1).

Walters et al. (2013) used six SNPs to represent significant genome-wide loci obtained from three GWAS using patients with schizophrenia and healthy controls. Five of the six loci were not associated with any cognitive measures. One of them, however, rs6904071, was associated with both delayed episodic memory and with decreased hippocampal volume. Similarly, Bakken et al. (2011) showed that two SNPs on the Prader-Willi and Angelman syndrome region of chromosome 15q12 (i.e., rs4906844 and rs11633924) showed a genome-wide association with both cognition and cortical thickness in schizophrenia. These findings underscore the point that many genes associated with impaired cognition may also be associated with abnormal brain structure. Consistent with this observation, a recent

review of candidate genes for abnormal brain structure in schizophrenia, (for example Kaymaz & van Os, 2009) included additional candidates genes/alleles for which this may be the case, including COMT Val58Met (Egan et al., 2001), DISC1 (Nicodemus et al., 2014), and BDNF (Simons et al., 2013).

One recent study compared nine putative susceptibility genes for schizophrenia that have been the subject of neuroimaging studies (all kinds, not just structural) and of cognitive investigations (Rose & Donohoe, 2013). A meta-analysis was performed to compare the effects of study methodology on effect size. The results demonstrated greater percentages of cognitive findings with small or medium effect sizes, and greater percentages of imaging studies with medium or large effect sizes. As a group, these genes thus show greater effects on brain structure or function than they do on cognition, though these findings do not apply to individual genes, cognitive functions, and brain regions or brain functions. As important, however, is the point that these genes appear to exert pleiotropic effects and may contribute to the genetic effects in heritability studies.

Nonpsychotic relatives also show many of the same relationships as patients. The Iowa HRS showed, for example, that NRG1 SNPs were associated with total cerebral gray matter volumes (Ho et al., 2008). The NIMH HRS also related a NRG1 risk allele (420M9–1395) to changes in total gray and white matter volumes (Addington et al., 2007), and related COMT Val158Met to cortical thinning (Raznahan et al., 2011). The Edinburgh HRS reported that COMT Val158Met was related to bilateral reductions in anterior cingulate gray matter density (McIntosh et al., 2007). Simons et al. (2013) showed that one of the SNPs associated with cognition in schizophrenia patients was also associated with their nonpsychotic siblings.

CURRENT AND FUTURE DIRECTIONS

This foray into even a limited number of schizophrenia related neuropsychological and structural neuroimaging endophenotypes yielded an almost overwhelming number of studies. This attests to the degree to which this construct has gained high levels of interest in schizophrenia, and in psychiatry in general. Moreover, the endophenotype concept is a foundation of the NIMH RDoC initiative, which underscores its growing importance as a window into psychopathology research (Casey et al., 2014; Cuthbert & Insel, 2010).

We present the schizophrenia endophenotype story as an exemplar of endophenotypes in psychiatry and hope that the readers will delve into other disorders based on this work. At this point, extensive investigations of neuropsychological deficits and structural brain abnormalities provide compelling evidence that specific measures in both domains meet proposed criteria for classification as endophenotypes for schizophrenia. Taking Gottesman's proposed criteria for endophenotypes as a starting point (Gottesman & Gould, 2003), multiple deficits in each broad domain have been associated with schizophrenia. Strong associations with schizophrenia were evident within these domains as well, in neuropsychological subdomains such as attention/working memory, declarative memory, executive functions, and intelligence. Similarly, abnormalities in a variety of brain regions were associated with the illness, such as whole brain and each lobe of the brain, but particularly in the frontal and temporal lobes. Moreover, structural abnormalities were evident cortically and subcortically (i.e., hippocampus).

Both neuropsychological measures and abnormal volumes in brain regions occur frequently in relatives, though they are often milder, and some that are more related to psychosis than to the underlying liability to schizophrenia may not be present in relatives. In both domains, the deficits that are associated with schizophrenia persist through all stages of the illness, though their expression may vary at different stages, or as a result of treatment or other environmental or epigenetic factors. Moreover, neuropsychological functions and brain structures are under significant genetic control in healthy individuals, and in schizophrenia. An extensive literature shows significant heritability for many neuropsychological deficits, and for many brain volumes. Increasingly, linkage and association studies, as well as other genetic strategies aimed at identifying susceptibility genes, such as gene expression (Glatt et al., 2011) and copy number variation (Addington & Rapoport, 2012) studies, show that genetic correlations between schizophrenia and expressions of these endophenotypes often reflect significant genetic influence. Consequently, these strategies have implicated individual genes to an extent that would have seemed unlikely as recently as a decade ago. With this foundation, we may look forward to the continued identification of genes and genetic mechanisms that underlie the liability to schizophrenia.

More specifically, the fulfillment of Gottesman's proposed criteria for neuropsychological and brain structure endophenotypes helps to validate the endophenotype concept in identifying disease-related abnormalities that may provide clues to the identification of underlying pleiotropic genes that contribute to both the observed endophenotype

and to the liability for schizophrenia. It is significant that many genetic studies linked neuropsychological and structural neuroimaging endophenotypes to each other, as well as to schizophrenia. These relationships may have been even more salient had we not limited this review to structural brain endophenotypes assessed through MRIs, but their relationships with each other were robust nevertheless. The relationships observed between the neuropsychological measures and structural neuroimaging variables raise the important question of how to utilize and conceptualize multiple endophenotypes.

The question may be considered in at least two broad dimensions. One of these is clinical. Do some relationships between endophenotypes have greater clinical significance than others, for example, in assessing liability to schizophrenia? We proposed preliminary steps toward a provisional liability syndrome in nonpsychotic relatives of schizophrenia subjects using neuropsychological measures and negative symptoms (Faraone et al., 2001; Tsuang et al., 1999b) and showed preliminary evidence of validation for the concept (Stone et al., 2001, 2012). Consistent with the view that endophenotypes could help define and characterize a significant portion of the schizophrenia spectrum (Figure 24.2), we hypothesized that a combination of genetic liability and the biological consequences of early adverse environmental factors (e.g., preeclampsia or other pregnancy or delivery complications) could create a liability syndrome for schizophrenia (schizotaxia). This syndrome, which was adapted from a concept proposed by Paul Meehl (Faraone et al., 2001; Meehl, 1962; Stone & Giuliano, 2013), in interactions with later environmental factors (e.g., stress, substance use), could result in a range of outcomes (depicted by Thermenos et al., 2013; Figure 24.4), including stable schizotaxia, schizophrenia spectrum disorder, the development of a prodromal high risk phase, and a conversion to psychosis/schizophrenia (Thermenos et al., 2013). Investigations such as these are promising; however, such syndromes will likely remain in the early stages of development, at least until strategies can be developed to select the most useful endophenotypes to include in them, and the most useful syndromes, themselves. Nevertheless, the field will need to continue to develop them if we are ever to identify the individuals most at risk for developing schizophrenia.

The second way to conceptualize the importance of multiple endophenotypes is related to their utility in leading to the clearest genetic etiologies in areas of interest. This pathway, in turn, may then lead to the identification of biological mechanisms of action influenced by the genes involved. Despite the recent progress in the field,

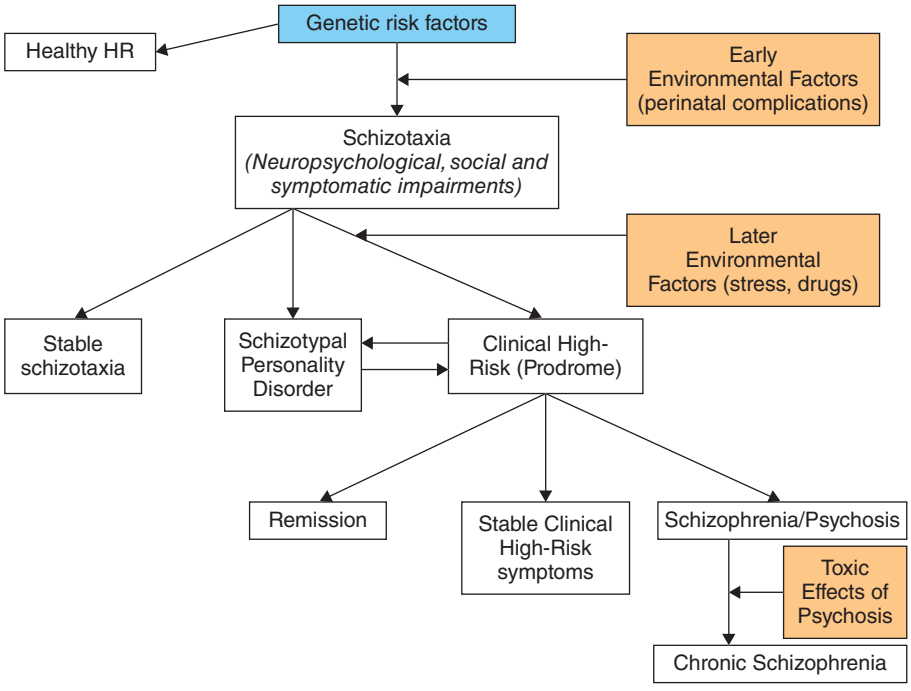

Figure 24.4 Developmental pathway of familial high risk for schizophrenia: Schizotaxia represents the syndrome associated with genetic risk. See footnote 1. *Source:* H. W. Thermenos, M. S. Keshavan, R. J. Juelich, E. Molokotos, S. Whitfield-Gabrieli, et al., A review of neuroimaging studies of young relatives of individuals with schizophrenia: A developmental perspective from schizotaxia to schizophrenia. *American Journal of Medical Geneicst B: Neuropsychiatric Genetics,* pp. 605, *162*, 2013. Used with permission.

the process of identifying valid endophenotypes among hundreds or thousands of candidates in the field, and then locating and testing candidate genes, is a slow and arduous one. Multiple factors contribute to this state-of-the-field, including the strong likelihood that most genes contribute small effect sizes that are difficult to detect. This point is magnified by the added complexity of detecting variants of genes, some of which are rare, that are actually etiological. Polygenic, epigenetic, gender, developmental, and environmental modulation of gene effects may increase complexity further.

We are, however, making progress. The recognition that many putative endophenotypes are heritable has allowed a database of these effects to emerge at the beginning of the twenty-first century. For example, in one of the largest and best known studies in identifying the genomic substrates of endophenotypes in schizophrenia, COGS investigators and their collaborators have identified common variant substrates from candidate gene (Greenwood et al., 2011) and linkage studies (Greenwood et al., 2013). Additional work has led to the detection of highly penetrant de novo events (Gulsuner et al., 2013) associated with schizophrenia endophenotypes. The identification of new biological anomalies (for example, through copy number variants and gene expression studies) has opened up new genetic fronts that likely will have relevance to the etiology of some endophenotypes. Unraveling the genomic and neurobiological substrates of schizophrenia will certainly be a time-consuming, but ultimately fruitful, task (Braff & Braff, 2013).

TRANSLATIONAL IMPLICATIONS

One of the first applications of endophenotype research in psychiatry was to identify disease-related abnormalities that could advance genetic research into complex disorders (such as schizophrenia) beyond the limits that were permitted by clinical diagnoses (Gottesman & Gould, 2003). In addition to the conceptual advances this perspective afforded, as discussed earlier in this chapter, the endophenotype perspective contributed to at least two other important developments.

One of these is the NIMH RDoC initiative, which is attempting to develop a classification system for psychopathology that is based on dimensions of behavior and its underlying neurobiology rather than on the formal clinical symptoms that are often more distal and less specific products of those processes (Casey et al., 2014; Cuthbert & Insel, 2010). The utilization of that strategy emphasizes a dimensional rather than a categorical or diagnostic approach that facilitates the study of how behaviors, neurobiological systems, and gene regulation change with time and in interaction with other biological and environmental events to facilitate or inhibit different outcomes (Casey et al., 2014). This perspective, which is multidisciplinary in nature, broadens the type of inquiries that may be posed through laboratory research, and encourages translational research, which is a second recent development related to endophenotype research. One of the goals of this approach is to identify and utilize laboratory-based discoveries in human clinical trials and other related studies (Rubio et al., 2010).

In looking to the future, whether the immediate focus is more clinical or more genetic, it will thus be essential to develop translational strategies to maximize the efficient use of endophenotypes. This is particularly true of many neuropsychological and structural neuroimaging endophenotypes, which are themselves complex etiologically (e.g., declarative memory, whole brain volumes). It is likely that one strategy will not fit all purposes. Conceptual considerations about the nature of liability to schizophrenia guided our initial attempts to define a liability syndrome, for example, as described above, but more objective, empirical strategies may be necessary to validate the syndrome and to increase its power. If it is true that endophenotypes show simpler genetic etiologies and more direct pathways to underlying gene identification, then one strategy may be to identify and use simpler, truer endophenotypes when possible, rather than more complex phenotypes whose heritabilities reflect a mixture of genetic etiologies. Another strategy might be to utilize an endophenotype ranking system that is based on differential genetic utility scores, as suggested recently (Glahn et al., 2012). Whichever endophenotype strategies are employed, it will be essential to increase our ability to capitalize on the opportunities they afford to identify genes that increase or decrease the risk for schizophrenia. The half-fulfilled promise of this approach remains particularly promising for neuropsychological and neuroimaging endophenotypes, in the hope of finding therapeutic interventions eventually to ameliorate or prevent these core features of the illness, and the illness itself.

Subject Index

Page numbers followed by f and t refer to figures and tables, respectively.

Abecedarian programs, 513
Abnormal behavior, expression, 205
A/B ratio, 405
Academic achievement, malnutrition (role), 219
Academic performance, nutritional deficits (effect), 219
Academic skills (acquisition), reaction range (understanding), 318–319
ACC. *See* Anterior cingulate cortex
ACM. *See* Adaptive calibration model
ACTH. *See* Adrenocorticotropic hormone
Action regulation
  constrained form, 674
  cybernetics, 675
Active genotype-environment correlation (active rGE), 244f
  defining, 243–244
  impact, 256–258
Activity-dependent plasticity
  control, 672–673
  motivation, 671
Activity-regulated cytoskeleton-association protein (Arc), 144
Acute nicotine administration, 862
Acute stress disorder (ASD), 529
  differentiation, 533
Acute stressors, biological responses, 695
Adaptation, 10–17
  emphasis, 33
  term, usage, 5
Adaptation, metatheoretical assumption, 5–6
Adaptive mechanisms
  constraints/trade-offs, 16
  developmental mismatches, 15–16
  evolutionary conflict, maladaptive outcomes, 14–15
  high-risk strategies, maladaptive outcomes, 13–14
  maladaptive outcomes, 13–16
  misfiring defenses, 15
Adaptive calibration model (ACM), 26–32
  adaptation emphasis, 33
Allostatic load model
  alternative, impact, 26
  benefits, 33
  comparison, 32–34, 32t
  core theoretical structure, 27f
  framework, emphasis, 113–114
  hypothesis, 31
  phenotype alternatives, development (cost-benefit trade-offs), 33
  proposal, 2
  responsivity, patterns, 29–32
  similarities/differences, 122
  synthesis, 49
Adaptive coin-flipping, 38
Adaptive defensive reactions, 16–17
Adaptive life history-related traits
  impact, 44
  symptoms, association, 43
Adaptive physiological outcomes, stressor exposure (relationship), 567–568
Adaptive plasticity, impact, 20–23
Adaptive stochastic variation, 38
Adaptive strategies, impact, 43–44
Adaptive, term (meaning), 8
ADCYAP1R1 gene, 430
Addiction
  adolescence, 701
  characterization, 153
Addictive disorders, 152–153
Additive model, transformation, 303
ADHD. *See* Attention-deficit/hyperactivity disorder
Adolescence
  addiction, 701
  aggressive adolescents, classmate rejection, 747
  amygdala-PFC development, 695–697
  anxiety, increase, 125
  behavior, changes (translational implications), 706–707
  biological changes, 729–735
    animal models, lessons, 730–731
  cognitive control, changes, 741–742
    psychopathology, relationship, 742–743
  community, impact, 750
  cross-lagged analyses, 346
  culture, impact, 750
  defining. *See* Rodents.
    historical perspective, 686–689
  depression, increase, 125
  developing brain, risk taking, 701–705
  development
    contexts, 743–752
    family, role, 745–746
    peers, positive/negative influences, 746–748
    romantic relationships, 748
    work, context, 749–750
  developmental period, observations, 722–727
  deviant outcomes, 751–752
  dopaminergic reorganization pattern, 699
  early-life adversity, 695–697
  environment enrichment, 588
  ethanol consumption, 732
  face processing, neuroperceptual changes, 689–691
    fusiform development, 691
    neurobiological correlates, 690–691
  family
    relationship, 704–705
    role, 745–746
  formative biological change, 722
  genetically informed studies, 351
  illness, progressive developmental pathophysiology, 910
  interval, expansion, 723
  intervention, differential sensitivity, 588

Adolescence *(Continued)*
learning environment perspective, 256
major depression, 463
media contexts, 750–751
negative affect-related neurobiology, 692–697
negative affect systems, changes, 739–740
psychopathology, relationship, 740–741
neurobiological correlates, 700
neurochemical changes, 699
parent-child relationships, 726
peers
contexts, 746
relationship, 703
psychopathology, 701
context, approaches, 751–752
peer-family joint effects, 748
study, developmental neuroscience/contextual approaches (integration), 720
understanding, brain-based frameworks (usage), 727–729
psychopathology, developmental processes (importance), 735–743
puberty, 724–725
development, 729
psychopathology, relationship, 729–730
research, future, 707–708
reward circuitry, 701
reward-seeking behavior models, 697–701
reward sensitivity
changes, 698–699
individual differences, 700–701
reward systems, changes, 736–738
psychopathology, relationship, 738–739
risk behavior regulation, macrosystem influences, 750
risk factors, 726–727
risk-taking behavior models, 697–701
risky behavior, increase, 728
schools, psychopathology (relationship), 748–749
self-injury, 847
sleep, 725–726
social cognitive development, 705–706
social motivations
increase, 736
systems, changes, 735–736
society, impact, 750
stress, 703–704
relationship, 588–589
sensitivity, 587–590
time of plasticity, 727
time of risk, 723–726
