Preface to Developmental Psychopathology, Third Edition

A decade has passed since the second edition of *Developmental Psychopathology* was published. The two prior editions (Cicchetti & Cohen, 1995, 2006) have been very influential in the growth of the field of developmental psychopathology. The volumes have been highly cited in the literature and have served as an important resource for developmental scientists and prevention and intervention researchers alike. In the present third edition, we have expanded from the three volumes contained in the second edition to four volumes. The increased number of volumes in this current edition reflects the continued knowledge gains that have occurred in the field over the past decade.

A not insignificant contributor to this growth can be found in the very principles of the discipline (Cicchetti, 1984, 1990, 1993; Cicchetti & Sroufe, 2000; Cicchetti & Toth, 1991, 2009; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). Theorists, researchers, and prevention scientists in the field of developmental psychopathology adhere to a life span framework to elucidate the numerous processes and mechanisms that can contribute to the development of mental disorders in high-risk individuals as well as those operative in individuals who already have manifested psychological disturbances or who have averted such disorders despite their high-risk status (Cicchetti, 1993; Masten, 2014; Rutter, 1986, 1987, 2012). Not only is knowledge of normal genetic, neurobiological, physiological, hormonal, psychological, and social processes very helpful for understanding, preventing, and treating psychopathology, but also deviations from and distortions of normal development that are seen in pathological processes indicate in innovative ways how normal development may be better investigated and understood. Similarly, information obtained from investigations of experiments of nature, high-risk conditions, and psychopathology can augment the comprehension of normal development (Cicchetti, 1984, 1990, 1993; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe, 1990; Weiss, 1969).

Another factor that has expedited growth within the field of developmental psychopathology has been its ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary and translational research (Cicchetti & Gunnar, 2009; Cicchetti & Toth, 2006). In keeping with its integrative focus, contributions to developmental psychopathology have come from many disciplines of the biological and social sciences. A wide array of content areas, scientific disciplines, and methodologies has been germane. Risk and protective factors and processes have been identified and validated at multiple levels of analysis and in multiple domains.

The increased emphasis on a multilevel, dynamic systems approach to psychopathology and resilience, the increased attention paid to gene–environment interplay in the development of psychopathology and resilience, and the application of a multiple levels of analysis developmental perspective to mental illnesses that have traditionally been examined nondevelopmentally (e.g., bipolar disorder, schizophrenia, and the personality disorders) not only have contributed to a deeper understanding of the dysfunctions but also have educated the public about the causes and consequences of mental disorder (see Cicchetti & Cannon, 1999; Cicchetti & Crick, 2009a, 2009b; Miklowitz & Cicchetti, 2006, 2010; Tackett & Sharp, 2014).

Advances in genomics, GxE interactions, and epigenetics; growth in our understanding of neurobiology, neural plasticity, and resilience; and progress in the development of methodological and technological tools, including brain imaging, neural circuitry, hormone assays, immunology, social and environmental influences on brain development, and statistical analysis of developmental change, pave the way for interdisciplinary and for multiple levels of analysis research programs that will significantly increase the knowledge base of the development and course of maladaptation, psychopathology, and resilience. Moreover, randomized control prevention and intervention trials are being conducted based on theoretical models and efforts to elucidate the mechanisms and processes contributing to developmental change at both the biological and psychological levels (Belsky & van IJzendoorn, 2015; Cicchetti & Gunnar, 2008).

Despite the significant advances that have occurred in the field of developmental psychopathology, much important work lies ahead. Undoubtedly these future developments will build on the venerable contributions of the past; however, as work in the field becomes increasingly interdisciplinary, multilevel, and technologically sophisticated, it is essential that even more emphasis be directed toward the process of development (Harter, 2006; Sroufe, 2007, 2013). It is not only genes and environments but also the cumulative developmental history of the individual that influences how future development will unfold (Sroufe, 2007, 2013).

Developmental psychopathologists have incorporated concepts and methods derived from other disciplinary endeavors that are too often isolated from each other, thereby generating advances in knowledge that might have been missed in the absence of cross-disciplinary dialogue. The continuation and elaboration of the mutually enriching interchanges that have occurred within and across disciplines interested in normal and abnormal development not only will enhance the science of developmental psychopathology but also will increase the benefits to be derived for individuals with high-risk conditions or mental disorders, families, and society as a whole.

CONCLUSION 51
REFERENCES 52

Since its inception in the 1970s and 1980s, the discipline of developmental psychopathology has pursued an ambitious project of theoretical integration. The grand vision of developmental psychopathology is that of a truly multidisciplinary approach to the complex interplay of biological, psychological, and social-contextual aspects of both normal and abnormal development (Cicchetti, 1990, 2006; Hinshaw, 2013). As testified by this volume, the project has been remarkably successful, generating an impressive amount of empirical work while maintaining a shared language and a common theoretical background.

In this chapter we argue that—despite its achievements—developmental psychopathology has yet to realize its full potential, and that its integrative power is limited by the lack of an adequate metatheory. We contend that developmental psychopathology has much to gain by embracing modern evolutionary theory, the unifying metatheory of the life and behavioral sciences. We then review a host of recent theoretical developments in the field of evolutionary-developmental psychology (EDP) that address the organization of individual differences, the nature of environmental risk, the role of early stress, the nature of gene-environment interactions, and many other critical issues. Together, these contributions paint the contours of an integrative theory of human development and provide a sophisticated evolutionary foundation for developmental psychopathology. We aim to show that, far from undermining the tenets of developmental psychopathology, the EDP-based framework we describe supports all its core principles while also extending them,

clarifying their underlying logic, and connecting them at a deeper level than previously possible.

We begin the chapter by considering the role of evolutionary theory in developmental psychopathology. After reviewing the core points of the discipline and the historical reasons for its separation from mainstream evolutionary biology, we present the integrative approach of EDP and discuss its metatheoretical foundations. The basic concepts we introduce here provide a general introduction to evolutionary biology and the overarching background for the rest of the chapter. We also review the main tenets of developmental systems theory (DST; Griffiths & Gray, 2004; Oyama, Griffiths, & Gray, 2001), consider its potential role as an alternative metatheory, and conclude that EDP provides a suitable framework for developmental psychopathology.

The second section explores the interplay between adaptation and maladaptation in the origin of disorders. We build on the distinction between adaptive and desirable traits and discuss how the concept of disorder can be specified in evolutionary terms. We then broaden our view to explore the many ways evolutionary and developmental processes—both adaptive and maladaptive—may result in undesirable outcomes at the individual level.

Next, we introduce the concepts of developmental plasticity and conditional adaptation. We discuss how organisms make use of environmental cues to adaptively match their phenotypes to their developmental context and the ways those processes can fail and result in maladaptive outcomes. We then present a nontechnical overview of life history theory, the dominant biological theory of conditional adaptation and a general framework for understanding the organization of individual differences in physiology, growth, and behavior. Drawing on life history concepts, we take a closer look at the multidimensional nature of environmental risk and examine the logic by which physical and social environmental factors shape and direct individual development.

The chapter then focuses on the central role of stress in the development of individual differences and psychopathology. We argue that the standard framework employed in developmental psychopathology—the allostatic load model (McEwen & Stellar, 1993)—fails to capture the multiple roles of stress in development, and promotes a limited understanding of stress as a risk factor and a source of physiological and behavioral dysregulation. As an alternative, we propose the adaptive calibration model (ACM; Del Giudice, Ellis, & Shirtcliff, 2011), a theory of individual differences in stress responsivity across the life span based on concepts from life history theory and the theory of conditional adaptation. The Adaptive Calibration Model offers a renewed understanding of the role of stress in development and illustrate the heuristic and integrative power of the evolutionary developmental approach.

People vary dramatically in the extent to which they respond to their developmental context. In recent years, it has become apparent that many of the genetic, temperamental, and neurobiological factors that make people more vulnerable to negative, stressful environments also make them more likely to benefit more from positive, supportive environments. Differential susceptibility to the environment is a source of systematic organism × environment interactions, with many implications for both normal and pathological development. We explore the evolutionary logic of differential susceptibility and review the main theoretical models that have been proposed to explain it (Belsky, 1997, 2005; Boyce & Ellis, 2005).

We conclude the chapter by showing how life history concepts provide the foundation for an integrative evolutionary approach to mental disorders (Del Giudice, 2014a, 2014b). The framework we outline is based on the idea that individual differences in life history strategy set the stage for the development of psychopathology. The resulting taxonomy offers a promising alternative to both the atheoretical approach of the Diagnostic and Statistical Manual and empirical classification systems based on the distinction between internalizing and externalizing disorders.

Each section in the chapter shows how an evolutionary developmental approach goes beyond current thinking and contributes to broaden our understanding of psychopathology. At the end of each section, we consider how the concepts and theories we discuss relate to the core points of developmental psychopathology. As our ultimate goal is to catalyze a paradigm shift in developmental psychopathology, we deliberately focus on general principles rather than specific disorders throughout the chapter.

TOWARD AN EVOLUTIONARY-DEVELOPMENTAL FRAMEWORK FOR PSYCHOPATHOLOGY

The Missing Foundation of Developmental Psychopathology

Over the years, a consensus has formed around a set of core points—methodological commitments, goals, and theoretical principles—that define developmental psychopathology as a scientific field. Developmental psychopathology adopts a multidisciplinary perspective; pursues integration across multiple levels of analysis; gives particular consideration to the social and cultural context,

as well as to brain and neurobiological factors; and emphasizes person-centered designs in empirical research. Researchers in the field aim to describe, understand, and synthesize the interplay between normal and pathological development, between developmental continuity and discontinuity, and between risk and protective factors. Finally, developmental psychopathology adopts three key principles from systems theory and developmental biology: the twin principles of equifinality and multifinality, and a view of ontogenetic causality as probabilistic, nonlinear, and involving reciprocal interactions between the developing organism and the environment (see Cicchetti, 1990, 2006; Hinshaw, 2013).

These points are extremely valuable and we subscribe to all of them. At the same time, we recognize that something crucial is missing. Developmental processes are biological processes, and biology is ultimately about function. Yet while developmental psychopathology is highly attuned to the complexities of *how* humans develop, its core points are silent with respect to the *whys* of development. Why do developmental processes unfold in one way rather than another? Why, for example, have they evolved so as to be exquisitely sensitive to contextual factors? And why do different processes show different degrees of context sensitivity? More generally, what is development *for*? Nikolaas Tinbergen (1963) famously summarized the four types of explanation required for a complete understanding of a biological system. With an updated terminology, they can be described as *mechanism* (what is the system like? How does it work?); *development* (how does it come to be over developmental time, and how does it change across the life span?); *phylogeny* (what is the evolutionary history of the system? How did it change across generations and species?); and *adaptation* (why is the system the way it is? What selective advantages does it confer, or used to confer, to the organism?).

Developmental and mechanistic explanations concern the way an organism works in the present, without reference to evolution and adaptation; collectively, they are called *proximate* explanations. In contrast, *ultimate* explanations (phylogenetic and adaptationist) consider the organism in relation to its past and to the evolutionary forces that shaped its body and behavior (Mayr, 1963). The four types of explanation are not mutually exclusive but complementary and synergistic: adaptive function crucially informs the study of mechanism and development, while development and mechanism constrain the range of plausible adaptive explanations (see Scott-Phillips, Dickins, & West, 2011; West-Eberhard, 2003). Restricting one's view to the proximate level of explanation can only result in a partial understanding of the investigated system, in direct contrast with the integrative stance of developmental psychopathology.

In spite of the growing influence of evolutionary theory on the study of human behavior and development (see Buss, 2005; Ellis & Bjorklund, 2005), developmental psychopathology has remained virtually insulated from mainstream evolutionary biology until very recently. Indeed, earlier authoritative introductions to developmental psychopathology (Cicchetti, 2006; Hinshaw, 2013) did not even mention evolutionary biology as one of its contributing disciplines. This state of affairs has historical reasons that should be considered, however briefly. The theoretical foundations of the discipline were largely laid down between the 1970s and the 1980s (Cicchetti, 1990). At the time, the inclusive fitness revolution (discussed in more detail later) was still under way in biology and had had only little impact on the human behavioral sciences. Debates within biology often pitted proximate (developmental) and ultimate (evolutionary) causation against one another rather than acknowledge their complementary nature (West-Eberhard, 2003, ch. 24), and early adaptationist thinking tended to ignore or downplay developmental dynamics. Moreover, initial attempts to apply the logic of adaptation and inclusive fitness to human social behavior were surrounded by heated and often heavily politicized arguments (Segerstrale, 2000).

Coming of age in this intellectual context, developmental psychopathology embraced the holistic, organismic approach prevalent in embryology (Cicchetti, 1990), as did other sectors of developmental psychology and psychobiology. Organismic theories—epitomized by modern DST—stress the hierarchical, self-organizing, active nature of development and the dynamic, reciprocal relationship between the developing individual and its environment (Reese & Overton, 1970). Clearly, this viewpoint has much to offer, and captures some crucial features of developmental processes. However, acceptance of organismic theories has often gone hand in hand with wholesale rejection of the adaptationist approach that informs large part of mainstream evolutionary biology. Psychological theorizing based on adaptationist concepts has been rejected—incorrectly and prematurely, in our view—as implying genetic determinism, a simplistic and unidirectional conception of causality, and an inability to deal with ontogenetic change and transformation. This stance has since become entrenched in developmental psychology (see Lickliter & Honeycutt, 2003; Overton, 2006), and has contributed to insulate the discipline from contemporary evolutionary thinking.

In contrast with this view, and in line with more than two decades of biological and psychological research, we believe that the basic adaptationist approach can be extended and revised to accommodate a sophisticated view of developmental processes. Importantly, this can be done without renouncing its main tenets—such as inclusive fitness theory and the proximate/ultimate distinction (e.g., Bjorklund & Ellis, 2005; Bjorklund, Ellis, & Rosenberg, 2007; Frankenhuis, Panchanathan, & Barrett, 2013; Olson, 2012; Tooby, Cosmides, & Barrett, 2003; West-Eberhard, 2003). Reconciling the logic of natural selection with a truly developmental approach to human behavior is the central goal of EDP, a fast-growing field at the intersection of developmental psychology and evolutionary biology. We now turn to a more detailed analysis of EDP and its theoretical underpinnings.

Evolutionary-Developmental Psychology

Evolutionary-developmental psychology (EDP) is the application of the principles of Darwinian evolution to explain contemporary human development (see Bjorklund & Ellis, 2005; Bjorklund & Pellegrini, 2002). The central assumption of EDP is that cognitive mechanisms, behavior patterns, and the developmental processes that produce them have been shaped by Darwinian selection processes across our phylogenetic history. The primary focus of the field is how evolved psychological mechanisms develop through bidirectional interactions between environmental and genetic factors. The approach of EDP is thus intrinsically interactionist, with a strong emphasis on contextual factors. Consistent with this outlook, EDP views the developing individual as a plastic organism that adapts to the local context while contributing to determine its own environment. Plasticity, however, is not understood as arbitrary malleability; rather, the plastic child responds to the environment following evolved rules that tend to guide development toward adaptive goals. In other words, developmental plasticity is to a large extent *adaptive*—and itself shaped by past selection history.

Universal, species-typical features of human development—such as play, extended immaturity, and language acquisition—are obviously a major research theme of EDP. At the same time, EDP aims to explain individual and gender *differences* in development and behavior—for example in play preferences, pubertal timing, and linguistic abilities. The emphasis of EDP on adaptive variation has been a driving force in the recent surge of interest in the evolution of individual differences in behavior and personality (e.g., Buss & Hawley, 2011; Carere & Maestripieri, 2013). Given the pivotal importance of individual differences in psychopathology, the theories and models we review in this chapter focus on the developmental processes that make individuals different from one another, including more or less at risk for different mental disorders.

Metatheoretical Foundations of EDP

When scientists formulate theories and hypotheses and evaluate them against empirical data, they rely on basic, a priori assumptions that inform theory-building. Once they have been established (empirically or otherwise), these assumptions are usually not directly tested thereafter; instead, they are used as a starting point for further research. Philosopher of science Imre Lakatos (1970) referred to these basic a priori assumptions as the *hard core* of a research program. For example, Newton's laws of motion provide the metatheory for classical mechanics, and the principles of adaptation through natural selection provide a metatheory for evolutionary biology. Metatheories operate like maps of the scientific terrain explored by a discipline: they provide boundaries between plausible and unlikely explanations, guidance in formulating hypothesis and interpreting empirical data, and heuristic rules for discovery. Between metatheories and specific empirical hypotheses are middle-level theories, which have limited scope and are more directly exposed to empirical testing. A metatheory integrates the relevant middle-level theories into an organized, internally consistent whole. Within a given metatheoretical program, scientists build middle-level theories and even narrower conceptual models, which are then used to generate hypotheses and predictions that can be empirically tested (for extended discussion, see Ketelaar & Ellis, 2000).

The metatheoretical foundations of EDP comprise both general and special assumptions (see Bjorklund & Ellis, 2005; Bjorklund et al., 2007; Durrant & Ellis, 2003; Ketelaar & Ellis, 2000). The general assumptions of EDP concern evolution by natural selection and are shared with mainstream evolutionary biology. Special assumptions concern (1) the application of evolutionary principles to the psychological level of analysis, and (2) the conceptualization of developmental processes in terms of probabilistic epigenesis. Assumptions about psychological mechanisms are shared with the sister field of evolutionary psychology, while the assumption of probabilistic epigenesis originates in developmental systems theory (DST). However, it should be stressed that EDP embraces a "soft" version of DST that is compatible with an adaptationist stance, while rejecting the most radical claims of DST proponents

(Bjorklund & Ellis, 2005; Bjorklund et al., 2007). We will examine the distinction between "hard" and "soft" DST in more detail in a later section.

General Metatheoretical Assumptions

Natural Selection. The Darwinian concept of natural selection is the cornerstone of evolutionary biology. For natural selection to occur in a population of organisms, three conditions must apply: (1) individuals differ from one another in their physical or behavioral traits (i.e., their *phenotype*); (2) at least some of these phenotypic traits affect an individual's ability to successfully reproduce in the next generation; and (3) phenotypic traits are heritable—that is, they are transmitted to descendants with some reliability. When these conditions are met, individuals that are better able to reproduce leave more descendants, which in turn carry the physical and behavioral traits that favored reproduction in the previous generations. Over time, successful traits tend to become more common in the population—that is, they are selected for because of their positive effects on reproductive success or *fitness*. Traits that enhance fitness are called *adaptive*, while those that reduce fitness are called *maladaptive*; if a trait does not affect fitness, it is considered *neutral* with respect to natural selection. It is important to note that natural selection is an abstract process, and does not require specific inheritance mechanisms (such as DNA) to work. All is required is the combination of heritable variation and differential reproduction based on that variation.

The most basic measure of Darwinian fitness is an individual's reproductive success, that is, the number of that individual's offspring that survive to maturity. Of course, to reproduce an organism also needs to survive, but—despite popular renditions of natural selection as "survival of the fittest"—survival without reproduction is an evolutionary dead end. It doesn't matter how well an organism is able to survive; if it fails to leave descendants, the traits responsible for its enhanced survival abilities will not be represented in subsequent generations. Organisms thus need to trade off longer survival against increased reproduction, the latter being the ultimate currency of evolution.

In species that reproduce sexually—that is, by mating—physical and behavioral traits can be selected for because they increase the number or quality of an individual's mates. This can happen in two ways: by making individuals compete more effectively with rivals, and by making individuals more attractive to potential mates. When selection arises from competition over mates, it is termed *sexual selection*. While sexual selection is a special case of natural selection, it has its own peculiar dynamics and can have dramatic effects on the evolutionary trajectory of sexual species. As Darwin noted, sexual selection can drive the evolution of extravagant displays designed to attract mates (the peacock's tail is a prototypical example). Even more importantly, sexual selection may lead to remarkable divergence in form (e.g., size, color, natural weapons), behavior (e.g., aggression, sexual behavior, parental behavior), and development (e.g., growth rate, maturation timing, life span) between males and females of the same species.

Adaptation. By constantly weeding out unsuccessful variation, natural selection produces incremental modifications in existing phenotypes, leading to an accumulation of characteristics that are organized to enhance survival and reproductive success. These characteristics are termed *adaptations*. Adaptations are inherited and reliably developing characteristics that have been selected for because of their causal role in enhancing the fitness of individuals that possess them (Williams, 1966). Through this process, adaptations acquire biological functions and the appearance of purposeful design—they are *for* something. The immune system functions to protect organisms from pathogens, the heart functions as a blood pump, and the cryptic coloring of many insects has the function of preventing their detection by predators. The core idea of evolutionary psychology is that many psychological characteristics are adaptations—just as many physical characteristics are—and that the principles of evolutionary biology that are used to explain our bodies are equally applicable to our minds (for extended discussion see Durrant & Ellis, 2003).

While adaptations are the product of evolution, evolution does not always produce adaptations; likewise, not every characteristic of an organism is an adaptation. For example, traits may become fixated in a population by random drift, whereby neutral or even deleterious characteristics become more prevalent due to chance factors. A neutral or weakly maladaptive trait may also spread because it is developmentally or genetically linked to another, positively selected trait (hitchhiking). In addition, many traits are not adaptations in themselves but rather by-products of other adaptations. The sound that hearts make when they beat, the white color of bones, and the human chin are all nonfunctional by-products of natural selection. Finally, random variation in traits can be maintained as residual noise, as long as it is selectively neutral. A variety of approaches can be employed—preferably in combination—to identify adaptations. They include making phylogenetic comparisons, directly measuring the fitness benefits of a trait, and building mathematical models of evolution. An especially useful method is looking for

evidence of *special design*: economy, efficiency, complexity, precision, specialization, and reliability in service of a specific biological function (Williams, 1966).

The logic of adaptation has an important consequence: as evolution proceeds, individual organisms are selected to develop and behave in a way that maximizes their expected fitness. This optimization principle can be aptly described as the *individual-as-maximizing agent* analogy (Grafen, 1999), and is a critical component of the adaptationist approach in biology. Of course, the analogy does not imply that a given individual will always obtain high fitness; of equal importance, optimization does not by any means imply unconstrained perfection—fitness maximization always takes place within the constraints and trade-offs imposed by the physical and social environment, as well as those imposed by previous phenotypic evolution and entrenched developmental biases. Finally, there is no assumption that individuals are intentionally or consciously maximizing expected fitness—they just tend to function *as if* they were attempting to do so.

Inclusive Fitness. The basic account of adaptation given in the preceding paragraphs has an important limit: it utterly fails to explain altruistic traits—that is, physical and behavioral traits that reduce an individual's reproductive success while increasing that of another individual. However, altruism is widespread in nature, as strikingly illustrated by the sterile castes found in eusocial insects such as ants, bees, and wasps. To solve this puzzle, William Hamilton (1964) developed *inclusive fitness theory*, also known (somewhat improperly) as *kin selection theory*. Inclusive fitness theory started a revolution in evolutionary biology, and provided the first unified explanation of social behavior—from parental care and family dynamics to altruism and self-sacrifice in groups. Today, inclusive fitness theory is the bedrock of the study of social evolution, from bacteria to humans (see Grafen, 2009; West, Griffin & Gardner, 2007).

In a nutshell, the theory shows that what is maximized by natural selection is not individual fitness, but a different quantity termed *inclusive fitness*. Inclusive fitness is the sum of (1) an individual's contribution to its own reproductive success, and (2) the individual's contribution to the reproductive success of other individuals, weighted by a coefficient of relatedness. Relatedness is an index of genetic similarity, ranging from $r = 1$ between two genetic clones (e.g., identical twins) and $r = 0$ between two unrelated individuals. In simplified terms, the relatedness between parent and child ($r = 0.5$) is the same as that between two full siblings; while that between grandparent and grandchild ($r = 0.25$) is the same as that between two half-siblings; and so on.[1] Inclusive fitness theory is encapsulated by Hamilton's rule:

$$rb > c$$

The rule states that an actor's behavior (or any other phenotypic trait with social effects) will be selected for if the fitness benefit b enjoyed by the recipient, weighted by the relatedness r between actor and recipient, is larger than the cost c incurred by the actor. Thus, costly altruistic behavior can evolve provided that the relatedness between actors and recipients is sufficiently high. The implications of inclusive fitness are not limited to altruism, and Hamilton's rule can be applied to a broad range of social dynamics, including competition and mutually beneficial cooperation (as distinct from purely altruistic behavior). Inclusive fitness theory leads to an updated version of the individual-as-maximizing agent analogy: when social interactions are involved, individuals will tend to behave as if they were maximizing their expected *inclusive* fitness (Grafen, 2006, 2009). Unlike individual fitness, maximizing one's inclusive fitness is equivalent to maximizing the replication of one's genes in future generations, since—by definition—related recipients (those for which $r > 0$) are carrying copies of the actor's own genes.[2] For this reason, inclusive fitness theory has sometimes been presented as a theory of the "selfish gene" (Dawkins, 1976)—a potentially misleading label, given its original focus on the evolution of altruism.

Inclusive fitness theory is also equivalent to *multilevel selection theory*, an approach to social evolution that focuses on group rather than individual dynamics (e.g., Sober & Wilson, 1998). While multilevel selection has often been viewed as alternative to inclusive fitness, it has since become clear that the two theories are mathematically interchangeable (see Marshall, 2011; West et al., 2007), and differ only in how they partition the costs and benefits of social traits. Whereas inclusive fitness partitions fitness

[1] More precisely, relatedness is a regression coefficient that predicts the recipient's genotype from the actor's genotype. Relatedness can become negative if two individuals can be expected to be genetically less similar than two randomly selected members of the population (see Grafen, 2009; West et al., 2007).

[2] The existence of epigenetic inheritance does not fundamentally change this picture. If epigenetic markings are reliably transmitted across generations, they are equivalent to genetic alleles from the standpoint of natural selection. If epigenetic markings are reversible and environmentally induced, they mediate short-term developmental plasticity and are irrelevant to inclusive fitness computations (see Shea, Pen, & Uller, 2011).

effects between actors and recipients, multilevel selection partitions them between individuals and their broader social groups. Thus, in a multilevel framework, altruism toward group members (to the point of self-sacrifice or sterility) can be selected for if it is counterbalanced by an appropriate benefit to the group as a whole. The equivalent explanation in terms of inclusive fitness is that group formation mechanisms typically increase relatedness within groups relative to that between groups. Thus, helping group members leads to an indirect fitness benefit that can be so strong as to override large individual costs.

Special Metatheoretical Assumptions

Psychological Mechanisms. Psychological adaptations, which govern mental and behavioral processes, are referred to by evolutionary psychologists as *psychological mechanisms*. Most research in evolutionary psychology focuses on identifying evolved psychological mechanisms because it is at this level where invariances occur. Indeed, evolutionary psychologists assert that there is a core set of universal psychological mechanisms that comprise our shared human nature (see Buss, 2005). The move to the level of psychological mechanisms is important to avoid a common fallacy—that of assuming that human behavior (1) has the conscious goal of maximizing inclusive fitness, and (2) actually maximizes inclusive fitness in current environments. At a very general level, natural selection does tend to produce organisms that behave as if they were trying to maximize their expected fitness (see above). However, actual behavior is ultimately mediated by a host of psychological mechanisms with local and sometimes conflicting goals (e.g., learning a language, finding and attracting mates, choosing food, avoiding diseases). There is no general "fitness maximization mechanism" anywhere in the brain. Each mechanism works and evolves within constraints (e.g., information availability, time constraints, coordination and conflict with other mechanisms, previous evolutionary history); as a result, the overall structure of the mind–brain is more akin to a gerrymandered contraption than an optimal, omniscient decision maker.

Even more importantly, the fact that a given adaptation was produced through differential reproduction does not imply that either (1) selection is *currently* favoring that adaptation or (2) variation in the expression of that adaptation will be associated with *current* reproductive success. For example, the dopamine-mediated reward mechanisms found in the mesolimbic system in the brain appear to have evolved to provide a pleasurable reward in the presence of adaptively relevant stimuli such as food or sex. In contemporary environments, however, these same mechanisms are subverted by the use of psychoactive drugs such as cocaine and amphetamines, which deliver huge dollops of pleasurable reward in the absence of the adaptively relevant stimuli, often to the user's detriment (Durrant & Ellis, 2003).

The concept of a psychological mechanism was updated by Bjorklund and colleagues (2007) to make it more consistent with EDP's metatheoretical assumption of probabilistic epigenesis. These authors proposed a definition of *evolved probabilistic cognitive mechanisms* (p. 22):

> [Psychological] mechanisms that are functionally organized to solve recurrent problems faced by ancestral populations, are highly probable when species-typical environments are encountered (i.e., when the developmentally relevant features of the environment are in the range typically encountered during a species' evolution), and are products of emerging developmental systems that have evolved over the course of the ontogenies of our ancestors.

This definition stresses the probabilistic nature of the ontogenetic processes responsible for building psychological mechanisms; it also makes it clear that, while evolved mechanisms prepare an organism for life in a species-typical environment, they are not preformed or specified in advance by a rigid genetic program.

Domain Specificity. As is apparent from the preceding paragraphs, evolutionary psychology views psychological mechanisms as having some degree of functional specialization. More specifically, psychological mechanisms are composed of structures that (1) exist in the form they do because they recurrently solved specific problems of survival and reproduction over evolutionary history; (2) are designed to take only certain kinds of information from the world as input; (3) process that information according to a specific set of rules and procedures; (4) generate output in terms of information to other psychological mechanisms and physiological activity or manifest behavior that is directed at solving specific adaptive problems (see Buss, 2012). In short, psychological mechanisms are designed by selection to address specific *domains* of the physical and social world. Although evolutionary psychologists assert that the mind is not comprised primarily of content-free (domain-general) psychological mechanisms, it is likely that different mechanisms differ in their levels of specificity, and that there are some higher level mechanisms that function to integrate information across more specific lower level mechanisms. In addition, some general-purpose abilities (e.g., associative learning) may be co-opted in the context of different specialized functions. It is important to stress that functional specialization of a psychological

mechanism does not imply clear-cut anatomical localization in the brain, nor complete functional independence from other mechanisms. Indeed, psychological mechanisms are expected to show a considerable degree of integration and reciprocal interaction.

The rationale behind the domain specificity argument is fairly straightforward: What counts as adaptive behavior differs markedly from domain to domain. The sort of adaptive problems posed by food choice, mate choice, and social exchange often require different kinds of solutions. A clear analogy can be drawn with the functional division of labor in human physiology. Different organs have evolved to serve different functions and possess properties that allow them to fulfill those functions efficiently, reliably, and economically: the heart pumps blood, the kidneys excrete urine, and so on. A super, all-purpose, domain-general internal organ faces the impossible task of serving multiple, incompatible functions. Analogously, a super, all-purpose, domain-general mind/brain mechanism faces the impossible task of efficiently and reliably solving the plethora of behavioral problems encountered by humans in ancestral environments. Thus, neither an all-purpose physiological organ nor an all-purpose psychological mechanism is likely to evolve.

Environment of Evolutionary Adaptedness. Biological adaptation is necessarily a historical concept, and all claims about adaptation are claims about the past. The environment in which a given trait evolved is termed its *environment of evolutionary adaptedness* (EEA). When we claim that the thick insulating coat of the polar bear is as an adaptation, we are claiming that possession of that trait advanced reproductive success in ancestral environments. However, traits that served adaptive functions and thus were selected for in past environments may not still be adaptive in present or future environments. In a globally warmed world, for example, the polar bear's pelt may become a handicap that reduces the fitness of its owner. While natural selection is expected—all else being equal—to weed out traits that have become detrimental to fitness, the process may often take a long time. This generates the potential for mismatch between an organism's adaptations and its present environment.

The possibility of mismatch raises a subtle but crucial point regarding the meaning of *adaptive*. Broadly speaking, psychological and physiological processes can be described as adaptive if they result from the unimpaired functioning of adaptations. Thus, adaptive in the broad sense is a shorthand to describe the functioning of naturally selected processes and mechanisms, regardless of whether they are *currently* promoting reproductive success (i.e., adaptive in the narrow sense). For example, pursuit of mating relationships with fertile partners is guided by adaptive psychological processes, regardless of whether contraceptive technology prevents reproduction in present-day societies.

Within the same organism, different adaptations will often have different EEAs (for extended discussion see Durrant & Ellis, 2003). Consider the human adaptations of language and infant attachment. While the origin of language is firmly anchored in approximately the last 2 million years, infant attachment reflects a much lengthier evolutionary history and a shared heritage with other mammalian and primate species. While evolutionary timing helps define the EEA of a trait, the EEA itself is not a specific time or place; rather, EEAs capture the statistical regularities of the environment in which the trait evolved (Tooby & Cosmides, 1990). Environmental variation itself can be part of an EEA; for example, metabolic processes can evolve so as to maximize survival in an unpredictable environment, whereby food abundance is suddenly followed by starvation. In this case, metabolic adaptations evolve in an EEA characterized by a consistent pattern of unpredictable variation.

Over the last few millennia—the span of a few hundred generations—humans have experienced rapid and constantly accelerating rate of change in health, nutritional, social, and technological conditions. While genetic evolution has been accelerating as well (e.g., Hawks, Wang, Cochran, Harpending, & Moyzis, 2007), many of our evolved adaptations can be expected to be at least partly mismatched to modern lifestyles. At the same time, many adaptation-relevant aspects of our environment have probably remained the same: humans everywhere, for example, still find and attract mates, have sex, raise families, make friends, compete for status, and gossip (Crawford, 1998). Most important is that current and ancestral environments do not have to be identical in every respect to sustain the normal development and expression of evolved psychological mechanisms.

Probabilistic Epigenesis. The concept of probabilistic epigenesis has a long history in embryology and is one of the central assumptions of DST (see Gottlieb, 2007). Probabilistic epigenesis holds that development involves continuous bidirectional influences between genetic activity, neural activity, behavior, and the physical and social environment (similar interactions take place in the development of non-neural mechanisms). In this view, neural structures begin to function when they are still developing, and their activity—both spontaneous and evoked by the

environment—plays an important role in the ontogenetic process. This is contrasted with predetermined models in which genetic programs build neural structures, that begin to function and interact with the environment only when they are mature. The reciprocal, bidirectional interaction between multiple levels introduces a probabilistic element in the outcomes of developmental processes.

A key implication of probabilistic epigenesis is that genetic activity is influenced and regulated by neural, behavioral, and external events. Gene–environment (GxE) interactions in development, whereby the effects of an allelic variant are contingent on contextual variables, are prime examples of probabilistic epigenesis (Gottlieb, 2007). Probabilistic epigenesis provides reasons for expecting widespread plasticity in the outcomes of developmental processes; however, it is not sufficient to explain *adaptive* plasticity and phenotype-environment matching (Bjorklund et al., 2007). Understanding adaptive plasticity requires a synthesis between the proximate and ultimate level of analysis—where development meets adaptation.

Developmental Systems Theory: An Alternative Metatheory?

Researchers in developmental psychopathology often refer to developmental systems theory (DST) as a metatheoretical framework for the discipline. DST is a general approach to development and evolution rooted in the organismic concepts of embryology and developmental psychobiology. The major themes of DST are probabilistic epigenesis and developmental plasticity, with a strong emphasis on bidirectional interplay between genes and environment; an extended view of inheritance that goes beyond DNA to include epigenetic processes, cellular structures, scaffolded developmental environments (e.g., nests), and culturally transmitted information; and a view of the developing organism as actively involved in shaping its environment (see Griffiths & Gray, 2004; Oyama et al., 2001). Consistent with the metatheoretical framework we have presented, DST emphasizes the multiplicity of factors that jointly determine phenotypic outcomes and stresses the contextual, contingent nature of development.

Soft Versus Hard DST

Much of the difficulty in discussing the role of DST stems from the fact that DST is not a single, unified theory; in fact, it is possible to recognize at least two versions of DST—a "soft" version and a "hard" version—with vastly different implications for developmental science (Frankenhuis et al., 2013; Robert et al., 2001). Soft DST is essentially a theory of development; in this view, a developmental system comprises all the resources (e.g., genes, cellular structures, sensory experiences, physical parameters of the environment) that contribute to the ontogeny of the individual organism. However, the organism remains the main biological entity, and evolutionary processes acts on populations of organisms. In other words, soft DST reconceptualizes the causal structure of development—for example by placing genetic inheritance in a broader perspective and emphasizing bidirectional effects—but is otherwise consistent with inclusive fitness theory and the logic of individual adaptation (Pradeu, 2010). Indeed, many developmentally oriented extensions of evolutionary biology already incorporate the main tenets of soft DST (e.g., West-Eberhard, 2003).

In contrast, hard DST is not so much a theory of development as a radical alternative to mainstream evolutionary theory. In hard DST, a developmental system comprises all the resources that produce the developmental outcomes that are *stably replicated* in that lineage. As a consequence, it is impossible to meaningfully distinguish between organism and environment, and what evolves are not populations of organisms but populations of replicating organism–environment systems. Such holistic reconceptualization of natural selection breaks down the individual-as-maximizing agent analogy and makes adaptationist analysis all but impossible (Pradeu, 2010). This is because hard DST is inconsistent with inclusive fitness theory: selection is no longer assumed to act on individuals that can be more or less genetically related with one another, but on whole developmental systems (comprising every recurring influence on development, including social and biogeographical factors) for which there is no meaningful definition of reproductive success or relatedness. In addition, hard DST not only objects to the concept of genetic programs, but—in a further break from mainstream biology—also rejects the very idea that genes store *information* as unacceptable preformationism (Oyama et al., 2001).

In summary, DST comprises two related but partially distinct approaches. Soft DST is a developmentally oriented extension of mainstream evolutionary theory, and is fully consistent with the metatheoretical framework of EDP. In contrast, hard DST advances a radically novel theory of evolution, and constitutes an alternative metatheoretical framework with little overlap with that of EDP. Embracing soft DST does not commit one to also adopt the assumptions of hard DST. Unfortunately, the distinction between the soft and hard version of DST is often obscured in the literature, leaving many researchers

confused as to the exact implications of the theory (see Frankenhuis et al., 2013; Pradeu, 2010).

Implications for Developmental Science

The distinction between soft and hard DST provides insight in the current theoretical status of developmental psychology and psychopathology. We surmise that, when developmental scientists embrace a DST perspective, they usually reason in terms of soft DST. However—and possibly without realizing it—they end up adopting the whole metatheoretical package of hard DST, with the added baggage of antiadaptationism and a priori rejection of mainstream evolutionary thinking. As a result, developmental science is deprived of some of the most powerful tools in biology, such as inclusive fitness theory and the concept of adaptation. By contrast, we contend that the metatheoretical framework of EDP—a synthesis of adaptationism and soft DST—provides a suitable evolutionary foundation for developmental psychopathology. In the remainder of the chapter we demonstrate the heuristic and integrative power of this approach.

BEYOND PATHOLOGY: ADAPTATION, MALADAPTATION, AND DISORDERS

In an evolutionary framework, the terms *adaptive* and *maladaptive* denote the effect of a trait or behavior on biological fitness. From the standpoint of the individual organism, adaptive traits are those that enhance inclusive fitness compared with potential alternatives. However, all adaptations have fitness costs as well as benefits; to be adaptive a trait does not have to be cost free but it only needs to yield a positive overall contribution to the organism's fitness. This notion of adaptation and maladaptation contrasts sharply with how the same terms are usually employed in developmental psychology and psychopathology. In these disciplines, adaptive traits and behaviors are those that promote health, safety, subjective well-being, and mutually rewarding social relations. Socially undesirable, aversive, or health-damaging traits are viewed as maladaptive. These definitions of adaptation and maladaptation are conceptually orthogonal and ought to be carefully differentiated. In this chapter we always refer to adaptation and maladaptation in the biological sense, and employ the terms *desirable* and *undesirable* to denote the implications of a trait for health, safety, well-being, and social values.

Unsettling as it may be, the logic of natural selection promotes reproductive success, not happiness or health (see Cosmides & Tooby, 1999; Gluckman et al., 2011; Nesse, 2004a). Thus, biologically adaptive traits may or may not be socially desirable or conducive to health and well-being; conversely, a trait is not maladaptive just because it has negative effects on an individual's welfare. Traits that consistently reduce well-being and adversely impact an individual's health can be selected for as long as they result in enhanced reproduction—a highly counterintuitive notion in mainstream psychology. At the same time, adaptiveness and desirability—though conceptually distinct—are functionally connected to some degree. This is because positive emotions such as joy, excitement, and pride and are generally aroused by the fulfillment of fitness-enhancing goals, while threats to fitness are generally met with negative feelings such as sadness, anger, and shame (Nesse, 2004a).

The functional connection between threats to fitness and negative emotions lends intuitive plausibility to the implicit assumption—firmly entrenched in psychopathology and psychiatry—that aversive traits are by default pathological or "maladaptive" (see Nesse & Jackson, 2006). The evolutionary approach challenges this assumption, and unpacks the intuitive concept of disorder by separating adaptation from health and desirability. The result is a general framework for thinking about pathology that can be applied to both medical and psychopathological conditions.

What Is a Disorder?

Mental disorder is a central concept of psychopathology, yet a satisfactory definition of disorder is notoriously difficult to achieve. In an influential paper, Jerome Wakefield (1992) built on previous biologically informed approaches to advance a definition of disorder as a *harmful dysfunction*. According to this definition, conditions are recognized as disorders when they (1) are caused by the failure of a biological mechanism to perform its evolved function, and (2) inflict some harm or damage on the affected person, as judged by sociocultural standards. This is a hybrid definition that combines the objective dysfunction criterion with the subjective, culturally bound harm criterion. In Wakefield's account, people evaluate a condition as a disorder when the subjective perception of harm or undesirability is coupled with the idea that something in the body or mind is not working properly. In line with an evolutionary approach, what constitutes proper functioning of a biological mechanism can be correctly evaluated only by considering the evolved functions of that mechanism. To understand pathology, one needs to understand the function of the relevant biological mechanisms, as well as

the structure of the environment in which they evolved (Nesse, 2001; Troisi & McGuire, 2002).

We believe that, correctly understood, the harmful dysfunction analysis is a useful heuristic for reasoning about pathology and disorders. Although Wakefield's proposal has been hotly debated, its core propositions have withstood criticism (see Wakefield, 1999, 2011). To avoid common misgivings, the following points should be kept in mind. First, evolved mechanisms are defined broadly; major organs like the heart are mechanisms, but so are specialized brain areas, microscopic cellular structures, and biochemical pathways. Accordingly, dysfunctions can occur in many ways and for a wide variety of causes (e.g., deleterious genetic mutations, pathogen infections, injuries and wounds, side effects of evolved defenses). Second, *dysfunctional* is not synonymous with *maladaptive*. Since dysfunctions interfere with evolved design, they can often be expected to reduce an individual's fitness; however, a reduction in fitness is not required to identify a dysfunction. It is quite possible for a dysfunction to be selectively neutral—for example, because it occurs too late in life to impact an individual's reproductive success, or because changes in the environment reduce its damaging effects. This is why myopia—a failure of the crystalline lens to project a focused image on the retina—remains a dysfunction even if glasses and contact lenses eliminate its negative effects on survival. Third, the concept of dysfunction is a fuzzy one rather than all-or-none, and evolved mechanisms can show varying degrees of functionality (Wakefield, 1999). Thus, obvious instances of dysfunction are going to be surrounded by borderline cases for which there is no clear-cut demarcating criterion—as for example in the case of hypertension, extreme variation in height, and personality disorders.

A Taxonomy of Undesirable Conditions

Despite their theoretical significance, harmful dysfunctions are only a fraction of what people regard as diagnosable problems or seek treatment for (Cosmides & Tooby, 1999; Lilienfeld & Marino, 1999). Fever is an evolved defense against pathogens; with rare exceptions, it reflects a well-functioning system rather than a dysfunction—yet it is often treated with drugs. More generally, conditions that are not harmful dysfunctions in Wakefield's sense may nevertheless be labeled and treated as disorders, especially if their etiology and functional implications are incompletely understood. For example, it has been hypothesized that some forms of psychopathy are adaptive behavioral phenotypes that exist at a low frequency and thrive by exploiting others (e.g., Mealey, 1995). If this hypothesis were correct, a number of apparent dysfunctions (e.g., reduced empathy, lack of guilt, impulsivity) would be better understood as design features of the psychopathic strategy. Still, psychopathy is a source of trouble for society at large, and would be legitimately regarded as a condition in need of treatment even if it were established as a biologically adaptive variant rather than a disorder in the strict sense. This example also illustrates how conflicts of interest between social actors modulate the perception and definition of a problematic condition; obsessional jealousy may appear desirable and useful to the affected individual, but harmful and undesirable to his/her partners (for a detailed analysis of this issue see Cosmides & Tooby, 1999).

We now take a wider perspective and consider the many ways evolutionary and developmental processes may result in undesirable conditions, including—but not limited to—harmful dysfunctions in the narrow sense (see Cosmides & Tooby, 1999; Gluckman et al., 2011). The taxonomy we present combines Wakefield's dysfunction criterion with the effects of a given condition on biological fitness (Figure 1.1). When considering the adaptiveness of a condition, we further distinguish between the fitness contribution of a *trait* or *mechanism*—averaged across all the individuals who express it—and the fitness of a *particular individual*. The distinction is useful because a mechanism may be fitness-enhancing *on average*, while imposing fitness costs on some individuals (e.g., Cosmides & Tooby, 1999). Distinguishing between individual and average fitness permits a fine-grained analysis of the interplay between adaptation and maladaptation in psychopathology (Frankenhuis & Del Giudice, 2012). Although we discuss them separately, the following categories are not mutually exclusive; a given condition or class of conditions may well reflect the interplay of multiple factors and require overlapping evolutionary explanations.

Harmful Dysfunctions

All biological and artificial mechanisms—no matter how well designed—are vulnerable to malfunctions, failures, and breakdowns. Developmental pathways typically evolve canalization properties (e.g., biochemical buffering mechanisms) that confer them robustness against accidents and perturbations. However, the accumulation of such events over time can affect development, resulting in random deviations from the target phenotype (*developmental instability*). More dramatically, an evolved mechanism may cease to perform its functions because of accidents or environmental insults beyond its regulatory

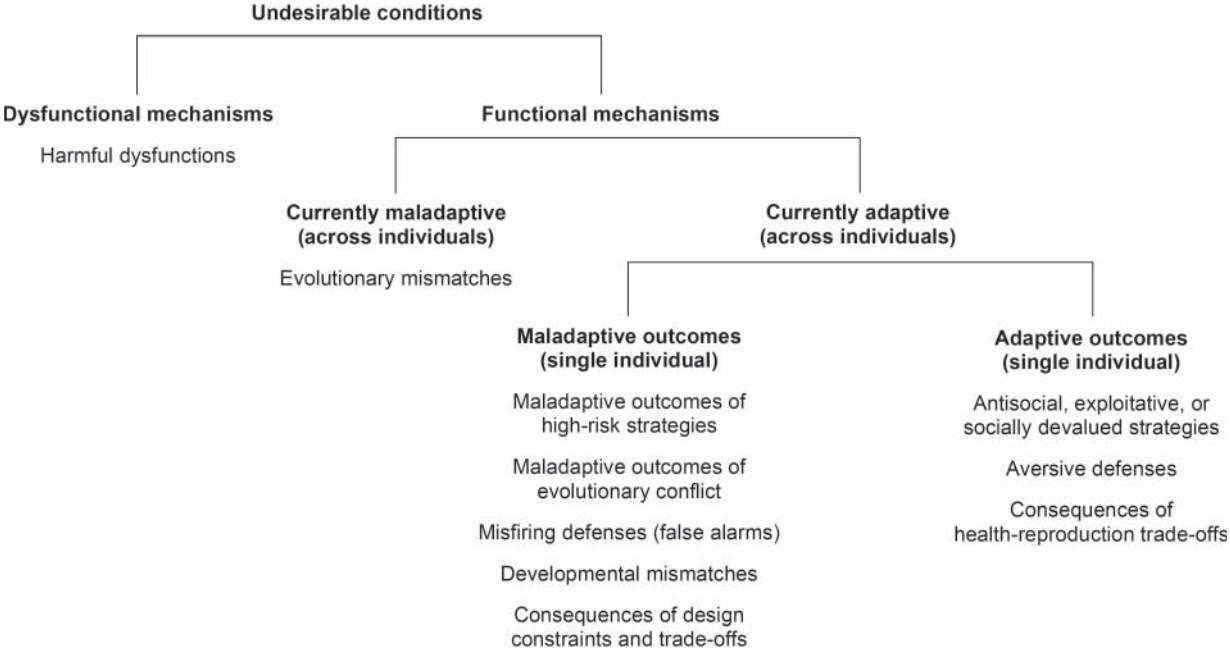

Figure 1.1 An evolutionary taxonomy of undesirable conditions.

capacity (e.g., brain injury, exposure to toxins), deleterious genetic/epigenetic changes (e.g., mutations and deletions), and attacks or manipulations by pathogens (see Crespi, 2000, 2010).

New deleterious mutations arise at every generation and they may be passed down to descendants, persisting for some time in a population until they are weeded out by natural selection. Harmful variants may be especially difficult to eliminate if they have recessive effects (i.e., they are expressed only when an individual inherits two copies of the same allele). The continuous process of creation and elimination of deleterious mutations is called *mutation–selection balance*; its dynamics determine the frequency and persistence of harmful variants in a population. Sometimes, a single mutation in a critical pathway is sufficient to cause a disorder; more often, disorders may result from the cumulative effect of many slightly deleterious mutations (*mutation load*), each with a small impact on phenotypic function. Mutation–selection balance has been proposed as a likely explanation for the persistence of common, heritable, and harmful mental disorders like autism, schizophrenia, bipolar disorder, and mental retardation (Keller & Miller, 2006). Since a large proportion of human genes are expressed in brain development, the likelihood that mutation load will have negative consequences on mental functioning is especially high. The role of mutation load in autism and schizophrenia is consistent with the high rate of new mutations in people with these disorders (e.g., Sanders et al., 2012).

Exposure to pathogens (harmful viruses, bacteria, and other parasites) is another common cause of biological dysfunction. Infectious diseases—especially when they occur in early development—have been associated with increased risk for a number of mental disorders including autism, schizophrenia, and depression (see Patterson, 2011; Benros, Mortensen, & Eaton, 2012). The role of pathogens in the etiology of mental disorders does not contradict that of genetic mutations. Infections, like mutations, can perturb developmental processes at critical stages; accordingly, mutation load and pathogen load may ultimately converge on the same neurobiological pathways and exert a cumulative effect on the risk for psychopathology. In addition to their direct effects on individual organisms, pathogens may indirectly contribute to the risk of harmful dysfunctions through their effect on the evolution of defenses. Pathogens and hosts are constantly involved in coevolutionary arms races, so that for every improvement in defensive mechanisms, new means of offense are going to be selected for on the other side (and vice versa). Coevolutionary arms races tend to produce increasingly complex offense/defense mechanisms (consider the intricacy of the immune system); in turn, increased complexity may render those mechanisms more vulnerable to failures and dysfunctions (Nesse, 2001).

Evolutionary Mismatches

Because of natural selection, evolving organisms tend to become progressively more successful at surviving and reproducing in their environment, broadly conceived to include not only physical factors but also social relations with conspecifics as well as interactions with other species (predators, prey, pathogens, and so forth). The environment, however, is not a static background: environments change all the time because of external events (e.g., geological change), social evolution within a species (e.g., increased population density), and coevolutionary processes between species (e.g., new pathogens). When environmental changes are rapid and extensive, previously adaptive mechanisms may suddenly become maladaptive and generate all sorts of unintended and/or undesirable consequences. Thanks to cultural and technological evolution, humans have gained an unprecedented power to alter their social and physical environment, and in so doing have created enormous opportunity for evolutionary mismatch.

Evolutionary mismatch occurs when an organism encounters a *novel environmental context* (outside of the range that was recurrently encountered over its evolutionary history) that disrupts normal development or impairs adult functioning. Evolutionary mismatches are likely to be implicated—to various degrees—in the etiology of mental disorders. In modern societies, for example, the media expose girls and women to a relentless stream of images of unrealistically attractive "competitors"—an artificial, evolutionarily novel kind of social stimulus. It has been hypothesized that such exposure hyperactivates the evolved mechanisms that regulate female competition for attractiveness and status, contributing to the rising incidence of eating disorders (e.g., Abed, 1998). Other instances of potential mismatch are less obvious. For example, sanitation in developed countries determines a lack of exposure to common microorganisms ("old friends") during development. These novel hygienic conditions appear to interfere with the early ontogenetic processes that train the immune system and set its overall functioning parameters. The resulting states of chronic inflammation may increase the risk for a range of physical and mental disorders, especially depression (Raison, Lowry & Rook, 2010).

Although we have emphasized its negative consequences, evolutionary mismatch is an unavoidable and often vital aspect of evolution. By definition, all evolving organisms exhibit some degree of mismatch to their present environment—otherwise they would stop evolving altogether. The very process of adaptation generates subtle forms of mismatch that may contribute to the etiology of undesirable conditions. When a trait has been subjected to strong recent selection, the resulting adaptive changes may co-occur with maladaptive side effects on other traits that are genetically and/or developmentally linked to the selected trait. Similarly, recently evolved adaptations are likely to show increased scope for dysregulation because they have yet to be fine-tuned by natural selection (see Crespi, 2010).

Maladaptive Outcomes of Adaptive Mechanisms

So far, we have reviewed case in which undesirable conditions are caused by failures of evolved design. Harmful dysfunctions occur when a biological mechanism fails to perform its evolved functions; conversely, evolutionary mismatches occur when an intact mechanism becomes maladaptive because of novel environmental conditions. However, maladaptive outcomes at the individual level may systematically occur even when adaptive mechanisms perform their evolved functions in an environment that matches the EEA on the relevant dimensions. This is one of the central insights of evolutionary psychopathology: observing maladaptive outcomes at the individual level is not sufficient to infer maladaptation at the level of evolved mechanisms. We now review some important reasons why adaptive mechanisms may systematically yield maladaptive outcomes (for in-depth discussion see Cosmides & Tooby, 1999; Crespi, 2010; Frankenhuis & Del Giudice, 2012).

Maladaptive Outcomes of High-Risk Strategies. An important source of maladaptation at the individual level is the evolution of risky adaptive strategies[3]. Risky behavior is part and parcel of daily life: many activities that contribute to survival and reproduction also increase the probability of harm, injury, loss, or death. Searching for food and competing for mates are both fraught with danger, but potential dangers are compensated by the potential fitness advantages of these activities. From an evolutionary perspective, we would expect natural selection to favor mechanisms that produce risk taking when the fitness benefits outweigh the costs. Further insight in the dynamics of risky strategies can be gained by defining risk in its technical sense of unpredictable variation in

[3]In an evolutionary framework, the term *strategy* denotes an organism's realized phenotype among a set of possible phenotypes. Adoption of a given strategy can depend on both environmental and genetic factors. It should be stressed that the term does not imply conscious planning, deliberation, or even awareness; an organism's choice between alternative strategies can be implemented by low-level physiological means, such as a hormonal switch or a change in genetic expression.

outcomes (see Frankenhuis & Del Giudice, 2012; Ellis et al., 2012). Whereas some behavioral decisions offer a narrow range of possible outcomes (low-risk), others entail widely variable outcomes (high-risk), with the potential for large gains as well as large losses. Consider a predator that can choose between two types of prey: larger and hard-to-catch animals versus smaller and easily caught ones. Imagine also that the expected energetic returns associated with hunting each prey type are identical: one results in a high reward with a low probability, the other in a low reward with a high probability. In this scenario, hunting larger prey qualifies as more risky, because it entails more variable outcomes.

Broadly speaking, natural selection favors risk aversion when the relationship between behavioral outcomes and fitness is characterized by diminishing returns. For instance, a well-fed animal should look for low-risk food items (or not forage at all) when additional calories only slightly improve its condition. Conversely, when better outcomes yield increasing fitness returns, organisms may become risk-prone. For example, an animal on the brink of starvation may choose to forage in a nutrient-rich habitat, even if it is infested with predators, because it has so much to gain from additional calories (discussed in Frankenhuis & Del Giudice, 2012). An analogous logic applies to competition for reproduction. In some mating systems, reproductive benefits are highly skewed towards top-ranking individuals (i.e., winner-takes-all systems). In such conditions, males are intensely selected to compete for top rank, even if this implies a greater risk of injury; for instance, male elephant seals engage in ferocious fights that often cause harm and sometimes result in death. Still, males benefit—on average—from participating in fights because not participating implies being shut out from reproduction.

The logic of risky strategies can shed light on the interplay between adaptation and maladaptation in development and psychopathology. For example, externalizing behavior can be interpreted as a high-risk tactic of social competition (Del Giudice et al., 2011; Ellis et al., 2012; Martel, 2013). In some cases, aggressive children and adolescents become dominant, respected, and popular leaders in their peer groups; in other cases, they do not succeed and become unpopular or rejected, incurring physical and psychological harm. These outcomes can be individually maladaptive even if they result from an adaptive strategy designed to achieve dominance and social status. A similar logic may apply to schizotypal personality traits (e.g., the tendency to experience unusual perceptions, bizarre ideation, and reference thoughts). While schizotypal traits increase the risk of schizophrenia (a severe, harmful disorder), when schizotypal individuals do not develop a disorder, their enhanced creativity may facilitate high mating success (e.g., Nettle, 2001; reviewed in Del Giudice, Angeleri, Brizio, & Elena, 2010); this would amount to a high-risk strategy with widely variable outcomes.

Maladaptive Outcomes of Evolutionary Conflict. Conflicts of interest between individuals abound in nature—for example between mating rivals, or between dominants and subordinates in a hierarchy. While cooperation and even altruism can be favored by natural selection, it is often the case that a given individual can maximize its own fitness only at the expense of another individual's reproduction. An especially intriguing kind of evolutionary conflict is that between parents and their offspring (Trivers, 1974; see Schlomer, Del Giudice, & Ellis, 2011). While a parent is equally related to all its offspring ($r = 0.5$), each offspring is more related to itself ($r = 1$) than to any of its present or future siblings ($r = 0.5$ in the case of full siblings). Offspring are thus selected to demand more than their "fair share" of their parent's investment in time, food, protection; conversely, parents are selected to resist such attempts, setting the stage for *parent–offspring conflict* over the distribution of parental investment. Of course, parents and offspring also have a lot of evolutionary interests in common, so conflict is tempered with a substantial amount of cooperation and altruism.

Although parent–offspring conflict is not maladaptive in itself—parents and offspring are both acting so as to maximize their own fitness—the dynamics of conflict often result in nontrivial costs for both parties. Furthermore, conflict may occasionally escalate to dangerous levels, yielding maladaptive outcomes for the parent, the offspring, or both. A dramatic example is provided by prenatal conflicts about fetal nutrition (Haig, 1993; reviewed in Schlomer et al., 2011). During pregnancy, the placenta—a fetal organ that only expresses the fetal DNA—releases massive amounts of hormones in the maternal bloodstream. These hormones affect maternal metabolism so as raise the nutrient content of maternal blood and increase the supply of blood to fetal circulation. The interplay between fetal hormones and maternal countermeasures may produce a range of undesirable side effects, including gestational hypertension and gestational diabetes. In rare cases, the physiological tug-of-war between mother and fetus may become dysregulated and result in life-threatening conditions such as preeclampsia (severe maternal hypertension). In a recent paper, one of us (Del Giudice, 2012) speculated that a similar

conflict may arise about fetal exposure to maternal stress hormones, with mothers favoring higher levels of exposure than fetuses. Indeed, several puzzling features of stress regulation in pregnancy could be explained by the interplay between fetal attempts at manipulation and maternal countermeasures (for a detailed exposition see Del Giudice, 2012). Elevated prenatal stress has been associated with increased risk for a broad range of psychopathological outcomes in children—including anxiety, hyperactivity, autism, and schizophrenia (reviewed in Glover, 2011). To some extent, these undesirable outcomes may arise as maladaptive side effects of parent–offspring conflict in pregnancy.

Evolutionary conflict usually takes place between different individuals, but this is not always the case. Indeed, conflicts of interest can also arise between different genes within the same individual (*intragenomic conflict*; for a thorough review see Burt & Trivers, 2006). Intragenomic conflicts may involve sexual chromosomes, mitochondrial genes, or "selfish" strands of DNA that—for various reasons—follow inheritance rules that differ from those of the rest of the genome. Most relevant to the present discussion, the maternally and paternally inherited halves of an individual's genome may have divergent fitness interests when parental investment is involved. In species that are not perfectly monogamous—that is, most sexually reproducing species including humans—the occurrence of multiple paternity increases the chance that siblings in the same family have the same mother but different fathers. As a result, the genes inherited from the father are—on average—less strongly related to those of one's siblings than the genes inherited from the mother. This generates complex dynamics in which maternal and paternal genes may favor opposite traits in the offspring (e.g., maternal genes may benefit from less demanding offspring, while paternal genes may benefit from *more* demanding offspring; see Schlomer et al., 2011). This latent conflict between the paternal and maternal genome is played out by *imprinted genes*, that is, genes that are differentially expressed depending on whether they were inherited from the mother or from the father (see Burt & Trivers, 2006; Schlomer et al., 2011; Wilkins & Haig, 2003).

Not surprisingly, imprinted genes have been found to be involved in prenatal conflicts about fetal nutrition (reviewed in Schlomer et al., 2011). In addition, many imprinted genes are expressed in the brain, and parent-of-origin effects have been detected in the key signaling pathways that mediate social behavior—including the dopaminergic, serotonergic, and oxytocinergic pathways (see e.g., Davies, Lynn, Relkovic, & Wilkinson, 2008). It is quite possible that intragenomic conflict between imprinted genes may contribute to the development of psychopathology. For example, Crespi and Badcock (2008) hypothesized that autistic spectrum conditions are characterized by overexpression of paternal genes, whereas psychosis spectrum conditions are characterized by overexpression of maternal genes. This diametrical model of autism and psychosis was revised and extended by Del Giudice and colleagues (2010) to account for nonclinical variation in autistic-like and schizotypal personality traits.

Misfiring Defenses. Adaptive defenses are mechanisms designed to protect individuals from physical and/or social harm. Most negative emotions—including fear, anxiety, disgust, and shame—can be conceptualized as defensive mechanisms, as they play crucial protective roles against physical danger, contamination by pathogens, social exclusion, and so forth (see Nesse, 2004a; Nesse & Jackson, 2006). The calibration of defenses involves a trade-off between the rate of false negatives (failing to activate a defense mechanism when a threat is present) and that of false positives (mistakenly activating the mechanism when no threat is present). Defensive mechanisms are usually designed by natural selection to accept a high rate of false positives so as to avoid catastrophic false negatives; this is known as the *smoke detector principle* (Nesse, 2005).

The smoke detector principle suggests that defensive mechanisms will often misfire or activate with excessive intensity, even when no actual threat is present. Adaptive defenses—like fever, cough, and anxiety—are usually aversive and often disabling; occasionally, inappropriate activation of a defensive mechanism may cause serious harm to the individual. For this reason, misfiring defenses are a likely source of undesirable conditions, ranging from benign "false alarms" to dangerous overreactions. The crucial point is that inappropriate activation of a defensive mechanism does not necessarily imply that the mechanism is dysfunctional or dysregulated—even optimally functional defenses may be designed to misfire from time to time. The logic of the smoke detector principle can be employed to shed light on the etiology of emotional symptoms such as panic attacks, anxiety, and phobic symptoms (Nesse, 2005; Nesse & Jackson, 2006).

Developmental Mismatches. Conditional adaptation is the process by which developing organisms make use of contextual cues to direct their developmental trajectory, so as to increase the likelihood that their future phenotype will match the state of the environment. Conditional adaptation is a manifestation of adaptive plasticity, and—when successful—it can dramatically increase the reproductive

success of an organism across a broad range of environments. However, the predictive accuracy (i.e., validity) of contextual cues is usually far from perfect; even when accuracy can be improved by sampling the environment more thoroughly, the potential benefit must be balanced against the required investment of time and effort. For these reasons, conditional adaptation is a fallible process, and a proportion of individuals end up developing a mismatched phenotype. Natural selection can favor conditional adaptation even if the fitness costs of mismatch are high, as long as the average benefits of plasticity are larger than the average costs across individuals. We will deal more extensively with the costs and benefits of developmental plasticity in a later section.

Constraints and Trade-offs. The design of an organism is always shaped by countless physical constraints that limit the range of phenotypic change and burden evolved adaptations with undesirable side effects. For example, the erect posture of humans necessarily increases the impact of falling; a larger body size makes organisms more vulnerable to starvation, and so forth. Physical constraints are compounded by the legacy of previous evolutionary history: natural selection builds incrementally on previous designs, and its inability to start from scratch introduces further constraints on adaptive design (*path dependence*). For example, the fact that human babies are delivered through the pelvic canal poses severe constraints on head size at birth; conversely, selection for larger head size at birth is the biggest ultimate source of maladaptive obstetrical complications. Equally important is the ubiquity of design trade-offs: increasing the functionality of one system may interfere with the functionality of another; increasing the efficiency of a system early in life may lead to decreased efficiency when the organism gets older; enhanced defenses against a given disease may increase vulnerability to another; and so forth. Specifically, a "risk factor" for disorder A may often protect the individual from disorder B. For example, it has been suggested that the long allele of the serotonin transporter gene promoter (5-HTTLPR) may offer protection against depression but increase the risk for psychopathy (Glenn, 2011).

Undesirable Adaptations

The last category in this taxonomy is also the most intriguing from an evolutionary standpoint. As we just discussed, undesirable conditions often reflect the individually maladaptive outcomes of otherwise adaptive mechanisms. However, it may also be the case that *adaptive* outcomes are perceived as undesirable conditions, or even classified as bona fide disorders (Nesse, 2004a; Nesse & Jackson, 2006). Distinguishing undesirable adaptations from maladaptive outcomes can be theoretically and empirically challenging (see Nesse, 2011), but is an essential step to correctly understand the meaning and etiology of the relevant conditions.

Antisocial, Exploitative, or Socially Devalued Strategies. In complex social species like ours there are many potential routes to reproductive success, and not all of them involve cooperation and prosociality. Individuals who develop antisocial, exploitative behavioral strategies may often reap considerable rewards—especially in harsh and unpredictable social contexts. Of course, the enhanced reproductive success of (some) antisocial individuals may come at a cost to their own emotional well-being as well as the welfare of their victims. We already mentioned the hypothesis that some types of psychopathy represent an adaptive strategy of this kind; the hypothesis is supported by the robust association between psychopathic traits and a pattern of precocious sexuality, promiscuity, and sexual coercion (see Barr & Quinsey, 2004; Del Giudice, 2014a; Glenn, Kurzban, & Raine, 2011; Mealey, 1995). A similar case has been made for borderline personality disorder, a pervasive pattern of impulsivity and emotional, affective, and relational instability that is more common in females (Brüne, Ghiassi, & Ribbert, 2010). The heterogeneous category of personality disorders is likely to include other biologically adaptive behavioral variants that are treated as problematic, for example because they cause harm or distress to an individual's social partners.

Aversive Defenses. When defenses activate inappropriately or respond with excessive intensity, the outcome may be correctly recognized as maladaptive. However, many protective mechanisms have strongly aversive effects (e.g., vomiting, panic); for this reason, they may give rise to undesirable conditions not only when they misfire but also when they respond appropriately in presence of actual threats. Sometimes, defensive processes can be altogether mistaken for disorders, especially if their logic is incompletely understood and if the correspondence between threat and response is imperfect (because of the smoke detector principle). Indeed, the "fallacy of mistaking defenses for diseases" is a pervasive feature of current psychopathological approaches (Nesse & Jackson, 2006). Many diagnosable instances of emotional disorders—involving low mood, anxiety, and so forth—may be better understood as unpleasant but adaptive responses to contextual factors.

As already noted, distinguishing adaptive defensive reactions from maladaptive outcomes or dysfunctional

responses is not an easy task (Nesse, 2011). This is exemplified by the debate on evolutionary models of depression. Some authors have argued that major depression can be adaptive as a mechanism of motivational disengagement from unproductive goals, signaling of social submission, and solicitation of help from family and friends (e.g., Sloman & Price, 1987; Watson & Andrews, 2002). However, while low mood has a number of crucial adaptive functions, the available evidence is more consistent with the idea that major depression usually reflects a maladaptive dysfunction of the systems involved in mood regulation (e.g., Nesse, 2006; Nettle, 2004).

Health–Reproduction Trade-Offs. Antisocial strategies and aversive defenses do not exhaust the potential range of undesirable adaptations. The more general point is that, since natural selection maximizes fitness rather than health, traits that increase reproductive success may often have substantial health costs. For example, many health problems associated with aging are the price we pay for more efficient functioning earlier in life (see Nesse, 2001). In developmental psychology, risk taking and impulsivity in adolescence are often viewed as dysfunctional; however, they are better explained as behavioral adaptations to the stronger mating competition faced by human males (e.g., Ellis et al., 2012; Nesse, 2001).

Implications for the Core Points of Developmental Psychopathology

The mutual interplay between *normal and pathological development* is one of the core points of developmental psychopathology. An evolutionary perspective offers a deeper understanding of how "normality" and "pathology" can be defined in the first place and provides researchers with a conceptual toolkit for analyzing the full spectrum of undesirable conditions—from harmful and/or maladaptive dysfunctions to adaptive but undesirable mechanisms that may be erroneously mistaken for disorders. In between lies a range of explanatory categories in which adaptation and maladaptation coexist to various degrees. All too often, models in developmental psychopathology converge on dysregulation as the default explanation of undesirable conditions (see the next section). As we have shown here, dysregulation is only one of many potential explanations of psychopathological outcomes; a biologically informed taxonomy like the one we presented (see also Cosmides & Tooby, 1999; Nesse, 2001, 2011) can be a useful guide to formulate alternative hypotheses and build more sophisticated explanatory models.

An especially intriguing case is that of high-risk strategies characterized by unpredictable outcomes. Strategic risk provides a powerful explanation of *multifinality*, since—by definition—individual variables associated with risky strategies can be expected to predict positive outcomes in some individuals *and* negative outcomes in others. Furthermore, the outcomes of high-risk strategies are often determined in large part by chance factors, highlighting the connection between multifinality and *probabilistic causality* in developmental trajectories. A similar picture emerges if one considers the calibration of adaptive defenses and the probabilistic trade-offs involved in the balance between misfiring and appropriate responding.

An evolutionary approach also provides a nuanced view of the interplay between *risk and protective factors*—another defining point of developmental psychopathology. In particular, the logic of constraints and trade-offs suggests that some putative "risk factors" for a given condition may actually protect individuals from other (and perhaps more severe) conditions. Similarly, the logic of adaptive defenses should alert researchers to the possibility that some putative "protective factors" involving defense downregulation may actually interfere with an individual's ability to protect itself from rare but potentially severe threats. In sum, the approach we advocate goes beyond intuitive notions of risk and resilience and contributes to draw a more realistic picture of the complex, layered relations between health and pathology.

BEYOND MENTAL HEALTH: CONDITIONAL ADAPTATION AND LIFE HISTORY THEORY

A widespread set of assumptions in developmental psychology is that children raised in supportive and well-resourced environments (e.g., who live in communities with social networks and resources for young people; who have strong ties to schools and teachers; who benefit from nurturing and supportive parenting; who are exposed to prosocial peers) tend to develop normally and express optimal trajectories and outcomes. By contrast, developmental processes among children raised in high-stress environments (e.g., who experience poverty, discrimination, low neighborhood attachment, and community disorganization; who feel disconnected from teachers and schools; who experience high levels of family conflict and negative relationships with parents; who are exposed to delinquent peers) put them at risk for dysregulation, leading to impaired functioning and problem behaviors that are destructive to themselves and others. This set of assumptions is powerful and pervasive, if usually implicit,

and underlies what we call the *mental health model* of developmental psychopathology.

In contrast with the mental health model, theory and research in evolutionary biology have come to acknowledge that, in most species, single best strategies for survival and reproduction are unlikely to evolve. Instead, the locally optimal strategy normally varies as a function of three overarching parameters. First, the costs and benefits of different strategies depend on the physical, economic, and social parameters of an organism's environment (e.g., food availability, mortality rates, quality of parental investment, social competition). This context-dependency means that a strategy that promotes success in some environmental contexts may lead to failure in others. Second, the success and failure of different strategies depends on an organism's condition or relative competitive abilities in the population (e.g., age, body size, health, history of wins and losses in agonistic encounters); that is, the cost–benefit trade-offs of different strategies varies depending on an organism's internal condition and competitive status. Third, an organism's sex often has important implications for the range of available strategies and their relative costs and benefits.

In this section we discuss how developmental processes increase adaptation by matching an organism's phenotype to local environmental conditions and individual characteristics. We begin by reviewing the general concepts of plasticity and conditional adaptation. We then introduce evolutionary life history theory and show how it provides a general framework for adaptive plasticity, as well as an integrative understanding of the development of individual differences in physiology, growth, and behavior.

Developmental Plasticity and Conditional Adaptation

Because the viability of different survival and reproductive strategies is so context- and condition–dependent, natural selection tends to maintain *adaptive developmental plasticity*: biological systems that reliably guide the development of alternative phenotypes (including anatomy, physiology, and behavior) to match an organism's internal condition and external environments (see West-Eberhard, 2003). Developmental plasticity involves "durable biological change in the structure or function of a tissue, organ, or biological system" (Kuzawa & Quinn, 2009, p. 132). Importantly, adaptive developmental plasticity is a nonrandom process; it is the outcome of structured interplay between the organism and its environment, shaped by natural selection to increase the capacity and tendency of individuals to track both their internal condition and external environments and adjust the development of their phenotypes accordingly. Developmental plasticity is ubiquitous throughout the animal world (see extensive reviews in DeWitt & Scheiner, 2004; West-Eberhard, 2003).

Developmental plasticity is critically important for enabling organisms to adapt to stress, which has always been part of the human experience. Indeed, almost half of children in hunter–gatherer societies—the best model for human demographics before the agricultural revolution—die before reaching adulthood (e.g., Volk & Atkinson, 2013). Thus, from an evolutionary-developmental perspective, stressful rearing conditions, even if those conditions engender sustained stress responses that must be maintained over time, should not so much impair neurobiological systems as direct or regulate them toward patterns of functioning that are adaptive under stressful conditions (see Ellis et al., 2012; Frankenhuis & de Weerth, 2013).

Because developmental plasticity involves durable change, it is inherently forward-looking; that is, it involves predicting—and preparing—for future environments. Boyce and Ellis (2005) make this explicit in their definition of *conditional adaptation*: "Evolved mechanisms that detect and respond to specific features of childhood environments, features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature, and entrain developmental pathways that reliably matched those features during a species' natural selective history" (p. 290). During fetal development and infancy, important features of the environment are communicated to the child via the placenta and lactation in nutrients, metabolites, hormones, growth factors, and immune factors that reflect the mother's current and past experiences (Kuzawa & Quinn, 2009). Beyond these molecular signals from the mother, relevant features of the environment are detected and encoded through the child's ongoing experiences.

Developmental plasticity necessitates developmental trade-offs. For example, tadpoles (*rana sylvatica*) alter their size and shape based on the presence of dragonfly larvae in their rearing environment (Van Buskirk & Relyea, 1998). These alterations involve development of smaller and shorter bodies and deep tail fins. Although tadpoles that do not undergo these morphological changes are highly vulnerable to predation by dragonflies, those that do but end up inhabiting environments that are not shared with dragonflies have relatively poor developmental and survival outcomes. In short, the predator-induced phenotype is only conditionally adaptive. This process highlights that in many cases, natural selection favors a primary phenotype that yields high payoffs under favorable

circumstances and a secondary phenotype that "makes the best of a bad situation" (West-Eberhard, 2003).

The Role of Genotypic Variation

As should be clear from the tadpole example, in addition to the apparent benefits of developmental plasticity, there can be substantial costs. On the one hand, there is the cost of producing and maintaining the appropriate regulatory and assessment mechanisms to support alternative patterns of development. On the other hand, environmental cues may have limited validity, and thus developmental plasticity in response to current conditions may fail to correctly predict future environmental conditions. Consequently, while adaptive developmental plasticity is widespread, it is not always be the best or only option. As an alternative to adaptive developmental plasticity, or in conjunction with it, natural selection may also maintain genetic variation as a solution to the critical adaptive problem of matching phenotypes to heterogeneous environments.

There are a variety of circumstances in which genetic contributions to alternative phenotypes are likely to be favored by natural selection. When individuals inhabit multi-niche environments, and they are able to choose the niche that best fits their phenotype, it may partly or fully obviate the need for developmental plasticity. Instead, a diversity of genetically regulated phenotypes that are specialized to the different social or physical niches can thrive in this context (see Wilson & Yoshimura, 1994). In addition, genetic variation can be maintained through *balancing selection,* whereby selection for alternative phenotypes systematically changes across time, space, population states, and so forth. A common type of balancing selection is *frequency-dependent selection*, which occurs when the fitness of different phenotypes changes as a function of their frequency in a population. The most viable form of frequency-dependent selection is negative, selecting against a given phenotype as it becomes more common. For example, aggressive individuals may be very successful when they are surrounded by tame individuals; however, as they multiply and begin to "invade" the population, their reproductive success may drop as they now compete mainly with other aggressive individuals. Balancing selection can also result from *heterozygote advantage* (when individuals who are heterozygous at a certain locus have higher fitness than either of the homozygous types) or from changes in selection pressures over time and space (*fluctuating selection*). Fluctuating selection pressures, by definition, weaken directional selection and therefore enable higher rates of genetically-regulated phenotypic variation (including neutral and deleterious forms of variation).

A crucial question is, to what degree should phenotypic variation be more developmentally contingent and plastic versus more strongly regulated by genotypic variation? The answer is not simple; indeed, what is typically found in organisms is a mixture of the two. Theoretical models suggest that one should often expect a balance between genetic and environmental determination of phenotypic individual differences. Depending on the structure of environmental variation, the costs and benefits of plasticity, and the life history of an organism, a given selection regime—for example one of temporally fluctuating selection—may maintain different proportions of developmental plasticity and genotypic variation.

The reproductive strategies of the male swordtail fish provide an example of this complexity, demonstrating the importance of adaptive genetic variation, adaptive developmental plasticity, and their interplay (reviewed in Ellis, Jackson, & Boyce, 2006). In the swordtail, three alleles at the *P* locus on the Y chromosome correspond to three modes in size distribution of mature males (small, intermediate, and large). Although all three genotypes perform the range of species-typical mating strategies, they do so at different size-related frequencies. Specifically, small, intermediate, and large males generally sneak, sneak and court, and court females, respectively. Size is the primary mediating mechanism in this species through which allelic variations influence mating strategies.

In determining alternative mating strategies, the key developmental event in male swordtail fish is gonadarche (maturation of the gonads). Specifically, the three alleles at the *P* locus differentially influence timing of gonadarche, which occurs earlier in genotypically small than in genotypically large males. In addition to these genetic influences, timing of gonadarche is also sensitive to a number of environmental factors, such as temperature and agonistic interactions with other males. These environmental influences can result in genotypically small males that are larger than genotypically intermediate males, and alternative mating strategies correlate more strongly with size than with genotype. In addition, mating strategies of male swordtail fish are competition-dependent in relation to interaction with other males. For example, males of intermediate size will sneak and chase females rather than court when in the presence of larger males.

In sum, both genomic and environmental factors influence timing of gonadarche, which in turn coordinates patterns of gene expression involved in the developmental cascade that induces sexual maturation and halts or dramatically reduces growth. Timing of gonadarche strongly influences size, and size is a major developmental

factor in entrainment of alternative mating strategies. At the same time, mating strategies are conditionally adjusted in response to current physical and social dimensions of the environment. Thus, although there are strong genotypic influences on size and developmentally-linked mating strategies, the development of the alternative phenotypes in fact emerges through a complex series of gene-environment interplay. Importantly, these developmental interactions occur through integrated effects of gene products and environmental conditions on the developing phenotype.

Reaction Norms

A useful tool for thinking about developmental plasticity is the concept of a *reaction norm*. A reaction norm is a function describing how a single individual may express different phenotypes in response to a range of environmental conditions. While reaction norms are often treated as a property of genotypes (see Schlichting & Pigliucci, 1998), genotypic effects on development—including individual differences in plasticity—are always mediated by the preexisting phenotype. Moreover, genetically different individuals may develop the same phenotype following different developmental trajectories. Thus, reaction norms may be legitimately employed to map phenotypic change on preexisting phenotypic (rather than genotypic) differences.

Figure 1.2 illustrates individual differences in developmental plasticity in the simple case of linear reaction norms. As can be seen in the figure, individuals may differ in the *elevation* and/or *slope* of their reaction norms. A steeper slope indicates higher susceptibility to environmental factors, as the same amount of variation in environmental conditions results in a larger change in the expressed phenotype. The *reaction range* of an individual is the difference between the minimum and maximum phenotypic score over a fixed range of the environmental variable, and denotes the individual's overall potential for plasticity. When the reaction norms of different individuals are not parallel (different slopes; Figures 1.2b and 1.2c), the result is a statistical genotype × environment (GxE) or phenotype–environment (PxE) interaction, whereby the effect of the environment is moderated by an individual's genotype/phenotype (and vice versa).

Adaptive Plasticity in the Development of Life History Strategies

From Life History Trade-offs to Life History Strategies

A major framework in evolutionary biology for explaining patterns of developmental plasticity and individual differences is life history theory (see Kaplan & Gangestad, 2005; Stearns, 1992). All organisms live in a world of limited resources; for example, the energy that can be extracted from the environment in a given amount of time is intrinsically limited. Time itself is a limited good; the time spent by an organism looking for mates cannot be used to search for food or care for extant offspring. Due to these structural and resource limitations, organisms cannot maximize all components of fitness simultaneously and instead are selected to make trade-offs that prioritize resource expenditures so that greater investment of time and/or resources in one domain occurs at the expense of investment in competing domains.

For example, resources spent on mounting a robust inflammatory response to fight infection cannot be spent on reproductive effort. Thus, the benefits of inflammatory response are traded off against the costs of lower ovarian function in women and reduced musculoskeletal function in men (Clancy et al., 2013; Muehlenbein & Bribiescas, 2005). Trade-offs between reproductive effort and health go in the opposite direction as well, as early reproductive maturation is linked to more physical health problems in

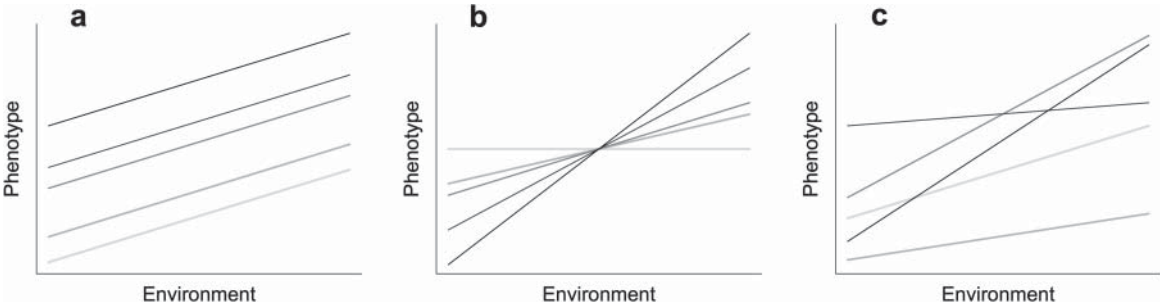

Figure 1.2 (1) Individual differences in phenotypic elevation but not in slope and reaction range; all genotypes have the same plasticity. (2) Individual differences in slope and reaction range (differential plasticity); all genotypes have the same elevation at the environmental mean. (3) Individual differences in elevation, slope, and reaction range.

adulthood (e.g., Allsworth, Weitzen, & Boardman, 2005). Each trade-off constitutes a decision node in allocation of resources, and each decision node influences the next decision node (opening up some options, foreclosing others) in an unending chain over the life course (Ellis, Figueredo, Brumbach, & Schlomer, 2009). This chain of resource-allocation decisions—expressed in the development of a coherent, integrated suite of physiological and behavioral traits—constitutes the individual's life history strategy.

Life history strategies are adaptive solutions to fitness trade-offs within the constraints imposed by social conditions, physical laws, phylogenetic history, and developmental mechanisms. An organism's life history strategy coordinates morphology, physiology, and behavior in a way that maximizes expected fitness in a given environment (Braendle, Heyland, & Flatt, 2011; Réale et al., 2010). At the most basic level, the resources of an organism must be distributed between *somatic effort* and *reproductive effort*. Somatic effort can be further subdivided into growth, survival and body maintenance, and developmental activity (Geary, 2002). Developmental activity includes play, learning, exercise, and other activities that contribute to building and accumulating *embodied capital*—strength, coordination, skills, knowledge, and so forth (Kaplan & Gangestad, 2005; Kaplan, Hill, Lancaster, & Hurtado, 2000). Reproductive effort can be subdivided into *mating effort* (finding and attracting mates, conceiving offspring), *parenting effort* (investing resources in already conceived offspring), and *nepotistic effort* (investing in other relatives, for example siblings and grandoffspring).

The critical decisions involved in a life history strategy can be summarized by the fundamental trade-offs between current and future reproduction, between quality and quantity of offspring, and—in sexually reproducing species—between mating and parenting effort (see Ellis et al., 2009). By delaying reproduction, an organism can accumulate resources and/or embodied capital, thus increasing the quality and fitness of future offspring; however, the risk of dying before reproducing increases concomitantly. When reproduction occurs, the choice is between many offspring of lower quality and fewer offspring of higher quality. Although intensive parental investment is a powerful way to increase the embodied capital (and long-term prospects) of one's descendants, the fitness gains accrued through parenting must be weighed against the corresponding reduction in mating opportunities. Different life history strategies solve these problems in different ways by determining how organisms allocate effort among fitness-relevant traits. The same basic framework can be used to describe differences between species, as well as differences between individuals of the same species.

At the broadest level of analysis, life history traits covary along a dimension of *slow* versus *fast* life history strategies. Variation along the slow-fast continuum is observed both between related species and between individuals of the same species (see Ellis et al., 2009; Réale et al., 2010). Slow growth and late reproduction correlate with long life span, high parental investment, fewer offspring of higher quality, and low juvenile mortality. Conversely, fast growth and early reproduction correlate with high juvenile mortality, short life span, larger numbers of offspring, and reduced parental investment in each (Figure 1.3). Fast life history strategies are comparatively high risk, focusing on mating opportunities (which typically involves more risky and aggressive behavior), reproducing at younger ages, and producing a greater number of offspring with more variable outcomes.

Sex Differences in Life History Trade-offs

The asymmetries introduced by sexual reproduction have important implications for the life histories of males and females. For example, in most species males tend to engage

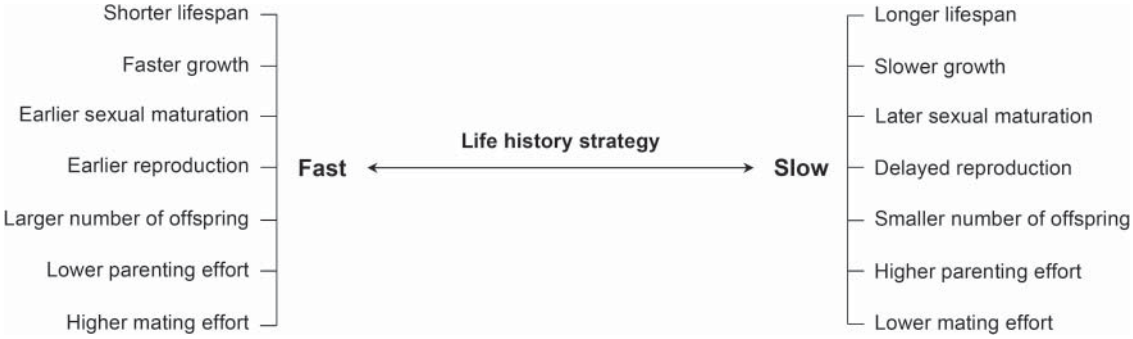

Figure 1.3 The fast–slow continuum of life history variation.

in higher mating effort and lower parental effort than females (Geary, 2002; Trivers, 1972). In addition, males usually undergo stronger sexual selection, that is, their reproductive success is more variable than that of females; they also tend to mature more slowly, in order to gain the competitive abilities and qualities needed for successful competition for mates. Sexual asymmetries in life history strategies can be attenuated in species with monogamous mating systems and when both parents contribute to offspring care. Compared with other mammals, humans show an unusually high degree of paternal investment; we are clearly adapted for the possibility of monogamous, long-term relationships. However, human paternal care is also highly variable and facultative (e.g., Geary, 2005; Quinlan, 2008), and strict monogamy is rarely if ever found. Overall, human mating is best characterized as strategically flexible (Gangestad & Simpson, 2000), with a widely documented tendency for men to engage in higher mating effort than women.

As a result, the trade-off between current and future reproduction is more pressing for women than for men: women's reproductive rate is limited by the long duration of gestation and the considerable energetic investment of pregnancy and lactation, and their window for successful reproduction necessarily ends with menopause. In contrast, men can potentially sire many offspring in a very short time, as well as for a more extended period of their lives. Men's crucial trade-off is the one between mating and parenting: the payoffs of high mating effort are potentially much larger for males, who can benefit directly from having access to a large number of partners; women can usually have only one child at a time, and thus benefit comparatively less from mating with multiple partners.

Environmental Determinants of Life History Strategy

Developmental calibration of slow versus fast life history strategies is a prototypical case of developmental plasticity. Key dimensions of the environment that regulate the development of life history strategies include energy availability, extrinsic morbidity–mortality, and predictability of environmental change (Ellis et al., 2009; Kuzawa & Bragg, 2012). Energetic resources—caloric intake, energy expenditures, and related health conditions—set the baseline for many developmental processes. Energy scarcity slows growth and delays sexual maturation and reproduction, resulting in a "slow" life history strategy. However, when bioenergetic resources are adequate to support growth and development, then proximal cues to extrinsic morbidity–mortality and unpredictability generally promote faster life history strategies.

Extrinsic morbidity–mortality refers to external sources of disability and death that are relatively insensitive to the adaptive decisions of the organism. Environmental cues indicating high levels of extrinsic morbidity–mortality cause individuals to develop faster life history strategies. Faster strategies in this context—a context that devalues future reproduction—function to reduce the risk of disability or death prior to reproduction. Moreover, high extrinsic morbidity–mortality means that investing in parental care has quickly diminishing returns, which favors reduced parental investment and offspring quantity over quality. Accordingly, exposure to environmental cues indicating extrinsic morbidity–mortality (i.e., observable cues that reliably covaried with morbidity–mortality risks during evolutionary history) can be expected to shift life history strategies toward current reproduction by anticipating maturation and onset of sexual activity. In humans, these cues may include exposure to violence, harsh childrearing practices, premature disability and death of other individuals in one's local ecology, and so forth.

In addition to extrinsic morbidity–mortality, environmental unpredictability—stochastic changes in ecological and familial conditions also regulates development of life history strategies (Ellis et al., 2009). In environments that fluctuate unpredictably (e.g., changing randomly between Conditions A and B, so exposure by parents or their young offspring to Condition A does not reliably forecast whether offspring will mature into Condition A or B), long-term investment in a development of a slow life history strategy does not optimize fitness; all of the energy invested in the future is wasted if the individual matures into an environment where life expectancy is short. Instead, individuals should detect and respond to signals of environmental unpredictability by adopting faster life history strategies. In humans, cues of unpredictability may include erratic neighborhood conditions, frequent residential changes, fluctuating economic conditions, changes in family composition, and so forth.

Belsky and colleagues (1991) were the first to hypothesize that harsh parenting, conflictual family relations, and insecure attachment would predict early sexual maturation, impulsivity, reduced cooperation, and exploitative interpersonal styles—the expected correlates of a fast life history strategy in humans. Empirical studies have confirmed these associations and detailed how harsh family relations, insecure attachment, and high levels of mortality in the immediate environment predict early puberty (in females), precocious sexuality, unstable couple relationships, and promiscuous mating styles (see special section of *Developmental Psychology*; Ellis & Bjorklund, 2012).

Key psychological mediators of fast life history strategies include insecure attachment styles, impulsivity, present orientation (the inability to delay gratification and/or wait for larger rewards in the future), and a short subjective life expectancy. These variables are reliably associated with earlier onset of sexual activity, unrestricted sociosexuality (a desire for short-term, promiscuous sexual relationships), larger number of sexual partners, earlier age at first birth in women, increased risk taking, reduced cooperation, and antisocial behavior (reviewed in Belsky, 2012; Chisholm, 1999; Del Giudice, 2009; Del Giudice, 2014a; Figueredo & Jacobs, 2010; Figueredo et al., 2006). At the level of personality traits, slow life history strategies are robustly associated with agreeableness and conscientiousness (Del Giudice, 2014a). Taken together, these results strongly support the existence of a fast-slow dimension underlying a broad spectrum of individual differences in humans.

Because extrinsic morbidity–mortality and unpredictability are distinct, developmental exposures to each of these environmental factors should uniquely contribute to variation in life history strategy (Ellis et al., 2009). Longitudinal analyses of the National Longitudinal Study of Adolescent Health, the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development, and the Minnesota Longitudinal Study of Risk and Adaptation (MLSRA) support this prediction (Belsky, Schlomer, & Ellis, 2012; Brumbach, Figueredo, & Ellis, 2009; Simpson, Griskevicius, Kuo, Sung, & Collins, 2012). For example, in the NICHD and MLSRA studies, exposures to environmental unpredictability in the first 5 years of life (e.g., parental changes, residential changes) uniquely predicted faster life history strategies in adolescence and emerging adulthood, independent of the effects of unpredictability in later childhood and indicators of extrinsic morbidity–mortality.

The Centrality of the Phenotype

All developmental processes are ultimately the product of structured organism–environment interplay. Development is always modulated by the organized phenotype, which is initially provided by the parents in the form of a zygote and then changes during ontogeny in response to both genetic and environmental influences.

Consider a central life history trait: timing of sexual maturation. As discussed above, sexual maturation is regulated by energetic conditions, so that—on average—individuals in well fed populations experience early puberty and poorly fed populations experience late puberty. The effects of energetic conditions, however, are modulated by the organized phenotype. For example, food-getting ability (a behavioral phenotype), metabolic efficiency (a physiological phenotype), and energy stores in the form of body fat (a morphological phenotype) all contribute to regulation of puberty; that is, these phenotypic traits modulate the effects of the critical environmental factor (energy availability) on maturation and functioning of the reproductive axis. The same logic applies to genetic effects: genes provide templates for the production of particular molecules that become incorporated into the phenotype, depending on the responsivity of the phenotype to those molecules and the presence of the necessary environmental building blocks (substances from outside the organism) to support gene expression (West-Eberhard, 2003). The effects of genes, environments, and phenotypes are hierarchically organized: The preexisting phenotype is the transducer of both genetic and environmental sources of information. Specifically, genetic and environmental effects depend on the phenotype being organized to accept them, and the modified phenotype retains these effects as development proceeds. In this sense, the phenotype embodies one's own particular history of genetic and environmental effects.

The organizational role of the phenotype is critical to understanding the development of life history strategies. As we will discuss in detail in the next section, Del Giudice and colleagues (2011) proposed that one of the key functions of the stress response system is to regulate an organism's life history strategy. According to the adaptive calibration model (ACM; Del Giudice et al., 2011; Ellis, Del Giudice, & Shirtcliff, 2013), the stress response system coordinates the development of alternative life history strategies by affecting a broad suite of physiological and psychological traits, including growth and maturation, sexual and reproductive functioning, social learning, aggression, competition and risk taking, pair bonding, and related factors. This occurs in part through extensive physiological linkages between the stress response system and the reproductive axis (Ellis, 2004). The key idea is that activation of stress, metabolic, and immune system responses during childhood provides crucial *information* about threats and opportunities in the environment, their type, and their severity. Over time, this information becomes biologically embedded in the parameters—recurring set points and reactivity patterns—of these systems. These parameters provide the developing person with statistical summaries of key dimensions of the environment. An alternative pathway for the effects of stress may revolve around somatic damage: if early stress causes permanent damage to the organism and thus reliably reduces life expectancy, it may be adaptive for individuals exposed to stress early in life to engage in faster

life history strategies even if the environment improves later on (Nettle, Frankenhuis, & Rickard, 2013). In total, the stress response system operates as a mechanism of conditional adaptation: it collects and biologically embeds information from the environment, and makes use of that information to match the developing phenotype to local environmental conditions. In this manner, the environment becomes instantiated in the phenotype.

At the same time, the phenotype modulates environmental effects at all points in development. As a result of differences in extant phenotypes, individuals differ in their reaction norms (Schlichting & Pigliucci, 1998). Because reaction norms differ in slope across individuals, some people are more likely than others to experience sustained developmental change in response to environmental exposures, including change in the physiological parameters that mediate development of alternative life history strategies. Moreover, as a result of differences in the organized phenotype, life history-relevant physiological parameters already differ across individuals at birth (cf. temperament). Stated differently, people differ in the elevation of their reaction norms. This means that developmental change in the physiological bases of life history strategies and their behavioral outcomes are likely to occur around different points on the life history spectrum (i.e., around the faster range of life history in some individuals and the slower range in others).

In total, the organized phenotype is present from conception and can be described in terms of the steepness and location of its reaction norms along various dimensions. These reaction norms, which have already undergone significant development by the time a child is born, are both regulated by and constrain the effects of environmental and genetic factors. The organized phenotype incorporates and biologically embeds environmental and genetic inputs throughout the life course. This ongoing process translates into individual differences in such critical traits as body size, energy reserves, metabolic efficiency, susceptibility to environmental influence, immune function, fecundity, mate value, and fighting ability. Differences between individuals in these phenotypic traits influence the cost–benefit trade-offs of different life history strategies and thus play a central role in regulating the development of these strategies.

Consider the trade-off between mating effort and parenting effort in men. Sexual selection models, such as Gangestad and Simpson's (2000) *strategic pluralism theory*, emphasize social and sexual competition as important factors shaping adaptive variation in reproductive strategies. According to this perspective, individuals who are competitively advantaged relative to peers (i.e., who possess social and physical attributes that make them successful in same-sex competition and targets of choice by the other sex) have more mating opportunities. These enhanced opportunities tend to bias resource allocations toward more mating effort at the expense of parental effort. Because male reproductive success is ultimately constrained by the ability to access, attract, and retain mates, alternative male mating strategies should be especially attuned to the demands and desires of women and the ability of men to successfully engage in intrasexual competition. To a large extent, this variable success arises from phenotypic traits that facilitate gaining status and attracting mates (e.g., size, aggressiveness, physical attractiveness, social relations with others). This leads to the hypothesis that intrasexual competitive abilities in men will regulate life history strategies, especially the mating-parenting trade-off.

This hypothesis has been supported by a large empirical literature showing that men who achieve high social status or who possess honest indicators of genetic quality (e.g., physical attractiveness, bilateral symmetry of body parts) engage in more mating effort. For example, anthropological evidence indicates that social status is directly related to male reproductive success in horticultural, agricultural, and pastoral societies (see Pérusse, 1993, for an extensive review). Men with higher status in industrial societies, as measured by education, occupation, and income, also report a greater number of sex partners than men of lower social status (Pérusse, 1993). In addition, men who report that they are more attractive to the opposite sex also report having sex at an earlier age, a greater number of sex partners, and an unrestricted sociosexual orientation (reviewed in James & Ellis, 2013). Finally, men who are more symmetrical in bilateral traits have been found to have more lifetime sexual partners as well as more extrapair sexual encounters during ongoing relationships (controlling for physical attractiveness). In contrast, no consistent relations have been found between women's symmetry and number of lifetime sexual partners or extrapair sexual relationships (reviewed in Thornhill & Gangestad, 2004).

Another critical life history trade-off that is regulated by phenotypic condition is current versus future reproduction. Effort put into reproducing now will use energy or resources that cannot be used or saved for future reproduction. The costs of current reproduction may be paid in terms of reduced number, quality, or survival of future offspring, as well as reduced growth and survival of the parent. This decision whether to pay these costs critically

depends of the physical condition of the individual. If either external conditions (e.g., infectious diseases, warfare) or internal state (e.g., poor health, oxidative stress) indicate a heightened probability of premature disability or death, then individuals should shift resource allocations toward current reproduction (presuming adequate bioenergetic resources to support a fast strategy).

Research examining relations between exposures to stress, biological aging or health, and reproductive strategies has provided preliminary support for this hypothesis. For example, Bleil and colleagues (2013) found that heightened psychosocial stress was associated not only with ovarian reserve depletion in older women but also with earlier puberty and higher antral follicle count in younger women, indicating a faster life history strategy. Likewise, women who were exposed *in utero* to the Dutch famine of 1944–1945 not only had increased risk of chronic degenerative disease but also started reproducing at a younger age, had more offspring, had more twins, and were less likely to remain childless (Painter et al., 2008), again indicating a faster life history strategy. An important qualification to these findings is that individuals with life-expectancy-reducing chronic disease diagnosed during childhood also shift toward current reproduction (e.g., early age at first reproduction), even though the incidence of serious chronic disease was uncorrelated with family and ecological stressors (Waynforth, 2012). These data indicate that internal factors, such as compromised phenotypic condition (i.e., damage), in and of itself, can contribute to accelerate life history strategies. Once again, this underscores the centrality of the phenotype in organizing adaptive plasticity through the reciprocal interplay of environmental and genetic factors, either of which can have more decisive effects in different developmental contexts (see extended discussion in West-Eberhard, 2003).

Implications for the Core Points of Developmental Psychopathology

While the mental health model of developmental processes resonates with the intuitions of many researchers, its narrow view of adaptation and maladaptation is an obstacle toward the goal of synthesizing *normal and pathological development* in a single framework. The concepts of adaptive plasticity and conditional adaptation offer a better appreciation of the logic of individual differences and that of gene-environment interplay in development. The crucial idea is that adverse environmental conditions often direct developmental processes along alternative adaptive pathways, rather than simply impair or dysregulate them.

The framework of life history theory adds a layer of specificity to this general picture. Life history concepts can be employed to make remarkably accurate predictions about the structure of individual differences in physiology, growth, and behavior, and the environmental factors that shift development along alternative trajectories. In particular, life history theory delineates basic dimensions of environmental stress and support that underlie the multitude of *risk and protective factors* described in developmental psychopathology—resource availability, morbidity/mortality risk, and unpredictability. This is especially useful given the confusing abundance of environmental/contextual variables that might be measured and correlated with developmental outcomes. It is also important to stress how adaptive plasticity and life history theory offer a thoroughly *contextualist* view of development, though one that is compatible with a major role of genetic factors and genotype × environment interactions.

Finally, the centrality of the phenotype in enabling and structuring adaptive plasticity has a number of implications for the prospect of integrating developmental psychopathology and EDP. First of all, it does away with the notion that EDP is wedded to any sort of genetic determinism and shows how it is possible to integrate a sophisticated view of developmental mechanisms within an explicitly evolutionary framework. Second, it suggests a deep theoretical rationale for the prevalence of *probabilistic causality* in development. Third, it affords a principled way to investigate the connection between behavioral strategies and *brain and neurobiological factors*, thanks to the concept of biological embedding. In the next section we will further illustrate this point by reviewing the role of the stress response system in collecting environmental information and regulating physical and behavioral development.

BEYOND ALLOSTATIC LOAD: THE STRESS RESPONSE SYSTEM AS A MECHANISM OF CONDITIONAL ADAPTATION

How does repeated or chronic childhood adversity shape biobehavioral development and, through it, mental and physical health? Consistent with the mental health model, there is a widely accepted answer to this question in the field of developmental psychopathology. Instantiated in models of "toxic stress" (Shonkoff et al., 2012) and "allostatic load" (Lupien et al., 2006; McEwen & Stellar, 1993), that answer posits a striking duality: biological responses to stress are usually adaptive in the short term, but protracted activation of stress response systems is

maladaptive and toxic in the long term. Toxic stress causes disruptions of brain structure and function, resulting in dysregulation of physiological mediators—autonomic, neuroendocrine, metabolic, and immune—"that are the precursors of later impairments in learning and behavior as well as the roots of chronic, stress-related physical and mental illness" (Shonkoff et al., 2012, p. e236). As eloquently stated by Juster and colleagues (2011), the wear and tear of toxic stress and altered stress hormone functioning "inexorably strains interconnected biomarkers that eventually collapse like domino pieces trailing toward stress-related endpoints" (p. 725).

These models of toxic stress and allostatic load, however, only tell half of the story. The other half is the central role of the stress response system (SRS) in orchestrating physical and psychosocial development of both humans and nonhuman species (Ellis et al., 2006; Korte, Koolhaas, Wingfield, & McEwen, 2005), both in terms of species-typical development and individual differences. One of the most remarkable features of the SRS is the wide range of individual variation in its physiological parameters. Some individuals respond quickly and strongly even to minor events, whereas others show flat response profiles across most situations. Furthermore, the balance of activation among primary SRS subsystems—the sympathetic nervous system (SNS), the parasympathetic nervous system (PNS), and hypothalamus-pituitary-adrenal (HPA) axis—can vary considerably across individuals.

In developmental psychopathology, the standard framework for understanding the development and meaning of individual differences in stress responsivity is that of the *allostatic load model* (ALM; see Juster et al., 2011; Lupien et al., 2006; McEwen & Stellar, 1993). A guiding assumption of the ALM is that there is an optimal level of stress responsivity; accordingly, both "hyperarousal" and "hypoarousal"—recurring over or under activity of physiological mediators—are routinely described as dysfunctional deviations from the norm, usually caused by a combination of excessive stress exposure and genetic or epigenetic vulnerability. In this framework, environmental stress is treated as a risk factor for all kinds of symptoms and disorders (Compas & Andreotti, 2013). While some authors have argued that optimal adaptation is fostered by environments that contain *moderate* amounts of stressors (e.g., Rutter, 1993; Seery, 2011), the underlying assumption remains that a single best environment exists, and that deviations from that optimum cause dysregulation and pathology.

In this section we argue that acceptance of these assumptions, without placing them in a larger evolutionary-developmental framework, has impeded our understanding of the role of stress response systems in adaptively regulating development (for a detailed exposition see Ellis & Del Giudice, 2014). Specifically, models of allostatic load focus on the long-term *costs* of childhood stress and adversity—the "wear and tear" on multiple organ systems induced by chronic stress—but do not address the *benefits* of calibrating autonomic, neuroendocrine, metabolic, and immune systems to match current and future environments. We argue that this overemphasis on costs misses something fundamental and thus weakens the conceptual power of the ALM perspective. The result has been an imbalanced approach to research that has yielded dramatically more empirical knowledge about dysfunction than adaptive function, making it difficult to gain a coherent big picture of the subject matter.

A promising alternative to the ALM is provided by the *adaptive calibration model* (ACM; Del Giudice et al., 2011), a theory of individual differences in stress responsivity that builds on the concepts of life history theory and developmental plasticity. The ACM supplements the ALM and revises some of its key assumptions, thus laying the foundation for a broad theory of individual differences in stress responsivity. In this section we summarize the key tenets of the ACM, explicitly compare the ACM with the ALM, and discuss the implications of the two models for understanding adaptive and maladaptive developmental responses to stress (for more extended discussion, see Ellis & Del Giudice, 2014). Besides offering a broader perspective on the role of stress in development, the ACM exemplifies how the principles of EDP can be leveraged to achieve theoretical integration across multiple levels of analysis, from social behavior to neurobiology.

The Adaptive Calibration Model

The ACM is a theory of developmental programing focusing on calibration of the SRS and associated life history strategies to local environmental conditions. The ACM has its main theoretical foundations in life history theory and the theory of adaptive developmental plasticity (West-Eberhard 2003); it integrates and extends previous evolutionary models of stress (e.g., Boyce & Ellis 2005; Flinn, 2006; Korte et al., 2005; Porges, 2007) into a coherent theoretical framework. For a detailed presentation of the model, see Del Giudice and colleagues (2011).

The central tenet of the ACM is that the SRS operates as a mechanism of conditional adaptation, with a key role in

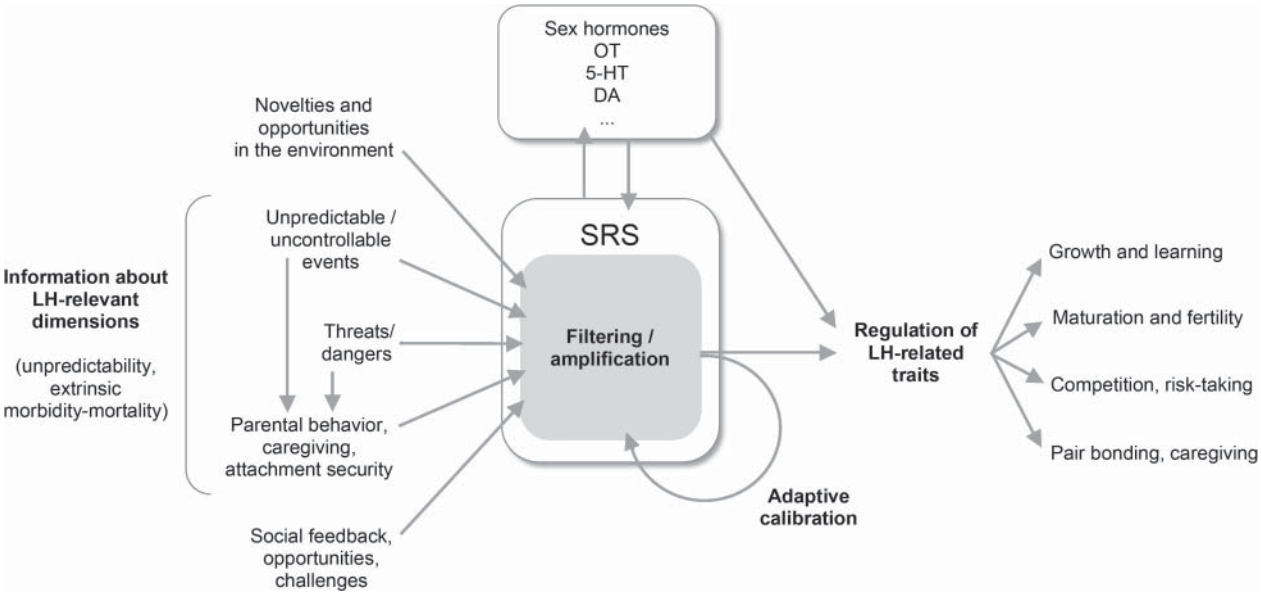

Figure 1.4 Core theoretical structure of the adaptive calibration model. SRS: stress response system; LH: life history; OT: oxytocin; 5-HT: serotonin, DA: dopamine. *Source:* Reprinted from M. Del Giudice, B. J. Ellis, & E. A. Shirtcliff, The adaptive calibration model of stress responsivity, *Neuroscience & Biobehavioral Reviews*, *35*, 1564, 2011.

regulating the development of individual life history strategies (Figure 1.4). In the ACM, the activation of autonomic, neuroendocrine, metabolic, and immune system responses during childhood provides crucial information about threats and opportunities in the environment, their type, and their severity. Over time, this information becomes embedded in the parameters—recurring set points and reactivity patterns—of these systems. These parameters provide the developing person with statistical summaries of key dimensions of the environment. For example, sustained activation of the HPA axis is generated by exposures to danger, unpredictable or uncontrollable contexts, and social evaluation, as well as energetic stress (see Dickerson & Kemeny, 2004; Gunnar et al., 2009); thus, the HPA axis tracks the key environmental variables involved in regulation of alternative life history strategies. Analogous arguments have been made regarding mesolimbic dopamine (Gatzke-Kopp, 2011). In turn, individual differences in SRS functioning regulate the coordinated development of a broad cluster of life history-relevant traits (Figure 1.4).

Although the ACM focuses on developmental plasticity, all developmental processes are the product of systematic organism–environment interplay. Because some individuals have steeper reaction norms than others, some individuals are more likely than others to experience sustained developmental change in response to environmental exposures. Further, as a result of differences in the organized phenotype, SRS parameter values already differ across individuals at birth. Consequently, individuals differ in the location of their reaction norms along SRS dimensions (Boyce & Ellis, 2005), with change more likely to occur for different individuals around higher versus lower ends of responsivity. Within these reaction norm constraints, the ACM articulates a theory of environmental regulation.

In total, the SRS (1) collects and biologically embeds information from the environment and (2) makes use of that information to match the developing phenotype to local environmental conditions. A crucial aspect of this matching process is the (iterative) calibration of the SRS itself in the service of life history goals (curved arrow in Figure 1.4). SRS activity also feeds back on the system itself, resulting in responsivity patterns that are adaptively calibrated to current environmental conditions and the individual's overall strategy. This underscores the fact that responsivity patterns develop over time, and may change—within limits—if the local environment undergoes prolonged changes in safety or predictability (i.e., recalibration). Changes in responsivity are also expected to occur in tandem with key hormonal switches such as adrenarche, gonadarche, childbirth, and menopause. More details on pathways and transitions in development of responsivity patterns can be found in Del Giudice and colleagues (2011).

The Role of the SRS in Allostasis and in Transduction of Environmental Information

Environmental events signaling threats to survival or well-being produce a set of complex, highly orchestrated responses within the neural circuitry of the brain and peripheral neuroendocrine pathways regulating metabolic, immunologic, and other physiological functions. The SRS comprises primarily three anatomically distinct yet integrated and cross-regulated circuits: the PNS, SNS, and HPA axis. The general function of the PNS is to promote vegetative functions in the absence of stress (i.e., rest and restorative behavior) and reduce or downregulate cardiac activity. When a stressor is encountered, the PNS responds quickly by withdrawing this inhibitory influence (i.e., *vagal withdrawal*), allowing the SNS to operate unopposed and thus causing rapid increases in physiological arousal. The PNS promotes flexible responding to stress, sustained attention, and coping with mild to moderate stressors (such as solving a difficult puzzle). More extreme defense reactions associated with freeze/hide behaviors also involve PNS activation, albeit via different efferent fibers (Porges, 2007).

If parasympathetic deactivation is not sufficient to cope with the present challenge, activation of the SNS occurs within seconds, providing a second layer of response in this hierarchy. Sympathetic activation mediates fight–flight responses following a fast, direct pathway via the noradrenergic innervation of visceral organs and a slower, hormonal pathway through innervation of the adrenal medulla (e.g., Gunnar & Vazquez, 2006). Following SNS activation, the adrenal medulla secretes epinephrine (E) and norepinephrine (NE) to increase heart rate, respiration, blood supply to skeletal muscles, and glucose release in the bloodstream.

The third component of the SRS is the HPA axis, which mounts more delayed, long-term responses to environmental challenge. The end point of the HPA response is cortisol release by the adrenal cortex, typically within 5 minutes after the triggering event, with a cortisol peak between 10 and 30 minutes (Gunnar & Vazquez, 2006). The main effects of cortisol are to (1) mobilize physiological and psychological resources (e.g., energy release, alertness and vigilance, memory sensitization), and (2) counter-regulate physiological effects of SNS activation, facilitating stress recovery.

The process by which the regulatory parameters of the SRS (as well as other neurobiological systems) are modified in the face of challenge is termed *allostasis* (i.e., "stability through change"). Allostasis refers to the moment to moment process of increasing or decreasing vital functions (i.e., adaptively adjusting physiological parameters within the organism's operating range) to new steady states in response to the demands of the environment and the organism's resources (McEwen & Stellar, 1993; see also Lupien et al., 2006). Allostasis functions to help the organism cope with challenging events or *stressors*, enabling short-term adaptation to environmental perturbations. However, the term allostasis is not always used consistently; for example, some authors restrict the meaning of allostasis to long-term, potentially permanent changes in the system's parameters in contexts of protracted stress (what McEwen and Wingfield [2003] labeled *allostatic states* and is now more commonly referred to as *biological embedding*).

The SRS orchestrates whole-organism reactions to challenge through a suite of coordinated responses (i.e., allostatic adjustments). Depending on the intensity and duration of a stressor, SRS activation can reorient attentional focus, increase the organism's readiness for action (e.g., by increased heart/respiratory rate and changes in blood flow to various organs), shift the balance between different memory- and learning-related processes, release glucose into the bloodstream, suppress (or enhance) reproductive functioning, regulate immune function, and so on. The concept of allostasis represents a significant point of convergence between the ACM and the ALM. The ACM explicitly embraces the concept of allostasis and describes the coordination of allostatic responses as one of the main biological functions of the SRS.

The SRS responds not only to threats and challenges in the environment but also to novelties and positive social opportunities (e.g., unexpected or exciting rewards, opportunities for status enhancement, potential sexual partners). More generally, the SRS appears to mediate susceptibility to both cost-inflicting and benefit-conferring features of the environment, operating as an amplifier (when highly responsive) or filter (when unresponsive) of various types of contextual information (see extended discussion in Ellis, Del Giudice, & Shirtcliff, 2013). As we will discuss in the next section, this dual function of the SRS is captured by the concept of biological sensitivity to context (Boyce & Ellis, 2005), which posits that a highly responsive SRS increases the organism's openness to environmental influence.

The Role of the SRS in Regulating Development of Life History Strategies

The ACM proposes that, across development, the environmental information collected by the SRS (in interaction with the child's genotype) canalizes physiological and

behavioral phenotypes to match local ecological contexts (Figure 1.3). The SRS coordinates the development of alternative life history strategies by affecting a broad suite of life history-related physiological and psychological traits, including growth and maturation, sexual and reproductive functioning, social learning, aggression, competition and risk taking, pair bonding, and related factors. The assumption is that these traits and trade-offs are regulated in ways that once—even if possibly no longer—reliably enhanced fitness across different environmental contexts.

First of all, the SRS is crucially involved in the regulation of growth and metabolism, and chronic stress has been linked to individual differences in physical growth patterns. The SRS also modulates learning in a number of different ways: HPA and autonomic profiles have been associated with individual differences in cognitive functioning, memory, and self-regulation. Second, the SRS is functionally implicated in all the components of mating and parenting, beginning with sexual maturation. The autonomic systems, HPA, and gonadal axes are connected by extensive functional cross-talk, and HPA activity is linked to variation in pubertal maturation and fecundity. Variation in SRS functioning is also associated with romantic attachment styles. In turn, attachment styles predict relationship stability, commitment, and investment—all key determinants of parenting effort in humans. More directly, SRS functioning affects parenting behavior, including controlling and intrusive parenting practices, inconsistent discipline, and parental sensitivity to children's needs and demands. In men, cortisol and testosterone work together to direct somatic and behavioral effort toward mating or parenting. Finally, sexual competition is a crucial aspect of mating effort. Dominance-seeking, aggression, and risk taking are all functionally connected to mating competition, and all are associated with SRS functioning in synergy and interaction with testosterone, serotonin, and dopamine. Furthermore, stress exposure regulates mating behavior by altering mate preferences and affecting the perceived attractiveness of potential sexual partners (reviewed in Del Giudice et al., 2011; Ellis & Del Giudice, 2014).

In summary, the SRS not only collects and encodes crucial life history-relevant information but is also involved in the regulation of all the major aspects of human life history strategies. Other systems that contribute to life history regulation include the hypothalamic-pituitary-gonadal axis, the serotonergic, dopaminergic, and oxytocinergic systems, and the immune system. Not coincidentally, all of these systems engage in extensive bidirectional cross-talk with the SRS (see e.g., Gatzke-Kopp, 2011; Miller, Chen, & Parker, 2011; van Goozen, Fairchild, Snoek, & Harold, 2007).

Patterns of Responsivity

Del Giudice and colleagues (2011) provide an extended theoretical and empirical treatment of the logic underlying the development of alternative responsivity patterns in the ACM (see Figure 1.5), including predicted relations between SRS physiology and serotonergic, dopaminergic, and oxytocinergic functioning. Here we briefly summarize this logic. In safe, low-stress environments, a highly responsive SRS enhances social learning and engagement with the external world, allowing the child to benefit more fully from social resources and opportunities (Boyce & Ellis, 2005), thus favoring development of a *sensitive* phenotype (pattern I). The association between high parental sensitivity, positive family relations, and the development of a highly responsive SRS is supported by a number of studies (e.g., Ellis et al., 2005; Evans et al. 2013; Hackman et al., 2013). According to the ACM, sensitive patterns should be characterized by moderate HPA/SNS responsivity and high PNS responsivity. A sensitive phenotype makes children better at detecting positive opportunities and learning to capitalize on them. For example, high PNS responsivity has been linked to socio-emotional competence, engagement, and self-regulation (e.g., Stifter & Corey, 2001). Social learning and sensitivity to context are especially adaptive in the context of slow life history strategies, as a form of protracted somatic investment (Kaplan & Gangestad, 2005). In very safe and protected settings, sensitive individuals will rarely experience strong, sustained activation of the SNS and HPA systems; thus, the individual enjoys the benefits of responsivity without paying significant health costs (e.g., immune, energetic).

At moderate levels of environmental stress, the cost–benefit balance begins to shift as the potential advantages of high sensitivity decrease and the physiological and health costs of maintaining a hyper-responsive SRS increase. The optimal level of SRS responsivity is predicted to fall downward, favoring development of *buffered* phenotypes (pattern II) characterized by moderately low reactivity and a slow life history strategy. Buffered responsivity is expected to be the modal pattern in most populations (with most SRS parameters set around the mean), particularly in the low-risk, middle-class populations that provide a majority of research participants in psychology and neuroscience. The emergence of buffered responsivity patterns under conditions of moderate environmental stress is empirically consistent with the *stress inoculation hypothesis*, the idea that early exposure to

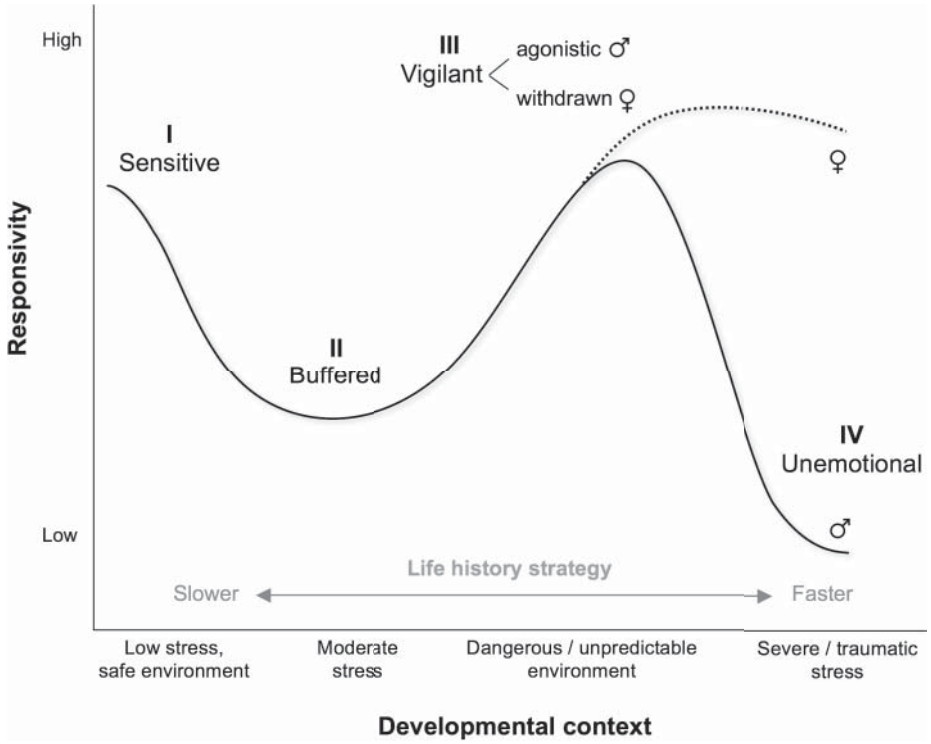

Figure 1.5 Predicted curvilinear relation between developmental context and optimal levels of stress responsivity. The figure does not imply that all components of the SRS will show identical responsivity profiles, nor that they will activate at the same time or over the same time course (see Del Giudice et al., 2011). Male and female symbols indicate sex-typical patterns of responsivity, but the model also predicts substantial within-sex variation. *Source:* Adapted from M. Del Giudice, B. J. Ellis, & E. A. Shirtcliff, The adaptive calibration model of stress responsivity, *Neuroscience & Biobehavioral Reviews*, *35*, 1577, 2011.

repeated mild stressors downregulates the SRS and leads to increased resistance to stress later on (e.g., Rutter, 1993). However, the ACM places stress inoculation in a broader theoretical perspective, in which moderate responsivity is only one out of many locally adaptive patterns of SRS functioning.

The benefits of increased responsivity rise again when the environment is perceived as dangerous and/or unpredictable. A responsive SRS enhances the individual's ability to react appropriately to dangers and threats while maintaining a high level of engagement with the social and physical environment. Moreover, engaging in fast life history strategies should lead the individual to allocate resources in a manner that discounts the long-term physiological costs of the stress response in favor of more immediate advantages. In this context, the benefits of successful defensive strategies outweigh the costs of frequent, sustained HPA and SNS activation, leading to *vigilant* phenotypes (pattern III). The predicted profile of vigilant individuals includes high HPA/SNS responsivity and low PNS responsivity (see Del Giudice et al. 2011). In turn, this physiological profile should be associated with fast life history-related traits such as fast maturation and high mating effort. Increased SRS responsivity in dangerous environments can be expected to go together with increased responsivity in other neurobiological systems; for example, hyper-dopaminergic function may contribute to the vigilant phenotype by boosting attention to threat-related cues and fast associative learning (Gatzke-Kopp, 2011).

Compared with their sensitive counterparts, vigilant individuals may show slower HPA recovery (i.e., they may take longer to return to baseline) and slower habituation (see Gunnar & Vazquez, 2006). For this reason, they are also likely to show stronger hypocortisolism following prolonged periods of stress. Although we argue that vigilant phenotypes represent biologically adaptive responses to early stress, their "hair trigger" regulation may render them especially vulnerable to breakdown or persistent dysregulation following extreme stressors. On average, males and females are expected to differ in the predominant behavioral correlates of vigilant patterns—aggressive and agonistic behavior versus anxiety and withdrawal—because of the different costs and benefits of aggression, impulsivity, and risk taking in the two sexes

(Archer, 2009; see also Martel, 2013). Indeed, several studies suggest that acute HPA activation—typical of vigilant patterns—tends to promote risk taking in males and risk aversion in females (see Mather & Lighthall, 2012; Starcke & Brand, 2012). Accordingly, high SRS responsivity can be associated with both internalizing and externalizing symptoms, especially in younger children (see Alink et al., 2008; Gunnar & Vazquez, 2006; van Goozen et al., 2007).

In very dangerous environments characterized by severe or traumatic stress, the balance shifts again toward low responsivity, especially for males who adopt a fast, mating-oriented life history strategy characterized by antagonistic competition and extreme risk taking. Such a strategy requires outright insensitivity to threats, dangers, social feedback and the social context. For an extreme risk-taker, informational insulation from environmental signals of threat is an asset, not a weakness (see also Korte et al., 2005). In particular, adopting an exploitative/antisocial interpersonal style requires one to be shielded from social rejection, disapproval, and feelings of shame (all amplified by heightened HPA responsivity; reviewed in Del Giudice et al., 2011). An *unemotional* pattern of generalized low responsivity (pattern IV) can be evolutionarily adaptive at the high-risk end of the environmental spectrum – especially in males – despite its possible negative consequences for the social group and for the individual's subjective well-being. This type of chronic low responsivity should be carefully distinguished from temporary exhaustion periods, usually arising after prolonged SRS activation in highly responsive individuals exposed to enduring stressors. The association of risk taking with low levels of SRS responsivity and basal activity is well documented, especially in males (e.g., Bubier & Drabick 2008; Halpern et al. 2002).

Unemotional profiles should be associated with high mating effort and early sexual maturation; this is consistent with the robust association between low SRS responsivity, externalizing behaviors (especially in male adolescents and adults), and callous-unemotional traits. As we discuss in a later section, this constellation of traits is associated with early maturation, precocious sexuality, and sexual promiscuity. Finally, the ACM hypothesizes two developmental pathways leading to unemotional responsivity patterns. In the first pathway, an initially responsive phenotype shifts toward unresponsivity following chronic severe stress. In particular, some children are expected to shift from pattern III to pattern IV during middle childhood or adolescence (Del Giudice et al. 2011). This prediction is consistent with the finding that associations between HPA activity and aggressive/externalizing behavior tend to be positive in preschoolers but negative in middle childhood and adulthood (Alink et al., 2008). In the second pathway, unresponsivity may develop even in low-stress environments because of strong genetic predispositions, and may be apparent already in early childhood.

The logic of sex differences in responsivity patterns is based on sexual selection theory informed by life history considerations. At the slow end of the life history continuum, both sexes engage in high parental investment, and male and female interests largely converge on long-term, committed pair bonds; sex differences in behavior are thus expected to be relatively small. As environmental danger and unpredictability increase, males benefit by shifting to low-investment, high-mating strategies; females, however, do not have the same flexibility since they benefit much less from mating with multiple partners and incur higher fixed costs through childbearing. Thus, male and female strategies should increasingly diverge at moderate to high levels of environmental danger/unpredictability. In addition, sexual competition takes different forms in males and females, with males engaging in more physical aggression and substantially higher levels of risk taking (e.g., Archer, 2009; Wilson, Daly, & Pound, 2002). As mating effort increases, sexual competition becomes stronger and sex differences in competitive strategies become more apparent. For these reasons, sex differences in responsivity patterns and in the associated behavioral phenotypes should be relatively small at low to moderate levels of environmental stress (patterns I and II) and increase in stressful environments (pattern III). Finally, we expect males to be overrepresented as high-risk, low-investment strategists (pattern IV).

The shifting equilibrium between costs and benefits of responsivity is predicted to result in a complex curvilinear relation between environmental stress and SRS responsivity (Figure 1.5). The ACM taxonomy of responsivity patterns is supported by preliminary empirical evidence on autonomic responsivity in middle childhood (Del Giudice, Hinnant, Ellis, & El-Sheikh, 2012). While the SRS has a crucial role in directing the development of alternative life history strategies, it does so in interaction with other neurobiological systems. Accordingly, the four responsivity patterns described in the ACM are characterized not just by different profiles of SRS functioning, but also by functionally organized individual differences in behavior, in the physiology of the hypothalamic-pituitary-gonadal axis, in serotonergic and dopaminergic pathways, and other systems (Del Giudice et al., 2011). Each pattern reflects a unique combination of costs, benefits, and specific vulnerabilities to pathology. Finally, it should be noted that

Figure 1.5 depicts an idealized, population-level reaction norm. In practice, different individuals may respond differently to the same level of environmental stress and show different degrees of plasticity—owing to different environmental sampling histories and the effects of genetic, epigenetic, and endophenotypic variation—as discussed in the section on differential susceptibility.

ALM and ACM: A Comparison

Allostatic load is a label for the long-term costs of allostasis; it is often described as the "wear and tear" that results from repeated allostatic adjustments (i.e., adaptation to stressors), exposing the organism to adverse health consequences. The ALM emphasizes that biological responses to threat, while essential for survival, have negative long-term effects that promote illness. The *benefits* of mounting biological responses to threat are traded off against *costs* to mental and physical health, and these costs (allostatic load) increase as the organism ages.

Basic tenets of the ACM an ALM are compared in detail in Ellis and Del Giudice (2014) and juxtaposed in Table 1.1. Both the ACM and ALM emphasize the adaptive nature of short-term physiological responses to stress (Table 1.1, row labeled *Activation of autonomic, neuroendocrine, metabolic, and immune systems*). Further, the ACM concurs with the ALM regarding the effects of childhood stress and adversity on regulation of allostatic mechanisms. Indeed, a substantial body of research has now documented biological embedding of early life stress in SRS parameter values (Table 1.1, row labeled *Changes in allostatic mechanisms*). In the ALM, however, this biological embedding is construed negatively, as the result of cumulative stress exposures that predispose the individual to morbidities and premature mortality. As shown in Table 1.1 (row labeled *Cognitive, behavioral, and emotional impairments in children*), some of these outcomes include lower performance on standard tests of intelligence and executive functions and increased mental health problems (reviewed in Ellis & Del Giudice, 2014). The ACM also acknowledges that chronic SRS activation carries substantial costs, in terms of biological fitness as well as health and well-being. While the ACM stresses conditional adaptation, it leaves open the possibility that, for a number of reasons, some developmental outcomes are biologically maladaptive. In terms of proximal responses

TABLE 1.1 Comparison of Adaptive Calibration Model and Allostatic Load Model[1]

Responses to psychosocial stress/ unpredictability	Examples of response	ACM	ALM
Activation of autonomic, neuroendocrine, metabolic, and immune systems	• Acute SNS and HPA responses mobilize energy reserves; protect against septic shock and nutrient deprivation; permit fight or flight responses that are normally protective against danger. • Inflammation accelerates the healing of wounds.	Central to theory	Central to theory
Changes in allostatic mechanisms	• Increased inflammatory tone • Elevated cortisol and catecholamines • Muted cardiovascular responses to stress	Central to theory	Central to theory
Cognitive, behavioral, and emotional impairments in children	• *Reduced scores on standard tests of intelligence, language, memory, and other abilities* • *Early onset and increased prevalence of psychopathology*	*Not inconsistent with theory*	*Central to theory*
Cognitive, behavioral, and emotional adaptations to stress in children	• *Tailoring of emotion systems, arousal responses, and perceptual abilities to the detection and monitoring of danger* • *Development of insecure attachments, mistrustful internal working models, opportunistic interpersonal orientations, oppositional-aggressive behavior*	*Central to theory*	*Not inconsistent with theory*
Long-term deleterious outcomes	• *Cognitive and physical impairments* • *Depression* • *Increased risk of cardiovascular disease and all-cause mortality*	*Not inconsistent with theory*	*Central to theory*
Long-term adaptive changes in biobehavioral systems	• **Adaptive calibration of autonomic, neuroendocrine, metabolic, and immunological systems** • **Regulation of alternative life history strategies to match ecological conditions**	**Central to theory**	**Beyond the scope of the theory**

[1] *Light shading* indicates a difference in emphasis between the ACM and ALM. **Dark shading** indicates a qualitative divergence between the two theories. Reprinted from B. J. Ellis & M. Del Giudice, Beyond allostatic load: Rethinking the role of stress in regulating human development, *Development and Psychopathology*, *20,* 9, 2014.

to childhood adversity, The ACM and ALM mainly differ in their emphasis on the benefits (ACM) versus the costs (ALM) of allostatic adjustments (shown in italics in Table 1.1).

Cost–Benefit Trade-Offs in the Development of Alternative Phenotypes.

The ACM and ALM diverge considerably in how they deal with cost–benefit trade-offs, individual differences, and long-term developmental changes. From an evolutionary standpoint, the ALM makes no distinction between the two meanings of *adaptive* and *maladaptive*, as conceptualized from a mental health versus evolutionary perspective. Indeed, maladaptation is typically inferred whenever there are substantial costs to the organism. For example, if elevated cortisol levels in adolescents are associated with an undesirable outcome, such as reduced working memory, then elevated cortisol is classified as a marker of allostatic load (see Juster et al., 2011). This reasoning ignores the crucial fact that biological processes are maintained by natural selection when their fitness benefits outweigh the costs, not when they are cost-free; indeed, even large costs can be offset by large enough expected benefits. Although there are practical reasons for identifying allostatic load biomarkers, this approach alone is incomplete because it only specifies dysfunction and not the adaptive functions of developmentally calibrated biological parameters.

Because of the failure to distinguish between (mal)-adaptive and (un)desirable outcomes, most applications of the ALM do not adequately address the trade-offs involved in the development of physiological and behavioral phenotypes; as a consequence, the ALM literature often lacks a theory of adaptive individual variation in stress responsivity (see Korte et al., 2005, for a notable exception). Instead the ALM focuses on optimal SRS parameter values, as defined by covariation with desirable health outcomes; deviations from these optimal settings form the basis of dysregulation. The applied goal of the ALM is to identify nonoptimal autonomic, neuroendocrine, metabolic, and immune profiles that predict psychiatric and biomedical disorder (Table 1.1).

In contrast, the ACM emphasizes adaptation in context and posits that optimal SRS parameter values vary as a function of environmental conditions. From this perspective, the notion of globally optimal baseline or responsivity levels for SRS parameters is highly problematic; indeed, the entire literature on biological sensitivity to context demonstrates that the value of hypo-responsivity versus hyper-responsivity is context dependent (see extended discussion that follows). The ACM gives full consideration to the costs and benefits of SRS responsivity. For example, consider heightened stress responsivity in a dangerous, unpredictable environment. In the ACM, it is hypothesized that the costs of repeated SRS activation are offset by improved management of danger. Although the system is on a hair trigger, with a resulting increase in anxiety and/or aggression, few instances of actual danger will be missed. In addition, engaging in a fast, present-oriented life history strategy makes it optimal to discount the long-term health costs of chronic SRS activation if the immediate benefits are large enough (for in-depth discussion, see Del Giudice et al., 2011).

In the ALM framework, the same pattern of responsivity would be treated as dysfunctional because the stress response is deployed even in absence of true dangers (e.g., "excessive" response, "unnecessary" triggering; e.g., Lupien et al., 2006) and because of the associated undesirable states and health risks (e.g., interpersonal distress). However, this approach fails to consider that biological defenses are usually designed by natural selection to accept a high rate of false positives. In most instances, unnecessary responding is an adaptive feature of the system—though a costly one—rather than a sign of dysregulation or malfunction.

Long-Term Adaptations to Stress: The Developmental Regulation of Alternative Life History Strategies

According to the ACM, childhood adaptations to stress may eventuate in long-term adaptive changes in biobehavioral systems. Herein lies the key difference between the ACM and ALM (shown in bold in Table 1.1). In the ALM, energy devoted to mounting autonomic, neuroendocrine, metabolic, and immune responses to threat is traded off against wear and tear on multiple organ systems. The ACM extends this logic by conceptualizing these trade-offs as decision nodes in allocation of resources. It is through this chain of resource-allocation decisions—instantiated in the regulatory parameters of the SRS and related biological systems—that the developing organism adapts to local conditions. Thus, the ACM shifts the emphasis from dysregulation to conditional adaptation (Table 1.1).

From an evolutionary perspective, increased wear and tear is a cost of pursuing a fast life history strategy. The fast strategy is instantiated in a chain of resource allocation decisions over the life course that "make the best of a bad situation" by trading off survival for reproduction. Thus, many biologically embedded changes that the ALM conceptualizes as costs (e.g., heightened HPA reactivity)

the ACM views as decision nodes in development of a faster strategy. Conversely, slower life history strategies involve greater allocation of resources toward enhancing growth, vitality, and long-term survival (e.g., DNA repair). Development of a fast life history strategy in dangerous and unpredictable contexts is not impairment or dysfunction; it is a coherent, organized response to stress that has been shaped by a natural selective history of recurring exposures to harsh and unpredictable environments.

Implications for the Core Points of Developmental Psychopathology

The integrative perspective on stress responsivity presented in this section touches on many core points of developmental psychopathology. First of all, the ACM illustrates that evolutionary principles are not just relevant to the behavioral level of analysis. On the contrary, they can be fruitfully applied to understand the role of *brain and neurobiological factors* in development, and employed to craft detailed models of neurobiological functioning. Like the ALM, the ACM helps synthesize *normal and pathological development* in a single framework; however, the ACM goes beyond the ALM with a broader view of costs and benefits and a detailed theory of adaptive matching between environment and phenotype. The ACM fully incorporates the *contextualism* of life history theory; in this perspective there is no single optimal phenotype or developmental trajectory—only locally adaptive, contextually sensitive strategies with their baggage of costs and trade-offs.

An important feature of the logic of responsivity patterns is that it invites—indeed, virtually requires—a *person-centered approach* to individual differences in stress physiology and neurobiology (e.g., Del Giudice et al., 2012). Even the schematic model depicted in Figure 1.5 shows that causal relations between environmental variables and developmental outcomes are predicted to be highly *nonlinear;* if the model is correct, attempts to model stress responsivity with standard linear models are doomed to yield inconsistent and misleading results. Responsivity patterns also provide a striking illustration of *equifinality* and *multifinality* in the interplay between environment, neurobiology, and behavior. In the ACM, dramatically different environments may entrain the development of similar responsivity profiles; for example, sensitive and vigilant patterns are both hypothesized to imply high HPA responsivity. In turn, similar responsivity profiles may predict remarkably different behavioral correlates—for example low impulsivity in sensitive patterns versus high impulsivity in vigilant patterns. While the resulting developmental trajectories may look empirically baffling, they become tractable when they are framed in the appropriate functional perspective.

Finally, the ACM potentially explains why, in the empirical literature, heightened and dampened stress responsivity seem to work as *risk factors* in some studies and as *protective factors* in others. Both sensitive and buffered phenotypes are associated with lower levels of psychosocial stress and concomitant development of slower life history strategies, whereas both vigilant phenotypes and unemotional phenotypes are associated with higher levels of psychosocial stress and concomitant development of faster life history strategies (Figure 1.5). Depending on the specific outcomes under investigation, heightened reactivity may look like a protective factor in sensitive phenotypes and a risk factor in vigilant phenotypes, while dampened reactivity may look like a protective factor in buffered phenotypes and a risk factor in unemotional phenotypes. As we discuss in a later section, the picture is further complicated by the possibility that some disorders are actually more likely to occur at the *slow* end of the life history continuum. Taming this complex interplay of cause and effect will only be possible with the help of a detailed theory of biological and developmental trade-offs.

BEYOND DIATHESIS-STRESS: DIFFERENTIAL SUSCEPTIBILITY TO ENVIRONMENTAL INFLUENCES

As discussed in the preceding sections, early experiences can have profound and lasting effects on psychological development. Nevertheless, people vary dramatically in the extent to which they respond to their social and physical environment. Similar developmental experiences may have profound effects on some individuals and slight or even negligible effects on others. The idea that some individuals are more susceptible than others to environmental adversity has a long history in psychology, and is captured by the complementary concepts of *vulnerability* and *resilience* (for a recent review see Compas & Andreotti, 2013). Individual differences in vulnerability may be determined by a combination of genetic factors and previous experiences, and explain why, for example, only some children develop such undesirable outcomes as aggression, insecure attachment, and cognitive difficulties in response to stressful or impoverished rearing experiences. The concept of vulnerability lies at the heart of the diathesis-stress model of psychopathology, which is arguably the dominant paradigm in the field.

Against this background, recent empirical and theoretical advances have brought about a conceptual revolution in the study of organism × environment interactions. As has become increasingly apparent, many of the same factors that determine increased vulnerability to stress and adversity also confer enhanced responsivity to the *positive*, supportive aspects of the environment (Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2007; Boyce & Ellis, 2005). No longer confined to vulnerability, susceptibility to environmental influence can be understood as a generalized trait that increases the range of potential developmental outcomes in a bivalent fashion. While some individuals are disproportionately likely to suffer damage if exposed to harshness and adversity, they are also disproportionately likely to benefit from nurturance and support. Here we introduce the concept of *differential susceptibility*, discuss its importance for developmental processes, and review the models that have been proposed to explain the evolution of systematic individual differences in susceptibility to the environment. For further discussion see Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn (2011a).

Differential Susceptibility: Orchids and Dandelions

In the differential susceptibility literature, highly susceptible children are referred to by the shorthand designation of *orchid children*, signifying their special sensitivity to both highly stressful and highly nurturing environments. For example, highly irritable infants tend to become less sociable than moderately irritable infants when they are insecurely attached, but *more* sociable if they experience secure attachment relationships (Stupica, Sherman, & Cassidy, 2011). Similarly, children with difficult temperament develop more behavior problems when they experience low-quality care, but *fewer* behavior problems when reared in a high-quality context (Pluess & Belsky, 2009). Children who are low in susceptibility to environmental influence, on the other hand, are designated as *dandelion children*, reflecting their relative ability to function adequately in species-typical circumstances of all varieties (Boyce & Ellis, 2005). Differential susceptibility can be distinguished from both vulnerability (specific sensitivity to negative environmental factors) and the more recent concept of *vantage sensitivity* (specific sensitivity to positive environmental factors; see Pluess & Belsky, 2013).

Converging evidence from different areas of research indicates that highly susceptible children share a cluster of interrelated traits including high physiological reactivity across multiple systems (including the SRS), negative emotionality, and difficult temperament (reviewed in Belsky et al., 2007; Boyce & Ellis, 2005; Ellis et al., 2011a). While the genetics of susceptibility is still incompletely understood, genes involved in serotonergic and dopaminergic pathways appear to play a central role (e.g., Bakermans-Kranenburg & Van IJzendoorn, 2011; Belsky & Beaver, 2011; Heiming & Sachser, 2011); as discussed above, serotonergic and dopaminergic pathways interact bidirectionally with the SRS. Together, these interconnected systems contribute to a general phenotypic dimension of *neurobiological susceptibility* to the environment (see Boyce & Ellis, 2005; Ellis et al., 2011a).

Figure 1.6 illustrates the concept of differential susceptibility by showing the reaction norms of high susceptibility and low susceptibility individuals in a population. Differential susceptibility requires that reaction norms cross somewhere in the middle range of environmental variation. Figure 1.6 may represent either a genotype × environment (GxE) or phenotype × environment (PxE) interaction, depending on whether individuals are distinguished by their genotype (e.g., variants of the serotonin transporter gene) or phenotype (e.g., high stress responsivity, negative emotionality).

In summary, differential susceptibility is a special case of developmental plasticity; its defining characteristics are (1) a crossover interaction in which more susceptible individuals have a broader reaction range and steeper reaction norms (compare with Figure 1.2b), and (2) a clear positive–negative polarity of the relevant environmental dimension. These two factors together result in systematic variation in the strength of relations between environmental exposures and developmental outcomes that maps on to the orchid–dandelion distinction. Whether environmental conditions can be labeled as "positive" or "negative" in a biological sense depends on their likely effects on an individual's fitness. As we discussed in the section on life history theory, many of the negative environmental factors investigated by developmental psychologists are ultimately correlated with danger, unpredictability, and resource scarcity.

Differential susceptibility has far-reaching implications for developmental psychology and psychopathology; it moderates the effects of environmental exposures on developmental and life outcomes. Ultimately, this means that the development of some individuals, more than others, will be influenced by their experiences and environments—even if these were exactly the same. Differential susceptibility to the environment, therefore, constitutes a central mechanism in the regulation of alternative patterns of human development. Over the last few years, the concept

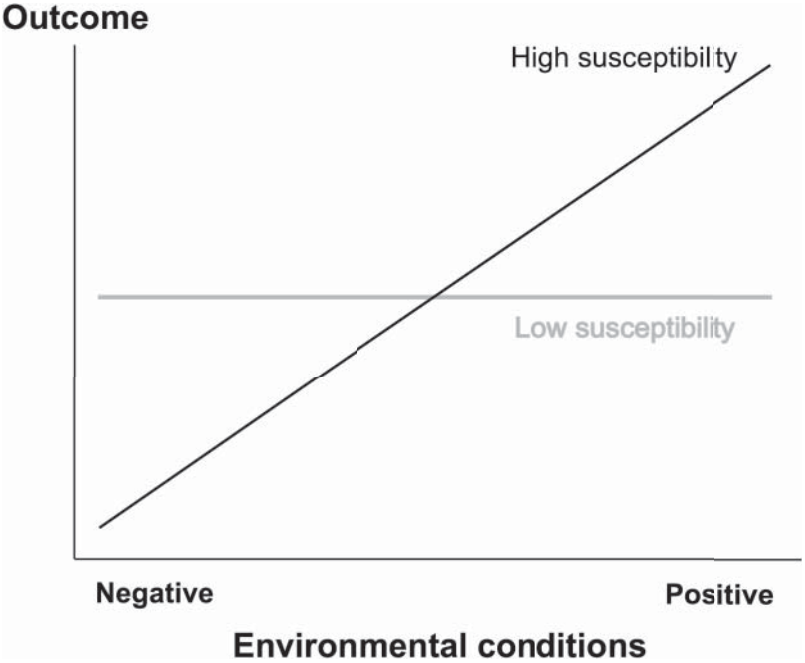

Figure 1.6 Reaction norms showing differential susceptibility. More susceptible individuals are disproportionally affected by both negative and positive environments.

of differential susceptibility has generated considerable enthusiasm in developmental psychology and has rapidly become the foundation of an expanding empirical literature. Evidence of differential susceptibility exists for a number of traits and outcomes including prosociality, sociability, externalizing and internalizing symptoms, depression, and timing of puberty (see Ellis & Boyce, 2011, and other papers in that special issue).

Evolutionary Models of Differential Susceptibility

Individual differences in neurobiological susceptibility to the environment raise many important questions. Why do they exist in the first place? Are they adaptive—and if so, what evolutionary processes are responsible for their maintenance in human populations? When do they emerge in development, and by what interplay of genetic and environmental factors? Evolutionary models of differential susceptibility (Belsky, 1997, 2005; Boyce & Ellis, 2005; Ellis et al., 2006) have explored different explanations for the maintenance of individual differences—balancing selection, selection for conditional adaptation, and selection for diversified bet-hedging. These explanations are not mutually exclusive, and indeed they can potentially be integrated within a single theoretical framework.We now briefly review each in turn.

Maintenance of Differential Susceptibility Through Balancing Selection

There is considerable evidence that individual differences in susceptibility can be attributed—at least in part—to individual differences in genotype. The best examples include allelic variation in the serotonin-transporter gene promoter (5-HTTPLR) and the dopamine D4 receptor gene (DRD4). Recent meta-analyses have demonstrated that these polymorphisms moderate environmental effects in a "for better *and* for worse" manner; that is, different variants of these genes are generally associated with differential susceptibility to both stressful and nurturing environmental conditions (Bakermans-Kranenburg & van IJzendoorn, 2011; van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012). Other genetic variants involved in differential susceptibility have been identified, not only in dopaminergic and serotonergic pathways but also in the oxytocinergic system and the HPA axis (see Cicchetti & Rogosch, 2012; Ellis et al., 2011a).

As discussed in a previous section, adaptive genotypic differences in a population may be maintained by various forms of balancing selection, including negative frequency-dependent selection. Building on the work of Wilson and Yoshimura (1994), Ellis and colleagues (2006) proposed a negative frequency-dependent model of the maintenance of genetically regulated variation

in differential susceptibility to the environment. In this model, developmental specialists are defined by relatively flat reaction norms, such that phenotypic development is minimally sensitive to normal environmental variation. Different developmental specialists are instead characterized by different genetically regulated behavioral types (e.g., shy vs. bold, slow vs. fast life history strategy). Although developmental specialists lack plasticity, their specialized personalities enable them to thrive in the niche that they are specialized to exploit. Developmental generalists, by contrast, are defined by relatively steep reaction norms, such that phenotypic development is highly context-dependent. Different developmental generalists thus experience different developmental outcomes based on their rearing experiences. All else being equal, the presence of multiple niches in a single environment will favor developmental specialists over developmental generalists when individuals can evaluate and select niches that increase their fitness. This is because specialists outperform generalists in their preferred niche. However, multi-niche environments are often characterized by negative density-dependence, meaning that as a given niche becomes more crowded (i.e., overexploited relative to its size), the fitness benefits of specializing in that niche decrease. This is the cost of specialization.

Models of genotypic variation in susceptibility are still in the formative stages. The general hypothesis that frequency-dependent selection can maintain individual variation in susceptibility or responsiveness to the environment is well supported by mathematical models (Wilson & Yoshimura, 1994; see also Wolf, van Doorn, & Weissing, 2008) but has not yet generated empirical work in humans. Another plausible but less explored possibility is that other types of balancing selection—for example spatially and temporally fluctuating selection—may coexist with frequency-dependent selection and contribute to maintain genotypic variation in human populations (see Ellis et al., 2011a).

Development of Differential Susceptibility Through Conditional Adaptation

Depending on the structure of the environment and of an organism's life cycle, conditional adaptation can be maintained alongside genetic variation by spatially and temporally fluctuating selection pressures (see Del Giudice, 2012, under review). The theory of Biological Sensitivity to Context (Boyce & Ellis, 2005) posits a *nonrandom distribution* of neurobiological susceptibility to the environment within populations that emerges through conditional adaptation to variable environmental conditions. From this perspective, differential susceptibility results, in part, from individuals tracking different environmental conditions and altering their development to match those conditions. The assumption is that this matching process promoted fitness across heterogeneous environmental contexts over human evolution.

Biological sensitivity to context theory identified physiological mechanisms of differential susceptibility—autonomic, adrenocortical, and immune reactivity to psychosocial stressors—and proposed that this psychobiologic reactivity moderated the effects of early environmental exposures on physical and mental health outcomes in the bivalent manner discussed above (reviewed in Pluess & Belsky, 2009; Ellis et al., 2011a). This dual function signified the need to conceptualize stress reactivity more broadly as biological sensitivity to context, which Boyce and Ellis (2005) defined as neurobiological susceptibility to both cost-inflicting and benefit-conferring features of the environment and operationalized as heightened reactivity in one or more of the stress response systems. In total, biological sensitivity to context theory proposed that individual differences in the magnitude of biological stress responses function to regulate openness or susceptibility to environmental influences, ranging from harmful to protective.

As discussed in the previous section, the ACM explicitly builds on the logic of biological sensitivity to context. In a nutshell, the theory of biological sensitivity to context proposes that heightened susceptibility is adaptive at both ends of the environmental continuum—in both highly stressful and highly protected environments. This results in a U-shaped curvilinear relation between early stress/adversity and susceptibility to later environmental effects (Boyce & Ellis, 2005). Consistent with the focus of biological sensitivity to context on adaptive plasticity, the ACM views early experience as a crucial determinant of individual differences in neurobiological susceptibility to the environment. Potential cues of danger and adversity versus safety and support include prenatal stress (e.g., fetal exposure to stress hormones), parenting quality, family stability and conflict, attachment security, and neighborhood quality.

These contextual factors are hypothesized to affect development mainly by upregulating or downregulating the activity of infants' and children's stress response systems, as shown in Figure 1.5. Whereas the original conceptualization of biological sensitivity context focused primarily on the functions of high stress responsivity, the ACM expanded this conceptualization to encompass the functions of low stress responsivity—and thus added

the unemotional pattern shown in Figure 1.5. This addition turned the original U-shaped curve into a more complex function (see discussion of the ACM responsivity patterns in the previous section). Like the theory of biological sensitivity to context, the ACM conceptualizes variation in neurobiological susceptibility to the environment as part of a conditional adaptation process that matches stress response profiles to local conditions. This conceptualization is supported by a large empirical literature demonstrating changes in SNS, PNS, and HPA parameter values over development in response to different developmental experiences (reviewed in Boyce & Ellis, 2005; Del Giudice et al., 2011), including prenatal experiences such as infections, fetal undernutrition, and exposure to maternal stress hormones (Pluess & Belsky, 2011).

Differential Susceptibility as Adaptive Stochastic Variation

According to the theory of differential susceptibility advanced by Belsky (1997, 2005), the main adaptive function of differential susceptibility is spreading the risk of mismatch by making some individuals resistant to environmental influences, including—but not limited to—the influences of parental behavior on children's development. When early cues correctly predict future states of the environment, susceptible individuals benefit from enhanced phenotype-environment matching; but when prediction fails (for example because the environment undergoes sudden and unpredictable changes), they end up developing a mismatched phenotype and potentially suffering large fitness costs as a result. Individuals who follow a fixed developmental trajectory may avoid the fate of their more susceptible counterparts when ecological cues fail to predict later environmental states. Thus, for a parent, producing offspring with varying degrees of susceptibility works as an insurance against future unpredictability.

In evolutionary terms, this is an example of reproductive *bet-hedging*—a strategy that reduces average individual fitness in the short term, but enhances the long-term reproductive success of the genetic lineage by decreasing fitness variance across generations (Bull, 1987; Seger & Brockmann, 1987; Starrfelt & Kokko, 2012). More specifically, differential susceptibility is conceptualized as an instance of *diversified* bet-hedging, that is, a strategy that reduces fitness variance between generations by increasing phenotypic variability among offspring (Philippi & Seger, 1989). Such a strategy could be maintained by an evolutionary history of exposure to environments that fluctuated unpredictably over time. Bet-hedging strategies increase the probability of achieving some reproductive success in every generation while limiting success in good conditions and shielding against total failure in bad (for a detailed treatment see Starrfelt & Kokko, 2012).

Theory and data from evolutionary biology indicate that fluctuating selection pressures, if sufficiently strong, can support variable or random generation of offspring phenotypes ("adaptive coin-flipping") arising from a monomorphic genetic structure. This strategy can be implemented through a stochastic developmental switch (presumably instantiated by epigenetic mechanisms), which generates one of several alternative phenotypes according to a probabilistic rule. For example, in a range of animal species, when mothers cannot forecast the likely environment of their offspring, or environmental cues in the maternal generation suggest that the offspring environment is likely to vary unpredictably, mothers hedge their bets by increasing variation in offspring phenotypes (Crean & Marshall, 2009). Although temporally fluctuating selection pressures can select for stochastic phenotypic variation, diversified bet-hedging cannot be instantiated through *genetic* polymorphisms because the resulting phenotypes do not all have the same average fitness (Bull, 1987; Philippi & Seger, 1989). Thus, the bet-hedging hypothesis can explain adaptive stochastic variation in susceptibility but not genotypic variation, in contrast with early formulations of the theory (Belsky, 1997). More recent formulations of the theory (e.g., Belsky, 2005; Pluess & Belsky, 2011) also acknowledge the role of early environmental influences—especially prenatal exposure to stress—in shaping individual levels of susceptibility.

In total, the bet-hedging hypothesis of differential susceptibility is valuable in that it provides a plausible adaptive explanation for stochastic variation in susceptibility to environmental influence. More generally, the larger framework advanced by Belsky (2005) emphasizes the potential adaptive significance of unsystematic within-family variability in susceptibility to the environment. However, adaptive stochastic variation coexists with many sources of neutral or maladaptive unsystematic variation, which result from the random effects of sexual recombination, nonadaptive phenotypic plasticity, random perturbations in developmental processes, harmful genetic and epigenetic mutations, and so forth. The empirical challenge for the theory advanced by Belsky (1997, 2005) is that it may be extremely difficult to distinguish between adaptive within-family variation that has been shaped by natural selection and within-family variation that is truly random and non-adaptive (see Ellis et al., 2011a).

Differential Susceptibility as a Model of Organism–Environment Interplay: The Case of Pubertal Development

The differential susceptibility framework returns us to the centrality of the phenotype and the complexity of organism–environment interplay. Susceptibility to the environment is instantiated in the biology of the nervous system; it is *neurobiological* susceptibility. Genetic susceptibility factors operate through neurobiological processes, and behavioral indicators of susceptibility are grounded in neurobiology. Neurobiological susceptibility itself is not a static trait; it develops and changes in response to genetic and environmental influences, which become incorporated into the phenotype over time. Genetic factors, environmental factors, and the extant phenotype all interact in intricate ways that are not yet entirely understood, including both systematic effects and stochastic processes.

A good demonstration of the real-life complexity of differential susceptibility is the interplay of early life stress, stress responsivity, and polymorphic variation in the estrogen receptor α gene (*ESR1*) in the regulation of pubertal development. The timing of pubertal development is a central life history trait; as discussed in a previous section, Belsky and colleagues (1991) first predicted that early stress would entrain fast life history strategies, leading to accelerated puberty timing (the *psychosocial acceleration theory*; see Ellis, 2004). Specifically, the theory posits that ecological stressors in and around the family create conditions that undermine parental functioning and lower the quality of parental investment—such as by escalating marital conflict, increasing negativity and coercion in parent–child relationships, and reducing positivity and support in parent–child relationships. According to the theory, children respond to these familial and ecological conditions (particularly those experienced in the first 5–7 years of life) by developing in a manner that speeds up pubertal maturation, anticipates the onset of sexual activity, and promotes the development of a cluster of behavioral traits associated with fast life histories, including impulsivity and unstable pair bonds.

A study by Ellis and Essex (2007) investigated the psychosocial acceleration theory in the Wisconsin Study of Families and Work. Consistent with predictions, higher quality parent–child relationships in preschool—more parental warmth and family positivity, less parent–child stress and conflict—forecast slower pubertal maturation in daughters. Although this association proved robust, the unique effect of parent–child relationships on puberty was relatively small. However, theories of differential susceptibility suggest that the weak main effects of environmental variables on many developmental outcomes may often reflect the fact the children differ in whether, how, and how much they are affected by rearing experiences. As articulated by Belsky (2000), the weak main effects of parenting variables on pubertal timing may overestimate the impact of family environments in some children (dandelions, more fixed reproductive development) and underestimate it in others (orchids, more plastic reproductive development).

This hypothesis was supported in a later study of the same data set (Ellis, Shirtcliff, Boyce, Deadorff, & Essex, 2011b). Specifically, higher SRS responsivity in first grade—a key facet of neurobiological susceptibility—moderated the effects of parental behavior on maturation: lower quality parent–child relationships forecast faster initial tempo of puberty and earlier pubertal timing, but only among children showing heightened SNS/HPA reactivity. In other words, the data revealed a clear PxE interaction between parent–child relationships and SRS responsivity, consistent with the biological sensitivity to context account of differential susceptibility (Boyce & Ellis, 2005).

This, however, is only part of the story. Neurobiological susceptibility is not a fixed trait but develops over time through the interplay of various causal factors—including genetic variation and early environmental effects. In the same dataset, growing up in either highly supportive or highly stressful home environments predicted development of high SNS reactivity (consistent with the U-shaped curve predicted by biological sensitivity to context theory; see previous discussion), whereas growing up in a highly stressful home environment predicted heightened HPA activation (Ellis, Essex, & Boyce, 2005). Thus, under conditions of early environmental stress and uncertainty, indexed by coercive and unsupportive family relationships, individuals developed heightened neurobiological susceptibility to the environment (as indexed by SNS and HPA activation) and subsequently accelerated pubertal maturation in early adolescence, with family stress and neurobiological susceptibility acting synergistically in this process. Heightened neurobiological susceptibility thus enabled a stronger pubertal response to adversity. According to psychosocial acceleration theory, this response may represent a strategic—that is, functional—way of developing under stress.

The other side of the coin is that under conditions of early environmental protection and stability, indexed by positive and supportive family relationships, individuals also developed heightened neurobiological susceptibility,

which in combination with high-quality parent–child relationships forecast slower initial pubertal tempo and later pubertal timing (Ellis et al., 2011b). In this case, heightened neurobiological susceptibility enhanced responsiveness to environmental resources and support. As suggested by life history models, the resulting pattern of late sexual maturation may also constitute adaptive variation. Specifically, Ellis (2004) hypothesized that children have been selected to capitalize on the benefits of high quality parental investment and reduce the costs of low quality parental investment by contingently altering the length of childhood. Given high family resources and support and biological sensitivity to these development-enhancing contexts, extending childhood by delaying onset of puberty or slowing pubertal tempo may function to improve socio-competitive competencies (i.e., embodied capital) that ultimately increase reproductive potential.

Timing of puberty depends not only on the environment; indeed, all measures of pubertal development also show heritability values indicative of robust genotypic effects (see Ellis, 2004). As can be expected from the vantage point of differential susceptibility theory, recent evidence indicates that GxE interactions are also involved in the regulation of pubertal development (Manuck, Craig, Flory, Halder, & Ferrell, 2011). Consistent with past research (reviewed in Ellis, 2004), Manuck and colleagues (2011) found that women who reported being raised in families characterized by distant interpersonal relationships and high levels of conflict tended to reach menarche earlier than women raised in close families with little discord. However, this effect was moderated by variation in the gene coding for estrogen receptor α (*ESR1*). Among women who were homozygous for minor alleles of the two *ESR1* polymorphisms examined in the study, a childhood history of low-quality family relationships was associated with earlier age of menarche compared with a childhood history of high-quality family relationships; no such effect was found among women with other *ESR1* genotypes. Intriguingly, estrogen receptor α is highly expressed in the hypothalamus, where it regulates the activity of the HPA axis (Bao, Meynen, & Swaab, 2008). Thus, among its other possible effects, variation in *ESR1* may affect pubertal development by contributing to the development of higher or lower levels of neurobiological susceptibility.

In summary, regulation of pubertal development depends on genetic factors and GxE interactions, such as between *ESR1* variation and family stress; on environmental factors, such as energetics and psychosocial stress; on interactions between these environmental factors and extant phenotypic characteristics that modulate neurobiological susceptibility to the environment, such as SRS responsivity; on the developmental calibration of these stress response systems, which filter and embed information about environmental stress and support, mediating the organism's openness to environmental inputs; and on genetic influences and GxE interactions in the regulation of neurobiological susceptibility to the environment (see extended discussion in Ellis, 2013). At the nexus of all of these processes is the organized phenotype, which exists from conception; modulates, integrates, and retains genetic and environmental effects; and is the basis of differential susceptibility. Yet even if all of these factors are taken into account, there is still be much unexplained variation due to stochastic developmental processes.

This is the tangled web of development. Theoretical models propose that differential susceptibility develops through a mixture of genetic regulation—maintained by balancing selection—and environmental regulation that enables conditional adaptation. Whereas balancing selection and conditional adaptation result in systematic variation in neurobiological susceptibility to the environment, unsystematic variation may also be maintained by natural selection as an insurance policy against unpredictably changing environments (diversified bet-hedging). Taken together, these evolutionary processes may result in large individual differences in whether, how, and how much people are affected by their experiences. Differential susceptibility, therefore, can be expected to play a key role in moderating the effects of environmental conditions on developmental outcomes, including the development of life history strategies.

Implications for the Core Points of Developmental Psychopathology

The theory of differential susceptibility brings about a fundamental change in the way one thinks about *risk* and *resilience* in development. First, the same genetic or phenotypic factor can behave as *both* a risk and a protective factor depending on the ecological context. Second, the very children whose heightened responsivity appears to make them vulnerable to developing psychopathology (orchid children) may also be most able to benefit from positive, supportive environments and interventions. The divergent outcomes associated with highly susceptible phenotypes also set the stage for pervasive, systematic manifestations of *multifinality* in development.

As we have seen, the development of susceptibility is itself a dynamic process, taking place through an intricate interplay of genetic, environmental, and stochastic

effects. This perspective combines the *contextualism* of conditional adaptation with new and potentially fruitful explanations of *probabilistic causality*. Whereas standard approaches tend to see probabilistic causality as opposed to biological adaptation, the theory of bet-hedging shows how natural selection can make adaptive use of developmental randomness as a response to unpredictable environmental change.

Still other implications for developmental psychopathology stem from the centrality of the phenotype in regulating differential susceptibility. First, a view of the phenotype as the result of sequential organism–environment interplay blurs the distinction between variable-centered and *person-centered approaches*. Second, the concept of neurobiological susceptibility is a powerful reminder that genetic, epigenetic, and environmental effects must ultimately be understood in terms of their influence on *brain and neurobiological* pathways; it also illustrates how multiple pathways and molecules—for example serotonin, dopamine, cortisol, and sex hormones—may exert synergistic effects by converging on general, adaptive dimensions of phenotypic variation.

BEYOND THE DSM: A LIFE HISTORY FRAMEWORK FOR MENTAL DISORDERS

In the preceding sections we showed that EDP provides an integrative biological perspective on human development, and sheds light on the origin and function of individual differences in life history strategy, developmental plasticity, and physiological responsivity to stress. We now take this approach one step further and show how the principles of life history theory can be employed to outline a unifying framework for the analysis and classification of mental disorders (for a detailed exposition see Del Giudice, 2014a, 2014b). For the sake of simplicity and consistency with standard usage, in this section we employ the term *disorder* as a synonym for diagnosable condition—regardless of whether the condition represents a harmful dysfunction in the narrow sense (Wakefield, 1992).

Limitations of Current Taxonomic Approaches

The dominant approach to the classification of mental disorders is that of the Diagnostic and Statistical Manual (*DSM*) of the American Psychiatric Association (2013). In the *DSM*, disorders are defined by lists of symptoms, and grouped together mainly on the basis of symptom similarity—in keeping with the atheoretical stance embodied by the Manual. Thus, *DSM-5* categories include, for example, anxiety disorders; disruptive, impulse-control, and related disorders; depressive disorders; obsessive-compulsive and related disorders; and feeding and eating disorders (American Psychiatric Association, 2013).

While the *DSM* system has many undisputable qualities—diagnostic reliability above all—it also has a number of significant problems (see, e.g., Beauchaine, Klein, Erickson, & Norris, 2013; Nesse & Jackson, 2006). The main limitation of the *DSM* is also its defining feature: the deliberate absence of a theoretical model of mental disorders. Since disorders and disorder categories are primarily defined by symptom similarity, many diagnostic classes are likely to include a heterogeneous mix of conditions with different etiological, developmental, and functional characteristics. More troubling, the *DSM* lacks a theory of normative mental functioning, and is therefore ill equipped to discriminate between adaptive defensive responses and disordered functioning (Nesse & Jackson, 2006).

The main alternative to the *DSM* system comes from a family of empirical approaches based on patterns of genetic and phenotypic correlations between disorders (e.g., Kendler, Prescott, Myers, & Neale, 2003; Lahey, Van Hulle, Singh, Waldman, & Rathouz, 2011; Lahey et al., 2008; Watson, 2005). Empirical taxonomic studies suggest the existence of broad, hierarchically organized clusters of disorders that overlap only in part with *DSM* categories. The fundamental distinction in empirical taxonomies is that between *internalizing* and *externalizing* disorders. Externalizing disorders are characterized by impulsivity, disinhibition, and high levels of aggressive, antisocial, and/or disruptive behavior. Internalizing disorders are marked by high levels of anxiety and negative emotionality. The internalizing spectrum comprises a cluster of *distress disorders* (depression, generalized anxiety disorder [GAD], post-traumatic stress disorder [PTSD]) and a cluster of *fear disorders* (panic disorder, agoraphobia, social phobia, and specific phobias; Clark & Watson, 2006). Obsessive-compulsive spectrum disorders are typically treated as a separate internalizing cluster; other disorders that are usually included in the internalizing spectrum are bipolar disorders and borderline personality disorder (BPD), although their exact placement is more problematic (see Beauchaine & Hinshaw, 2013; Lahey et al., 2008; Watson, 2005). A recent factor-analytic study by Caspi and colleagues (2014) supplemented the internalizing and externalizing categories with a *thought disorder* factor comprising schizophrenia, mania (bipolar spectrum), and obsessive-compulsive disorder (OCD). Moreover,

the authors identified a general, higher-order factor of psychopathological risk they labeled the *p factor* (see Caspi et al., 2014).

The internalizing–externalizing distinction has received considerable empirical support, and has become a standard tool in developmental psychopathology (Beauchaine & Hinshaw, 2013). In the latest edition of the *DSM*, the authors explicitly recognized the usefulness of the broad distinction between internalizing and externalizing disorders (American Psychiatric Association, 2013, p. 13). However, this approach also has a number of important limitations. First of all, disorders are grouped based on their emotional and affective characteristics; however, emotions can serve multiple motivational goals, and associations between emotions and motivational processes are often remarkably nonspecific (see Nesse, 2004a). For example, anger can be triggered by aggressive competition, by threats to one's dominance or status, by suffering or witnessing acts of injustice, by separation from an attachment figure, and so forth. Anxiety, shame, and sadness are prominently associated with psychopathology, but their motivational specificity is also extremely low. Thus, classifications of disorders based on emotion and affect are unlikely to reliably capture the underlying motivational structure.

Moving to the empirical level, there is mounting evidence that the interalizing–externalizing dichotomy is riddled with ambiguities and inconsistencies. To begin with, depression and GAD—often regarded as prototypical internalizing disorders—are in fact bridge diagnoses that overlap with both internalizing and externalizing disorders at the phenotypic, genetic, and developmental level (e.g., Lahey et al., 2008, 2011). Also, some disorders that are usually considered part of the internalizing spectrum—such as obsessive-compulsive disorder (OCD) and BPD—show atypically large correlations with externalizing disorders (Crowell, Kaufman, & Lenzenweger, 2013; Lahey et al., 2008). Finally, the interalizing–externalizing taxonomy excludes many important pathological conditions—notably schizophrenia, autism, and most personality disorders—because they are not primarily characterized by mood/emotional alterations and do not fit the conceptual distinction between internalization and externalization (the recent analysis by Caspi and colleagues [2014] is a partial exception).

A Life History Framework for Psychopathology

In the preceding sections we discussed how life history strategies play a central role in the organization of physiology and behavior. They define an organism's priorities and determine the allocation of effort and resources toward competing biological goals. Differences in life history strategy are the joint product of genetic and environmental influences on development, and are reflected in organized patterns of individual differences in motivation, affect, self-regulation, and personality. By organizing individual differences on such a broad scale, life history strategies set the stage for the development of psychopathology. More precisely, individual differences in life history strategy can be expected to determine individual differences in risk profiles for a broad range of mental disorders. As one moves along the fast–slow continuum of life history variation, some disorders and symptoms should become more frequent, while others should become less likely to occur.

The predictable association between life history strategy and risk for psychopathology offers a high-level functional criterion for the classification of mental conditions. This leads to the novel distinction between *fast spectrum* and *slow spectrum* disorders—that is, disorders that cluster at the fast or slow end of the life history continuum (Del Giudice, 2014a, 2014b). Until recently, life history approaches to psychopathology have focused almost exclusively on the fast end of the fast-slow continuum. As widely recognized in the literature, fast life history strategies can predispose individuals to a variety of disorders, either as maladaptive outcomes of life history-related traits or potentially adaptive but undesirable behavioral strategies (e.g., Belsky et al., 1991; Brüne et al., 2010; Figueredo & Jacobs, 2010; Jonason, Li, Webster, & Schmitt, 2009; Salmon, Figueredo, & Woodburn, 2009). The framework advanced by Del Giudice (2014a) extends this approach by addressing the role of *slow* strategies in setting the stage for the development of mental disorders.

It is important to stress that the functional connection between life history strategy and psychopathology is usually an *indirect* one. Causal pathways to psychopathology involve a multiplicity of traits and mechanisms—including temperament and personality, self-regulatory processes, and so forth. The general idea is that an individual's configuration of life history-related traits may increase the likelihood of developing a certain disorder or cluster of disorders—often in interaction with other causal factors including developmental insults, deleterious genetic or epigenetic mutations, infections, nutritional deficits, and psychosocial stressors. The power of life history theory lies in the ability to integrate these diverse etiological processes within a common frame of reference. The result is a large-scale map of the psychopathological landscape

organized along the fast-slow axis of life history variation. Such a map is an invaluable guide in understanding comorbidity patterns, since functionally related disorders—for example different disorders in the slow spectrum—can be expected to co-occur more frequently in the same individual. At the same time, the fast-slow distinction can be used to tease apart functionally distinct conditions that coexist within the same descriptive category because of their phenotypic similarity.

In total, a functional analysis based on life history principles helps to "carve nature at its joints" by revealing commonalities between separate categories and suggesting important distinctions between phenotypically similar disorders (Keller & Nesse, 2006). Of course, mental disorders are complex biosocial phenomena, and as such they can be analyzed at many different levels. A life history analysis is only the first step toward a comprehensive functional account of psychopathology: the broad perspective afforded by the fast–slow distinction should be complemented by narrower accounts focusing on specific motivational/behavioral systems, cognitive mechanisms, genetic pathways, and so forth.

Four Pathways From Life History Strategy to Psychopathology

The general statement that life history strategies set the stage for the development of psychopathology can be supplemented by a finer-grained analysis of the causal pathways that lead to the onset of mental disorders. First of all, some *adaptive life history-related traits may be regarded as symptoms*. This is most likely to happen with fast life history strategies characterized by impulsive, exploitative, or aggressive tendencies. The resulting phenotype may be classified as a disorder, even if it does not reflect maladaptive or dysfunctional processes. Even if they are biologically adaptive, or used to be adaptive in ancestral environments, such strategies may often involve substantial costs in terms of health and emotional well-being. Another important category of adaptive traits that may be diagnosed as symptoms of a disorder is that of aversive defenses. When defenses activate inappropriately or respond with excessive intensity, the outcome may be correctly recognized as maladaptive. However, many protective mechanisms have strongly aversive effects, and can be occasionally harmful to the individual. For this reason, they may give rise to undesirable conditions not only when they misfire but also when they respond appropriately in presence of actual threats.

The correlates of life history strategies often include upregulation or downregulation of psychological and physiological defensive mechanisms. Upregulated defenses have a lower threshold for activation and/or respond with higher intensity when they activate. Defense upregulation can be associated with both fast and slow strategies, although the specific type of mechanism involved is likely to differ between the two. In the context of fast life histories, upregulated defenses help protect the individual from immediate danger in risky, unpredictable environments. In the context of slow strategies, upregulated defenses may help the individual prevent dangerous events and avoid potentially risky situations, even if the current environment is reasonably safe. Moreover, protecting oneself from even minor damages and losses contributes to the long-term maintenance of the soma (i.e., somatic effort)—a key priority for slow life history individuals. In contrast, downregulation of defenses is most likely in the context of fast life history strategies, especially those involving a high degree of risk taking. As discussed in a previous section, the underlying logic is that, to fulfill their purpose, such strategies require insensitivity to threats, dangers, and so forth.

The second pathway from life history strategy to psychopathology derives from the fact that *life history-related traits may be expressed at maladaptive levels*. Even phenotypic traits that are biologically adaptive within a certain range may become maladaptive if they exceed that range. Sometimes, the expected fitness associated with a trait may slowly increase up to an optimal level, then decrease abruptly following a "cliff-edged" function. In such cases, selection for optimal trait levels may result in a high frequency of maladaptive phenotypes that overshoot the fitness optimum (Nesse, 2004b). A trait can reach maladaptive expression levels owing to a combination of genetic, epigenetic, and environmental factors that contribute to push the phenotype in the same direction. In the simplest case, extreme levels of a trait may appear in the offspring of two individuals who are both high on that trait, yet still within the adaptive range. Thus, assortative mating—the tendency for sexual partners to be more similar than average on a certain trait—can increase the risk for psychopathology due to extreme trait values. Parent–offspring conflict and intragenomic conflict are other likely causes of maladaptive trait expression. When conflict is present, phenotypic development can be conceptualized as the result of opposing forces, much like a game of tug-of-war. If for any reason this dynamic equilibrium is broken (for example, a mutation in the offspring may make it unable to counteract parental manipulation), the resulting imbalance may easily determine dysregulated or pathological outcomes.

In principle, the pathway leading from maladaptive trait expression levels to psychopathology may involve traits associated with both fast and slow life histories. However, there is some evidence that assortative mating on life history-related traits in humans tends to become stronger toward the slow end of the continuum (Figueredo & Wolf, 2009). If so, disorders that involve maladaptive expression levels of adaptive traits should occur more frequently in association with slow strategies, as similarity between parents increases the likelihood that offspring will inherit extreme genotypic combinations.

Third, as noted in a previous section, even *adaptive strategies may yield individually maladaptive outcomes*. Risky strategies are a prime candidate as a systematic source of individually maladaptive outcomes. Life history-related traits can steer individuals on high-risk pathways, thus increasing the likelihood of maladaptive and/or undesirable outcomes in case of strategy failure—even when the strategy is adaptive on average. This is more likely to happen in the context of fast life history strategies, which tend to promote risk taking and favor the pursuit of large, immediate returns regardless of the potential costs. While some individuals engaging in high-risk strategies may end up developing mental disorders, other individuals expressing the same traits may enjoy desirable or biologically adaptive outcomes, often depending on chance and unpredictable contextual factors. Another important category of adaptive traits that systematically produce maladaptive outcomes is that of defensive mechanisms. Following the logic of the smoke detector principle, defensive mechanisms are usually designed to misfire occasionally, even in absence of threats. Individual differences in life history strategy are reflected in the calibration of behavioral and physiological defenses (see earlier discussion of the ACM), and indirectly affect the risk of inappropriate defense activation.

Fourth and last, *adaptive life history-related traits may increase vulnerability to dysfunction*. While life history traits are designed to promote adaptation, they can nevertheless increase vulnerability to some types of dysfunction as a side effect. For example, some configurations of personality traits within the adaptive range (for example schizotypy or autistic-like personality) may become especially conducive to psychopathology when they are coupled with high mutation load or brain-damaging infections (see Del Giudice, 2010). Also, fast life history-related traits such as risk proneness and future discounting may indirectly increase an individual's exposure to environmental factors such as pathogens. Finally, upregulated defensive systems are not only more prone to misfiring but also more vulnerable to actual instances of malfunction and dysregulation (Nesse, 2001). These four pathways from life history strategy to psychopathology are logically distinct but not mutually exclusive and may coexist in the etiology of any given disorder.

Correlates of Fast and Slow Spectrum Psychopathology

The conceptual distinction between fast and slow spectrum pathology provides a powerful heuristic criterion for the functional classification of mental disorders. Whatever the specific causal pathway (or combination of pathways) that determine the onset of a given disorder, fast spectrum conditions will be associated with traits such as low agreeableness and conscientiousness, impulsivity, disinhibition, and early sexual maturation (especially in females). Conversely, slow spectrum conditions will exhibit a signature of slow life history-related traits in the areas of motivation, self-regulation, personality, and sexual maturation. Correlations between life history–related traits and specific disorders may or may not imply a *causal* role of those traits in the etiology of the disorders. However, regardless of their role in the etiology of a given disorder, life history correlates can be employed as convergent *markers* of the underlying life history strategy. In principle, this approach can be extended to include genetic, epigenetic, and neurobiological markers (e.g., Del Giudice et al., 2011; Figueredo et al., 2004, 2006). A nonexhaustive list of markers of fast and slow spectrum psychopathology is presented in Table 1.2.

A life history perspective yields novel predictions about the environmental correlates of mental disorders. Ecological harshness and unpredictability tend to entrain development of fast life history strategies, while slow strategies are favored in safe and predictable contexts. As a result, many classic risk factors for psychopathology—such as stressful life events, low socioeconomic status, negative family relationships, trauma, and abuse—are predicted to increase the occurrence of fast spectrum disorders, but not that of slow spectrum disorders. On the contrary, slow spectrum disorders should be associated—at least on average—with safe, predictable environments, higher socioeconomic status, and *reduced* exposure to ecological and family stressors.

Sex Differences

If life history strategies set the stage for psychopathology, sexual asymmetries in life history trade-offs should produce consistent patterns of sex differences in the epidemiology of mental disorders. The first key asymmetry concerns the mating versus parenting trade-off. On average, human males invest more in mating effort and less in parenting effort than females. The intensity

TABLE 1.2 Correlates of fast and slow spectrum psychopathology

	Fast spectrum psychopathology	Slow spectrum psychopathology
Motivation	Social antagonism	Social compliance, conformity
	Unstable attachments	Stable attachments
	Precocious sexuality	Delayed sexuality
	Sexual promiscuity, high sex drive	Sexual restraint, low sex drive
	Sensation/novelty seeking	Preference for routines
	Risk taking	Risk aversion, harm prevention
Self-regulation	Disinhibition, impulsivity	Inhibition, restraint
	Discounting of future rewards	Discounting of immediate rewards
Personality traits	Low conscientiousness	High conscientiousness
	Low agreeableness	High agreeableness
Sexual maturation	Early, fast maturation	Late, slow maturation
Environment	Harsh, unpredictable	Safe, predictable
	High exposure to stressors	Low exposure to stressors

Source: Reprinted from M. Del Giudice, An evolutionary life history framework for psychopatholgy, Psychological inquiry, 25, 274, 2014a.

of mating effort increases sexual selection for competitive traits such as risk taking, dominance-seeking, and physical aggression (see Archer, 2009; Wilson et al., 2002). In total, higher mating effort in males should predispose them to fast spectrum disorders characterized by high levels of risk taking, such as those in the externalizing cluster (Martel, 2013). In contrast, females have generally less to gain and more to lose from high-risk strategies than males and can be expected to invest more effort in somatic maintenance and protection. As a consequence, they should be more prone to develop disorders that involve the upregulation of protective defenses, and to exhibit more psychological and physiological symptoms reflecting defense upregulation. This prediction applies to disorders across the fast-slow continuum, since upregulated defenses can be functionally associated with both fast and slow life history strategies. The higher incidence of anxiety disorders in females (see Martel, 2013) is consistent with this prediction.

Another important asymmetry in life history strategy concerns the trade-off between current and future reproduction. As already discussed in the section on life history theory, this trade-off plays a more critical role in the organization of female life history strategies, since decisions concerning reproductive timing are more critical for females than for males. As a consequence, the timing of sexual maturation in females should be more sensitive to cues of danger and unpredictability (James et al., 2012). Indeed, the available data suggest that ecological stress in the first years of life anticipates gonadal puberty in girls, but not in boys (reviewed in Belsky, 2012). In addition, indices of sexual maturation in females can be expected to form a tighter cluster with other life history-related traits including motivation, personality, self-regulation, and so forth. It follows that maturation timing and rate should be stronger predictors of psychopathology in females than in males. This prediction is well supported by empirical research; the bulk of evidence indicates that individual differences in sexual maturation are more robustly associated with psychopathology in girls than in boys (see Ge & Natsuaki, 2010; Mendle, Turkheimer, & Emery, 2007).

Predictions about sex differences based on life history theory (Del Giudice, 2014a) can be integrated with those from a recent evolutionary model advanced by Martel (2013). Martel employed sexual selection theory to explain the male-biased prevalence of childhood-onset externalizing disorders and the symmetrical, female-based prevalence of adolescent-onset internalizing disorders. Because of differential sexual selection for social dominance versus interpersonal competence in males and females, she also predicted that males should be more sensitive to early environmental stressors related to the broader ecological conditions (including those occurring prenatally), whereas females should be more sensitive to interpersonal stressors occurring around puberty. These predictions are supported by considerable empirical evidence, and can be extended to the neurobiological level to yield insight in the role of prenatal testosterone, dopamine, and serotonin in the etiology of common mental disorders in the two sexes (reviewed in Martel, 2013).

Toward a Life History Taxonomy of Mental Disorders

The general framework outlined in this section can be applied to individual disorders and categories of disorders, yielding an initial life history taxonomy based on the fast-slow continuum. In what follows, we briefly discuss how six common categories of mental disorders relate to the fast–slow distinction. For an extended analysis and review of the relevant empirical literature, see Del Giudice (2014a, 2014b).

Externalizing disorders

The externalizing spectrum comprises various disorders marked by aggressive, antisocial, and/or disruptive behavior, including oppositional defiant disorder (ODD), conduct disorder (CD), and antisocial personality disorder (APD). Externalizing disorders are also associated with

high risk for substance abuse. Disorders in the externalizing spectrum are strongly male-biased and show high phenotypic and genetic correlations with one another, indicating the existence of a coherent, heritable dimension of externalizing behavior. At the same time, the development of externalizing behaviors is strongly conditioned by environmental factors, such as harsh-rejecting parenting, aggregation of high-risk youth in after-school programs, and exposure to neighborhood violence and criminality (reviewed in Beauchaine, Hinshaw, & Pang, 2010).

In a life history perspective, externalizing spectrum disorders are prototypical instances of fast spectrum psychopathology. Externalizing symptoms are associated with impulsivity and undercontrol, early puberty timing and fast sexual maturation in both sexes, earlier onset of sexual activity, and larger numbers of partners in adolescence and young adulthood. Low socioeconomic status, harsh or unpredictable parental discipline, parental conflict, family disruption, and child abuse—all cues of danger and unpredictability—are consistent predictors of externalizing behavior, consistent with predictions derived from life history theory.

Evolutionary models of externalizing spectrum disorders tend to stress the potential biological adaptiveness of aggressive, exploitative, and risky behavior—especially when coupled with promiscuous short-term sexuality (e.g., Barr & Quinsey, 2004; Figueredo & Jacobs, 2010; Jonason et al., 2009; Mealey, 1995). Accordingly, many evolutionary scholars see externalizing disorders as adaptive but undesirable constellations of traits. In some instances, externalizing disorders may represent maladaptive extremes of potentially adaptive traits (see MacDonald, 2012). It should be stressed that externalizing disorders can be adaptive even if their social outcomes are negative *on average*. This can happen if successful outcomes yield disproportionate fitness returns, even in a minority of cases. Finally, high-risk behavioral strategies are likely to involve downregulation of defensive mechanisms; indeed, externalizing disorders in adolescents and adults are often associated with reduced anxiety, fearlessness, and dampened responsivity of the SRS.

Schizophrenia Spectrum Disorders

Schizophrenia is a family of mental disorders characterized by delusions, hallucinations, and cognitive disorganization. Given the severe reduction in reproductive success associated with a schizophrenia diagnosis, most evolutionary scholars regard this disorder as a maladaptive outcome of dysregulated sociocognitive processes (e.g., Burns, 2004; Keller & Miller, 2006). While schizophrenia spectrum disorders (SSDs) are highly heritable, schizophrenia risk is also increased by adverse environmental factors such as nutritional deficiencies, infections, and birth complications. This suggests that accumulated deleterious mutations and environmental insults may converge on common neurobiological pathways, increasing the risk of cognitive breakdown.

Even if SSDs are biologically maladaptive conditions, there may be evolutionary advantages associated with *schizotypal traits*—a constellation of personality traits associated with increased risk of psychosis. Most individuals who have psychotic experiences at some point in their life recover completely, and never transition to a diagnosable SSD. Various authors have proposed that schizotypal traits may be maintained by sexual selection processes based on mate choice. According to the sexual selection model of schizotypy (Nettle, 2001, 2006; Shaner, Miller, & Mintz, 2004), schizotypy-increasing alleles affect brain processes so as to increase traits such as verbal and artistic creativity, thus conferring mating advantages on those individuals who do not develop a psychiatric condition. However, the outcomes of schizotypy may be either beneficial (mating success) or harmful (schizophrenia), depending in part on the individual's genetic quality (i.e., lack of deleterious mutations) and developmental condition (e.g., good nutrition and low exposure to pathogens).

Consistent with the sexual selection model, positive schizotypal traits—unusual cognitive and perceptual experiences, tendency to magical ideation, reference and paranoid thoughts—are associated with verbal and artistic creativity, larger numbers of sexual partners, unrestricted sociosexuality, and reduced investment in long-term couple relationships. Large-scale studies of patients and their relatives show a robust familial association between schizophrenia and creativity. Schizotypal traits peak in adolescence/young adulthood and show a marked decline with age, mirroring typical changes in mating effort. In addition, positive schizotypy is associated with lower agreeableness and higher levels of aggression, suggesting a degree of overlap between the schizophrenia spectrum and the externalizing spectrum.

In light of this convergent evidence, SSDs can be provisionally classified as belonging to the fast spectrum of psychopathology, although there are reasons to expect a degree of functional heterogeneity (see Del Giudice, 2014a). According to sexual selection models, schizotypy can be understood as a high-risk strategy oriented toward short-term mating, whose negative outcomes become manifest as schizophrenia and other SSDs. Alternatively,

the milder disorders of the schizophrenia spectrum (e.g., schizotypal personality disorder, brief psychotic disorder) may result from maladaptive levels of expression of potentially adaptive traits associated with fast life history strategies.

Autism spectrum disorders

The autism spectrum comprises disorders of variable severity characterized by impairments in social interaction, communication problems, and restricted and repetitive behaviors/interests. Severe autism is almost certainly maladaptive, and some theorists have focused specifically on the negative aspects of autism spectrum disorders (ASDs). For example, Shaner and colleagues (Shaner, Miller, & Mintz, 2008) hypothesized that autism—like schizophrenia—may represent the negative extreme of a fitness indicator, a hypothesis consistent with the large number of deleterious mutations found in ASD patients.

This negative emphasis should be balanced by accumulating evidence that autistic-like traits in the normative range—also known as the *broader autistic phenotype*—have a number of desirable and potentially adaptive correlates. Specifically, autistic-like traits predict higher systemizing abilities and attention to detail, better visuospatial skills, and enhanced low-level sensory processing in the visual and auditory domains. The autistic facets of repetitive behaviors, restricted interests, and detail-oriented cognitive style are associated with the development of outstanding talents in children. More generally, autistic-like traits are higher in people with technical-scientific interests and careers. Accordingly, several theorists have argued that ASDs can be seen as extreme and usually maladaptive manifestations of otherwise adaptive traits (e.g., Baron-Cohen, 2003; Crespi & Badcock, 2008).

In this perspective, Del Giudice and colleagues (2010) hypothesized that sexual selection may contribute to maintain autistic-like traits in the population despite the fitness costs of severe ASDs. Specifically, they argued that autistic-like traits in their non-pathological form contribute to a male-typical strategy geared toward high parental investment, low mating effort, and long-term allocation of resources—in other words, a male-typical manifestation of slow life history strategy. This hypothesis offers a parsimonious explanation of the male-biased distribution of both autistic-like traits and ASDs. In support of this hypothesis, autistic-like traits predict lower interest in short-term mating, increased investment of time and resources in one's partner, and stronger commitment to long-term romantic relations. People high in autistic-like traits report shorter duration of friendships but longer duration of romantic relationships, and their partners are on average just as satisfied as those of people low in autistic-like traits.

In a life history perspective, ASDs are thus likely candidates for inclusion in the slow spectrum of psychopathology. Further evidence comes from the finding that sexual maturation is delayed in women high in autistic-like traits as well as in women with ASD. Autistic-like traits may function adaptively as part of a slow life history strategy—especially in males—and become maladaptive only when they cross a certain threshold. Given the remarkable heterogeneity of ASDs, this functional explanation is likely to apply only to a subset of people diagnosed with autistic disorders. Different ASD subtypes may well require different explanations. The existence of functionally distinct subtypes of ASDs may explain the inconsistent correlation of autism risk with socioeconomic status in epidemiological studies.

Obsessive-Compulsive Spectrum Disorders

Disorders in the obsessive-compulsive spectrum are primarily characterized by patterns of compulsive, repetitive thoughts and/or behaviors, usually associated with worry and anxiety. In addition to obsessive-compulsive disorder (OCD), the OC spectrum includes body dysmorphic disorder, hoarding disorder, grooming disorders (skin picking and hair pulling), and obsessive-compulsive personality disorder (OCPD)—a pervasive profile of orderliness, rigid perfectionism, and need to control one's self and environment.

In the evolutionary literature, OCD is usually treated as a maladaptive exaggeration of an adaptive trait or the result of a dysfunction in precautionary cognitive systems. However, the milder forms of the disorder are not necessarily maladaptive in the biological sense. Current models converge on the idea that the main functional substrate of OCD is an adaptive mechanism—the *hazard-precaution system* or *security motivation sy*stem—specialized for dealing with potential low frequency threats such as food poisoning (e.g., Boyer & Lienard, 2006; Szechtman & Woody, 2004; Woody & Szechtman, 2011). The peculiar logic of potential threats explains many features of compulsions (see Woody & Szechtman, 2011); obsessions can be explained as the involuntary generation of potential risk scenarios, a mechanism designed to increase future harm avoidance. Consistent with a threat prevention account and with the prediction that females should be more likely to develop symptoms reflecting upregulated defenses, adult OCD patients are overwhelmingly women.

A life history analysis indicates that the OC spectrum is best understood as a functionally heterogeneous category comprising two clusters of disorders—a slow spectrum one and a fast spectrum one. Slow-spectrum OCD is marked by *reactive* obsessions (Lee & Kwon, 2003); reactive obsessions concern realistic fears of contamination, mistakes, accidents, or disarray. They are triggered by cues of potential threats and are typically followed by preventive behaviors such as ordering or cleaning; anxiety is directed at the possible consequences of one's actions rather than at the obsession itself. Reactive obsessions are associated with high conscientiousness, perfectionism, heightened responsibility and personal standards, normal levels of motor and cognitive inhibition, and a prevalence of contamination/cleaning symptoms. Reactive OCD fits straightforwardly in the slow spectrum of psychopathology, as a combination of exaggerated trait expression, upregulation of adaptive defenses, and dysfunctional protective responses. Obsessive-compulsive personality disorder (OCPD) also fits this classification, given its many overcontrol features and strong association with conscientiousness.

Fast-spectrum OCD is characterized by *autogenous* obsessions—obsessions with sexual, aggressive, or blasphemous content. Autogenous obsessions tend to be bizarre, ego-dystonic, and threatening. They often have no apparent trigger, or are triggered by remote/bizarre thought associations (Lee & Kwon, 2003). Autogenous obsessions are associated with positive schizotypy, indices of psychotic thought disorganization, low conscientiousness, and reduced inhibitory control. The heterogeneous nature of the OC spectrum explains why OCD shows high comorbidity with both ASDs and SSDs. The two OC clusters can be expected to show markedly different epidemiological profiles; for example, traumatic events and low SES should be more strongly associated with fast-spectrum OCD, whereas slow-spectrum OCD should often arise in safe and predictable environments. Consistent with placement in the slow-spectrum cluster, OCPD is uniformly associated with high education levels, and OCDP patients have the highest socioeconomic status of all personality disorders (for extended discussion see Del Giudice, 2014b).

Eating Disorders

Eating disorders (EDs) are defined by heightened concern with body shape and weight and associated behaviors such as dieting, binge eating, purging, and exercising. Eating disorders occur almost exclusively in females, and their age of onset peaks in adolescence. Most evolutionary models of eating disorders focus on the connection between dieting behavior and female reproduction. Two main alternative hypotheses have been proposed so far. First, dieting may work as a means to suppress fertility and delay or forego reproduction when the social environment is not optimal—for example, when social support by relatives and partners is low, or when social competition is too harsh (e.g., Mealey, 2000; Surbey, 1987). Second, dieting may work primarily as a female strategy in mating and status competition (e.g., Abed, 1998; Ferguson, Winegard, & Winegard, 2011; Salmon et al., 2009). Thinness is a reliable signal of youth, and dieting can increase one's attractiveness because of men's strong preference for younger partners; in addition, dieting can enhance status in female groups (thus indirectly influencing mating success), especially when cultural emphasis on thinness is strong. This hypothesis is supported by the robust pattern of associations among perceived sexual competition, dieting behavior, and eating symptoms. Under both hypotheses, the psychological processes that underlie dieting behavior are fundamentally adaptive, and lead to maladaptive outcomes (such as severe EDs) only when they become dysregulated or get trapped in vicious cycles.

The mating competition hypothesis of eating disorders can be easily reframed in a life history perspective. Both fast and slow strategists can face intense competition for mates; the main difference is that fast strategists compete primarily to become desirable sexual partners, whereas slow strategists compete primarily to be chosen as long-term partners in committed relationships. Thus, eating disorders can arise at both ends of the fast-slow continuum.

A life history analysis confirms that EDs are indeed a functionally heterogeneous category. Slow spectrum EDs are associated with *high-functioning/perfectionist* personality profiles, low comorbidity rates (mostly with OCD and OCPD), and the most favorable clinical outcomes (see e.g., Thompson-Brenner et al., 2008; Westen & Harnden-Fischer, 2001). This cluster of eating disorders is associated with high self-esteem, relatively intact family and couple relationships, and a history of *fewer* stressful life events. Another profile that can be included in the slow spectrum is that of *overcontrolled* patients. This profile is associated with high rates of depression, low self-esteem and passivity, restricted emotionality, and comorbidity with OCPD. Overcontrolled ED patients might be engaging in reproductive suppression—an intrinsically future-oriented strategy—following loss of status or social support, as suggested by their depressed mood, low self-esteem, and acute sense of social exclusion.

In contrast, fast spectrum EDs are associated with *dysregulated* personality profiles (see Thompson-Brenner et al., 2008). Dysregulated ED patients show high levels of impulsivity and antisocial/externalizing behavior, high comorbidity (especially with borderline personality disorder), and many stressful life events including high rates of sexual abuse. While patients in the high-functioning/perfectionist and overcontrolled groups can be diagnosed with either anorexia nervosa (AN) or bulimia nervosa (BN), the dysregulated subtype is strongly associated with BN (Westen & Harnden-Fischer, 2001). As a result, patients with BN—considered as a whole—show higher average levels of impulsivity, earlier sexual maturation, and earlier sexual debut than AN patients.

Depression

Depression is characterized by protracted episodes of distress and low, dejected mood. The clinical presentation of depression is quite heterogeneous; attempts to subtype depressive disorders based on empirical patterns of symptom co-occurrence consistently identify (1) a subtype characterized exclusively by depressed mood and feelings of worthlessness; (2) one or more subtypes characterized by somatic symptoms in absence of depressed mood; and (3) one or more subtypes in which depressed mood and somatic symptoms coexist. Somatic symptoms of depression include sleep disturbances (insomnia or hypersomnia), appetite disturbances (increased or decreased appetite), psychomotor disturbances (agitation or retardation), fatigue, and pain. All these symptoms are functionally related to the SRS, and in particular the HPA axis.

Most evolutionary theories of depression focus on low mood and its motivational and behavioral correlates. In the prevailing view, depressed mood is an adaptive defensive mechanism, whereas clinical depression is usually maladaptive and reflects a dysfunction of the same mechanism (e.g., Allen & Badcock, 2003; Nesse, 2006; Nettle, 2004, 2012). Some theorists have argued that clinical depression may be an adaptation itself (e.g., Price, Sloman, Gardner, Gilbert, & Rohde, 1994; Watson & Andrews, 2002). Although this hypothesis appears reasonable in the specific case of postpartum depression (Hagen, 1999), there are many reasons to doubt its general applicability. The function of low mood as a protective mechanism is twofold. First, low mood helps people disengage from the pursuit of central life goals that have become unproductive. Second and more specifically, it promotes a risk-averse approach in unfavorable social circumstances—especially following losses in social support (typically in females), close relationships, and social status or dominance (typically in males). While affective reactivity determines one's susceptibility to episodes of low mood, stress reactivity is the crucial factor in the development of somatic symptoms. Thus, a complete evolutionary account of depression cannot be separated from evolutionary models of SRS functioning.

By synthesizing the ACM with evolutionary models of depressed mood, it is possible to predict a complex relation between depression and life history strategy. Both fast and slow strategists can fail to obtain or maintain crucial social resources—status, dominance, and support—resulting in episodes of depressed mood and risk for clinical depression. At the slow end of the continuum, males and females are both expected to develop relatively high levels of stress responsivity (Del Giudice et al., 2011), even if the actual intensity of stress responses is buffered by the availability of social support and lack of chronic stressors. As a result, symptom profiles at the slow end of the spectrum should not differ greatly between the sexes. Intriguingly, some subtypes of depression—in particular those characterized by pure depressed mood or pure somatic symptoms—are associated with very low rates of trauma, neglect, and abuse.

Moving toward the fast end of the continuum, both sexes face increasing threats to their ability to gain and maintain social resources. The availability of social support and stable, intimate relationships declines rapidly as environments become dangerous and unpredictable, exposing females to increased risk for depressed mood. At the same time, sex differences in stress responsivity can be expected to become proportionally larger, as more males develop unemotional responsivity patterns. Vigilant SRS profiles can be adaptive in dangerous and unpredictable contexts, especially in females; however, they also increase the risk of SRS dysregulation and dysfunction. In total, fast life history strategies should lead to increased risk for depression in both sexes, with females showing the highest rates of depressed mood and somatic symptoms. Consistent with these predictions, early and/or fast sexual maturation is a risk factor for depression in both sexes, with stronger effects in females. In addition, depression subtypes involving a combination of low mood and somatic symptoms are overwhelmingly more common in females, and are also associated with the highest rates of early trauma, neglect, and abuse. In conclusion, depression may occur at both ends of the fast–slow continuum, suggesting the existence of functionally distinct clusters of depressive disorders. Unfortunately, the current literature defines depression subtypes exclusively in terms of symptom co-occurrence; further research in a life history framework should attempt

to identify functional subtypes of depression based on motivation, personality, self-regulation, and comorbidity with other fast and slow spectrum disorders.

Summary and Integration

A life history analysis of mental disorders reveals a coherent picture of associations between individual differences in life history strategy and specific patterns of risk for psychopathology. The constellation of fast spectrum conditions includes externalizing disorders, schizophrenia spectrum disorders, OCD with autogenous obsessions, the dysregulated subtype of eating disorders (typically expressed as BN), and depressive disorders characterized by a combination of mood and somatic symptoms. These disorders tend to co-occur, both within families and within individuals; many of them share elements of impulsivity, disinhibition, and/or bizarre ideation. Slow spectrum psychopathology includes OCPD, OCD with reactive obsessions, autism spectrum disorders, the perfectionist and overcontrolled subtypes of eating disorders, and a cluster of depressive disorders of lesser severity. These comorbid disorders tend to share elements of inhibition, overcontrol, and cognitive rigidity. They are also characterized by lack of association with standard risk factors for psychopathology such as stressful life events, low SES, and early abuse; in some cases, they are actually associated with more favorable ecological and socio-economic conditions. The same approach can be easily extended to other disorders. For example, borderline personality disorder (BPD) bears the hallmarks of fast life history strategies—impulsivity, unstable attachments, risk taking, promiscuous sexuality, antisocial and paranoid personality features, and high comorbidity with externalizing disorders (Brüne et al., 2010; see also Crowell et al., 2013). Similarly, disorders in the bipolar spectrum show substantial genotypic and phenotypic overlap with schizotypy and schizophrenia, including a familial association with enhanced creativity (see Del Giudice, 2014a, 2014b). A provisional classification of slow and fast spectrum disorders is shown in Figure 1.7.

This classification is still tentative and incomplete, and many gaps and questions remain—for example about the possible functional heterogeneity of autism and schizophrenia, the role of reproductive suppression in disordered eating, or the identification of fast and slow spectrum subtypes of depression (see Del Giudice, 2014b). However, even this initial analysis illustrate how a life history framework can bring an integrative perspective to psychopathology, highlight connections between previously separate models, and suggest novel empirical questions. Even more importantly, this approach has the potential to overcome the limitations of current taxonomic systems and offer a more solid foundation for the classification of mental disorders. In particular, the fast-slow distinction is both more *inclusive* and more *accurate* than the interalizing–externalizing distinction. It is more inclusive because it integrates mood and anxiety disorders with personality disorders, schizophrenia spectrum disorders, and autism spectrum disorders—all within the same conceptual framework. It is more accurate because it resolves many inconsistencies inherent in the basic interalizing–externalizing distinction. For example, the ambiguous placement of OCD in the internalizing spectrum is explained by the heterogeneity of OCD; specifically, the autogenous subtype of OCD is a fast spectrum disorder with strong functional connections with externalizing symptoms. More generally, the interalizing–externalizing distinction may be problematic because it is in large part

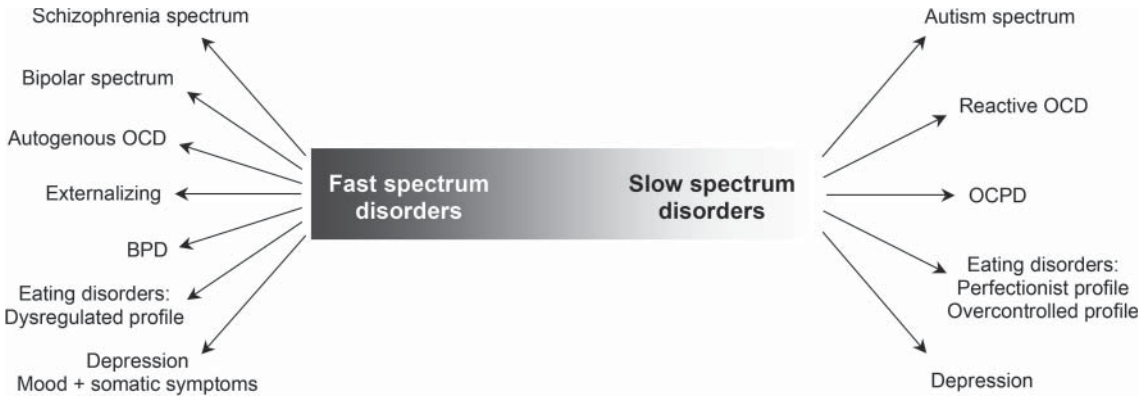

Figure 1.7 Provisional life history taxonomy of common mental disorders. BPD = borderline personality disorder, OCD = obsessive-compulsive disorder, OCPD = obsessive-compulsive personality disorder. *Source:* Reprinted from M. Del Giudice, An evolutionary life history framework for psychopatholgy, Psychological inquiry, 25, 285, 2014a.

illusory. The obvious genotypic and phenotypic coherence of the externalizing spectrum may have led researchers to assume that internalizing disorders must form a symmetrical category with similar properties of coherence. A life history perspective suggests that this assumption is probably mistaken, and that the internalizing spectrum may turn out to be a largely artificial collection of disorders with divergent functional properties.

Implications for the Core Points of Developmental Psychopathology

The life history framework discussed in this section has important implications for developmental psychopathology. Most crucially, it shows how *equifinality* and *multifinality* in the development of mental disorders can be explained in a functional perspective. On one hand, the same kind of symptom—for example eating symptoms and obsessions—can arise in relation to different life history strategies. As a result, phenotypically similar disorders can be associated with opposite profiles of personality, sexual maturation, ecological factors, and so forth. On the other hand, the same basic dimensions of life history strategy can play a role in the etiology of functionally related but superficially different disorders. While these manifestations of equifinality and multifinality may be problematic in the context of the standard externalizing–internalizing distinction, they can be easily understood in terms of the fast–slow distinction advanced by Del Giudice (2014a).

A closely related point is that, in this perspective, not all disorders are expected to arise in association with typical *risk factors* such as early stress, negative family relationships, and low SES. This helps make sense of the puzzling fact that some disorders seem to develop more frequently in safe, predictable ecologies and families with high socioeconomic status. The model presented here may also explain why insecure attachment—a robust psychological correlate of fast life history strategy—is consistently associated with externalizing symptoms but only weakly predictive of internalizing symptoms (Groh, Roisman, van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012). Finally, the coexistence of fast and slow spectrum subtypes within the same diagnostic category may go a long way toward explaining inconsistent or contradictory patterns of epidemiological findings.

CONCLUSION

We started this chapter with a promise—to show how an evolutionary approach can help developmental psychopathology realize its full potential, and to demonstrate how EDP provides an integrative, powerful metatheory for the field. We hope we fulfilled our promise and succeeded in arousing the reader's interest in the EDP approach. Throughout the chapter, we sought to illustrate how an evolutionary-developmental perspective supports and extends the core points of developmental psychopathology. Consider for example the concept of *multifinality*. In the standard view, multifinality is a ubiquitous, general property of complex developmental systems. However, the mechanisms that generate of multifinality are usually left unspecified; as a result, the concept is often used to redescribe empirical findings rather than explain them. The EDP approach demystifies multifinality by grounding the concept in adaptive function, and provides the tools for predicting *when* multifinality should apply (or not) to a given developmental process, stage, or outcome. Thus, multifinality can be understood as a necessary consequence of differential susceptibility; the logic of the ACM predicts when similar physiological profiles may predict widely divergent behavioral outcomes; and life history theory (together with sexual selection theory) explains why similar developmental experiences may set the stage for phenotypically different but functionally related disorders. Even more importantly, these apparently disparate aspects of development can be understood in relation to one another and unified within an integrative theoretical framework.

Even if we covered a lot of ground, we barely scratched the surface of our topic. The evolutionary approach to development and psychopathology is a growing multidisciplinary enterprise, and new theories, models, and findings are published at an ever increasing pace. We therefore conclude by suggesting a reading list for further explorations of the field. Ellis and Bjorklund (2005) and Burgess and MacDonald (2005) offer a more complete overview of EDP, including discussion of cognitive processes such as memory and language. Special sections of *Development and Psychopathology* on differential susceptibility (Ellis & Boyce, 2011) and *Developmental Psychology* on conditional adaptation (Ellis & Bjorklund, 2012) provide useful collections of relevant work. An introduction to theories and models in evolutionary psychopathology can be found in Brüne (2008) and McGuire and Troisi (1998). Finally, Ellison and Gray (2009) show how evolutionary thinking can be applied to neurobiological and endocrinological processes. Explaining the development of psychopathology is a formidable task, calling for convergence and integration across myriad disciplines and levels of analysis. We believe that evolutionary theory offers invaluable tools for

this task, and hope that developmental psychopathology will join forces with EDP toward a common understanding of human development in all its living complexity.

DIFFERENTIAL SUSCEPTIBILITY TO ENVIRONMENTAL INFLUENCES

Central to much thinking about human development is the presumption that experiences in the early years of life—and even thereafter—influence individual differences in later development. Indeed, such developmental plasticity is a central tenant of most theories of human development, including attachment theory, social-learning theory and life-course sociology. Moreover, it guides a diverse array of research, including, for example, work chronicling links between prenatal maternal stress and temperament in infancy (Huizink, de Medina, Mulder, Visser, & Buitelaar, 2002), between maternal sensitivity in the first year and attachment security thereafter (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003), between quality of child care in the preschool years and vocabulary scores at age 10 (Belsky, Vandell, et al., 2007), between parental divorce/separation in early adolescence and school grades in the later teenage years (Lansford et al., 2006), and

Jay Belsky's work on this chapter was made possible with the support of the endowment for the Robert M. and Natalie Dorn Professorship that he holds.

between early family environment and depression symptomatology in early adulthood (Taylor et al., 2006).

In this chapter we provide a detailed introduction to theory and evidence pertaining to differential susceptibility (DS) (Belsky, 1997b, 2005; Belsky & Pluess, 2009a, 2013a), a relatively new conceptual framework stipulating that individuals differ substantially in their degree of developmental plasticity, with some being generally more and some generally less plastic. Importantly, this differential susceptibility hypothesis is based on evolutionary reasoning about developmental plasticity. What many developmentalists have failed to appreciate regarding developmental plasticity is that such plasticity carries costs (DeWitt, Sih, & Wilson, 1998; Frankenhuis & Del Giudice, 2012; Schlichting & Pigliucci, 1998; Sih, 2011). First there is the cost associated with increased phenotypic complexity that may be required for an organism to be able to develop in diverse ways, depending on contextual conditions. Some of these costs derive from the fact that as complexity increases, so does the risk of something going wrong, in the same way that a machine with more moving parts has more ways of breaking down than one with fewer. Consider as well the following and related costs of plasticity enumerated by DeWitt and associates (1998): energetic costs of the sensory and regulatory mechanisms of plasticity; the production cost of environmentally inducible structures and processes; the cost of acquiring information about the environment, including the energy expended and potential risks incurred; and the imprecision in manufacturing a phenotype based on environmental experience. Collectively, these would seem to imply a trade-off between the benefits of being able to adjust development in accord with prevailing or anticipated contextual conditions—and thus being able to thrive in more than a single ecological niche—and the costs of a breakdown in the developmental machinery and processes needed to do so.

Also important to appreciate with respect to the costs of plasticity is that modifying development early in life in response to developmental experiences and environmental exposures may result in a "mismatch" between the developed organism and the environment in which it finds itself later in life (Nederhof & Schmidt, 2012; Sih, 2011). In this way, seemingly adaptive developmental plasticity, selected to allow the organism to be programmed on the basis of early experience to fit the later environment, may, in some cases, actually undermine developmental opportunity and eventual fitness rather than enhance it.

The potentially high costs associated with developmental plasticity as well as the potential risk of mismatch between programmed phenotype and future environment would seem to provide grounds to expect individual differences in the degree of developmental plasticity within a species, the fundamental focus of this chapter. After all, individuals whose development is more canalized and less programmable by environmental exposures would be less likely to experience a mismatch resulting from developmental plasticity. Of course, such highly canalized specialists with more or less fixed characteristics could still end up mismatched to their environment, but for reasons different from that of the more plastic, programmable generalist who may develop in a manner guided by experiences had earlier in life.

In sum, what these observations imply is that being developmentally malleable should not be regarded, as it typically is by developmental scholars, as an unmitigated good for the developing organism and thus as something that should be pronounced in all individuals. In some cases it would appear wiser not to be plastic or to be less malleable—manifesting a more canalized pattern of development—than others and thus less susceptible to environmental regulation. What this suggests, as now noted repeatedly, is that we should expect individual differences in developmental plasticity. In other word, developmental plasticity should be conceptualized as a phenotype in its own right, something that will vary across individuals—for a variety of reasons (Belsky & Pluess, 2009b).

As it turns out, this notion of individual differences in developmental plasticity has long been appreciated by students of both normal development and psychopathology, even if not always expressed in such terms. Indeed, the notion of individual differences in plasticity is central to the model of human development and environmental action that dominates so much thinking and research. For example, the diathesis–stress framework presumes that not all individuals are equally vulnerable to the negative effects of adverse environmental influences (Gottesman & Shields, 1967; Monroe & Simons, 1991; Zuckerman, 1999). In recent years, an alternative framework has been advanced, that of differential susceptibility to environmental influence (Belsky, 1997b, 2005; Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Belsky & Pluess, 2009a; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011), which is the primary subject of this chapter. We thus begin by considering the diathesis–stress framework before outlining that of differential susceptibility. We then discuss some methodological issues pertinent to the investigation of differential susceptibility before proceeding to review evidence consistent with the latter, highlighting organismic factors (i.e., temperament, physiology, genotype) that moderate responsiveness to environmental influences. Because

all the work reviewed through this point is observational in character, a subsequent section focuses on experimental manipulations of the environment that illuminate whether intervention effects are moderated by plasticity factors. Thereafter, we call attention to studies that actually consider repeated-measurement involving how the very same individuals behave when exposed to both negative and positive contextual conditions. Finally, we raise a host of issues under the guise of unknowns in the differential susceptibility equation to guide future research before drawing some general conclusions.

DIATHESIS–STRESS

Developmental Psychopathology Foundations

As already noted, behavioral scientists and developmental psychopathologists have long appreciated that individuals vary in their susceptibility to the influence of environmental factors and forces. It is this presumption, after all, that has long motivated interest among many in treatment–aptitude interactions, including personalized medicine today (Shoham & Insel, 2011). But in the realm of both normal and psychopathological functioning and development, it is the diathesis–stress model of environmental action (Gottesman & Shields, 1967; Monroe & Simons, 1991; Zuckerman, 1999) that most clearly highlights the issue at hand—*individual differences in responsiveness to the environment*. Of especial importance is that the diathesis–stress framework is principally, even exclusively, concerned with variation in response to contextual *adversity*. More specifically, diathesis–stress thinking stipulates that some individuals are disproportionately, if not exclusively, likely to succumb to the negative effects of some contextual stressor (e.g., poverty, negative life events). This heightened vulnerability to adversity may be due to organismic characteristics of the individual, such as genetic makeup, personality or temperament, which will be of principal concern here, as well as family factors and processes or extrafamilial conditions.

Not unrelatedly, developmental psychopathologists have embraced the concept of resilience, which is really the inverse of vulnerability (Garmezy, Masten, & Tellegen, 1984; Masten, Best, & Garmezy, 1990; Rutter, 1987; Werner & Smith, 1982). Empirical research on risk and resilience first emerged in the 1970s (e.g., Garmezy, 1974; Rutter, 1979; Werner & Smith, 1977) and has come to exert a major influence on the study of development and psychopathology (for reviews, see Luthar, Cicchetti, & Becker, 2000; Masten, 2007; Rutter, 2012). Indeed, one of the most important and valuable insights that emerged over the past decades has been that individuals differ in the degree to which they are affected by contextual adversity. Whereas some vulnerable children and adults are likely to develop problematically in response to negative contextual conditions—by becoming emotionally and behaviorally dysregulated or disordered—others are not and thus regarded as resilient. Like vulnerability, resilience may be a function of a variety of factors, including organismic (e.g., intelligence, humor, genes) and contextual ones (e.g., supportive friend or teacher (Garmezy, 1974)) (Figure 2.1). To be appreciated, however, is that resilience from this perspective is understood as a dynamic process rather than an inherent characteristic of an individual (Cicchetti & Rogosch, 2012; Rutter, 2012).

Prior to the emergence of theorizing about adaptive functioning in the face of significant adversity (i.e., resilience), investigations of risk and psychopathology generally portrayed the developmental process as somewhat deterministic, resulting in negative or maladaptive outcomes (Cicchetti & Rogosch, 2012). Ultimately, the concept of resilience had its origins in the observation that "there is huge heterogeneity in response to all manner of environmental hazards: physical and psychosocial"

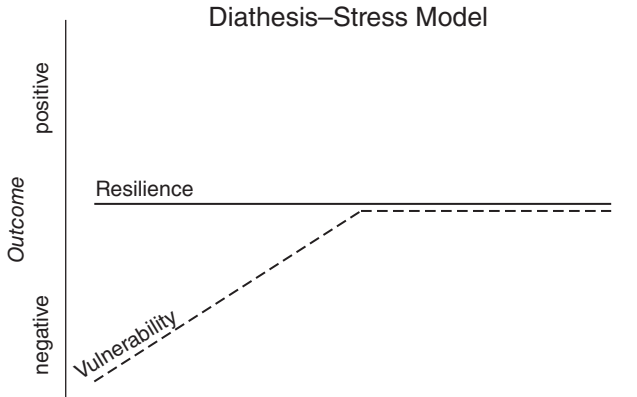

Figure 2.1 Graphical illustration of diathesis–stress. Vulnerability (i.e., diathesis) describes the propensity to respond negatively to adverse experiences, as a function of individual characteristics, whereas resilience reflects protective resistance from the same negative influences. No differences are predicted in response to positive influences. *Source:* Adapted from M. J. Bakermans-Kranenburg & M. H. van IJzendoorn, Gene–environment interaction of the dopamine D4 receptor (DRD4) and observed maternal insensitivity predicting externalizing behavior in preschoolers. *Developmental Psychobiology, 48*(5), 2006, Figure 1.

(Rutter, 2012, p. 336). But it needs to be appreciated given what is to follow in the discussion of differential susceptibility that "resilience is defined in terms of a better outcome than that seen in other individuals from a similarly adverse background . . . there is no requirement of superior functioning in relation to the non-deprived population as a whole" (Rutter, 2012, p. 342). As we will see, this feature of the resilient individual distinguishes diathesis–stress thinking from that of differential susceptibility.

Intriguingly, similar views were advanced by ecological scientists and biologists (Hanson & Gottesman, 2012), starting with Holling's (1973) work on ecological systems, with resilience defined as the capacity of a system to absorb disturbance and reorganize while undergoing change to retain essentially the same function, structure, identity, and feedbacks (Walker, Hollin, Carpenter, & Kinzig, 2004). Developmental geneticists captured a similar notion using the term *canalization* (Gottesman, 1974; Waddington, 1942).

A Psychological Challenge

It is not surprising that those who think predominately in diathesis–stress and resilience terms when considering human development—given their specific research interest in disordered, troubled and problematic functioning or the absence thereof—have rarely wondered about what might be regarded as the other half of the person–context interaction equation: How do individual differences, including with regard to organismic vulnerability factors, play out when circumstances are not adverse but benign, supportive or even enriching (Pluess & Belsky, 2013)? This critical question is central to this chapter because the differential susceptibility paradigm posits that those putatively vulnerable to adversity are also likely to be more responsive to positive and growth-facilitating developmental experiences and environmental exposures (Belsky, 1997b, 2005; Belsky, Bakermans-Kranenburg, et al., 2007; Belsky & Pluess, 2009a; Ellis, Boyce, et al., 2011). From this perspective, questions can be raised as to whether one should even speak of vulnerability factors (alone). By the same token, from the differential susceptibility perspective, those resilient and thus protected or buffered from the negative effects of adversity are also less likely—or entirely unlikely—to reap the rewards of a benign, supportive or enriching environment. This alternative analysis raises the prospect that so-called vulnerable individuals are not as unlucky or unfortunate as they might appear, nor are the so-called resilient as fortunate as they would seem to be according to traditional developmental psychopathological thinking.

An Evolutionary Challenge

An evolutionary perspective also raises issues about the prevailing developmental-psychopathological analysis of dysfunctional or maladaptive outcomes within settings of adversity. In particular, it contends that both stressful and supportive environments have been part of human experience throughout our evolutionary history, and that developmental systems shaped by natural selection respond adaptively to both kinds of contexts. Thus, when people encounter stressful environments, this does not so much *disturb* their development—as widely assumed—as *direct or regulate* it toward strategies that are *adaptive* under stressful conditions—even if those strategies are currently harmful vis-à-vis the long-term welfare of the individual or society as a whole (Ellis, Boyce, et al., 2011; Hinde & Stevenson-Hinde, 1990; Main & Solomon, 1990).

Consider the extensive experimental work conducted by Michael Meaney and colleagues showing that putatively low-quality maternal care in the rat (i.e., low levels of maternal licking and grooming) alters pups' stress physiology and brain morphology. Although such changes seem disadvantageous (i.e., higher corticosterone levels, shorter dendritic branch lengths, and lower spine density in hippocampal neurons), they actually *enhance* learning and memory processes under stressful conditions (Champagne et al., 2008). Moreover, such physiological and morphological changes mediate the effects of maternal behavior on central features of defensive and reproductive strategies—behavior under threat, open-field exploration, pubertal development, sexual behavior, and parenting (Cameron, Fish, & Meaney, 2008; Cameron et al., 2005)—in ways consistent with evolutionary models of adaptive reproductive strategies (Belsky, Steinberg, & Draper, 1991; Chisholm, 1993).

In the rodent model, then, enhanced learning under stressful conditions, increased fearful and defensive behaviors, accelerated sexual maturation, increased sexual behavior, and reduced parental investment in offspring apparently represent strategic—that is, functional—ways of developing when suffering parental neglect. In this context, neglect itself can be regarded as a mechanism through which rat mothers guide or program their offspring's development toward optimal survival and reproductive strategies *under conditions of adversity*. It would seem mistaken, therefore, to view diminished licking and grooming as inherently negative or the development induced by such care as disturbed. From an evolutionary perspective, the care provided by the putatively neglectful parents may be appropriate preparation of their offspring for the

ecological conditions into which they are likely to mature (Ellis, Boyce, et al., 2011).

It is important to note that optimal adaptation (in the evolutionary sense) to challenging environments is not without real consequences and costs. Harsh environments often harm or kill children, and the fact that children developmentally adapt to such rearing conditions (reviewed in Ellis, Figueredo, Brumbach, & Schlomer, 2009; Pollak, 2008) does not imply that such conditions either promote child well-being or should be accepted as unmodifiable facts of life (i.e., David Hume's naturalistic fallacy). There can be no doubt that high-stress environments that are dangerous and lack essential resources, compared with low-stress environments that are safe and well-resourced, cause substantial distress and eventually undermine fitness. In other words, developmental adaptations to high-stress environments simply enable individuals to make the best of a bad situation (i.e., to mitigate the inevitable fitness costs), even though the best may still constitute a high-risk strategy that jeopardizes the person's health, well-being and survival (e.g., Mulvihill, 2005; Shonkoff, Boyce, & McEwen, 2009). It is also important to mention here the possibility of genuinely novel environments that are beyond the normative range of conditions encountered over human evolution. Exposures to such challenging yet (evolutionarily) unprecedented conditions can be expected to induce pathological development that does not reflect evolutionarily adaptive strategies (Ellis, Boyce, et al., 2011).

In sum, an evolutionary-developmental perspective emphasizes *conditional adaptation*: "evolved mechanisms that detect and respond to specific features of childhood environments, features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature, and entrain developmental pathways that reliably matched those features during a species' natural selective history" (Boyce & Ellis, 2005, p. 290; for a comprehensive treatment of conditional adaptation, see West-Eberhard, 2003; for applications to human development, see Belsky et al., 1991, 2000; Chisholm, 1996; Ellis, 2004). From within such a perspective, the highly susceptible child who responds to a dangerous environment by developing insecure attachments, adopting an opportunistic interpersonal orientation, and sustaining an early sexual debut is no less functional than the context-sensitive child who responds to a well-resourced and supportive social environment by developing the opposing characteristics and orientations. Children have evolved to function competently—to survive and ultimately reproduce—in a variety of contexts, and the default assumption should be that alternative patterns of development in response to both stressful and supportive environmental conditions (within the range encountered over human evolution) constitute adaptive variation (Ellis, Boyce, et al., 2011).

BEYOND DIATHESIS–STRESS

Evolutionary-Developmental Theories of Differential Susceptibility

In addition to shaping species-typical developmental responses to diverse environmental conditions, natural selection has also maintained variation—adaptive individual differences—in neurobiological susceptibility to the environment. Two different evolutionary accounts of such variation in human development have emerged in recent years (Ellis, Boyce, et al., 2011): DS (Belsky, 1997b, 2005; Belsky, Bakermans-Kranenburg, et al., 2007); and biological sensitivity to context (BSC; Boyce & Ellis, 2005; Boyce et al., 1995; Ellis, Essex, & Boyce, 2005). With a central focus on person–environment interactions, both models highlight the role of organismic characteristics of individuals in moderating the effects of both stressful and supportive environmental conditions on human development (Figure 2.2). Thus, both presume that there

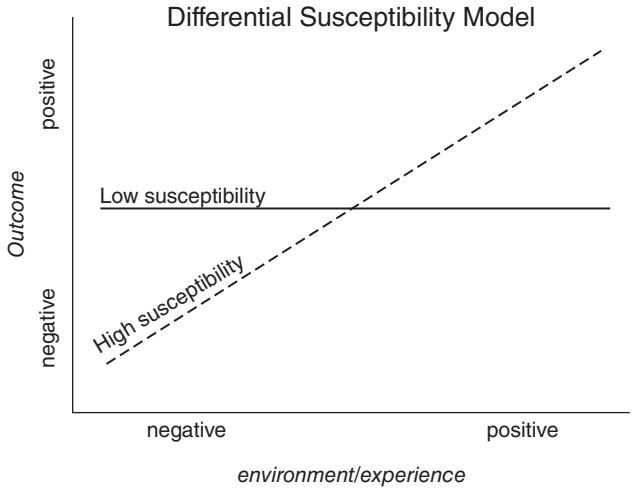

Figure 2.2 Graphical illustration of differential susceptibility. High susceptibility is characterized by increased responsivity to both negative and positive experiences, as a function of individual characteristics, in contrast to low susceptibility, which reflects a general psychological inertia to environmental influences independent of quality. *Source:* Adapted from M. J. Bakermans-Kranenburg & M. H. van IJzendoorn, Gene–environment interaction of the dopamine D4 receptor (DRD4) and observed maternal insensitivity predicting externalizing behavior in preschoolers. *Developmental Psychobiology, 48*(5), 2006, Figure 1.

are individual differences in sensitivity and responsiveness to environmental influence but, importantly, not in the manner of diathesis–stress. Both theories incorporate the traditional diathesis–stress view while extending it, by making the critical observation that those individuals most likely to be adversely affected (according to conventional mental health standards) by negative environmental conditions are also most likely to benefit from supportive ones.

Focusing on the role of the person in moderating environmental effects on development, DS and BSC theories follow in the tradition of Bronfenbrenner's (1993) person–process–context model, which posits that parenting and other environmental factors may vary in their developmental influence as a function of the characteristics of the child. The theories also converge with Wachs and Gandour's (1983) organismic-specificity hypothesis, which posits differential reactivity of children to similar rearing experiences as a function of differences in children's cognitive, behavioral, or emotional characteristics.

Before proceeding with a review and comparison of DS and BSC theories, it is important to note that these perspectives share much in common with Aron and Aron's (1997; Aron, Aron, & Davies, 2005) theory of sensory-processing sensitivity (SPS). The main difference is that DS and BSC began with a focus on child-developmental processes, whereas SPS started with a focus on cognitive processes in adults (in terms of variation in depth of processing of sensory information, with more sensitive individuals processing information more thoroughly before acting). Although some SPS studies have included retrospective assessments of childhood experiences, SPS did not originate from a developmental perspective. Given that longitudinal work on the role of SPS in regulating child (or adult) development has yet to be conducted, we consider it premature to endeavor to integrating SPS theory with BSC and DS at this time.

Differential Susceptibility Theory

The question of why childhood experiences should influence later development—one rarely posed by developmentalists concerned principally with how experience influences development—was the origin of DS theory, along with challenges posed by behavior-genetic critiques by Rowe (2000) of Belsky et al.'s (1991) evolutionary theory of socialization (Belsky, 2000). From an evolutionary perspective, developmental mechanisms that use earlier experiences to guide later development should only evolve in recurring contexts in which the future is tolerably related to the past (Pigliucci, 2001), at least within generations. Only then could there be reliable fitness payoffs in using experiences in childhood to regulate adolescent and adult development (i.e., conditional adaptation). The fact that the future is inherently uncertain, however, meant that conditional adaptation was theoretically problematic (i.e., risk for potential mismatch). This realization led Belsky (1997a, 1997b, 2000, 2005) to propose that, as a form of bet-hedging against an uncertain future, natural selection has maintained genes for both conditional and alternative developmental strategies. Whereas conditional strategies are shaped by environmental factors to better fit the organism to the future environment, alternative strategies, in a manner consistent with much behavior-genetic thinking, are largely fixed and less subject to environmental regulation (Rowe, Vazsonyi, & Figueredo, 1997).

Because the future is and always has been uncertain, no parent could ever know for certain what rearing strategies, whether consciously or unconsciously implemented, would prove most successful in terms of promoting the child's reproductive fitness and thus the parent's inclusive fitness. This suggested to Belsky (1997a, 1997b, 2000, 2005) that—especially within families—children should vary in their susceptibility to the rearing environment, broadly construed. Indeed, while it would make sense for parents to produce some children who pursued *alternative* strategies, perhaps entirely impervious to socialization efforts, and who would thrive in particular contexts that fit their proclivities, it would also make sense for them to bear some *conditional* strategists capable of fitting and thriving in a variety of niches depending upon the rearing conditions encountered while growing up.

Belsky (2005) subsequently observed not only that parents would be (unconsciously) hedging their bets by diversifying their progeny's susceptibility to rearing influence but also that the same would be true of children themselves. This was due to the fact that, just like parents and children, siblings share 50% of the same genetic alleles. Thus, if one child benefited from parental influence, so would the other, less susceptible sibling—but indirectly, via shared genes. By the same token, if one child's development was undermined, inadvertently, by parental influence, the less susceptible child would be protected, thereby providing an indirect, inclusive-fitness benefit to the child whose susceptibility proved counterproductive in individual terms. From the perspective of both parent and child, then, differential susceptibility to rearing and perhaps other environmental factors and processes was considered to be evolutionarily advantageous.

Although Belsky's theorizing stipulated that children should vary in their susceptibility to environmental

influence, it did not specify what might distinguish those children who were more susceptible from those who were less. Indeed, the theory lacked any explanatory mechanism, something we will see distinguished it substantially from BSC theorizing which was stimulated by mechanistic thinking. Early attempts to identify potential susceptibility factors or markers called attention, somewhat surprisingly, to negative emotionality or difficult temperament early in life (Belsky, 1997a, 2005; Belsky, Hsieh, & Crnic, 1998), whereas gene × environment interaction work, as well as theory and research on physiological reactivity by Boyce and Ellis (Boyce et al., 1995, 2005), called attention to physiological and genetic markers of variation in susceptibility (e.g., Bakermans-Kranenburg & van IJzendoorn, 2007; Belsky & Pluess, 2009a).

The differential susceptibility hypothesis, while not directly influenced by Plomin and Daniel's (1987) important insights about nonshared environmental effects, was eminently consistent with it. Indeed, in some respects the differential susceptibility perspective offered an explanation as to why nonshared, within-family effects should be the rule, as they have proven to be in behavior-genetic research, rather than the exception, with shared environmental effects proving so modest (Plomin & Daniels, 1987; Reiss, Neiderhiser, Hetherington, & Plomin, 2000; Turkheimer & Waldron, 2000). Because children within families vary in their susceptibility to rearing influences, they should be differentially affected by exposure to the very same developmental experience. Differential susceptibility thinking could also account for why environmental effects have proven both variable and generally modest across studies—perhaps because samples have varied, inadvertently, in the proportion of more and less susceptible individuals which they include, and because such individuals have not been distinguished in estimations of average rearing effects (Belsky, Hsieh & Crnic, 1998).

Biological Sensitivity to Context Theory

Whereas DS thinking emerged initially as a totally theoretical account of human development, not stimulated by any empirical findings, just the reverse proved true of BSC thinking. Indeed, the concept of BSC has its early roots in Boyce and colleagues' (1995) two studies of naturally occurring environmental adversities and stress reactivity as predictors of respiratory illnesses in 3–5-year-old children. Results revealed, first, that children showing low cardiovascular or immune reactivity to stressors had approximately equal rates of respiratory illnesses in both low and high adversity settings. Second, and consistent with the prevailing diathesis–stress model, highly biologically reactive children exposed to high adversity child care settings or home environments had substantially higher illness incidences than all other groups of children. The third—and unexpected—finding was that highly reactive children living in lower adversity conditions (i.e., more supportive child care or family settings) had the *lowest* illness rates, significantly lower than even low reactivity children in comparable settings. Such unanticipated results—in need of an explanation—led Boyce et al. (1995, p. 419) to suggest that "reactive children . . . with a heightened sensitivity to . . . the environment might . . . be expected to experience unusually poor outcomes in high-stress, unsupportive social conditions. The same children might flourish, on the other hand, under low-stress, nurturing, and predictable conditions. . . ." Such a conclusion would subsequently lead to the differential susceptibility view that some children are more responsive to the environment for better and for worse (Belsky, Bakermans-Kranenburg, et al., 2007).

Of critical and distinguishing importance is that the initial Boyce et al. (1995) research, together with subsequent work (Boyce & Ellis, 2005), identified a *physiological mechanism* of environmental susceptibility—autonomic, adrenocortical, or immune reactivity to psychosocial stressors—and proposed that psychobiologic reactivity moderated the effects of early environmental exposures on physical and mental health outcomes in a bivalent manner. More reactive children displayed heightened sensitivity to both positive and negative environmental influences and thus were given the shorthand designation of orchid children, signifying their special susceptibility to both highly stressful and highly nurturing environments. Children low in reactivity were designated as dandelion children, reflecting their relative ability to function adequately in species-typical circumstances of all varieties (Boyce & Ellis, 2005).

Mechanistic analysis of BSC led Boyce and Ellis (2005) to highlight the significance of the stress response system, but not just as a long-appreciated means of regulating behavior in the face of adversity, but also in response to resources and support in the ambient environment (e.g., positive social opportunities, cooperative information). This dual function signified the need to re-conceptualize stress reactivity more broadly as biological sensitivity to context, which Boyce and Ellis (2005) defined as neurobiological susceptibility to both cost-inflicting and benefit-conferring features of the environment and operationalized as a physiological property indexed by heightened reactivity in one or more of the stress response systems. Depending on levels of nurturance and support versus harshness and unpredictability in their

developmental environments, highly reactive children experience either the best or the worst of psychiatric and biomedical outcomes within the populations from which they are drawn (Boyce, 1996; Boyce et al., 1995, 2006; Bubier, Drabick, & Breiner, 2009; Ellis, Shirtcliff, Boyce, Deardorff, & Essex, 2011; Essex, Armstrong, Burk, Goldsmith, & Boyce, 2011; Obradovic, Bush, & Boyce, 2011; Obradovic, Bush, Stamperdahl, Adler, & Boyce, 2010; Quas, Bauer, & Boyce, 2004). BSC theory therefore posits that individual differences in the magnitude of biological stress responses function to regulate openness or susceptibility to environmental influences, ranging from harmful to protective.

Given past evidence that early trauma can increase stress reactivity and newer evidence that high reactivity can enhance developmental functioning in highly supportive settings, Boyce and Ellis (2005) postulated a curvilinear, U-shaped relation between levels of early support-adversity and the magnitude of biological response dispositions. Specifically, Boyce and Ellis hypothesized that: (1) exposure to acutely stressful childhood environments up-regulates BSC, increasing the capacity and tendency of individuals to detect and respond to environmental dangers and threats; (2) exposure to especially supportive childhood environments also up-regulates BSC, increasing susceptibility to social resources and support; and (3) by contrast, and typical of the majority of children, exposure to childhood environments that are not extreme in either direction down-regulates BSC, buffering individuals against the chronic stressors encountered in a world that is neither highly threatening nor consistently safe.

Toward an Integrated Differential Susceptibility Paradigm

Even though DS and BSC theories emerged independently and differ in important respects, they share much in common (Ellis, Boyce, et al., 2011). First, both theories, based as they are on an evolutionary analysis of human development, advance the claim that individuals differ systematically in their susceptibility to environmental influences (i.e., developmental plasticity) and seek to explain the nature of such individual differences. As will become apparent in the next major section of this chapter, this begins with the recognition that susceptibility to the environment is instantiated in the multiple genetic polymorphisms, physiological mechanisms, and behavioral phenotypes that operate as susceptibility factors, moderating the influence of environmental exposures on developmental and life outcomes. Several of the physiological mechanisms may be considered endophenotypes (Gottesman & Gould, 2003) constituting links between genes and behavior, whereby (single or multiple) genetic markers of differential susceptibility operate through the same neurobiological processes in which behavioral indicators of differential susceptibility are grounded.

Second, both DS and BSC theories presume that individuals *should* differ in their neurobiological susceptibility to environmental influence, and that such differential susceptibility underlies many reliable person–environment interactions regulating human development and functioning. Indeed, both theories embrace, implicitly if not explicitly, Bronfenbrenner's (1979) dictum that when it comes to human development, *the main effects are in the interactions*, be those gene–environment, temperament–parenting, stress reactivity–family stress, or other person–environment processes. More specifically, central to both DS and BSC theories is the assumption that environmental influences on developmental and life outcomes are moderated by neurobiological susceptibility to the environment. Both theories thus conceptualize variation in neurobiological susceptibility as a central mechanism in the regulation of alternative patterns of human development.

Third, neither theory presumes that differential susceptibility is restricted to any one developmental period or even just to childhood; both appreciate that at all developmental stages during the life span, individuals may differ in the extent to which they are affected by both supportive and challenging environments. Along these lines, research documenting differential susceptibility in children, adolescents, and adults is considered later in this chapter. Nonetheless, both DS and BSC theories were originally developed to explain neurobiological susceptibility in childhood, as clearly reflected in the preceding summaries of these perspectives.

Finally, a core assertion of both DS and BSC theories is that individuals differ in neurobiological susceptibility to environmental contexts that are both positive in character (i.e., afford resources and support that potentially enhance fitness) and negative in character (i.e., embody stressors and adversities that potentially undermine fitness). In other words, and in contrast to widely embraced diathesis–stress models, it is not simply that some individuals are more susceptible to the negative effects of adversity, making them vulnerable. Rather, DS and BSC theories regard those disproportionately vulnerable to adversity as also disproportionately likely to benefit from supportive and enriching environments. Such individuals are thus affected by the environment in a manner that can be characterized as for better and for worse (Belsky, Bakermans-Kranenburg, et al., 2007). Another way of

describing or even conceptualizing the individual differences in question is in terms of reaction norms (Manuck, 2010). Whereas some individuals have a wide range of reaction in terms of their developmental functioning, depending on the environments they encounter, others have a much narrower range of reaction, responding less markedly—if at all—to positive and negative life experiences.

It is critical to appreciate that differential susceptibility to positive and negative environments has different implications when viewed from developmental-psychopathology and evolutionary perspectives (Ellis, Boyce, et al., 2011). In the developmental-psychopathology framework, heightened neurobiological susceptibility increases the ability and tendency of individuals to experience good outcomes in positive environments (i.e., for better, as defined by dominant Western values like secure attachment, happiness, high self-esteem, emotion regulation, educational and professional success, stable marriage) and bad outcomes in negative environments (i.e., for worse, as defined by that same value system such as insecure attachment, substance abuse, conduct problems, depression, school failure, teenage pregnancy). By contrast, according to the evolutionary perspectives central to both DS and BSC theories, heightened neurobiological susceptibility to the environment functions to direct or regulate development in ways that, over human evolution, recurrently matched individuals to both positive and negative environments, thereby promoting reproductive fitness. In positive environments, this translates into adjusting development to optimize reproductively relevant processes and behaviors such as growth, status, fertility, and offspring quality. This form of conditional adaptation would typically be considered for better in a developmental psychopathology framework. In negative environments, however, this translates into making the best of a bad situation, often resulting in developmental outcomes that are typically regarded as nonoptimal in Western culture. A key difference, then, between the evolutionary and developmental-psychopathology perspectives is that evolutionary models conceptualize conditional adaptation to negative environments as a functional and strategic output of evolved developmental systems shaped by natural selection in the service of fitness goals. Consequently, even though susceptible individuals in negative environments may be especially vulnerable to poor mental health (as defined by dominant Western values), for example, they may still be acting in ways that promote—or once promoted—status and reproductive success in dangerous environments (e.g., gang membership in bad neighborhoods (see Palmer & Tilley, 1995), advantage taking, sexual promiscuity, limited parental investment).

Beyond these points of agreement, it is worth highlighting that both DS and BSC theories derive from evolutionary analyses of human development which, even if not identical, are grounded in the view that natural selection maintains alternative patterns of development (phenotypic variation) in the context of multiniche environments (e.g., Hinde & Stevenson-Hinde, 1990; Penke, Denissen, & Miller, 2007). Both theories posit that variation in neurobiological susceptibility to the environment has been adaptively structured and functions as a central mechanism in regulating alternative developmental pathways to match—as best possible—different environmental niches (Ellis, Boyce, et al., 2011). Fundamental to this view is the assumption that optimal developmental strategies vary as a function of the physical, economic, and social parameters of an individual's specific environment. Levels of neurobiological susceptibility that promote success in some environments may therefore lead to failure in others. It is this kind of environmental heterogeneity—multiniche environments in which a trait's effect on fitness varies across time or space—that provides the ecological basis for the maintenance of adaptive phenotypic variation (whether through balancing selection, conditional adaptation, bet hedging, or a combination thereof; see Ellis, Jackson, & Boyce, 2006; Ellis, Shirtcliff, Boyce, & Essex, 2009; Penke et al., 2007).

In sum, the DS and BSC models largely converge on an integrated theory of neurobiological susceptibility to the environment. Taken together, these perspectives shed new light on the potency—and impotency—of a broad range of environmental contexts, from highly positive and enriching to dangerous and corrosive, to shape the gamut of developmental outcomes.

Having delineated the theoretical framework of differential susceptibility while contrasting it to that of diathesis–stress, attention now turns to empirical evidence, seemingly consistent with differential susceptibility. Before reviewing relevant research, however, some methodological comments are regarding the empirical evaluation of differential susceptibility.

METHODOLOGICAL CONSIDERATIONS IN EVALUATING DIFFERENTIAL SUSCEPTIBILITY

Three distinct methodological issues relating to differential susceptibility are of concern here: measurement of the environment; cultural and racial variation; statistical evaluation.

The Importance of Securing Adequate Environmental Variance

Because the essence of the differential susceptibility model is that individuals who display high neurobiological susceptibility to the environment are not only disproportionately affected by negative contexts but also respond more favorably to positive environmental influences (Figure 2.2), it is imperative that tests of this hypothesis secure adequate variance in environmental conditions (Belsky, Bakermans-Kranenburg, et al., 2007; Ellis et al., 2005). This is because targeting risky environments may obscure the potential benefits of exposure to positive contexts for susceptible individuals, while a narrow focus on only positive environments or outcomes (though less often seen in practice) may have the opposite effect. Thus, a broad range of environmental qualities is a minimum condition to reveal differential susceptibility—a condition that is often not met in studies of developmental psychopathology and much of the research to be cited below.

The importance of careful measurement of the environment (and the outcome) cannot be overestimated (Ellis, Boyce, et al., 2011). Some two decades ago Wachs and Plomin (1991) identified what they called Plomin's paradox: if interaction effects—which are central to the evaluation of differential susceptibility—are ubiquitous in nature, why are they so difficult to detect in behavioral studies (see, McClelland & Judd, 1993)? One of the explanations could have to do with unstable or unreliable measures of the environment. When the error components of the genetic and environmental parts of the GxE equation strongly diverge, testing for moderation is at risk for both type 1 and type 2 errors. Therefore, in studies on differential susceptibility, more than usual care should be taken to assess the environment (and behavioral outcome) reliably and validly by extended behavioral observations in various situations, the use of multiple informants, and aggregation of data across settings and measures. Many of these conditions are not met in the research to be reviewed.

Tests of differential susceptibility involve variation in organismic characteristics, environmental factors, and developmental outcomes (Figure 2.2). These variance components may be highly interdependent and context-dependent. Indeed, child effects and by extension person–environment-interaction effects are highly dependent on variance in the environment (Ellis, Boyce, et al., 2011). Quite importantly, person–environment interactions are much more likely to emerge in the range of average expectable environments than at environmental extremes (Cicchetti & Valentino, 2006; Hartmann, 1958), where the power of context to shape human development may restrict the range of phenotypic variation. In twin studies, for example, physical growth (e.g., height) and IQ have been shown to be highly heritable, but the majority of children growing up in institutions show delays in growth and diminished IQ that become exponentially greater with longer institutionalization (e.g., Rutter & English Romanian Adoptees, 1998; van IJzendoorn, Luijk, & Juffer, 2008). Drastically improved care through adoption, foster care, or interventions within institutions results in massive catch up for virtually all children (Marian J. Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2008; Nelson et al., 2007), leaving little room for interaction effects between environment and child characteristics.

Ecological, Cultural, and Racial-Ethnic Dimensions of Differential Susceptibility

Further, cross-cultural research raises the issue of the cultural specificity of the environment, the susceptibility/plasticity factor, and the developmental outcome that together constitute the differential susceptibility equation (Ellis, Boyce, et al., 2011). Cross-cultural studies of differential susceptibility have documented that the meaning and context of specific parental behaviors, as well as the value placed on specific developmental outcomes, may vary between different cultural groups and across different ecological niches (Deater-Deckard, Pinkerton, & Scarr, 1996; Hinde & Stevenson-Hinde, 1990; Scheper-Hughes, 1992). Moreover, and with regard to race/ethnicity, it is not just familial factors and developmental outcomes that may be different, but neurobiological susceptibility as well. Attempting to replicate and extend Caspi and associates' (2002) GxE findings (on child maltreatment, the MAOA genotype, and antisocial behavior), Widom and Brzustowicz (2006) replicated the original GxE result and detected evidence of differential susceptibility (Belsky & Pluess, 2009a). However, they also discovered that the GxE finding only applied to Caucasians, not to African Americans. (For examples pertaining to dopamine-related genes, see Bakermans-Kranenburg & van IJzendoorn, 2011).

The explanation for this racial difference may be that the genetic effects in question are dependent on race: Short alleles of 5-HTTLPR are associated with the production of *higher* levels of serotonergic function in the central nervous system of African American participants but *lower* levels of serotonergic function among European American participants (Williams et al., 2003). Moreover, the distributions of genotypes differs substantially among the various parts of the world, showing for instance lower prevalence of

the DRD4–7-repeat allele on the African continent and more carriers of the 5HTT short allele in Asia compared with Europe and North America (Chen, Burton, Greenberger, & Dmitrieva, 1999; Gelernter, Cubells, Kidd, Pakstis, & Kidd, 1999). Ethnically homogeneous samples are thus preferred in GxE investigations but not restricted to Caucasian samples in Western countries. The generalizability of GxE interaction effects reflecting differential susceptibility to populations of different cultures and races is not self-evident but should each time be empirically established.

Statistical Criteria for Evaluating Differential Susceptibility

The statistical test of differential susceptibility first proposed by Belsky et al. (2007) consists of a series of five consecutive steps. In short, the first always concerns the application of conventional statistical criteria for evaluating moderation (Dearing & Hamilton, 2006). The second step refers to various shapes moderator effects can take, not all of which are indicative of differential susceptibility (see Belsky, Bakermans-Kranenburg, et al., 2007, for a figure delineating various interaction effects). Interactions with regression lines that do not cross (sometimes referred to as removable interactions) do not document differential susceptibility, although they are not necessarily incompatible with aspects of differential susceptibility (depending on the range of environments covered). Differential susceptibility is more conclusively shown when the moderation reflects a crossover interaction that covers both the positive and the negative aspects of the environment. The slope for individuals high in neurobiological susceptibility should be significantly different from zero and at the same time significantly steeper than the slope for the individuals low in neurobiological susceptibility. If both slopes are significantly different from zero but in opposite directions (i.e., look like an X), contrastive effects rather than differential susceptibility effects are indicated.

The next step requires that there be no association between the moderator (i.e., the susceptibility factor) and the environment (see Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). In other words, differential susceptibility should be distinguished from GxE or temperament–environment correlations (which may reflect rearing experiences evoked by child characteristics) and from dual-risk models (Figure 2.1). Belsky et al. (1998), for example, tested the independence of negative emotionality and parenting as a critical step in their investigation of differential susceptibility. Had these factors been correlated, then the evidence would not have shown that the predictive power of parenting was greater for highly negative infants. Instead, it would have indicated either that highly negative infants evoke negative parenting or that negative parenting fosters infant negativity. Similarly, Caspi and Moffitt (2006) determined that boys' MAOA genotype did not elicit maltreatment. Correlations between the environment and the moderator may be dealt with by partialling out the variance in the moderator explained by the environmental factor prior to testing for differential susceptibility as described already. Pluess and Belsky (2010) used this approach to overcome the problem in their investigation of differential susceptibility to parenting. A further step concerns the association between moderator (i.e., susceptibility factor) and outcome, which has to be zero to reflect differential susceptibility. If the susceptibility factor and the outcome are related, dual risk (or gain, when positive factors are involved) may be a more plausible model. Along these lines, if an intervention proves successful in counter acting the negative effects of a risk gene (or other risk factor) that is correlated with the outcome (e.g., 5-HTTLPR and youth risk behavior initiation, as in Brody, Beach, Philibert, Chen, & Murry, 2009), the experiment tests a protective factor model more than a differential susceptibility model in which the polymorphism should be a risk as well as a susceptibility gene. As a final step, Belsky et al. (2007) suggested testing the specificity of the effect by replacing the susceptibility factor (i.e., moderator) and outcomes (see Caspi, Harrington, et al., 2003, for an example of such replacement establishing discriminant validity in the GxE tradition).

Because we are still in the early stages of testing differential susceptibility, not all of the empirical work to be considered below actually meets all the statistical criteria just enumerated. Moreover, as we will highlight in the last major section of the chapter on unknowns in the differential susceptibility equation, new statistical approaches have been proposed recently which afford competitive evaluation of differential susceptibility and other models of environmental action, including diathesis–stress. Now, however, attention turns to research chronicling differential susceptibility, organized in terms of first psychological, then physiological and finally genetic susceptibility factors.

BEHAVIORAL MARKERS OF DIFFERENTIAL SUSCEPTIBILITY

The first evidence of differential susceptibility to be considered comes from research showing that temperamental and

emotional characteristics of (mostly very young) children moderate the effect of developmental experience on behavioral development. Some of this work highlights the role of early negative emotionality/difficult temperament vis-à-vis parenting effects, some of it the moderated influence of child-care experience, and some of it individual differences in plasticity beyond the early childhood years. Each set of evidence is considered in turn. Of note is that unless otherwise indicated the work to be cited was conducted without regard to the differential susceptibility hypothesis and, if anything, informed by diathesis–stress thinking. It is highlighted, nevertheless, due to evidence generated of differential susceptibility, whether appreciated by the investigators or not.

Negative Emotionality and Difficult Temperament as Plasticity Markers

Some of the earliest and most suggestive evidence of differential susceptibility to environmental influences emerged in research on temperament–parenting interaction, a long-standing focus of inquiry, typically conducted from a dual-risk/diathesis–stress perspective (Rothbart & Bates, 2006). In fact, after advancing the differential susceptibility hypothesis that, it will be recalled, included no claims regarding proximate factors or mechanisms that would make some children more susceptible than others, Belsky sought to identify some in existing and continually emerging developmental research. Indeed, well before any GxE research on humans was reported, he called attention to infant and toddler negative emotionality and difficult temperament as potential differential susceptibility factors (for review, see Belsky, 2005). Whether operationalized in terms of difficult temperament, irritability, fearfulness, or inhibition, cross sectional and longitudinal studies by Kochanska (1993); Belsky, Hsieh, and Crnic (1998); and Feldman, Greenbaum, and Yirmiya (1999) showed, for example, that diverse measures of rearing of infants and toddlers (e.g., discipline, interactional synchrony, positive and negative parenting) accounted for substantially more variance in self-control, externalizing problems and inhibition in the case of more negatively emotional infants/toddlers than other children. (All but the Kochanska, 1993, study were explicitly designed to test differential susceptibility.) But it was not just in research on very young children that such shorter and longer term rearing effects emerged. Morris and associates (2002) found, for example, that harsh and hostile mothering also proved to be a stronger predictor of teacher-reported externalizing problems in first and second grade when children scored high rather than low on irritable distress.

Most of the research on children reviewed by Belsky (2005) showed, following documentation of significant temperament–parenting interactions, that *greater variance* in a variety of developmental outcomes could be explained by rearing experiences in the case of more negatively emotional children, statistical analyses in the studies reviewed often did not afford determination of whether this result was itself a function of a for-better-and-for-worse parenting effect. In consequence, it remained undetermined whether individual differences in plasticity—or just vulnerability—were responsible for the repeatedly detected finding that more variance was explained in one group's functioning than in another's by the environmental factor investigated.

Fortunately, a growing number of studies provide substantial empirical evidence that rearing and other environmental effects do not just account for more variance in the functioning of more negatively emotional children—or even that such individuals are simply more vulnerable to negative experiences as the dual-risk/diathesis–stress model would suggest—but that they are indeed differentially susceptible to environmental experiences in a for-better-and-for-worse manner. Van Aken, Junger, Verhoeven and Dekovic (2007) found, for example, that 16–19-month-old boys (N = 115) with difficult temperament showed the smallest increase six months later in externalizing problems scores when reared by highly sensitive mothers who only infrequently used negative control, but the largest increase when highly insensitive mothers relied heavily on negative control. These striking parenting effects simply did not obtain in the case of other children.

In a series of investigations Kochanska, Aksan, and Joy (2007) evaluated whether child temperament moderated parenting effects on positive developmental outcomes. In one study children's fearfulness, maternal power assertion, and mother–child positive relations were assessed behaviorally when children were 22 and 33 months old and children's moral self was measured using a puppet interview at 56 months ($N = 74$). Although no parenting effects emerged in the case of children who, as toddlers, scored low in fear, those who were highly fearful evinced a greater moral sense if their mothers (at 22 months only) relied little on power assertion to regulate their behavior, but a limited one if their mothers relied heavily on power to control earlier child behavior. The fact that child fearfulness was itself significantly and negatively related to maternal power assertion raises some questions about how much confidence to place in this study when it comes

to inferring individual differences in plasticity. Recall that in circumstances such as these in which the putative susceptibility factor is itself related to the environmental factor, thereby raising the prospect of evocative person effects, a better approach would be to partial the effect of the susceptibility factor from the environmental one before testing interactions between the two. This would statistically eliminate the potential evocative effect that confounds interpretation of differential susceptibility.

In a second study ($N = 100$ families), this time focused on father's reliance on power assertion (15 months), children's fearfulness (7 and 15 months) and their rule compatible conduct (38 months), Kochanska et al. (2007) once again documented evidence of for-better-and-for-worse parenting effects: Whereas high versus low power assertiveness made no apparent difference for children scoring low in fearfulness (at 7 and 15 months), children who had been highly fearful infants proved less obedient than all others when fathers' power assertion was high, yet more obedient than all others when fathers' power assertion was low. And this time child fearfulness was not associated with paternal power assertion or rule-compatible conduct, hence fulfilling important criteria for inferring differential susceptibility.

Drawing on data of the large-scale longitudinal National Institute of Child Health and Human Development (NICHD) study of Early Child Care and Youth Development (NICHD Early Child Care Research Network, 2005) and focusing on maternally reported difficult temperament at one and six months (composited), Bradley and Corwyn (2008) specifically tested and discerned (repeated) evidence of differential susceptibility. More specifically, these investigators evaluated effects of three measures of parenting quality (sensitivity, harshness, productive activity), each composited and averaged across multiple measurement occasions from infancy through first grade, on teacher-reported behavior problems in first grade ($N = 929$). Results showed that children with more difficult temperaments had more behavior problems in first grade than all other children if they experienced low-quality parenting, but fewer problems than all other children if they experienced high-quality parenting; the anticipated effect of parenting quality was weaker in the case for children with intermediate levels of difficult temperament and weaker still in the case of children scoring very low on difficult temperament (i.e., easy temperament). Such findings suggest that rather than conceptualizing some children, categorically, as malleable and others as not, it might be more appropriate to conceptualize and measure individual differences in plasticity dimensionally, in terms of a plasticity gradient (Belsky, 2000; see also Warren & Simmens, 2005, for similar results using the same data).

Stright, Gallagher, and Kelley (2008) were able to extend work explicitly testing differential susceptibility to positive developmental outcomes by also drawing on data from the NICHD study of Early Child Care (NICHD Early Child Care Research Network, 2005). Once again a temperament–parenting interaction emerged, this time between difficult temperament (at 6 months) and parenting style (composited across 6, 15, 24, 36, and 54 months) in predicting teacher-rated academic competence, social skills, teacher–child relationships, and peer-status at first grade. Predictive power proved greater for infants with more difficult temperaments than for infants with less difficult temperaments. Although all interactions were of a cross-over nature and in line with a for-better-and-for-worse parenting effect for only some children, not all criteria for differential susceptibility were met; of special significance, as already noted, is that the temperament susceptibility factor itself predicted the parenting predictor (as well as at least one outcome measured).

Pluess and Belsky (2010) overcame this problem in their analysis of differential susceptibility while drawing on the same NICHD study. After finding that parenting quality prior to school entry predicted reading, math, picture vocabulary, social competence and academic work habits in the fifth grade more strongly for children with difficult temperament than for those with easy temperaments—and in a for-better-and-for-for worse manner—they reran their analysis using the method proposed earlier for discounting discerned evocative effects of a putative susceptibility factor (i.e., temperament) on the environmental predictor (i.e., parenting quality). When the composite measure of parenting quality was statistically adjusted to control for the effect of 6-month, mother-reported difficult temperament, differential susceptibility findings remained virtually unchanged.

Since reviewing the just-cited evidence some years ago (Belsky & Pluess, 2009a), even more evidence of this differential susceptibility related, negative emotionality/difficult temperament moderational effect has emerged in the case of children. This has been revealed in research linking maternal empathy (Pitzer, Jennen-Steinmetz, Esser, Schmidt, & Laucht, 2011) and anger (Poehlmann et al., 2012) with externalizing problems, mutual responsiveness observed in the mother–child dyad with effortful control (Kim & Kochanska, 2012), intrusive maternal behavior (Conway & Stifter, 2012), and poverty (Raver, Blair, & Willoughby, 2013) with executive functioning; and sensitive

parenting with social, emotional and cognitive-academic development (Roisman et al., 2012).

Moreover, other new research suggests that "emotion regulation in part explains why negative reactivity can be associated with poor outcomes in supportive contexts and beneficial outcomes in supportive contexts" (Ursache, Blair, Stifter, & Voegtline, 2013, p. 129). More specifically, after discovering that executive functioning at 4 years of age was highest among children who were highly negatively reactive (to fear-evoking stimuli) and high in regulating such reactivity at 15 months of age, but lowest among 4-year-olds who were similarly high in negativity but low in regulation as toddlers, Ursache and associates (2013) tested—and found support for—the proposition that the former children had experience especially positive parenting. Considered together, such data suggest that by promoting emotional regulation, supportive rearing sets the stage for highly negatively reactive children to become especially competent.

Although discussion through this point has focused upon the influential role of parenting, it is important to note that it is not just susceptibility to the effects of parenting that negativity seems to moderate in a for-better-*and*-for-worse manner, as documented in recent work examining the influence of teacher-child conflict on change in symptomology during the primary-school years (Essex et al., 2011). We would be remiss, however, if we failed to call attention to studies showing it was less rather than more negatively emotional or reactive children who proved highly responsive to environmental experiences in a manner consistent with differential susceptibility (Essex et al., 2011, Figure 2, bottom; Schudlich, White, Fleischhauer, & Fitzgerald, 2011) and to other evidence showing that sometimes difficult temperament operates only in a manner consistent with the diathesis–stress rather than differential susceptibility framework (Kochanska & Kim, 2013; Roisman et al., 2012; Yaman, Mesman, van IJzendoorn, & Bakermans-Kranenburg, 2010).

The fact that the research cited reveals that diverse indices of negative emotionality function as plasticity factors (e.g., fear, inhibition, distress, difficult temperament, negative affect) raises several issues that future research should address. First, is there a particular component or feature of negativity that is principally responsible for the moderational effects detected (Buss, 2011)? Or might more progress be made with regard to this issue by embracing the integrated, evolutionary, hawk-dove model of temperament (Korte, Koolhaas, Wingfield, & McEwen, 2005) that Sturge-Apple, Davies, Martin, Cicchetti, and Hentges (2012) recently found to be empirically useful. Whereas hawk-like strategies are characterized by approach, dominant-negative affect (e.g., anger), and activity, dove-like ones involving avoidance, inhibition, and vulnerable affect (e.g., fear) seem more consistent with heightened plasticity according to existing research.

We can also wonder about the extent to which the moderational effect of negative emotionality depends on the origins of this plasticity factor, given evidence that negativity is heritable (e.g., Buss & Plomin, 1984; Rhee et al., 2012), but also shaped by prenatal and postnatal experience (Belsky & Pluess, 2009b; Davis, Glynn, Waffarn, & Sandman, 2011; Glynn & Sandman, 2011; for review, see Pluess & Belsky, 2011)—though sometimes more so in the case of some genotypes than others (Ivorra et al., 2010; Pluess et al., 2011). Thus, what may be particularly important is distinguishing negative emotionality, which reflects an experience-induced failure to self-regulate and a general hypersensitivity to the environment.

Beyond Parenting: Child-Care Quality

All of the rearing data considered through this point pertains to parenting. But as children, especially in the contemporary Western world, are routinely cared for by alternative caregivers in child-care settings, the question arises as to whether quality of child care differentially affects children's development as a function of their phenotype. In perhaps the earliest pertinent study, Volling and Feagans (1995) detected a relevant and thus noteworthy interaction between children's social fear (i.e., negative emotionality?), as rated by mothers, and the observed quality of center-based child care in the prediction of observed nonsocial activity (i.e., solitary play, onlooker behavior) a year later when children were 14–48 months of age ($N = 36$). The highly fearful children manifested both the most and least nonsocial activity, depending on the quality of child care, whereas no such environmental effect emerged in the case of the low-fear children.

Given Volling and Feagan's (1995) small sample size, perhaps more convincing evidence that differential susceptibility characterizes some effects of child care comes from a recent analysis of data from the aforementioned NICHD Study of Early Child which investigated both negative and positive developmental outcomes (Pluess & Belsky, 2009). In this work on samples ranging from 761 to 915 children that explicitly tested differential susceptibility, the observed quality of care (averaged across measurements at 6, 15, 24, 36, and 54 months) differentially predicted behavior problems and social competence rated by caregivers in the year before school entry and by kindergarten teachers. Not

only did children with difficult temperament (6 months) have more behavior problems when reared in low-quality environments and fewer problems when quality was high compared with children with easy temperaments, but also the regression lines (i.e., slopes) proved significant only for the children who scored high on difficult temperament as infants. Similar results emerged when Pluess and Belsky (2010) extended their research to determine if, after imputing missing data and thereby increasing their sample size to 1,364, differential susceptibility to the effects of good and poor quality child care in the first 4.5 years of life extended to teacher-reported behavior problems and teacher–child conflicts when children were 10–11 years of age.

Beyond the Early Years: Middle Childhood

Although the Pluess and Belsky (2009, 2010) work indicates that differential susceptibility effects pertaining to early parenting and child-care experience and involving phenotypic susceptibility factors extend beyond the early childhood years, the question arises as to whether rearing and related experiences *in later childhood* operate in a similar manner. Evidence that they might emerges in research on conflict in families with 7–10-year-olds. Using structural equation modeling with nested-group comparisons, Ramos, Wright Guerin, Gottfried, Bathurst, and Oliver (2005) found that greater conflict predicted more behavior problems ($N = 108$), but principally in the case of children evaluated as having difficult temperaments when 3–5 years of age and not in the case of those scoring low in difficulty. Unfortunately, the manner in which data are presented precludes determination of whether a true for-better-and-for-worse rather than just dual-risk pattern of results was responsible for the findings reported.

Perhaps somewhat more compelling differential susceptibility evidence comes from Lengua's (2008) temperament–parenting interaction study that sought to explain change in internalizing and externalizing problems using a community sample ($N = 188$) of 8–12-year-old boys and girls. Children's reports of their mothers' parenting style (i.e., rejection–acceptance, inconsistent discipline) predicted change over a 1-year period in mother-reported internalizing and externalizing problems, but differentially as a function of temperament. No doubt in line with expectations developed through this point, results revealed that children highly prone to negative emotion in the form of frustration increased in externalizing problems over time when mothers were rejecting, but decreased when mothers manifested little rejection, with no such apparent effects of rejection evident in the case of children scoring low on frustration. It needs to be noted, however, that other findings from this inquiry, even when consistent with the differential susceptibility hypothesis, clearly seem to be at odds with what other cited investigations have found. For example, Lengua (2008) also reported that it was children who scored high on frustration who were *not* affected by inconsistent discipline with respect to the development of internalizing problems and children who scored low on frustration who were. Although another interaction indicated that inconsistent discipline did not affect the development of internalizing problems in low-anxious boys but did so in the case of high-anxious ones, thus being in line with previously cited evidence, other reported results proved inconsistent with expectations. Most notable was the fact that low levels of inconsistent parenting predicted increases in internalizing problems among high-anxious boys, with high levels of such putatively problematic parenting predicting decreases.

Other perhaps surprising middle-childhood findings emerge in Leve, Kim, and Pears (2005) work on behavior-problem trajectories from ages 5–17 years ($N = 373$). After controlling for marital adjustment, parental depression and income (all at age 5), evidence indicated, consistent with expectations, that highly impulsive 5-year-old girls manifest both the most and least externalizing problems across the developmental period under study (parental report) and that this depended on whether they experienced, respectively, high or low levels of harsh punishment at age 5 (parental interview). No such rearing effect emerged in the case of those rated low on impulsivity. At the same time, however, girls rated high on fear/shyness proved less susceptible than those rated low in terms of the influence of harsh punishment on externalizing problems. In summary, even though evidence in line with the differential susceptibility hypothesis emerged in all cases just considered, it should be clear that the substantive nature of differential effects, including who proves most susceptible, are by no means always nor entirely consistent across—or even within—studies.

Given claims by Harris (1998) that when it comes to influences on development, peers are actually more important than parents, recent research in middle childhood chronicling differential susceptibility-like effects takes on special importance. In a noteworthy inquiry focused on peer effects, Mezulis, Hyde, and Abramson (2006) observed that 11-year-olds ($N = 289$) reporting more negative life events involving age mates showed greater cognitive vulnerability to depression when 9 and 11 but somewhat less negative cognitive style when experiencing fewer life events compared with children low in the temperamental trait of withdrawal negativity.

Also of special interest is work that treats physiological traits, rather than just behavioral functioning, as developmental outcomes shaped by developmental experience. Gilissen, Bakermans-Kranenburg, van IJzendoorn, and van der Veer (2008) detected a significant interaction between child fearfulness (parent report) and parent–child relationship quality (observed during interaction or based on a story-completion task administered to children) in the prediction of skin conductance level (SCL) reactivity in response to a fear-inducing film clip. This cross sectional investigation involving 78 4-year-olds and 92 7-year-olds specifically testing differential susceptibility found that more fearful children manifest lower and higher SCL reactivity than all low-fear children, depending on whether their parent–child relationships were, respectively, secure or insecure. Of indisputable interest is that SCL reactivity—a marker for the activity of the sympathetic nervous system—has been found to moderate effects of the environment in a differential susceptibility manner, as will be reported in the next major subsection dealing with physiological susceptibility factors. Important to mention, the just summarized Dutch findings are consistent with the Boyce and Ellis (2005) claim that plasticity may itself be a function of environmental influence (Belsky & Pluess, 2009b).

Beyond Middle Childhood: Adulthood

Intriguingly, there is also suggestive evidence of the legacy or even operation of differential susceptibility in early adulthood. Of importance in this regard are a series of cross sectional studies testing hypothesized interactions between sensory-processing sensitivity, a personality characteristic measureable by means of the Highly Sensitive Person scale (see Aron & Aron, 1997) and various environmental factors in predicting adult shyness and negative affectivity (Aron et al., 2005). According to Aron and Aron (1997), about 20% of the population are characterized by a high-sensitive personality which encompasses a sensitive nervous system, awareness of subtleties in surroundings, and a tendency to be more easily overwhelmed when in a highly stimulating environment. One study of especial relevance showed that a problematic (and retrospectively reported) childrearing history predicted high levels of (self-reported) shyness and negative affectivity in a sample of 213 undergraduate students, whereas its absence predicted low levels of these same dependent constructs; but this relation obtained principally in the case of students scoring high on sensory-processing sensitivity, resulting in significant differences between regression lines (i.e., slopes) for high- and low-sensitivity groups. Also of note is research showing that marital quality proves more strongly related to sensitive mothering—and in a for-better-and-for-worse manner—in the case of mothers who score high on negative affect (Jessee et al., 2010). Considered together, the findings just summarized make it clear that it is not just children who prove differentially susceptible to environmental effects.

Comment

The repeatedly discerned moderational effect of negative emotionality/difficult temperament in the case of parenting, child care quality, and other environmental experiences raises the question of why this should be the case. This would seem especially important to address in view of the fact that even though Belsky (1997a, 2005) theorized that children should vary in their susceptibility to environmental influences (i.e., developmental plasticity) for evolutionary-biological reasons, his differential susceptibility hypothesis did not stipulate that more negatively emotional children or those with difficult temperament would prove especially malleable; this was an empirical observation (Belsky, 2005). One possible reason why those high in negative emotionality, operationalized as it has been in a variety of ways, may prove most susceptible to environmental influence is because a negatively emotional/difficult temperament reflects a highly sensitive nervous system on which experience registers especially strongly, irrespective of whether the experience is positive and growth-promoting or negative and undermining of well-being, broadly conceived (see also Aron & Aron, 1997).

Whatever the mechanisms involved in making more negatively emotional children seemingly more malleable—in an often for-better-and-for-worse manner, consistent with differential susceptibility thinking—it would be mistaken to conclude that this is the most important psychological marker of plasticity. Even though this could turn out to be the case, it may well be an artifact of the disproportionate attention that investigators guided by diathesis–stress/dual-risk perspective pay to individual risk factors that interact with contextual adversity in producing problematic functioning (Belsky & Pluess, 2009b). If this is so, then it certainly behooves the field to consider other potential behavioral markers of plasticity/malleability rather than reify one. Nevertheless, the evidence considered through this point indisputably suggests that differential susceptibility is operative in not just the opening years of life and, most critically, that regarding negatively emotional or difficult infants and children as

at risk and vulnerable may represent a fundamental mischaracterization of their more general highly malleable/plastic nature.

PHYSIOLOGICAL MARKERS OF DIFFERENTIAL SUSCEPTIBILITY

Recall that central to Boyce and Ellis' (2005) biological-sensitivity-to-context theorizing is the claim that children who are highly physiologically reactive to stress manifest the most developmental plasticity. Given that many such children probably begin life as highly negative infants or ones with difficult temperaments, it seems likely that many of the very same children Belsky (1997a, 2005) first called attention to in this regard are being identified by different means. In any event, what Boyce and Ellis (2005) viewpoint highlights is the fact that physiological characteristics, not just the psychological ones considered in the preceding section, might moderate environmental influences, functioning thereby as plasticity markers. In this section evidence consistent with the claim is considered after first providing a brief summary of the two separate physiological systems with specific functions—the autonomous nervous system and the neuroendocrine system.

The so-called fight-or-flight response to stress is primarily controlled by the autonomous nervous system (ANS), which is further divided into the sympathetic (SNS) and the parasympathetic nervous system (PNS). The SNS controls those activities that are mobilizing during stress and anxiety (e.g., acceleration of heart rate, increased blood pressure, enhanced blood flow to the skeletal muscles, decreased blood flow to the internal organs and extremities, sweating). Physiologically opposing activities under PNS control serve the basic functions of rest, repair, and relaxation of the body and restoration of energy stores (e.g., decreases in heart rate and blood pressure, stimulation of the digestive system, sexual arousal, sleep). The neuroendocrine response to stress is primarily controlled by the hypothalamus-pituitary-adrenal axis (HPA). Corticotropin releasing hormone (CRH)—which is released from the hypothalamus in response to stress—activates the secretion of adrenocorticotropic hormone (ACTH) from the pituitary gland, which then causes the adrenal cortex to release cortisol into the general bloodstream. Finally, cortisol leads to a large number of diverse physiological and metabolic changes to prepare the organism for optimal functioning under stressful conditions (e.g., increase of blood pressure and blood sugar, breakdown of lipids and proteins, mobilization of amino acids, reduction of immune responses).

In the earliest pertinent investigation of physiological reactivity of which we are aware that detects differential susceptibility-like effects, Gannon, Banks, Shelton and Luchetta (1989) studied 50 undergraduates on whom a range of SNS markers of physiological reactivity were obtained (before and after a math-problems' stress test; plasticity factor). These students also reported on daily hassles (environmental factor), as well as common physical symptoms and depression. Compared to individuals showing low reactivity of blood volume pulse amplitude, high-reactive students reported both few physical symptoms when experiencing few daily hassles and many when experiencing many hassles. Also consistent with differential susceptibility thinking, those students showing slow heart rate recovery after the stress test reported fewer depressive symptoms when experiencing fewer daily hassles and more symptoms when experiencing more daily hassles compared with individuals with a fast recovery.

Findings in line with those just presented, but evident at much younger ages, emerged in Boyce and associates (1995) aforementioned test of the hypothesis that mean arterial blood pressure reactivity to a stress test at ages 3–5 would interact with a composite measure of child-care quality (measured across a 2-year period) in predicting frequency of respiratory illness during the six months following the physiological-reactivity assessment. Specifically, children with higher blood pressure reactivity exhibited higher rates of respiratory illness than other children when growing up in stressful rearing contexts, yet under low-stress conditions such high-reactive children had a significantly lower incidence of respiratory illnesses than other children.

Reactivity-moderated effects of environmental experiences are also evident when skin conductance level (SCL) reactivity serves as the index of physiological functioning. This is perhaps noteworthy in view of the fact that SCL is controlled solely by the SNS, in contrast to the other cardiovascular-reactivity measures that are generally innervated and controlled by both SNS and PNS. Thus, El-Sheikh, Keller, and Erath (2007b) investigated associations between SCL reactivity (assessed during a star-tracing problem solving task), marital conflict (parent report), and change (from age 9–11.5 years) in adjustment problems (parent report). Compared with girls with low SCL reactivity, highly reactive girls showed the largest increase in internalizing problems if from highly conflicted homes, but the smallest increase when marital conflict was low in their families. A significant cross-over interaction consistent with differential susceptibility also emerged for boys with respect to change in externalizing problems but, rather surprisingly, it was those scoring low in physiological

reactivity who appeared (exclusively) susceptible to the adverse effect of marital conflict.

The same research team has also used vagal tone (indexed by respiratory sinus arrhythmia [RSA]) and vagal suppression (during exposure to an audio recording of a male-female verbal conflict) to investigate whether and how PNS measures moderate effects of marital conflict on child adjustment in middle childhood (El-Sheikh, Harger, & Whitson, 2001). Compared to children with high vagal tone (who were not seemingly affected by marital conflict), those scoring low in vagal tone proved less anxious when growing up in families with little marital conflict, but more anxious when residing in high-conflict homes. Similar cross-over-interaction results emerged with respect to vagal suppression, but for boys only.

In a cross sectional study of more than 300 5-years-olds, Obradovic, Bush, Stamperdahl, Adler, and Boyce (2010) reported yet more data chronicling the role of RSA in moderating environmental effects, along with some pertaining to cortisol reactivity (both assessed during a stress test). In this research, a composite index of childhood adversity (based on parental reports of financial stress, parenting overload, marital conflict, negative/anger expressiveness, maternal depression, and harsh and restrictive parenting) proved predictive of composite well-being measures (based on parent, teacher, and child reports); but this proved true more so in the case of children with a more reactive parasympathetic nervous system (in contrast to El-Sheikh, Erath, & Keller, 2007; El-Sheikh et al., 2001). More specifically, children with high RSA reactivity were rated as more prosocial under low-adversity conditions and less prosocial under high-adversity conditions compared with children with low-RSA reactivity. High RSA reactivity children also scored higher on school engagement under low-adversity conditions and lower under high-adversity conditions compared with children with low-RSA reactivity.

Despite the fact that multiple PNS investigations provide evidence in line with the differential susceptibility hypothesis, seeming to highlight individual differences in plasticity, not just vulnerability, work involving the *neuroendocrine system* appears to provide comparable evidence. In the just summarized work by Obradovic et al. (2010), children with high-cortisol reactivity were rated as more prosocial under low adversity and less prosocial under high adversity relative to children with low-cortisol reactivity. It is difficult to be sure that this apparent imbalance in evidence across the autonomous nervous system and the neuroendocrine system is due to the two stress reactivity systems playing fundamentally different roles vis-à-vis environmental influences; the alternative possibility is that one has just received more empirical attention as a moderator of environmental effects. This would seem likely given that most developmentalists measuring cortisol reactivity in studies of environmental effects treat it as an outcome to be explained rather than as a moderator of environmental influences on development (Fernald, Burke, & Gunnar, 2008; Gunnar & Quevedo, 2007).

Beyond the work just cited and summarized by Belsky and Pluess (2009a), ever more research highlights the potential role of physiological reactivity as a plasticity factor. Consider in this regard recent evidence indicating that more physiologically reactive children are more susceptible, in a for-better-and-for-worse fashion, to the effect of actual marital conflict (Obradovic et al., 2011) and simulated interparental aggression (Davies, Sturge-Apple, & Cicchetti, 2011), on externalizing problems; of family adversity on school achievement (Obradovic et al., 2010); of chronic family aggression on adolescent anti-social behavior and symptoms of posttraumatic stress disorder (Saxbe, Margolin, Shapiro, & Baucom, 2012); of peer victimization on self-reported depressive symptoms (Rudolph, Troop-Gordon, & Granger, 2011); and of teacher–child conflict on change in symptom severity (Essex et al., 2011). Work showing similar moderational effects of physiological reactivity with respect to family influences on female pubertal development by Ellis and associates (2011) is especially noteworthy, given the roots of this work in psychosocial acceleration theory (Belsky et al., 1991) and the way its findings proved consistent with the differential susceptibility-related revision of the theory (Belsky, 2000). After all, Belsky (2000) postulated that some females would be alternative strategists whose pubertal development proved unrelated to their rearing experiences, just as Ellis and associates (2011) found for girls low in physiological reactivity, whereas others would be conditional strategists susceptible to the accelerating and delaying effects of unsupportive and supportive rearing, respectively, just as Ellis et al. (2011) observed in the case of highly reactive girls. Once again, though, we would be remiss if we did not highlight some evidence inconsistent with the BSC thinking, such as that from the aforementioned Obradovic et al. (2011) investigation showing that it was young children with low—rather than high—RSA reactivity who seemed, in some analyses, to benefit from growing up under supportive family conditions characterized by little marital strife.

As it turns out, it may not just be high levels of physiological *reactivity* that demarcates more malleable individuals. In studying the effects of change over time

in parent depressive symptoms on change in children's internalizing problems, Laurent and associates (2013) recently observed plasticity-like processes when evaluating the moderating effect of children's evening cortisol levels. Thus, children with higher evening levels of cortisol increased in internalizing problems over time if fathers' depressive symptoms increased, but decreased if they had declined; no father depression effect of any kind was discernible in the case of children scoring low in evening cortisol. The fact that the study was focused on adoptive parents and their adopted children means, of course, that the physiologically moderated environmental effects discerned in this inquiry could not be the result of genes shared between parent and child.

One of the key questions that still remains to be answered regarding BSC concerns its life span implications. More specifically, do those individuals who are induced to be highly physiologically reactive early in life—and thus developmentally plastic—remain that way over time? It seems hard to imagine that a child induced by supportive rearing to be highly physiologically reactive, in accordance with the theory (Boyce & Ellis, 2005), would remain highly reactive as the years go by. But, of course, this is an empirical question—one that has implications for our understanding of the role physiological reactivity does or does not play as a plasticity factor as the individual develops.

GENETIC MARKERS OF DIFFERENTIAL SUSCEPTIBILITY

Whereas almost all the evidence cited through this point derives from studies of children, gene–environment (GxE) interaction findings consistent with the differential susceptibility hypothesis often derive from research with adults. This is especially true of psychiatric research focused upon pathological outcomes (e.g., depression, antisocial behavior). The fact that most of this work has been guided by traditional diathesis–stress thinking—at least until recently—means that on many occasions evidence that those carrying a putative risk allele actually function better than others when not exposed to the risk condition being studied (e.g., negative life events) frequently goes unnoticed or at least is not discussed in primary reports. Uher and McGuffin (2008) called attention to such differential susceptibility-like findings, even if not in such terms, in their review of GxE research on life events, the serotonin-transporter gene and depression. Here we discuss findings seemingly reflective of differential susceptibility across a diverse array of candidate genes.

Dopamine Receptor D4 Gene (DRD4)

A number of genes are known to play a role in regulating the dopaminergic system, which is engaged in attentional, motivational, and reward mechanisms have figured importantly in GxE research. One of these—which probably has revealed more evidence of genetic plasticity than any other polymorphism—is the dopamine receptor D4 (DRD4) gene. Variants of the DRD4 differ by the number of 48-base pair tandem repeats in exon III, ranging from 2 to 11. The 7-repeat variant has been identified in psychiatric-genetic studies as a vulnerability factor due to its links to ADHD (Faraone, Doyle, Mick, & Biederman, 2001), high novelty seeking behavior (Kluger, Siegfried, & Ebstein, 2002), and low dopamine reception efficiency (Robbins & Everitt, 1999), among other correlates.

A number of observational studies indicate that children carrying this putative risk allele are not only more adversely affected by poorer quality parenting than other children; they also benefit more than others from good-quality rearing. The first two investigations to be considered may be regarded as particularly important because a good environment was not just operationalized as the absence of adversity—as is all too often the case in GxE investigations—but in terms of high-quality parenting. In a longitudinal investigation of 47 infants, maternal sensitivity observed when children were 10 months predicted externalizing problems reported by mother more than two years later, but only for children carrying the 7-repeat DRD4 allele (Bakermans-Kranenburg & van IJzendoorn, 2006). Moreover, although children with the 7-repeat DRD4 allele displayed the most externalizing behavior of all children when mothers were judged insensitive, they also manifested the least externalizing behavior when mothers were highly sensitive (but see, for contradictory results, Propper, Willoughby, Halpern, Carbone, & Cox, 2007).

A cross sectional study of sensation seeking in 45 18–21-month-old children generated results in line with those just summarized. Toddlers carrying the 7-repeat allele were rated by parents as showing, compared with children without the 7-repeat allele, less sensation seeking behavior when parenting quality was high but more when it was low (Sheese, Voelker, Rothbart, & Posner, 2007). Whereas parenting proved significantly associated with sensation seeking in the 7-repeat individuals, it did not in other children.

The same team of Dutch of investigators whose work examining effects of maternal sensitivity on toddler's externalizing problems also found evidence that the DRD4 7-repeat allele moderated the effect of a maternal

psychological condition, unresolved loss or trauma (as measured by means of the Adult Attachment Interview), on a known early developmental marker of psychological disturbance later in life, infant attachment disorganization (Carlson, 1998). But, importantly, this proved true only in the case of infants carrying the 7-repeat allele (van IJzendoorn & Bakermans-Kranenburg, 2006). Such infants manifest both the most and least disorganized attachment behavior when stressed depending on whether their mothers had or had not experienced unresolved loss or trauma in their own lives.

In a study with a focus rather different from all those previously considered, Seeger, Schloss, Schmidt, Ruter-Jungfleisch, and Henn (2004) evaluated whether the *season of the year* in which a child was born interacted with the dopamine DRD4 polymorphism in predicting hyperkinetic conduct disorder (ADHD). Employing a cross sectional design involving 64 children with the disorder and 163 healthy controls (mean age 11–12, +/–3 years), they found that it did—and in ways consistent with what is known about photoperiod exposure during pregnancy. When comparing patients with controls, children with one copy of the DRD4 7-repeat allele born in autumn and winter (i.e., long photoperiod during pregnancy) had a 5.4-fold decreased relative risk for hyperkinetic conduct disorder, whereas children with the same genotype born in spring and summer (i.e., short photoperiod) had a 2.8-fold increased relative risk for hyperkinetic conduct disorder. Neither season of birth nor the presence of DRD4 7-repeat allele increased the risk of hyperkinetic conduct disorder on their own.

Beyond these DRD4-related studies first reviewed by Belsky and Pluess (2009a), even more recent work has emerged indicating the 7R allele functions as a plasticity factor. Consider in this regard work showing heightened—or exclusive—susceptibility of individuals carrying the 7-repeat allele when the environmental predictor and developmental outcome were, respectively, maternal positivity and prosocial behavior (Knafo, Israel, & Ebstein, 2011); early nonfamilial childcare and social competence (Belsky & Pluess, 2013b); contextual stress and support and adolescent negative arousal (Beach et al., 2012); childhood adversity and young adult persistent alcohol dependence (Park, Sher, Todorov, & Heath, 2011); and newborn risk status (i.e., , gestational age, birth weight for gestational age, length of stay in NICU) and observed maternal sensitivity (Fortuna et al., 2011). To be noted, however, is that at least one investigatory team finds that it is those without the 7-repeat allele who prove most responsive to childhood adversities—in a diathesis–stress manner (Das, Cherbuin, Tan, Anstey, & Easteal, 2011). Nevertheless, a recent meta-analysis of GxE research involving dopamine-related genes revealed that children eight and younger respond to positive and negative developmental experiences and environmental exposures in a manner consistent with differential susceptibility (Bakermans-Kranenburg & van IJzendoorn, 2011).

Serotonin Transporter Gene (5-HTT)

The serotonin-transporter-linked polymorphic region (5-HTTLPR) is another genetic polymorphism that has figured importantly in psychiatric-genetic research. The 5-HTTLPR is a degenerate repeat polymorphic region in SLC6A4, the gene that codes for the serotonin transporter. Most research focuses on two variants—those carrying at least one short allele (s/s, s/l) and those homozygous for the long allele (l/l)—though more variants than these have been identified (Nakamura, Ueno, Sano, & Tanabe, 2000). The short allele has generally been associated with reduced expression of the serotonin transporter molecule—which is involved in the reuptake of serotonin from the synaptic cleft—and thus considered to be related to depression, either directly or in the face of adversity.

Caspi and associates (2003a) were the first to show that the 5-HTTLPR moderates effects of stressful life events during early adulthood on depressive symptoms and on probability of suicide ideation/attempts and of major depression episode at age 26 years. Individuals with two s alleles proved most adversely affected whereas effects on l/l genotypes were weaker or entirely absent. Of special significance, however, is that carriers of the s/s allele scored best on the outcomes just mentioned when stressful life events were absent—though just as was true among low-MAOA activity individuals in Caspi et al. (2002)—not by very much.

Multiple research groups have attempted to replicate Caspi et al.'s findings (2003) of increased vulnerability to depression in response to stressful life events for individuals with one or more copies of the s allele, with many succeeding (see below), even if not all (Surtees et al., 2006). Of note is that the data presented in quite a number of these studies indicates that individuals carrying short alleles (s/s, s/l) did not just function most poorly when exposed to many stressors, but best—showing least problems—when encountering few or none. While calling explicit attention to such a pattern of results, Taylor and associates' (2006) reported that young adults homozygous for short alleles (s/s) manifested greater depressive symptomatology than individuals with other allelic variants when exposed to

early adversity (i.e., problematic childrearing history), as well as many recent negative life events, yet the fewest symptoms when they experienced a supportive early environment or recent positive experiences, that is, not just the absence of adversity.

A similar pattern of environmental effects emerged in still other investigations of stressful life events and depression, including one targeting depressed patients, healthy controls and experiences during the six-month prior to study enrollment (Zalsman et al., 2006), and another of a sizeable community sample ($N = 567$) and life events up to two years prior to the assessment of depression (Lazary et al., 2008). The same for-better-and-for-worse pattern of results are evident—and noted—in Brummett et al.'s (2008) investigation of more than 200 adults (mean age 58 years) who differed in whether or not they served as caregiver of a relative with Alzheimer's disease and in Eley et al.'s (2004) research on adolescent girls who were and were not exposed to risky family environments. In fact, secondary analysis of the latter findings revealed that the for-better environmental effect size exceeded the routinely evaluated for-worse size (Belsky et al., 2009). Although all the work just cited, with the exception of Caspi et al. (2003), was cross sectional in design, Wilhelm and associates' (2006) longitudinal data also shows that individuals with the s/s genotype had the lowest probability of lifetime major depression if exposed to no adverse life events in a five-year study period, but the highest probability when reporting two, three, or more adverse life events compared with other genotypes.

The effect of 5-HTTLPR in moderating environmental influences in a manner consistent with differential susceptibility is not restricted to depression and its symptoms. It also emerges, perhaps unsurprisingly, in studies of anxiety and ADHD. Gunthert et al. (2007) documented the former result in longitudinal research on 350 college students. At study entry and a year later, participants reported anxiety and negative events daily for 30 days. Genotyping distinguished three alleles, but the L_G allele was grouped with s alleles due to its functional equivalence vis-à-vis promoter activity. Individuals homozygous for short alleles (including s/L_G and L_G/L_G) reported more anxiety in the evening when daily-event stress was high compared with individuals with different genotypes, but also less anxiety than other genotypes when experiencing little daily-event stress; this pattern of results proved consistent across measurement occasions.

In a second study focused on undergraduate students ($N = 247$) and anxiety (Stein, Schork, & Gelernter, 2008), but this time concerned with (retrospectively reported) emotional abuse in childhood, a GxE interaction once again emerged. The significantly steeper abuse–anxiety slope in the case of students homozygous for short alleles relative to those with one or more long alleles indicated that s/s individuals scored highest in anxiety sensitivity when exposed to abuse and lowest when not exposed.

Moving on to consider ADHD (in childhood and adulthood), Retz and associates (2008) focused on the moderated effects of an adverse childhood environment in their study of 184 male delinquents who averaged 34 years of age. Using a retrospective assessment of childhood ADHD, as well as of early adversity, but a clinical interview to assess functioning in adulthood, these investigators detected a crossover interaction with respect to the persistence of ADHD over time. Compared with l/l genotypes, individuals with s alleles had more and less persistent ADHD, depending on whether or not, respectively, they experienced an adverse early environment.

Yet another differential susceptibility-relevant finding involving 5-HTTLPR comes from Manuck, Flory, Ferrell, and Muldoon (2004) test of a GxE interaction involving socioeconomic status in the prediction of central nervous serotonergic responsivity; the sample included 139 adults ranging in age from 26 to 60. Central serotonergic responsivity was measured indirectly by means of the fenfluramine challenge test. Fenfluramine increases serotonergic neurotransmission by release of serotonin stores and reuptake inhibition. Such stimulation of hypothalamic serotonin receptors promotes as well the pituitary release of the hormone prolactin. This relative release in circulating prolactin concentration provides an index of the serotonergic responsivity in the HPA axis. Consistent with all the findings summarized above pertaining to depression, anxiety and persistent ADHD, s/s individuals manifest the most and least serotonergic responsivity, depending on whether they were, respectively, low or high SES.

In the short time since the aforementioned studies involving 5-HTTLPR were reviewed by Belsky and Pluess (2009a), yet more evidence that short alleles operate as plasticity factors has emerged. Consider in this regard, evidence showing for-better-and-for-worse results in the case of those carrying one or more 5-HTTLPR short alleles when the rearing predictor and child outcome were, respectively, maternal responsiveness and moral internalization (Kochanska, Kim, Barry, & Philibert, 2011), child maltreatment and antisocial behavior (Cicchetti, Rogosch, & Thibodeau, 2012), and supportive parenting and positive affect (Hankin et al., 2011). Differential susceptibility-related findings also emerged (among male African American adolescents) when perceived racial

discrimination was used to predict conduct problems (Brody et al., 2011); when life events were used to predict neuroticism (Pluess, Belsky, Way, & Taylor, 2010) and life satisfaction of young adults (Kuepper et al., 2012); and when retrospectively reported childhood adversity was used to explain aspects of impulsivity among college students (e.g., pervasive influence of feelings, feelings trigger action; Carver, Johnson, Joormann, Kim, & Nam, 2011).

Just to be clear, other 5-HTTLPR-related findings prove more consistent with the diathesis–stress than differential susceptibility framework (e.g., Bakermans-Kranenburg, Dobrova-Krol, & van IJzendoorn, 2012; Brody et al., 2013; Pluess et al., 2011), sometimes even in GxE studies which also provide evidence of differential susceptibility (e.g., Kochanska et al., 2011). Moreover, in apparently rare instances it is—surprisingly—those with long rather than short alleles who prove most susceptible to environmental influences, even when differential susceptibility-related findings emerge (e.g., Cicchetti, Rogosch, & Oshri, 2011; Sulik et al., 2012). Especially noteworthy, therefore, are the results of a recent meta-analysis of GxE findings pertaining to children under 18 years of age showing that short-allele carriers are more susceptible to the effects of both positive and negative developmental experiences and environmental exposures, at least in the case of Caucasians (van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012).

Monoamine Oxidase A Gene (MAOA)

The neurotransmitter-metabolizing enzyme monoamino oxidase A or MAOA gene is located on the X chromosome. It encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine, serotonin, and dopamine, rendering them inactive. Two sets of evidence—one linking the low-activity MAOA allele to antisocial behavior and another linking abuse and neglect in childhood to the same developmental outcome—led Caspi and associates (2002) to hypothesize that inconsistency in findings in both literatures could be a result of the fact that maltreatment effects are moderated by genotype. This is exactly what they discovered in their groundbreaking and widely cited GxE research carried out on a New Zealand birth cohort followed into young adulthood. More specifically, it was principally young men—females were not studied—with one form of the gene (i.e., that associated with low MAOA activity) who proved more violence prone when subject to child maltreatment. For those children with the high-MAOA-activity allele, a substantially smaller effect of child maltreatment emerged.

Although most interpret these findings, not unreasonably, in diathesis–stress terms, few seem to have noticed that those most vulnerable to the adverse effects of maltreatment actually scored lowest in antisocial behavior when not exposed to maltreatment, suggesting perhaps greater plasticity rather than just greater vulnerability to adversity in the case of those with the low-activity MAOA allele. This interpretation would seem substantiated by results of a significant number of efforts to replicate the Caspi et al. (2002) findings. For example, Kim-Cohen et al. (2006) studied 975 boys to determine whether the MAOA polymorphism moderated effects of mother-reported physical abuse in early childhood on later mental health problems. At age 7 years boys with the low-MAOA-activity variant were rated by mothers and teachers as having more mental health problems—and specifically ADHD symptoms—if they had been victims of abuse, but fewer problems if they had not, compared with boys with the high-MAOA-activity genotype. In a longitudinal study of 514 adolescent twin boys aged 8 to 17 years, Foley et al (2004) found that childhood adversity—based on parent and child report—predicted three-month history of conduct disorder (DSM-III) differently for children with the low- and high-activity MAOA allele. Once again, boys with the low-MAOA-activity allele were more likely to be diagnosed with conduct disorder if exposed to higher levels of childhood adversity and less likely if exposed to lower levels of adversity, compared with boys with the high-MAOA-activity allele. Similar results emerged in Nilsson and associates' (2006) cross sectional investigation of 81 adolescent boys when the predictor was psychosocial risk, operationalized in terms of maltreatment experience and living arrangement. Only boys with the low-MAOA-activity allele were affected by such risk, such that those with a history of adversity engaged in more criminal behavior (composite of vandalism, violence, stealing) and those lacking this history engaged in less.

Three additional studies extend the Caspi et al. (2002) findings: One was a prospective investigation of 631 male and female and white and black victims of (court-substantiated) child abuse and neglect, along with a comparison group matched on age, sex, race/ethnicity, and social class background (Widom & Brzustowicz, 2006); the second a retrospective study of 235 adult psychiatric outpatients and healthy controls who reported on trauma experienced in childhood and physical aggression in adulthood (Frazzetto et al., 2007); and the third a cross sectional retrospective study with an American Indian sample of 291 adult women, 50% of whom had a history of childhood sexual abuse (Ducci et al., 2008). White (but not black)

males and females with the low-MAOA-activity allele in the longitudinal study manifest the most violent and antisocial behavior during adolescence and across their lifetimes when measured around 40 years of age, if they had been maltreated. But those with the same alleles engaged in the least such behavior (at both times of measurement) if they had not been victims of abuse. In the second study, men (only) with the low-MAOA-activity variant reported more physical aggression if they experienced one or more (retrospectively reported) objective traumatic events while growing up (e.g., death of mother, severe physical handicap of sibling) and less physical aggression if there was no history of trauma, compared with high-MAOA-activity men (for whom trauma proved unrelated to aggression). In the third study, women homozygous for the low MAOA activity variant had the highest count of antisocial personality disorder symptoms when reporting childhood sexual abuse and the lowest count when having no history of sexual abuse, compared with women homozygous for the high-MAOA-activity genotype.

The fact of the matter is that since the just-cited studies were reviewed by Belsky and Pluess (2009a), no additional GxE evidence has emerged suggesting that MAOA should be regarded as a plasticity rather than vulnerability factor. The same is true for the remaining genes to be considered in this section, raising questions about the confidence that can be placed in genes other than perhaps DRD4 and 5-HTTLPR as plasticity genes. To be appreciated, of course, is that none of these other genes have received the empirical attention in the GxE literature that DRD4 and 5-HTTLPR have, which could account, at least in part, as to why no new differential susceptibility-related findings have emerged for these other genes that Belsky and Pluess (2009a) highlighted in their review of relevant research.

Serotonin Receptor 2A Gene (HTR2A)

Irrespective of these necessary and cautionary comments, evidence consistent with differential susceptibility thinking emerges from GxE studies of another serotonergic system related genetic polymorphism: the single nucleotide polymorphism (SNP) rs6313, located on the serotonin receptor gene (HTR2A), which comes in two forms—the C and the T allele. Whereas some research reveals an association between the C allele and depression (e.g., see Du, Bakish, Lapierre, Ravindran, & Hrdina, 2000), others find the T allele to confer depression risk (Eley et al., 2004). Recent work by Jokela and associates (Jokela, Keltikangas-Jarvinen, et al., 2007a; Jokela, Lehtimaki, & Keltikangas-Jarvinen, 2007b, c)—drawing from data of a longitudinal population-based study in Finland, the Cardiovascular Risk in Young Finns Study, that will be cited frequently in coming paragraphs—suggests that individuals carrying the T allele are generally more affected by environmental factors than others in a for-better-and-for-worse manner. When nurturance reported by mother was averaged across baseline—when 820–1212 study participants were 3–18 years old—and again 3 years later, offspring with at least one T allele scored highest and lowest on self-reported depression some 2 decades after baseline, depending on whether they experienced, respectively, more or less supportive care (Jokela, Keltikangas-Jarvinen, et al., 2007a). Similar results emerged when the predictor was family SES and the outcome to be explained was self-reported harm avoidance; those carrying one or more T alleles scored highest on harm avoidance if they grew up in low-SES households but lowest if they grew up in high-SES ones (Jokela, Lehtimaki, et al., 2007b). This result led the investigators to suggest that this allele might function as an opportunity allele, not just a risk gene.

Yet more support for this differential susceptibility interpretation comes from a third Finnish report focused on whether adults resided in remote rural, rural, suburban, or urban areas. T/T individuals showed the most and least depressive symptoms of all study participants depending on whether they resided, respectively, in remote rural or urban areas (Jokela et al., 2007b). In sum, these Finnish findings are consistent with a differential susceptibility interpretation.

Tryptophan Hydroxylase 1 Gene (TPH1)

As it turns out, the same research group identified similar interaction effects involving yet another SNP on a serotonergic system related gene: rs1800532 located in the tryptophan hydroxylase 1 gene (Jokela, Räikkönen, Lehtimäki, Rontu, & Keltikangas-Järvinen, 2007); this gene codes for a rate-limiting enzyme in the biosynthesis of serotonin. Of the two variants A and C, the A allele has been associated with low serotonin levels (Jönsson et al., 1997) and suicidal behavior/depression, though findings are not consistent (e.g., see Bellivier, Chaste, & Malafosse, 2004; Lalovic & Turecki, 2002).

Jokela, Räikkönen, et al. (2007) detected a moderating effect of TPH1 on the association between social support and depressive symptoms, again using data from the Cardiovascular Risk in Young Finns Study. Depressive symptoms and social support were assessed when participants were between 20 and 35 years old, with the

former measurements taken again four year later. A GxE interaction emerged irrespective of when the depression outcome was assessed. A/A individuals experienced the most and least depression compared with all other individuals, depending on whether they experienced, respectively, low or high social support. This proved to be even more so the case when change in depressive symptoms was the outcome to be explained.

When the Finnish researchers turned their attention to the effect of a hostile childhood environment (based on maternal report) on harm avoidance in adulthood, yet more differential susceptibility like findings emerged involving TPH. Keltikangas-Jarvinen and associates (2007b) found that female participants carrying the A/A genotype reported more adulthood harm avoidance if raised in a hostile environment but less if raised in a non-hostile one relative to those with one or two A alleles. In fact, no apparent effect of childhood environment was detected in the case of women carrying C alleles (or in men).

Dopamine Receptor D2 Gene (DRD2)

Another polymorphism in the dopaminergic system that has been a focus of GXE research is located on the DRD2 gene that encodes the D2 subtype of the dopamine receptor. The Taq1A (A1) SNP (rs1800497)—a C to T substitution located in a noncoding region of the DRD2 locus—is thought to affect dopamine receptor D2 availability in postmortem striatal samples (Thompson et al., 1997). The A1 allele has been associated with low dopamine density and lower mean relative glucose metabolic rate in dopaminergic regions in the human brain (Noble, Gottschalk, Fallon, Ritchie, & Wu, 1997), high novelty seeking (Suhara et al., 2001), and a number of substance use disorders, particularly alcoholism (Bowirrat & Oscar-Berman, 2005).

Some study findings suggest that the DRD2 polymorphism moderates environmental influences in differential susceptibility terms. For example, Mills-Koonce and associates (2007) detected an interaction between DRD2 and sensitive mothering observed when children were 6 and 12 months of age in the prediction of children's psychological well-being. Infants with the A1 allele reared by more and less sensitive mothers had, respectively, fewer and more affective problems at 3 years of age than agemates with other genotypes. Indeed, rearing experience proved unrelated to well-being among these latter children.

A differential susceptibility like effect also emerged in what appears to be the first ever report of GxE in humans, one involving an interaction between the DRD2 gene and family stress in the prediction of visuospatial ability (i.e., line orientation test) and 2 years later, P300 amplitude in ERP research (Berman & Noble, 1997). In this cross sectional study of 10–13-year-old boys, those carrying the A1 allele scored lower than those lacking this allele under high stress conditions, but higher under low stress conditions (even if the differential was more substantial under higher stress conditions).

Focusing as well on a physiological outcome, Propper et al. (2008) found DRD2 to moderate effects of 6-month maternal sensitivity on, 6 months later, respiratory sinus arrhythmia (RSA) reactivity. Children carrying the A1 allele had lower RSA change at 12 months when experiencing low maternal sensitivity and higher RSA change when experiencing high maternal sensitivity compared with children without the A1 allele.

Turning to cognitive outcomes, Keltikangas-Järvinen et al (2007b) found DRD2 to moderate the association between birth weight, presumed to reflect quality of the uterine environment to which the fetus has been exposed, and educational achievement in the Cardiovascular Risk in Young Finns Study, though only in the case of males in this large-sample study of 1,512 adults (27 to 34 years old). Whereas men with the A1 allele achieved less academically if born of low birth weight but more if born of high birth weight, no such birth-condition-achievement association emerged in the case of other men. (Individuals with birth weight > 5000g were excluded from the analysis.)

Somewhat surprisingly given the DRD2 work already reviewed, other findings from the Cardiovascular Risk in Young Finn's study suggest that it is not always individuals carrying the A1 genotype who appear disproportionately susceptible to environmental conditions. When it came to predicting depressive symptoms in 1,636 24–39-year-olds, Elovainio et al. (2007) found that it was young adults lacking the A1 allele who had more depressive symptoms if they experienced many negative life events and fewer depressive symptoms if they reported no such events across the preceding 9-year period compared with their counterparts carrying this allele.

Additional Plasticity Genes?

Emerging evidence has also begun to suggest that a polymorphism in the brain-derived-neurotrophic factor gene (BDNF) may function a plasticity gene (e.g., Chen, Li, & McGue, 2012; Gunnar et al., 2012; Juhasz et al., 2011; Mata, Thompson, & Gotlib, 2010; Suzuki et al., 2011) and a polymorphisms in the oxytocin receptor gene (OXTR; Johansson et al., 2012; Poulin, Holman, & Buffone, 2012; Sturge-Apple, Cicchetti, Davies, & Suor, 2012),

and the FKBP5 gene (Bevilacqua et al., 2012; Xie et al., 2010; Zimmermann et al., 2011). There are perhaps less frequent indications of this in the case of a SNP in the catechol-o-methyl transferase gene (COMT; Laucht et al., 2012; Nijmeijer et al., 2010). It will be worth monitoring these polymorphism—and others—as more work emerges to see whether additional evidence proves consistent with differential susceptibility.

In fact, given that virtually all the polymorphisms just considered have been studied in GxE perspective as a result of the original interests of psychiatric geneticists in simple genotype-phenotype linkages, we cannot but wonder whether an entirely different set of polymorphisms reflecting sensitivity to the environment would have emerged had the phenotype of interest been not some psychiatric disorder but developmental plasticity itself. It therefore behooves investigators to expand the list of genetic suspects beyond those thought to be related to disturbances in functioning by thinking biologically about genes that might be related to physiological processes instantiating plasticity. An excellent recent example of this approach is to be found in Grazioplene and associates (2013) work showing that a polymorphisms located on CHRNA4 interacts with childhood maltreatment to predict features of personality in a differential susceptibility-related manner. Of especial significance is that this polymorphism was selected for investigation because it is involved in the production of the neurotransmitter acetylcholine, a component of the cholinergic system that is strongly involved in neural plasticity and learning. A similarly noteworthy GxE study focused on a GABRA2 polymorphism on the presumption that it enhances responsiveness to the environment due to the role it plays in regulating neuronal excitability. Simons and associates (2013) observed that it functioned just as one would expect of a plasticity gene when investigating the influence of parenting experienced at age 10–12 on hostility toward romantic partners in early adulthood.

Polygenetic Plasticity

Most GxE research, like that just considered, has focused on one or another polymorphism. In recent years, however, work has emerged which we believe should be encouraged, focusing on multiple polymorphisms and thus reflecting the operation of epistatic (i.e., GxG) interactions (e.g., Beaver, Sak, Vaske, & Nilsson, 2010; Conner, Hellemann, Ritchie, & Noble, 2010), as well as GxGxE ones. One can distinguish polygenetic GxE research in terms of the basis used for creating multigene composites. One strategy that seems fundamentally problematic to us involves identifying genes that show main effects and then compositing only these to then test an interaction with some environmental parameter (e.g., Docherty, Kovas, & Plomin, 2011). What leads us to question the wisdom of this approach is that genes—or any other factors for that matter—that do not exert main effects could still be involved in interactions with the environment, just as some recent GxE research reveals (e.g., Cicchetti & Rogosch, 2012; Cicchetti, Rogosch, & Oshri, 2011; Pluess et al., 2011).

Another approach is to composite genes for a secondary, follow-up analysis that have been found in a first round of inquiry to generate significant GxE interactions (e.g., Brody, Chen, & Beach, 2013; Simons et al., 2013; Sonuga-Barke et al., 2009). When Cicchetti and Rogosch (2012, Figure 2) applied this approach using four different polymorphisms, they found that as the number of sensitivity-to-the-environment genotypes increased (i.e., S/S of 5-HTTLPR, zero copies of CRH1 TAT haplotype, the T/T genotype of DRD4–521C/T, and A carrier of OXTR), so did the degree to which maltreated and nonmaltreated low-income children differed on a composite measure of resilient functioning—in a for-better-and-for-worse manner.

A third approach which has now been used successfully a number of times to chronicle differential susceptibility involves compositing a set of genes selected on an a-priori basis before evaluating GxE (e.g., Brody et al., 2013). Consider in this regard evidence indicating that two-gene composites moderate links between sexual abuse and adolescent depression/anxiety and somatic symptoms (Cicchetti, Rogosch, & Sturge-Apple, 2007), between perceived racial discrimination and risk-related cognitions reflecting a fast versus slow life-history strategy (Gibbons et al., 2012, Figure 2), between contextual stress/support and aggression in young adulthood (Simons et al., 2011) and between social class and postpartum depression (Mitchell et al., 2011); that a three-gene composite moderates the relation between a hostile-demoralizing community and family environment and aggression in early adulthood (Simons et al., 2011); and that a five-gene composite moderates the relation between parenting and adolescent self-control (Belsky & Beaver, 2011), as well as between marital stability experienced across the first 15 years of life and income earned in young adulthood (Wickrama & O'Neal, 2013).

No matter how informative the approach to compositing polymorphisms on a-priori grounds has proven to be when it comes to detecting differential susceptibility, we suspect that the wave of the future will be the system-level genetic approach. This involves combining

genes considered to collectively influence a particular biological process or pathway, such as the dopaminergic or serotonergic system (e.g., Brody et al., 2013; Conner et al., 2010; Nikolova, Ferrell, Manuck, & Hariri, 2011) or neurological endophenotypes for increased susceptibility, such as amygdala volume (Yap et al., 2008), hippocampus volume (Whittle et al., 2011) and ventral striatum reactivity (Nikolova, Bogdan, Brigidi, & Hariri, 2012), to list just a few possibilities. Further insight could be gained, conceivably, by even more refined analysis of such subsystems, including those reflecting synthesis, degradation/transport, receptor and modulation (Chen et al., 2011).

GxE Mechanisms

There are likely multiple explanations as to why—in terms of mechanisms—the GxE findings we have highlighted and the ones we have not prove consistent with differential susceptibility and thus Belsky and Pluess's (2013a) claim that developmental plasticity should be regarded as a phenotype in its own right. When considering mechanisms, however, we must be sensitive to the fact that this term means very different things to different scholars. For a brain scientist, mechanism may refer to brain structure or function, whereas for an endocrinologically oriented investigator it may refer to a hormonal phenomenon, for a geneticist to an epigenetic cascade, and for a cognitive neuroscientist an attentional process, to name just some of the possibilities. Thus, what for a cognitive scientist may qualify as a proximate mechanism (e.g., attentional bias) may well be regarded by a geneticist focused on the epigenome as a distal predictor. Developmental and behavioral scientists should not be arrogant, then, when it comes to stipulating what does and does not qualify as a mechanism. It ultimately depends on the level—or levels—of analysis one is working at.

In what follows we call attention, based on recent empirical evidence, to some possible differential susceptibility-related mechanisms—at different levels of analysis. But rather than emphasizing—as most genotype–phenotype and even GxE reports do—findings linking particular genes directly to particular psychological or biological processes, we highlight instead research showing that such processes are themselves responsive to environmental exposures in a differential susceptibility-related manner.

When it comes to *cognitive processes*, the following have been found to be moderated by 5-HTTLPR and an environmental factor in a for-better-and-for-worse manner: positive and negative attentional biases (Fox, Zougkou, Ridgewell, & Garner, 2011; see also Pergamin-Hight, Bakermans-Kranenburg, van IJzendoorn, & Bar-Haim, 2012); reward sensitivity (Roiser, Rogers, Cook, & Sahakian, 2006); and accurate processing of emotional faces (Jacobs et al., 2011). The same is true of inattention in the case of DRD4 (Berry, Deater-Deckard, McCartney, Wang, & Petrill, 2013); working-memory accuracy and reaction time in the case of BDNF (Gatt et al., 2009); and rumination in the case of a two-gene composite (5-HTTLPR, BDNF: Clasen, Wells, Knopik, McGeary, & Beevers, 2011) and street code reflecting high value placed on being tough and aggressive, standing up for one's rights and being ready to fight in the case of a three-gene one (5-HTTLPR, DRD4, MAOA: Simons et al., 2012).

When it comes to *physiological processes*, 5-HTTLPR and an environmental factor have been found to interact in a differential susceptibility related manner in predicting cortisol reactivity (Way & Taylor, 2010), with the same being true of BDNF when the dependent variable is heart rate (Gatt et al., 2009) or evening salivary cortisol (Vinberg et al., 2009). Turning to *brain measurements*, Alexander and colleagues (2012) present evidence that 5-HTTLPR interacts with stressful life events in a for-better-and-for-worse manner to predict left amygdala reactivity to fearful faces, while Gatt et al. (2009) document much the same when using BDNF to forecast grey matter volume in both the hippocampus and the amygdala. Additionally, Klucken and associates (2013) report that BDNF interacts with positive and negative feedback in a for-better-and-for-worse manner during appetitive conditioning when predicting hemodynamic response in the amygdala. Also worth considering is evidence that individuals homozygous for the Iso allele of the rs5522 SNP located on the mineralocorticoid receptor gene (MR) manifest the most and least right amygdala reactivity, relative to Val carriers, when they (retrospectively) reported experiencing, respectively, high and low levels of emotional neglect in childhood (Bogdan, Williamson, & Hariri, 2012).

But it may not be just adversity to which the amygdala of certain individuals proves especially sensitive to. After all, an extensive meta-analysis showed that the amygdala responds to both negative and—even more strongly—to positive stimuli (Sergerie, Chochol, & Armony, 2008). This suggests to us, as does the work cited in the preceding paragraph, that amygdala reactivity might be one of several central nervous mechanism by which differential susceptibility operates. This would certainly be consistent with the hypothesis, proposed by the differential susceptibility framework (Belsky & Pluess, 2009a) as well as the concept of sensory-processing sensitivity (Aron & Aron, 1997; Aron, Aron, & Jagiellowicz, 2012), that heightened

susceptibility is the function of a more sensitive central nervous system on which experiences register more easily and deeply. According to this neurosensitivity hypothesis (Pluess & Belsky, 2013), specific gene variants (e.g., 5-HTTLPR short allele, DRD4 7-repeat) contribute to the increased sensitivity and responsivity of specific brain regions that then manifests itself in increased negative emotionality and physiological reactivity (Pluess, Stevens, & Belsky, 2013), in part because highly sensitive individuals are more easily aroused.

What this brief summary of diverse findings related to putative plasticity genes should make clear is that a variety of plausible mechanisms—at multiple levels of analysis—may help to account for the GxE findings noted or referred to earlier. Not only is more such research required, but the big challenge going forward will surely be to put Humpty Dumpty together, even if not again, so that a multilevel *system of causation* can be illuminated (Hyde, Bogdan, & Hariri, 2011). Needless to say, this represents a huge agenda, if not the holy grail of inquiry.

EXPERIMENTAL EVALUATION OF VARIATION IN DEVELOPMENTAL PLASTICITY

All the research cited through this point has been observational and correlational, even if often longitudinal, in character. One of the fundamental risks of interpreting evidence of such work, as noted earlier when considering methodological issues, is that what appears to be a function of person–environment interaction could actually reflect person–environment correlation. In other words, rather than such interaction effects reflecting the moderation of environmental influence by some person characteristic, they could reflect the fact that person characteristics and environments are correlated, perhaps due to the shared heritability of each, the fact that certain people tend to be exposed to certain experiences or that individuals with certain attributes evoke or provoke particular developmental experiences. The common strategy employed in observational work for discounting the possibility that organism-environment correlation is masquerading as organism–environment interaction is to insure that the temperamental, physiological, or genetic moderator under study is not correlated with the contextual predictor under consideration. However laudable such efforts are, they are not without limits. For example, just because the moderating polymorphism under investigation (e.g., DRD4) proves unrelated to the contextual predictor of interest (e.g., sensitive parenting) does not mean that this is true of all other unmeasured or unexamined organismic factors (e.g., BDNF). Ultimately, the fact that environments have not been systematically manipulated in most plasticity-related research means that one cannot be certain, even in the case of the putatively malleable, that truly causal environmental effects are being detected (van IJzendoorn & Bakermans-Kranenburg, 2012).

One way around this problem, pioneered by Dutch investigators in the case of genetic plasticity factors (Bakermans-Kranenburg, van IJzendoorn, Mesman, Alink, & Juffer, 2008b; Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, & Juffer, 2008c), involves conducting intervention experiments in which individuals are randomly assigned to a treatment condition. Because it is unethical to assign individuals, especially children, to conditions of adversity, this approach has only been used to evaluate differential response—as a function of some hypothesized plasticity factor—to an experience presumed to promote positive functioning. Such a design is of course limited, as it can only evaluate the for-better side of developmental plasticity (Pluess & Belsky, 2013). Nevertheless, it represents an ideal way to determine whether those considered to be resilient to adversity on the basis of observational research also prove relatively unresponsive to supportive conditions and whether those considered vulnerable to adversity disproportionately benefit from environmental enrichment. As it turns out, there is ever growing experimental evidence that this is indeed the case.

Negative Emotionality and Physiological Reactivity

With regard to the plasticity factor of negative emotionality, consider the re-analysis of data from the Infant Health and Development Program (1990), a well-known, early intervention which involved the random assignment of poor, low-birth infants and their families to treatment or control condition, putatively generating positive, across-the-board program effects. Blair (2002) tested Belsky's (1997a, 1997b) proposition that an enriched rearing experience (involving educational day care in the second and third year of life, combined with home visiting and parent support over the child's first three years) would differentially impact children with varying temperaments. As predicted, infants who were highly negatively emotional and assigned to the early-intervention group scored substantially lower on externalizing problems at 3 years of age than did similarly tempered infants randomly assigned to the control group; no such treatment effect occurred in the case of other infants. Especially intriguing given the fact that virtually all research considered through this

point has focused on differential susceptibility vis-à-vis social and emotional functioning, is that exactly the same results emerged when the outcome in question was severely impaired cognitive functioning. More specifically, highly negative infants assigned to the experimental intervention were five times less likely to score at or below 75 on an IQ test at age three than their negatively emotional counterparts assigned to the control condition; no such experimental effect occurred in the case of infants scoring low on negative emotionality.

Not inconsistent with these findings are those showing that (1) it was infants who scored relatively low on irritability as newborns who failed to benefit from an otherwise security-promoting intervention (Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011) and (2) infants who showed few, if any, mild perinatal adversities—known to be related to limited negative emotionality—who failed to benefit from computer-based instruction otherwise found to promote preschoolers' phonemic awareness and early literacy (van der Kooy-Hofland, van der Kooy, Bus, van IJzendoorn, & Bonsel, 2012). In other words, only the putatively vulnerable—those manifesting or likely to manifest high levels of negativity—experienced developmental enhancement as a function of the interventions cited. Similar results emerge among older children. Consider in this regard the results of Scott and O'Connor's (2012) parenting intervention that generated the most positive change in conduct among emotionally dysregulated children (i.e., loses temper, angry, touchy). Van de Wiel and associates (2004) presented related results when the plasticity factor was physiological reactivity, finding that an intervention for children with disruptive behavior disorder proved effective, but only for those displaying high cortisol-related, stress reactivity.

Genetics

Recent genetically informed evaluations of intervention programs also indicate that alleles presumed to place individuals at risk in the face of adversity (e.g., 5-HTTLPR short allele, DRD4 7-repeat) or to promote resilience (i.e., no 5-HTTLPR short allele/no DRD4 7-repeat) are associated with them being, respectfully, susceptible or not to the benefits of intervention (but see Cicchetti, Rogosch, & Toth, 2011, for counter evidence). Consider first experimental intervention research designed to enhance parenting which chronicles a moderating effect of the 7-repeat allele on parenting. When Bakermans-Kranenburg, van IJzendorn, Pijlman, Mesman, and Juffer (2008) looked at change over time in parenting—from before to well after a video-feedback parenting intervention was provided on a random basis to 157 mothers of 1–3-year-olds who scored high on externalizing problems—they found that the intervention succeeded in promoting more sensitive parenting and positive discipline. Moreover, this intervention effect translated into improvements in child behavior, but only for those children carrying the DRD4 7-repeat allele. The same was true when, at post-treatment follow up, stress reactivity was measured by means of change in salivary cortisol before and after the administration of an experimental stressor (i.e., area under the curve) (Bakermans-Kranenburg, van IJzendoorn, Mesman, et al., 2008). Indeed, DRD4 7-repeat children in the experimental group not only showed the least physiological stress reactivity of all children, but the most if their mothers had been assigned to the control group.

Of note, too, is that the most pronounced reduction in children's problem behavior occurred when two conditions obtained: (1) the parenting intervention *substantially* improved mother's use of positive discipline techniques; and (2) the child carried the DRD4 7-repeat allele. When only the first condition was met, children's behavior did not change. One cannot help but wonder why some mothers benefited more from the experimental treatment than others in terms of improved parenting and thus whether an untested GxGxE interaction was responsible for the problem-behavior findings discerned. Could it be that mothers with certain susceptibility genes—including perhaps the 5-HTTLPR short allele—proved most responsive to the intervention and it was this, in combination with their child's genetic susceptibility to rearing, that generated the results described? This question raises a more general one: when parenting interventions prove effective in changing child behavior, does a small subset of parent–child dyads carry the overall treatment effect—and, specifically, ones comprised of a parent and a child who are both highly malleable for genetic reasons? As no intervention investigation has considered parent as well as child genotype, this possibility remains to be evaluated.

Further evidence of DRD4 in moderating intervention effects can be found in Kegel, Bus, and van IJzendoorn's (2011) work showing that it was DRD4 7-repeat carriers who benefited from specially designed computer games promoting phonemic awareness and, thereby, early literacy in their RCT. Other RCT results point in the same direction with regard to DRD4 7-repeat, including research on African-American teens in which substance use was the outcome examined (Beach, Brody, Lei, & Philibert, 2010; Brody et al., 2013, 2014)

Also of importance is intervention evidence highlighting the moderating role of 5-HTTLPR. Consider in this regard Drury and associates' (2012) data showing that it was only children growing up in Romanian orphanages who carried short alleles who benefited from being randomly assigned to high-quality foster care—in terms of reductions in the display of indiscriminant friendliness. Eley and associates (2012) also documented intervention benefits restricted to short-allele carriers, but their design included only treated children (i.e., not RCT).

Attention must be called, however, to another non-RCT intervention study which found that it was individuals suffering from Posttraumatic Stress Disorder who carried short alleles who benefited the least from cognitive behavior therapy (Bryant et al., 2010).

Last to be considered is research examining genetically moderated intervention effects using multigene composites rather than single candidate genes. Consider in this regard the Drury et al. (2012) findings showing that even though BDNF—all by itself—did not operate as a plasticity factor when it came to distinguishing those who did and did not benefit from the foster-care intervention, the already-noted moderating effect of 5-HTTLPR was amplified if a child carried BDNF Met alleles *along with* short 5-HTTLPR alleles. In other words, the more putative plasticity alleles children carried, the more their indiscriminant friendliness declined over time when assigned to foster care and the more it increased if they remained institutionalized. In light of these results and other research from nonintervention studies focused on BDNF suggesting that BDNF Met alleles are associated with susceptibility to environmental effects in a positive and negative manner (e.g., Chen et al., 2012; Gunnar et al., 2012; Juhasz et al., 2011; Mata et al., 2010; Suzuki et al., 2011), it is somewhat surprising to discover that in a non-RCT treatment study it was individuals carrying BDNF Val rather than Met alleles who benefitted the most from exposure therapy when it came to reducing the symptoms of posttraumatic stress disorder (Felmingham, Dobson-Stone, Schofield, Quirk, & Bryant, 2013).

In an intervention study that involved a RCT, Brody, Beach and Chen (2013) confirmed their prediction that the more GABAergic and dopaminergic plasticity-related gene variants African American teens carried, the more protected they were from increasing their alcohol use over time when enrolled in a whole-family prevention program. These findings along with those of Drury et al. (2012) once again call attention to the benefits of moving beyond single polymorphisms when it comes to operationalizing the plasticity phenotype. Moreover, the Drury et al. (2012) results indicate that even if a single gene may not by itself moderate an intervention (or other environmental) effect, in could still play a role in determining the degree to which an individual benefits. These are insights future investigators—and interventionists—should keep in mind when seeking to discover what works for whom.

REPEATED MEASUREMENTS

All the differential susceptibility-related work cited herein, as well as in our earlier reviews (Belsky, 2005; Belsky & Pluess, 2009a; Ellis, Boyce, et al., 2011), essentially presumes that children and adults who share the same characteristics, be they temperamental, physiological or genetic plasticity factors, would function in a manner opposite to what was observed were they exposed to contrasting conditions. For example, we have presumed that children carrying the DRD4 7-repeat and showing high levels of externalizing problems in the face of insensitive parenting would score low on such problems if they were raised by skilled caregivers, and this is certainly what some of the just summarized research on genetically moderated intervention effects suggests. But the truth is that there is almost no research validating this assumption, in part because it is unethical to provide a child growing up under for-better, supportive conditions with for-worse, adverse ones just to test for differential susceptibility. One of the few studies that systematically addressed the repeated-measurement issue under consideration, even if not in such differential susceptibility-related terms or with children, examined the probability of taking a risk in a gambling-decision-making game when the chances of winning were high (i.e., for-better condition) and when they were low (i.e., for-worse condition) (Roiser et al., 2006). Results revealed the more 5-HTTLPR short alleles an individual carried, the more likely the person would make a bet (i.e., take a risk) when the chance of winning was high (i.e., for-better condition) and the less likely such a decision would be made when the probability of winning was low (i.e., for-worse condition).

In addition to constructing repeated-measurement experiments of the kind just described—though not necessarily having to do with gambling decision making—future researchers would be well advised to take advantage of experiments in nature that could serve this purpose. Consider in this regard the imaginative work of Verschoor and Markus (2011) who took advantage of days in which undergraduates did and did not have examinations to see how those homozygous for long and short 5-HTTLPR

alleles functioned, finding that that the latter experienced the most tension, negative mood and perceived stress on exam days (i.e., for-worse condition), yet the least on nonexam days (i.e., for-better condition). Consider as well Schoebi and associates' (2012) marital research indicating that spouses homozygous for 5-HTTLPR short alleles proved more sensitive to their partner's positive and negative emotion during marital interactions, seeming to reflect exposure to for-better and for-worse conditions.

UNKNOWNS IN THE DIFFERENTIAL SUSCEPTIBILITY EQUATION

As much as anything else, the central thesis of this chapter, namely, that individuals differ in their developmental plasticity and thus susceptibility to environmental influence, raises many issues in need of further investigation, many of which have already been highlighted. Here we call attention to additional ones.

Same Individuals, Different Plasticity Markers?

Is the research conducted by investigators often working in different fields—psychology, physiology, genetics—actually identifying the same more-and-less-susceptible individuals by different means? Consider in this regard that the very children who score high in negative emotionality, physiological stress reactivity and who have 5-HTPLR short alleles could often be one and the same (5-HTTLPR and cortisol reactivity: Gotlib, Joormann, Minor, & Hallmayer, 2008; 5-HTTLPR and infant negative emotionality: Holmboe, Nemoda, Fearon, Sasvari-Szekely, & Johnson, 2011). Some recent evidence raises the possibility, however, that empirically related plasticity factors may not be interchangeable. Even though recent work indicates that DRD4 and negative emotionality early in life are related (Holmboe et al., 2011; Ivorra et al., 2010), Belsky and Pluess (2013b) observed that the moderating effect of DRD4 does not account for a parallel moderating effect of negative emotionality, at least in a study of effects of child care on children's social functioning.

Categorical or Dimensional Scaling of Plasticity?

Another issue that merits consideration in future work is whether individual differences in plasticity are best conceptualized in typological or dimensional terms. Adopting evolutionary terminology pertaining to reproductive strategy, we can ask whether there exist plastic and fixed strategists who are and are not, respectively, susceptible to environmental experiences, thereby following conditional and alternative pathways of development (Belsky, 2000). Or does it make more sense to think in terms of a plasticity gradient, as mentioned earlier, with individuals varying in *degree* of susceptibility to environmental influences? But perhaps in the same way that light is best conceived as both a wave and a particle, depending upon the circumstance, the choice between a typological and dimensional conceptualization and parameterization of plasticity is a false one, as the approach which proves best will vary across conceptual purposes and empirical inquiries.

Domain Specific or Domain General?

Also unknown is whether it makes the most sense to regard more and less plasticity as a global, macro, trait-like characteristic of individuals or consider it in more domain-specific terms? Are some people simply more malleable than others across the board, almost irrespective of the environmental factor and aspect of functioning under consideration, or are people a complex mosaic of components that are more and less susceptible to environmental influence, thus making them both more and less malleable relative to others? Whereas the latter conceptualization might make more intuitive sense, two new sets of evidence underscore the domain generality of plasticity. The first involves the nature and effects of two dramatically different and already cited Dutch interventions which used different approaches to influence children, one indirectly and the other directly, and focused on different developmental outcomes, yet revealed that children sharing the same plasticity factor were the primary beneficiaries of each. More specifically, even though one intervention promoted sensitive parenting via video feedback to reduce toddler's externalizing behavior (Bakermans-Kranenburg, van IJzendoorn, Pijlman, et al., 2008) and cortisol-related stress reactivity (Bakermans-Kranenburg, van IJzendoorn, Mesman, et al., 2008) and the other relied on a computerized instructional program to promote preschooler's phonemic awareness and, thereby, early literacy (Kegel et al., 2011), it was children carrying the DRD4–7-repeat allele who disproportionately or exclusively benefited in both cases.

Then there is the longitudinal data evaluated by Roisman and associates (2012) showing that infants with difficult temperaments measured in the first six months of life proved more susceptible to the positive and negative effects, respectively, of sensitive and insensitive mothering experienced during their first three years of life when

it came to predicting teacher-reported social competence, behavior problems, and academic skills across the primary-school years. Also, this was so even with different teachers rating the children each and every academic year. Moreover, even though a diathesis–stress rather than differential susceptibility model fit the data best when it came to predicting performance on objective tests of academic performance through 15 years of age, it once again proved to be children who as infants had difficult temperaments who were disproportionately susceptible to the shorter and longer term effects of early mothering.

Despite such evidence, it still seems premature to embrace the broad domain-general interpretation of developmental plasticity. Nevertheless, the results just summarized caution against its premature dismissal. Ultimately, further work is called for before any firm conclusions can be drawn. Our own suspicion is that there will be variation across individuals in that some will prove highly susceptible to many developmental experiences and environmental exposures (i.e., extremely plastic) and that some will prove susceptible to virtually none (i.e., extremely fixed), but that most will prove to be intermediate between these extremes. One might even envision a bell curve with regard to the degree of plasticity that individuals manifest.

Origins of Plasticity: Nature or Nurture (or Both)?

A fundamental issue that should be raised for future research pertains to whether, or at least the extent to which, plasticity should be regarded as principally a function of nature or nurture. Certainly the GxE evidence calls attention to heritable individual differences in plasticity, as well as to the fact that so-called vulnerability genes or risk alleles might in many cases be better conceptualized as plasticity genes (Belsky et al., 2009). After all and with regard to the latter point, why would natural selection, for example, maintain much less select genes that only functioned to foster depression in the face of negative life events or antisocial behavior in the face of child maltreatment? Were these perhaps down-side costs of selecting and preserving genes that engendered benefit in the face of supportive contextual conditions, or even operated as adaptations when also functioning in a diathesis–stress manner, it would seem to make more sense for them to be selected.

But just because GxE studies are replete with evidence, often unnoticed, of differential susceptibility should not lead to the presumption that plasticity is only function of genetics. Central to Boyce and Ellis's (2005) thinking, it will be recalled, is the role of extremely supportive and unsupportive environments in fostering physiological reactivity and, thereby, developmental plasticity. Especially notable, in fact, is recent research on the putatively adverse effects on the developing child of maternal stress during pregnancy. This is because so-called fetal programming appears to influence several of the very susceptibility factors already considered that seem to be markers of differential susceptibility (Belsky & Pluess, 2009b; Pluess & Belsky, 2011). Consider in this regard research showing (1) that maternal stress during pregnancy predicts difficult temperament at 3 months of age (Huizink et al., 2002) and emotional reactivity to novelty in 4-month-olds (Möhler, Parzer, Brunner, Wiebel, & Resch, 2006); (2) that prenatal maternal depression and elevated cortisol levels in late pregnancy predict negative reactivity at age 2 (Davis et al., 2007); and (3) that maternal prenatal anxiety predicts awakening cortisol in 10-year-olds (O'Connor et al., 2005).

On one hand, such data suggest that very early experience—in the womb—may shape plasticity, not just genetics, as the outcomes just mentioned are among the very child characteristics found in work cited herein to demarcate heightened susceptibility to environmental influences. Just as importantly, this re-interpretation of putatively negative effects of prenatal stress raises fundamental questions about the disturbance-focused perspective that pervades virtually all research and theory on prenatal programming: Is it the case that prenatal stressors compromise later development, as prevailing thinking presumes, or do these prenatal experiences promote plasticity—and thus the organism's openness to future experiential input, be it positive or negative in character? That is, is there prenatal programming of postnatal programming (Pluess & Belsky, 2011)? Oberlander et al.'s (2008) epigenetic findings showing that maternal depressed mood in pregnancy predicts increased methylation of the human glucocorticoid receptor gene (NR3C1, measured in neonatal cord blood), which itself forecasts elevated cortisol stress reactivity at age three months, illuminates at least one biological mechanism that may be central to such fetal programming of postnatal plasticity. Recall in this regard that cortisol reactivity may well demarcate heightened susceptibility to rearing influences (Boyce & Ellis, 2005).

Before concluding on the basis of fetal programming research that plasticity may be a function of experience as much as a function of genetics, we should not lose sight of the fact that GxE may characterize the fetal programming process (Gluckman & Hanson, 2005). This raises the possibility that some fetuses may be more susceptible to fetal programming than others, for genetic reasons.

If they are, it would suggest that plasticity is a function not just of nature or nurture, but of their interaction (Belsky & Pluess, 2009b). That is, some individuals may be more likely than others to be affected by experience, most notably perhaps fetal experience, in ways that subsequently affect whether or to what degree they will be influenced by the postnatal world they encounter. Initial evidence to this effect was found in recent GxE work based on data from a large Dutch cohort study in which maternal anxiety during pregnancy significantly predicted negative emotionality—a putative susceptibility factor—in infants carrying one or more copies of the 5-HTTLPR short allele, but not in those homozygous for the long allele (Pluess et al., 2011). These results provide the first empirical evidence consistent with the aforementioned hypothesis that individuals with certain genotypes who are also exposed to specific prenatal environments may be more likely than those not carrying such alleles or not so exposed to prove susceptible to postnatal environmental influences (Pluess et al., 2011). However, it has to be noted that whether infants characterized by high negative emotionality where also more affected by subsequent postnatal contextual factors, consistent with a differential susceptibility pattern, has not yet been determined within this sample. This would be necessary to conclusively test whether genetic factors moderate the effects of prenatal programming on postnatal plasticity (Pluess & Belsky, 2011).

Not to be ignored in this discussion of the determinants of developmental plasticity is evidence that physiological and behavioral susceptibility factors are also shaped by postnatal experiences (e.g., Heim et al., 2000; Kaplan, Evans, & Monk, 2008). Figure 2.3 represents a schematic model outlining the multiple means and pathways by which developmental plasticity is likely regulated: (1) genetic contributions to susceptibility; (2) genetic contributions mediated by behavioral and physiological susceptibility factors; (3) prenatal and (4) postnatal environmental effects on behavioral and physiological susceptibility factors; (5) GxE interactions involving the prenatal and (6) postnatal environment; and (7) interactions between the prenatal and postnatal environment in shaping susceptibility factors.

Population Variation in Plasticity?

Do populations differ in the degree to which children are malleable? If we consider for a moment the fact that selection for plasticity perhaps only pays off in fitness terms, especially given its potential costs, if what happens at one point in time is systematically related to what happens at a later point in time, the possibility emerges that human populations may vary in the degree to which children are malleable. After all, in some ecological niches past and future could have been more systematically related than in others. Future research can thus address whether in ecological niches in which the present and future are (or have been) more related, the payoff for plasticity could well be greater, with greater selection for plasticity in human populations.

Three observations seem noteworthy in this context. First, the DRD4 7-repeat allele not only recently

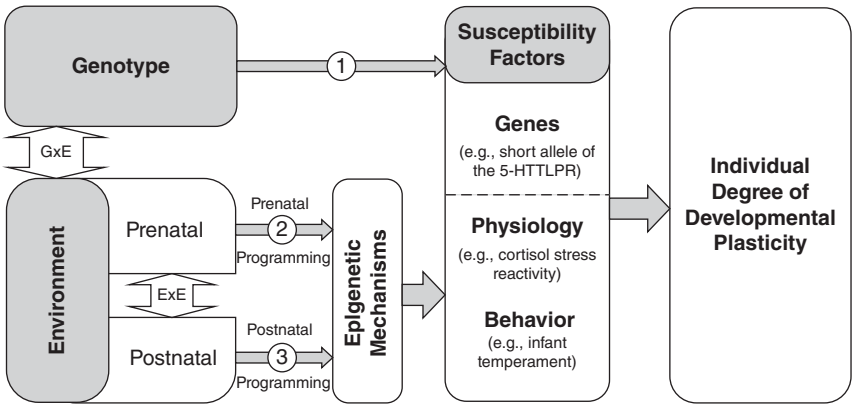

Figure 2.3 Nature, nurture, and differential susceptibility: a process model. 1 = genetic contribution to general susceptibility partially mediated by susceptibility factors (nature); 2 = prenatal environment shapes susceptibility factors (nurture); 3 = postnatal environment shapes susceptibility factors (nurture). In addition, genotype interacts with both prenatal and postnatal environment and prenatal and postnatal environments interact with each other to shape susceptibility factors. GxE = Gene–environment interaction; ExE = environment–environment interaction. *Source:* Pluess, M., Stevens, S., & Belsky, J. (2013). Differential Susceptibility: Developmental and Evolutionary Mechanisms of Gene-Environment Interactions. In M. Legerstee, D. W. Haley & M. H. Bornstein (Eds.), *The Infant Mind: Origins of the Social Brain* (pp. 77–96). New York: Guilford.

emerged in human populations (~40k years ago), but varies substantially across them, having an extremely low incidence in Asia yet a high frequency in the Americas (Ding et al., 2002); intriguingly, the reverse is true of another possible plasticity gene, the s/s genotype of 5-HTTLPR (Kim et al., 2007). Second, one wild bird population shows evidence that selection favoring individuals who are highly plastic with regard to the timing of reproduction has intensified over the past three decades, perhaps in response to climate change causing a mismatch between the breeding times of the birds and their caterpillar prey (Nussey, Postma, Gienapp, & Visser, 2005). Finally, Suomi (2006) observed that only two species of primates fill diverse ecological niches around the world, humans and rhesus macaques, and that what distinguishes these two weed species from all other primates is the presence of a polymorphism in the serotonin transporter gene (5-HTTLPR). In the same way, then, that not all primates seem to share the 5-HTTLPR, populations may differ generally in the presence of plasticity alleles, as already noted, due to variation in historical continuity of contextual conditions over time.

Gender Differences in Plasticity?

Originally, the differential susceptibility hypothesis did not have anything to say about the prospect of gender differences in developmental plasticity (Belsky, 1997b, 2005; Belsky & Pluess, 2009b). Therefore, it is not surprising that most research pertaining to differential susceptibility do not consider gender other than as a covariate to control for gender differences in the dependent variables under investigation. Nevertheless, it seems potentially—even if not certainly—noteworthy that some research on differential susceptibility has revealed gender differences in developmental plasticity. Consider in this regard one study involving a behavioral susceptibility factor, infant negativity, which detected differential susceptibility related effects of father involvement on prosocial behavior, but only in the case of girls (Ramchandani, van IJzendoorn, & Bakermans-Kranenburg, 2010). Consider next research focused on physiological reactivity as a susceptibility factor, with El-Sheikh, Keller, et al. (2007) reporting that skin conductance reactivity of children moderated the effects of marital conflict on externalizing problems, again in a differential susceptibility related manner, but this time only in the case of boys.

Several GxE studies involving the 5-HTTLPR have also detected the for-better-and-for-worse pattern of environmental influence, but only for females (Brummett et al., 2008; Eley et al., 2004; Hammen, Brennan, Keenan-Miller, Hazel, & Najman, 2010). Nevertheless, other work which has formally tested three-way interactions involving gender, 5-HTTLPR and an environmental factor has failed to detect sex-differentiated GxE patterns taking the form of differential susceptibility (Pluess et al., 2010, 2011). Finally, GxE-related gender differences emerged in work that composited putative plasticity genes, finding that it was only adolescent boys whose self-control proved related to the parenting they experienced in a for-better-and-for-worse manner (Belsky & Beaver, 2011). In summary, although gender differences in the operation of differential susceptibility emerge in a number of investigations, one is hard pressed to discern order in the empirical chaos. Perhaps if the issue is addressed more systematically and consistently—and theory as to why such should be expected emerges to motivate such inquiry—future research will tell a different story.

Competitive Evaluation of Models of Person–Environment Interaction

Much of the evidence cited in our earlier reviews of differential susceptibility-related evidence (Belsky et al., 2009; Belsky & Pluess, 2009a), as well as herein, was selected for consideration based on eyeball tests of graphed interactions between an environmental predictor and developmental outcome moderated by a plasticity factor. The limits of this approach to testing for differential susceptibility led Belsky et al. (2007) to propose explicit empirical criteria which we summarized earlier, while calling attention to the fact that much of the research cited in this chapter does not meet such seemingly rigorous evidentiary standards. Indeed, Kochanska and associates (2011) extended this effort to establish standards for distinguishing differential susceptibility from diathesis stress using the regions-of-significance approach (Preacher, Curran, & Bauer, 2006; Takane & Cramer, 1975) to evaluate, separately, the for-better and for-worse sides of the differential susceptibility hypothesis upon documenting the required cross-over interaction.

Roisman and associates (2012) recently offered an even more demanding approach for evaluating differential susceptibility by providing two new quantitative metrics in combination with the regions-of-significance analysis: the *proportion of interaction* index, which represents the proportion of the total area of an interaction plot that is uniquely attributable to differential susceptibility; and the *proportion affected* index, which quantifies the proportion of people in the sample who fall above the crossover point

(i.e., proportion of sample in the for-better condition). In addition, Roisman et al. (2012) recommend testing for nonlinear relationships between predictor and outcome and correction for multiple comparisons.

All the approaches offered to date to evaluate differential susceptibility have involved conducting essentially *exploratory* tests of organism–environment interactions as a first step before further interrogating the data at hand. Widaman and associates (Belsky, Pluess, & Widaman, 2013; Widaman et al., 2012) recently advanced a strategy which sidesteps such approaches, moving directly to test competing theoretical models. In a first step the cross-over point between high- and low-susceptible individuals is estimated with the help of a re-parameterized regression equation (Widaman et al., 2012). If the estimated cross-over point lies within the observed range of the predictor, four additional re-parameterized regression models are applied, two constrained to reflect a weak and a strong version of diathesis–stress and two to reflect a weak- and a strong-version of differential susceptibility. Fit indices of the four models are then compared to evaluate whether the data fits better with a diathesis–stress or differential susceptibility model (Belsky et al., 2013). The strong version of differential susceptibility presupposes that there are those who are susceptible to both positive and negative contextual conditions and others who are not, whereas the weak version presupposes that while many may be susceptible to environmental influences to some extent, some are more affected than others.

The time has thus come to move beyond exploratory tests of organism–environment interaction in regression and ANOVA designs, and more formally evaluate in a competitive manner the a-priori hypotheses central to diathesis–stress and differential susceptibility models of environmental action.

Variation in Environmental Cue Reliability

Whether children develop in a generally supportive or unsupportive environment, it is likely that the reliability of environmental cues indicative of the valence of the rearing milieu will vary. One can imagine in this regard two different hostile environments, one in which conflict is constant and thus highly predictable and another in which conflict is episodic and unpredictable. Frankenhuis and Panchanathan (2011) have insightfully observed that highly plastic individuals growing up in these two environments may differ in terms of when they commit to a developmental strategy, with the former deciding to specialize early, having high confidence about the state of the environment, but the latter deferring commitment and choosing to keep sampling the environment until a better estimate of the environment can be established. Whether this is actually the case or not is an issue that should be pursued empirically in the future. Indeed, Frankenhuis and Panchanathan's (2011) intriguing ideas lead us to wonder whether it is when cue reliability is low that individuals call upon the epigenome to infer from markings passed down across multiple generations what past environments were like and thus what is the best developmental pathway to pursue. Such a process would be consistent with Kuzawa's (2005) notion of intergenerational phenotypic inertia that highlights the fact that it is not just the experiences of the immediately preceding generation that developing organisms are sensitive to, but even ones preceding that.

Parent–Child Conflict of Interest

Like all-too-many developmental scientists lacking foundational knowledge about evolutionary theory, virtually all our thinking and writing about differential susceptibility to date has presumed that malleable children will have their development regulated by their rearing experiences. But as Trivers (1974) pointed out more than four decades ago, the fact that parents and children share, on average, 50% of their genes means that their biological interests are not one and the same and thus that they often experience a conflict of interest (see also Schlomer, Del Giudice, & Ellis, 2011). In discussing the influence of prenatal stress on development, Del Giudice (2012) recently pointed out that it is because of this fact that children, even highly malleable ones, may not simply take instructions from their parents. What are the implications of this observation for understanding developmental plasticity?

Family Dynamics

However intrigued we have become with theory and evidence pertaining to differential susceptibility and the notion that there exist individual differences in developmental plasticity, one issue has always caused us concern: We have *never* heard a parent characterize one of their children as more susceptible to their influence than another, which we regard as distinct from their saying that their children are temperamentally different, with perhaps one being more sensitive to challenging or stressful situations than others or even being more difficult to care for. Why is that? Evolutionary reasoning would seem to imply that parents should detect for whom their socialization efforts, be they implicit or explicit, pay off and for whom they

do not and so adjust those efforts accordingly. Yet we are aware of no evidence suggesting, much less indicating this to be the case. Indeed, should not more malleable siblings seek to alert their parents to the fact that they are more responsive to rearing inputs to obtain more attention and other resources? Might it be the case, however, that such children do engage in such efforts, but that they do not prove effective because less malleable children employ tactics to camouflage in some way this characteristic of theirs? Perhaps it is such children who prove most likely to claim it's not fair within families when siblings are perceived as being treated better as a way of throwing their parents off track. At the very least, it would be interesting to study parental awareness or perception of variation in susceptibility across siblings within a family.

Timing of Susceptibility

It is widely assumed by many developmentalists that it is during the early years of life when human development is most susceptible to environmental influences, for better and for worse (e.g., Blair & Raver, 2012; Ganzel & Morris, 2011), as plasticity is presumed to be greatest when biological systems are being laid down. But even if this is true in general, does it mean that it is true in the case of each and every individual? It certainly seems conceivable that at times in the ancestral past that individuals who were especially susceptible to environmental influence at some later point or points in the life span might have experienced an adaptive advantage, leading perhaps to the selection of genes for later rather than earlier plasticity. If this is so, it implies that variation should exist in terms of *when* children and even adults are especially developmentally plastic. And if this is the case, does it not imply that those who appear not to be especially malleable may simply not be so at the developmental point in time when developmental experiences and environmental exposures are measured? In fact, might it be the case that some are especially susceptible to contextual regulation early, others later, others at all times and still others more or less never?

For Better and For Worse—or Just for Better?

One important unknown in the differential susceptibility equation is whether some individuals could be especially susceptible to just adversity, some to just environmental support and enrichment, some to both, and some to neither. Of note in this regard is that whereas the English language has terms to characterize those highly susceptible to both positive and negative conditions (i.e., plastic/malleable) and highly susceptible to adversity (i.e., vulnerable), it is difficult to find a term that would characterize those disproportionately responsive to supportive conditions only. Indeed, the only term that Belsky and Pluess (2009b) could identify—in tongue-and-cheek fashion—to characterize those disproportionately likely to benefit from positive experiences and exposures was *lucky*. And this was after asking speakers of diverse languages, including French, German, Italian, Chinese, Czech, Spanish, Korean, and Polish, whether there was a word or term in their native tongue that captured the for-better side of differential susceptibility. The fact that there did not seem to be such a term in any of these languages raised the intriguing possibility that one reason variability in response to positive—as opposed to negative—experiences went unnoticed, or at least unheralded, for so long was that we simply lack terminology to direct attention to it.

Recently, Manuck and associates (2011a; Sweitzer et al., 2013) introduced the term vantage sensitivity to characterize the for-better side of differential susceptibility and more generally variability in response to *positive* experiences. *Vantage* is short for *advantage*, but in addition to implying benefit, gain or profit, it is also defined as a position, condition, or opportunity that is likely to provide superiority or an advantage (HMCO, 2000). In Manuck's own words (Manuck, 2011b), *vantage* bespeaks a position conferring advantage, benefit, or gain without bearing the singularity of a particular advantage. We embrace and promote the term vantage sensitivity to describe the notion that some individuals are more sensitive and positively responsive to the environmental advantages to which they are exposed to, but not especially susceptible to adverse experiences, as is presumed in the case of differential susceptibility. These advantages may take the form of security of attachment derived from sensitive parenting, academic achievement resulting from high-quality child care, prosocial behavior due to supportive friendship networks, and life satisfaction stemming from positive life events, as well as sense of efficacy following psychotherapy, to name just a few possibilities.

In hopes of stimulating work which would distinguish vantage sensitivity from differential susceptibility, Pluess and Belsky (2013) proposed the following concepts to characterize variability in response to positive experiences: (1) vantage sensitivity reflects the general proclivity of an individual to benefit from positive and presumptively well-being– and competence-promoting features of the environment, just as vulnerability depicts the tendency to succumb to negative effects of adversity in the diathesis–stress framework; (2) the degree

of vantage sensitivity is a function of the presence of vantage-sensitivity factors (i.e., promotive factors), just as vulnerability/risk factors increase vulnerability to negative effects of adversity in the diathesis–stress framework; (3) vantage resistance describes the failure to benefit from positive influences, just as resilience characterizes resistance to negative effects of adversity in the diathesis–stress framework; and (4) the degree of vantage resistance is a function of the presence of vantage-resistance factors or absence of vantage-sensitivity ones, just as protective factors increase resilience to negative effects of adversity in the diathesis–stress framework. In summary: vantage-sensitivity factors increase vantage sensitivity to the beneficial effects of positive experiences and exposures, whereas vantage-resistance factors diminish or even completely eliminate positive response to the same supportive conditions (Figure 2.4 for graphical illustration).

Having delineated the nature of vantage sensitivity, some evidence consistent with the notion merits consideration. Testing the a priori hypothesis that children characterized by a high sensitive personality (Aron & Aron, 1997) would show vantage sensitivity to psychological intervention, Pluess and Boniwell (2015) investigated variation in the anticipated positive effects of a school-based resilience-promoting program administered to a sample

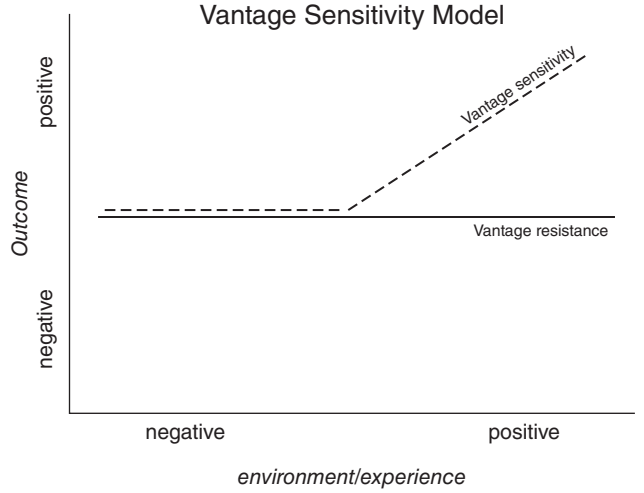

Figure 2.4 Graphical illustration of vantage sensitivity. Vantage sensitivity describes the propensity to respond favorably to positive experiences as a function of individual characteristics, whereas vantage resistance reflects the inability to benefit from supportive influences. No differences are predicted in response to negative influences. *Source:* Adapted from M. J. Bakermans-Kranenburg & M. H. van IJzendoorn, Gene–environment interaction of the dopamine D4 receptor (DRD4) and observed maternal insensitivity predicting externalizing behavior in preschoolers. *Developmental Psychobiology, 48*(5), 2006, Figure 1.

of 200 11-year-old girls in one of the most deprived areas in London, United Kingdom (Pluess, Boniwell, Hefferon, & Tunariu, submitted). The intervention led to a decrease of depression symptoms observable up to the 12 month follow-up assessment, but, consistent with vantage sensitivity, exclusively among children who scored in the upper quartile of the highly-sensitive-child questionnaire. All other children failed to benefit from the intervention, at least regarding changes in depression symptoms.

An example of vantage sensitivity as a function of a physiological moderating factor emerged recently in Eisenberg et al.'s (2012) work of 213 toddlers and their families. Baseline RSA moderated effects of the home environment (based on a composite of maternal and paternal education, family income, and marital quality) in early childhood on repeatedly assessed child aggression. For children with high RSA activity, high environmental quality was associated with less aggression at 54 months, whereas children characterized by low RSA activity—displaying vantage resistance—did not benefit from high-quality environments at all.

Eley et al.'s (2012) evaluation of whether 5-HTTLPR moderated effects of cognitive-behavioral therapy for anxiety disorders provides an example of genetic vantage sensitivity. Clinical diagnoses of anxiety disorders and symptom severity were assessed before and after treatment as well as 6 months after treatment ended. Although all children appeared to benefit from the treatment, the positive effect of the intervention was particularly pronounced in the case of those children carrying the short allele in this work with 6–13-year-old boys and girls ($N = 359$). More specifically, those homozygous for the 5-HTTLPR short allele showed a significantly greater reduction in symptom severity from pre-treatment to follow-up assessment, so much so, in fact, that they proved 20% more likely than others to be free of anxiety disorder at the 6-month follow-up assessment.

FUTURE DIRECTIONS IN RESEARCH ON DIFFERENTIAL SUSCEPTIBILITY

Here we highlight a number of issues that future research should prioritize to advance knowledge regarding individual differences in developmental plasticity. Following this, we draw some general conclusions.

Differential susceptibility is a rather new concept with most empirical work having emerged in just the past few years. Although already an influential framework, particularly within the fields of developmental and clinical psychology, providing answers to some long-standing

questions regarding individual differences in response to environmental influences, differential susceptibility reasoning actually appears to raise more new questions than answering old ones.

1. *Mechanisms of differential susceptibility*. Among all the unknowns in the differential susceptibility equation that have been discussed in this chapter as well as in previous publications (Belsky & Pluess, 2009a, 2009b, 2013a; Pluess & Belsky, 2013), that regarding *mechanisms* underlying individual differences in susceptibility seems especially important to apply differential susceptibility in practice, a thorough understanding of *how* susceptibility gets instantiated will be crucial. Future work should therefore endeavor to identify specific mechanisms and related processes across different levels of analysis from genetic and molecular, to neurological and hormonal, to behavioral.
2. *Domain specificity*. Are some individuals generally more and others less susceptible to all kinds of developmental experiences and environmental exposures, or are they more susceptible to certain influences compared with others? For example, might some be especially sensitive to peer influence and others to parental influence; or some especially susceptible to the effects of punishment and others to the effects of reward? Empirical investigation of this important question will require studies testing whether the same susceptibility factor increases plasticity of the same individual across different environmental influences and with respect to different phenotypic characteristics.
3. *Nature and nurture of susceptibility*. Is an individual's degree of susceptibility biologically fixed or can it be influenced through intervention or particular experiences? As discussed earlier, susceptibility seems to have a genetic basis. The question of determinants of susceptibility is particularly important regarding potential intervention efforts to foster both resilience and vantage sensitivity. Future studies with large longitudinal prospective samples that include molecular genetic measures are required to investigate the genetic and environmental determinants of susceptibility as well as the interaction of the two.
4. *Development of developmental plasticity*. Closely linked to the question of whether susceptibility is a fixed or malleable trait is a developmental question: Does susceptibility evolve during development or is it established early in life, perhaps even by the time of birth? Future research should seek to illuminate, for example, whether an individuals' propensity for vulnerability to environmental adversity may increase in response to accumulated negative experiences (i.e., diathesis–stress) and whether susceptibility to positive experiences (i.e., vantage sensitivity) may increase over time as a result of exposure to positive influences. Evidence of such would prove consistent with the notion of upward spiral dynamics (Fredrickson & Joiner, 2002).
5. *Susceptibility to what?* There appear to be three general models of person–environment interaction today: diathesis–stress (i.e., variability in response to exclusively negative experiences, Monroe & Simons, 1991), vantage sensitivity (i.e., variability in response to exclusively positive experiences, Pluess & Belsky, 2013), and differential susceptibility (i.e., variability in response to both negative *and* positive experiences, Belsky & Pluess, 2009a), with the latter reflecting the combination of both diathesis–stress and vantage sensitivity as a function of the same moderating variable. Empirical evidence for each of these models suggests that whereas some individuals may be disproportionately susceptible to negative experiences others may be disproportionately susceptible to positive environmental conditions and still others may be disproportionately susceptible to both—or to neither. Future research should investigate whether these four different types of environmental sensitivity exist in the population (Pluess, 2015).
6. *Susceptibility versus vulnerability versus vantage sensitivity factors*. Susceptibility, Vulnerability and Vantage Sensitivity have often been associated with the same psychological, physiological and genetic characteristics. Future research should aim to determine whether there are, in fact, specific factors for vulnerability, vantage sensitivity, and differential susceptibility and associated specific mechanisms and related processes.
7. *Sensitive periods*. Is an individual's susceptibility constant across development or are there sensitive periods where susceptibility to environmental influences is more pronounced compared with other developmental periods? Furthermore, do different susceptibility factors increasing susceptibility to environmental influences during different developmental periods? Addressing these questions requires studies testing interactions between putative susceptibility factors and environmental influences within the same person repeatedly across different developmental periods.
8. *Measures of susceptibility*. To apply differential susceptibility to psychological and educational services, it will be important to develop measures of susceptibility that are both reliable and easily applicable. Measures of

physiological reactivity or genetic susceptibility are currently not suited for that purpose. Future efforts should be directed toward the development of rating scales and observational indices of susceptibility. Although some existing self-report measures have been found to predict differential susceptibility as well as vantage sensitivity (for example, sensory-processing sensitivity, Aron & Aron, 1997; Pluess & Boniwell, 2015) more specific measures—validated rigorously in empirical studies—are required.

9. *Ethical considerations*. Give the potential application of differential susceptibility reasoning in clinical, educational, child care and other settings, it will be important to consider ethical challenges before applying differential susceptibility thinking to these services. Besides the mere identification of ethical challenges (e.g., systematic screening for high and low susceptibility, stigma of being found high or low in susceptibility, treating individuals differently given their susceptibility) it will be important to explore solutions for dealing with these potential problematic issues (e.g., offering alternative treatments rather than no treatment to low susceptible individuals).

GENERAL CONCLUSION

One of the most striking features of the empirical work reviewed in this chapter is how diverse the evidence base for differential susceptibility is, involving a myriad of developmental experiences and environmental exposures (e.g., parenting, child-care quality, life events, rural vs. urban residence, birth season), numerous phenotypic outcomes from different developmental periods (e.g., disorganized infant attachment, externalizing problems in childhood, antisocial behavior in adolescence, depression throughout adulthood), and distinct susceptibility factors (e.g., temperamental and other behavioral attributes of children, physiological and genetic characteristics).

Beyond highlighting empirical evidence for differential susceptibility, we have sought to emphasize the utility of thinking about development from an evolutionary perspective, without which the differential susceptibility framework seems unlikely to have emerged. Indeed, what is striking is how simple a concept differential susceptibility appears to be. It thus seems likely that failure to appreciate that there are individual differences in developmental plasticity, whether general or specific in nature, has been due, at least in part, by the general lack of an evolutionary orientation among many students of human development and related disciplines.

Beyond documenting the utility of an evolutionary perspective, one great benefit of differential susceptibility reasoning is its generativity—in stimulating new thinking and thus new avenues of research about the human development process. We thus feel confident that differential susceptibility thinking will continue to inspire, stimulate, and guide empirical and theoretical research efforts in human development and look forward to the scientific progress this should occasion.

INTRODUCTION

A History of the Nature–Nurture Culture Wars

Modern technology is advancing and refining scientific knowledge at an unprecedented pace. In the three decades between the graduate academic training of this chapter's authors, significant shifts in the nature vs. nurture debate have occurred. And now, as we write this chapter, trainees are being steeped in a more-evolved formulation, representing yet another qualitative shift in understanding. While quickly paced paradigm shifts are somewhat commonplace in science, these nature–nurture debate shifts are particularly striking when one considers the centuries that passed with little progress in this argument before these more recent, rapid advancements.

Students of philosophy will note that the *nature versus nurture* debate is centuries old. The debate rose to popular public awareness in the seventeenth century, when French philosopher René Descartes proposed that individual humans each possess certain innate ideas that underpin our approach to the world—a stance that was later strongly contested by British empiricists, exemplified by John Locke's claim that humans were blank slates upon which experience marks its influence, fully shaping behavior. In 1874, Francis Galton, a second-cousin to Charles Darwin, presented a more integrated view of the influence of genetics and environment on a person's development, stating: "[Nature and nurture are] a convenient jingle of words, for it separates under two distinct heads the innumerable

Preparation of this chapter was supported in part by funds provided by the UCSF Divisions of Child and Adolescent Psychiatry and Developmental Medicine to Dr. Bush. Dr. Bush is an Assistant Professor of Pediatrics and Psychiatry and the Associate Director of Research for the Division of Developmental-Behavioral Pediatrics at UCSF. Dr. Boyce is the Lisa and John Pritzker Distinguished Professor of Developmental and Behavioral Health in the Departments of Pediatrics and Psychiatry at UCSF; he is also a Senior Fellow and Codirector of the Child and Brain Development Program at the Canadian Institute for Advanced Research (CIFAR). We thank the Robert Wood Johnson Foundation Health and Society Scholars Program, the CIFAR, the John and Lisa Pritzker Family Foundation, and the National Institutes of Health for supporting our work.

elements of which personality is composed. Nature is all that a man brings with himself into the world; nurture is every influence that affects him after his birth" (Galton, 1874, p. 12). Although this latter approach considered both nature and nurture when describing development, both were presented as separate, unique entities with different time courses of effect. This type of dual conceptualization was carried forward into the study of disease over the next century. Few trains of thought were more integrative than the predominant dual conceptualization allowed, though historians note that Freud was one of the first to integrate contrasting conceptualizations of psychiatric disease as both hereditary and environmentally acquired through childhood experiences, which is one likely reason for the endurance of his thinking (Sulloway, 1992). However, by and large, the leading investigators and scholars within the field of developmental psychopathology were academically reared within a scientific generation marked by a confluence of two distinctive views of the origins of human disorders. Within this single generation, physicians, clinical and developmental psychologists, social workers, and laboratory investigators were steeped in the twin agendas of environmental and biological determinism.

In the environmental determinism view, prominent in the scientific world of the 1960s and 1970s, disease and disorder were held to be products of contextual exposures and adversities. Human afflictions, it was believed, were due almost exclusively to the acute and chronic, cumulative influences of environmental agents of disease. Such agents included psychological stressors, impoverished living conditions, physical toxins, infectious pathogens, and inadequate or malevolent parenting. In the field of psychopathology, disease formulations were particularly influenced by behaviorist theories of B. F. Skinner and John Watson, who famously claimed, "Give me a dozen healthy infants . . . and my own specified world to bring them up in and I'll guarantee to take any one at random and train him to become any type of specialist I might select—doctor, lawyer, artist, merchant-chief and yes, even beggar-man and thief, regardless of his talents, penchants, tendencies, abilities, vocations, and race of his ancestors (Watson, 1930 p. 82)." Within this nurture framework of behavior and disease, schizophrenia was misleadingly viewed as the product of psychological double-binds within dysfunctional family units, autism was regarded as the legacy of cold, distant mothers, and maternal overprotectiveness figured prominently in the presumed etiology of childhood anxiety disorders. Thus, prevention and treatment were taken to require alterations in the range of causative environmental exposures.

Within a second canonical view, emerging at the pinnacle of the first by virtue of a revolution in molecular biology, human disorder was thought principally to be the result of biological frailties built into the structure of the heritable genome. Individual genetic differences, occurring on average in one of every thousand nucleotide base pairs, became seen as likely biological substrates for many human disorders, and quantitative trait loci (QTLs) were thought to constitute the multiple gene systems that, in isolation, code for variation in complex behavioral traits (Plomin & Crabbe, 2000). Most if not all disease, it was posited by some, would one day become explicable within the frameworks of evolutionary biology and human genetics, and eagerly anticipated gene therapies would transform the treatment and prevention of disordered biology. Thus, Alzheimer disease would one day be accounted for by mutations in the gene coding for apolipoprotein E4; a polymorphism in the promoter region of the serotonin transporter gene would eventually elucidate anxiety disorders and phobias; and the long repeat allele of the DRD4 dopamine receptor gene would explain the etiology of ADHD and other externalizing behavior problems. Within 3 decades' time, two opposing and mutually exclusive causal orthodoxies captured and held the high ground of scientific discourse on the genesis of human disease.

Early Evidence for Biology–Context Interactions

Vulnerabilities in both positions first became evident as three bodies of research findings emerged in the final years of the twentieth century. First, the nascent field of behavior genetics increasingly documented shared genetic and environmental accounts for variance in the incidence and severity of a broad array of behavioral and psychopathological disorders (Plomin, DeFries, McClearn, & McGuffin, 2001). Using heritability statistics derived from genetically informative research designs, behavioral geneticists became able to decompose phenotypic variance into genetic and environmental components. The genetic component was further subdivided into additive and nonadditive effects, and the environmental component was parsed into shared and nonshared influences (Goldsmith, Gottesman, & Lemery, 1997). While the neuroscience of schizophrenia provided compelling evidence for a heritable disorder of the brain, epidemiological studies revealed that, even among monozygotic twins, the concordance rate for a diagnosis of schizophrenia never exceeded 50%. Schizophrenia was demonstrably a biological disorder with heritable components, but as much as half of the variance in its rate of occurrence was attributable to environmental exposures. The science of behavior and development thus faced a Kierkegaardian dilemma (Kierkegaarad, 1986 (1843)), in which an uncompromising either–or became a more illuminating both–and. Schizophrenia, like

virtually all forms of human behavior (Rutter et al., 1997), became understood as a product of both biological and contextual etiologies.

A second set of findings revealed the previously unsuspected bidirectional influences of biology and context, each on the other. While it had become apparent that genes affected both normative and disordered human behavior, new evidence indicated: (1) the heritability of environmental experience, and (2) the potentially profound regulatory effects of social environmental exposures on the transcription of DNA. Discoveries of such bidirectional effects led to a recognition of genotype-environment correlations and to the categorization of such correlations into passive, reactive, and active forms (Plomin, DeFries, & Loehlin, 1977). Studies by Plomin and colleagues demonstrated heritable influences on parental behavior and the home environment (Braungart, Fulker, & Plomin, 1992; O'Connor, Hetherington, Reiss, & Plomin, 1995), and other work showed that even random misfortune, such as stressful events (Kendler, Neale, Kessler, Heath, & Eaves, 1993) and the loss of friends (Bergeman, Plomin, Pederson, McClearn, & Nesselroade, 1990), were partly attributable to genetic variation. Animal research by Meaney and colleagues demonstrated that brief maternal separations among rat pups alter maternal behavior, leading to down-regulation of the CRH system and diminished adrenocortical reactivity extending even into adult life (Anisman, Zaharia, Meaney, & Merali, 1998). Other studies in mice found that disruption of social hierarchies led to viral infection-related mortality, which was attributable to an over-expression of genes for cytokine proteins (Sheridan, Stark, Avitsur, & Padgett, 2000), and that caloric restriction prevented aging-related alterations in the expression of genes governing protein metabolism (Lee, Klopp, Weindruch, & Prolla, 1999). While both environmental and biological determinism assumed impenetrable divisions between contexts and genes, new evidence revealed a capacity for the genome to influence environmental experience and for social and physical environments to switch on and off the decoding of genetic material (Cacioppo, Berntson, Sheridan, & McClintock, 2000). Social experience became a heritable predisposition, and the transcription of genes became a process governable by the character of social experience.

The third source of vulnerability in the twin dogmas of biological and environmental determinism at the turn of this century was the accelerating emergence of evidence for biology–context interactions in studies of disease etiology. Much of the work examining biological and contextual contributions to pathogenesis was initially preoccupied with partitioning variance into the two distinctive categories of causal factors. Other studies began to illuminate how the interplay between biology and context serves a central etiologic role. Mednick, Gabrielli, and Hutchings (1987), for example, found that a child's rearing by an adoptive parent with a criminal conviction did not increase the likelihood of criminality in the child, unless one of the child's biological parents had also been convicted of a crime. Similarly, a polymorphism in the promoter region of the gene encoding corticotrophin releasing hormone (CRH) was shown to moderate the association between maternal stress and preterm birth (Wang et al., 2001). Self-perceived maternal stress was associated overall with pregnancies that were an average of 1.3 weeks shorter, but when a mother possessed a variant allele of the CRH gene, perceived stress was associated with a 2.9-week shortening. Another example was the finding that a polymorphism in the monoamine oxidase A (MAOA) gene promoter moderated the association between early life trauma and increased risk for antisocial behavior, such that the increased risk for individuals abused as children was higher for those carrying the genotype that confers lower levels of MAOA expression but those carrying the genotype that confers higher levels of MAOA expression were somewhat buffered from this maladaptive effect (Caspi et al., 2002). Even in so-called monogenic diseases, such as phenylketonuria, phenotypic expression of the disease depends upon dietary exposure to phenylalanine, suggesting environmental factors influence disease severity and course (Scriver & Waters, 1999). Common to each of these examples is a biogenetic vulnerability that amplifies the pathological effects of a social or physical environmental exposure.

Taken together, those emerging lines of evidence constituted a convincing empirical threat to a monodeterministic view of pathogenesis, and a race to integrate biology and context into a coherent model ensued. Accumulating evidence from the past few decades has made real the current position that, while human morbidities will undoubtedly be identified that have their origins in solely genetic or environmental causes, variation in the onset and course of *most* human disorders will be most likely ultimately explained by interactions among biological and environmental forces (Rutter, 2006; Weatherall, 2001).

As a field, we have moved past the simple partitioning of developmental variance into genetic and environmentally determined components and into the examination of more complex and potentially rewarding questions of genetic change and continuity, relations among dimensional symptoms and diagnosable psychopathology, and the interplay between biology and context (Meaney, 2010; Plomin & Crabbe, 2000). This chapter will outline some of the theories and empirical evidence for biology and context interactions in the etiology of healthy and pathological psychosocial development, with an eye toward highlighting

the conceptual and methodological controversies in this work and translational implications. We also describe the challenges awaiting a new generation of investigators and theorists poised to bring the nature–nurture discussion into its next evolutionary form.

SENSITIVITY TO CONTEXT WITHIN A DEVELOPMENTAL PSYCHOPATHOLOGY FRAMEWORK

Within the field of developmental psychopathology, as well as in the broader fields of medicine and biology, there is a strong focus on discovery of the mechanisms by which environmental forces get under the skin to affect health. Using the term *biological embedding* (Hertzman & Wiens, 1996) to describe the process whereby differential human experiences systematically affect health across the life cycle, Hertzman (1999, 2012) provided an articulation of the range of potential processes for these effects. Placing special emphasis on early development, he offered a hypothesis that systematic differences in early environment quality, including emotional and physical support and stimulation, will affect the neurochemistry and shaping of the central nervous system in ways that will adversely affect cognitive, social, and behavioral development. Although myriad biologic processes may be affected by social experience, some candidate systems are more likely to transduce social environmental factors into aspects of human biology with the capacity for embedding and influencing mental or physical health throughout the rest of the life course. Hertzman and Boyce (2010) identified four systems that are influenced by daily experience, respond to experience throughout an organism's development, have meaningful impacts on health/learning/behavior, and are known to function differentially in response to variations in early experience. The four systems comprise: (1) the hypothalamic-pituitary-adrenal (HPA) axis and its expression of the glucocorticoid, cortisol; (2) the autonomic nervous system and its neurotransmitters, epinephrine and norepinephrine; (3) the prefrontal cortex, subserving memory, attention, and other executive functions; and (4) systems for social affiliation involving connections between the amygdala, locus coeruleus, and higher order cerebral connections, which are mediated by serotonin and other neurohormones. Other systems, such as the mesolimbic dopamine system, which mediates attentional processes, reward seeking, learning and behavioral engagement, and biological processes such as epigenetic modifications of neuroregulatory genes and telomerase activity are emerging as likely processes by which biological embedding occurs. Despite the plausibility of biological embedding and the champions behind it, and that nationally representative studies have shown that adverse experiences early in life predict nearly 45% of childhood-onset and 30% of adult-onset psychopathology (Green et al., 2010), there is surprisingly little research on the early life effects of social environment on biology. Thus, the increasing attention to this gap in the empirical literature is merited. However, while understanding the mechanistic (i.e., mediation) processes by which an environmental exposure is linked to disordered development can be a powerful aid to elucidating pathogenesis and imagining novel interventions, understanding of mechanistic linkages, although perhaps necessary, is insufficient for a comprehensive understanding of causation. The quest for accurate determination of the mechanisms underpinning associations across early social contexts, stress, development, and psychopathology necessitates elucidation of the effects of modifiers (i.e., moderators) that reveal when, at what ages, or in what subgroups such associations hold (Baron & Kenny, 1986; Kraemer, Kiernan, Essex, & Kupfer, 2008; Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001).

NEUROBIOLOGICAL SENSITIVITY TO CONTEXT THEORIES AND EVIDENCE

Contexts and experiences do not have universal influence across individual organisms, and the parsing of populations into subgroups of varying exposure susceptibility, through the discovery of moderator variables, can advance comprehension and the tractability of a given association between experience and pathology outcome. Indeed, the modern movement toward precision medicine (National Research Council, 2011) is, in part, motivated by the clinical advantage of identifying patients who are more susceptible to certain diseases, who will respond to treatments differently, and whose diseases or conditions may progress on a different course than others in the general population. Psychology has paid particular attention to understanding organismic factors (e.g., gender, IQ, and impulsivity) that place some individuals at greater risk for development of problems in adverse environments. This diathesis–stress or stress–vulnerability model (Figure 3.1) has been a prevailing view within medical and psychological frameworks since the 1960s, and emphasizes how individuals possessing biological vulnerabilities are most likely to develop functional impairments when exposed to particular stressors (for a review, see Ingram & Luxton, 2005). This framework is often conceptualized as a multicausal developmental model that proposes multiple risk factors across levels interact over the course of development, which has been remarkably useful in advancing

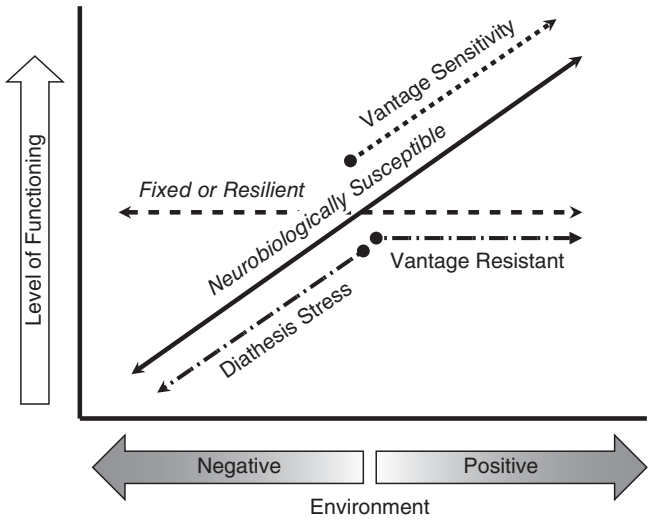

Figure 3.1 Visual model of various theoretical concepts of sensitivity to environment.

understanding of individual variability in stress response and risk for pathology. Perhaps the most famous case of biologic sensitivity to adversity is the 2003 finding of Caspi and Moffitt's group (Caspi, Sugden, Moffitt, Taylor, Craig, Harrington, McClay, et al., 2003), who pioneered longitudinal family gene–environment (GxE) research using their Dunedin study of roughly 1,000 individuals tracked over 40 years. Their 2003 paper linked experiences of childhood maltreatment with higher levels of adult depressive symptoms, but only among those possessing one or two copies of the short allele in the promoter region of the 5-HTT serotonin transporter gene—the gene that regulates transport of serotonin to the brain. They further found that possession of the longer allele was protective against those harmful effects. This first evidence demonstrating that one allele could lead to exacerbation or buffering of the stress–illness association was received with considerable scientific and media attention, and launched a gold rush of sorts into a quest for GxE interactions in mental health. This finding has been the source of considerable debate ever since, which we describe below, but nevertheless marked a major turning point in the conceptualization of and public awareness of the manner in which individual differences in a biological marker could confer varying sensitivity to harmful contexts.

More recently, emphasis has shifted from the predominant diathesis–stress conceptualizations to a pursuit of understanding the individual difference factors that reliably allow some individuals to be anomalously resilient in the face of adversity (see Luthar & Lyman, in press; Masten, 2012; Rutter, 2012; Werner, 2012). In particular, an individual's stress reactivity appears to be an important individual difference variable that influences the manner in which an organism responds to environmental experiences (Bush & Boyce, 2014; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011; Obradović, Bush, Stamperdahl, Adler, & Boyce, 2010). Although heightened stress reactivity has traditionally been considered to be a factor that uniformly increases risk, burgeoning empirical evidence suggests instead a differential neurobiological susceptibility to environmental conditions among some individuals who show exaggerated sensitivity or permeability to both negative and positive environmental conditions (Belsky, 1997, 2005; Boyce & Ellis, 2005; Boyce et al., 1995; Ellis et al., 2011). Specifically, a theory known as biological sensitivity to context (BSC) suggested that higher levels of physiologic stress reactivity may promote adaptation in settings characterized by support, predictability, and protection, but exacerbate risk for maladaptive outcomes in stressful childhood environments characterized by adversity (Boyce, 1996, 2007; Boyce et al., 1995; Boyce & Ellis, 2005; Ellis, Essex, & Boyce, 2005b). Such individuals thus show either the least or most adaptive outcomes within the population, depending on the character of the proximal social contexts in which they are reared. BSC theory had clear parallels with Belsky's differential susceptibility theory, which emphasized the manner in which behavioral reactivity made individuals particularly susceptible to both positive and negative experiences (Belsky, 1997, 2005). Although originally devised separately, through separate streams of thought and literature, the two theories shared considerable features and are now frequently presented together and referred to as *differential neurobiological susceptibility* (DNS; see Figure 3.1; Boyce, Obradović, et al., 2012; Ellis et al., 2011; Pluess & Belsky, 2013), which is inclusive of multiple levels of endogenous susceptibility factors. Thus, in this chapter when referring to findings applicable to this integrated framework, we hereafter use this DNS term.

A range of factors across multiple levels of biology have been thought to represent or subserve neurobiological sensitivity to social contexts, including genetic variation, chromatin modification, gene transcriptional control, ANS and HPA activation, and differences in brain structure and functions. The dominant lines of DNS research have tested differential susceptibility models by demonstrating interactive effects between various types of contextual stress (e.g., marital conflict, financial stress, parental psychopathology) and psychobiological reactivity in the prediction of health outcomes (e.g., Belsky & Pluess, 2009; Boyce et al., 1995; Obradović et al., 2010). Such research finds support for the claim that associations between risky and

supportive environmental exposures and adaptation vary across different levels of stress reactivity.

In one of our lab's early empirical examinations of the DNS theory using the Peers and Wellness Study (PAWS) longitudinal community sample of 328 kindergarten children, we found support for DNS within two different biological systems and across multiple outcomes of adaptive functioning. Specifically, although children demonstrating high parasympathetic nervous system (PNS) reactivity (assessed via respiratory sinus arrhythmia) to a set of standardized challenges had the worst outcomes when they lived in families with high levels of family adversity, high parasympathetically reactive children demonstrated the highest levels of prosocial behaviors and school engagement and the lowest levels of externalizing behavior when they lived in contexts with low levels of family adversity. High parasympathetically reactive children also showed improvement in academic competence from fall to spring of the kindergarten year in the context of low adversity but declines in competence in the context of high adversity; whereas the inverse was true for low reactive children. In a similar fashion, children demonstrating high HPA axis reactivity (assessed via salivary cortisol) to the challenge protocol had the highest levels of prosocial behavior in the sample when they were in family contexts with low levels of adversity but the lowest levels of prosocial behavior when they were in family contexts with high adversity. The results of this study provided strong support for DNS in that the findings were relatively robust, particularly for parasympathetic reactivity, which emerged as a significant moderator of family environment across four domains of child adaptation—each pattern of which was consistent with BSC or DNS theory. Moreover, the DNS interactions were found for both positive and negative indices of adaptation, which are rarely examined simultaneously in empirical reports and allow for the test of the theory across a continuum of adjustment. These findings within a typically developing sample were also exciting because they suggested that, if stress reactivity moderated the effects of adversity on development in a community sample of children, who on average do not face extreme disadvantage or show clinical levels of problem behavior, the interactive effects are likely to be larger at the extreme ends of such distributions.

Essex, Armstrong, Burk, Goldsmith, and Boyce (2011) tested DNS theory in a longitudinal sample of children to understand the roles of physiological and behavioral reactivity to the environment of classroom climate in the prediction of mental health symptoms across a 6-year period of childhood. Measuring both positive (teacher–child closeness) and negative (teacher–child conflict) aspects of the classroom environment in first grade, they found that both autonomic (mean arterial blood pressure) and behavioral (objectively coded temperamental inhibition) reactivity moderated the impact of classroom climate on mental health problem severity in seventh grade, after adjusting for mental health problem severity in first grade. It is striking that all four biological sensitivity to context × teacher–child relationship interaction terms were statistically significant demonstrating DNS moderated associations of both adverse and supportive aspects of the early teacher–child relationship on the development of early adolescence symptom severity.

Even within samples of children reared in poverty, wherein all study children are experiencing significant socioeconomic disadvantage, Conrad and colleagues found clear evidence that phenotypic reactivity can confer sensitivity to the risks and advantages conferred by other environmental factors such as objectively coded attachment security. In their study of infants born into disadvantaged conditions, infants with high baseline respiratory sinus arrhythmia (RSA) who were raised in contexts of high security had lower levels of problem behavior (actually below community norms), and infants with high baseline RSA who were raised in caregiving environments that fostered disorganization had the greatest number of problem behaviors at 17 months. Attachment security did not relate to problem behavior for infants with low RSA. These differences were also evident in the large effect sizes for these varying associations. These findings bolster evidence that poverty is not a uniform risk for problem behavior, particularly for children raised by nurturing caregivers; but they also reveal that children high in basal RSA are best able to take advantage of such opportunities and most at risk for harm if not provided with sensitive, responsive caregiving environments. Raver, Blair, and Willoughby's (2013) work also demonstrates that even in low-income populations, variation in temperamental reactivity can confer sensitivity to variations in the stressors of poverty. Although chronicity of poverty shows a negative linear association with young children's effortful control, their study found that it had no association for children low in reactivity. However, children high in reactivity demonstrated the highest levels of effortful control when they were not from families with chronic financial strain but the lowest levels of effortful control when they resided in the most chronically poor families—thus, demonstrating the *for-better-or-for-worse* effect even within a population with a restricted range of income.

Researchers using sophisticated modeling techniques on data from the Caucasian subsample of 1,030 adolescents and young adults from the nationally representative National Longitudinal Study of Adolescent Health have recently provided a compelling example of how sensitivity via a polymorphism in the serotonin transporter gene (5-HTTLPR) can convey DNS (Li, Berk, & Lee, 2013). Despite the widely demonstrated effects of high-quality family support on depression, they found that level of family support (cohesion, communication, and warmth) had little to no effect on depression scores in male individuals with the ll genotype. However, male s-carriers in families with high levels of support had the lowest levels of depression in the sample while s-carriers in families with the lowest levels of support had high levels of depression. This interaction was only marginally significant for females. Findings within this large representative sample, and across a broad range of environmental exposure (low to high quality of family support), have added support for DNS theories.

Studies demonstrating this greater susceptibility of neurobiologically responsive children to both positive and negative aspects of their environments have now included a wide variety of the following:

Stressors and adversities: peer victimization and aggression (Rudolph, Troop-Gordon, & Granger, 2010, 2011); parental depression and antisocial behavior (Cummings, El-Sheikh, Kouros, & Keller, 2007; Shannon, Beauchaine, Brenner, Neuhaus, & Gatzke-Kopp, 2007); marital conflict (El-Sheikh, 2005; El-Sheikh, Keller, & Erath, 2007); overall family distress (Obradović et al., 2010); child maltreatment (Grazioplene, DeYoung, Rogosch, & Cicchetti, 2013)

Positive environments: parental warmth (Ellis, McFadyen-Ketchum, Dodge, Pettit, & Bates, 1999); supportive child-care settings (Phillips et al., 2012); supportive interventions (Bakermans-Kranenburg, Van, Pijlman, Mesman, & Juffer, 2008)

Defining behavioral and biological parameters: temperament (Lengua, 2008; Pluess & Belsky, 2009) and personality (Grazioplene et al., 2013); physiologic reactivity (Alkon et al., 2006; Boyce et al., 1995); structural and functional differences in brain circuitry (Whittle et al., 2011); gene polymorphisms (see Belsky & Pluess, 2009 for a review; Knafo, Israel, & Ebstein, 2011; Manuck, Craig, Flory, Halder, & Ferrell, 2011)

Further, there is evidence for differential susceptibility across positive and negative types of environment as described previously but also for differential susceptibility to experience across the variety of characters that play important roles in children's lives, including mothering (Conradt, Measelle, & Ablow, 2013; Davies & Cicchetti, 2014), fathering (Boyce et al., 2006), quality of child-care settings (Pluess & Belsky, 2009), and teacher relationships (Essex et al., 2011). Most importantly, this body of literature reveals that highly susceptible children show bidirectional effects on outcomes in contrasting low- and high-stress settings, not simply an attenuation of negative effects in low-stress circumstances.

Implications for Conditional Adaptation

Within the Biological Sensitivity to Context Theory body of work, Boyce and Ellis (2005) also argued, in the second, less extensively explored component of the theory, for the importance of considering U-shaped associations, predicted from evolutionary principles, between the stressful versus supportive character of early rearing environments and the proportion of individuals evincing highly reactive phenotypes. The second of the 2005 papers advancing the BSC theory provided provisional evidence from two studies supporting the postulated U-shaped association between adversity and the prevalence of high reactivity phenotypes (Ellis, Essex, & Boyce, 2005a). The character of early contextual experiences likely plays a role, through conditional adaptations, in *shaping* the development of children's physiology. Those raised in stimulating and nurturing contexts may disproportionately acquire heightened biological sensitivity as a means of maximizing the advantages of resources and opportunities therein. On the other hand, children reared in harsh, threatening environments might also develop greater biological sensitivity to enhance vigilance to threats and other hazards. In contrast, the majority of children, raised within species-typical environments falling within these two extremes, may acquire diminished, more normative biological sensitivity, as the environments to which they are exposed are neither highly nurturing nor highly threatening (see Ellis & Boyce, 2011; Ellis et al., 2011 for the full argument in this regard). More recently, the concept of differential susceptibility has been usefully elaborated in a more detailed evolutionary framework referred to as the adaptive calibration model (ACM; Del Giudice, Ellis, & Shirtcliff, 2011). The ACM is a theory of developmental programing that focuses on calibration of organismic stress response systems and life history strategies in response to local environmental conditions. The ACM framework emphasizes a model of highly variable inter-individual patterns of stress responsivity

across life stages, prototypical responsivity patterns, the emergence of sex differences, and the primacy of the adaptive nature of long-term changes in biobehavioral systems, which its authors suggest promotes cross-field theoretical and research integration.

Boyce, Ellis, and colleagues thus suggest that high-reactivity phenotypes will be most prevalent in the contexts of low and high adversity exposure. In accordance with this theory, a U-shaped association between adversity and physiologic reactivity could provide for diverging trajectories of subsequent mental health over time. For example, although high reactivity may be adaptive across very low and very high stress contexts in the short term, as high reactivity becomes established (i.e., canalized), subsequent exposures to adversity over time would predispose the highly reactive individual to disorders of mental health. However, only longitudinal studies of the interplay between environmental effects and stress reactivity, starting with prenatal development and within broadly variable social contexts, can provide credible empirical evidence for this hypothesis. Moreover, to date, research has rarely considered U-shaped associations despite the value to be gained from understanding with greater precision the shape of associations between contextual stressors and the biological systems that contribute to psychopathology.

Three papers specifically explore curvilinear influences of early environmental stressors on the development of physiologic systems, specifically the HPA axis. Gunnar and colleagues (Gunnar, Frenn, Wewerka, & Van Ryzin, 2009) reported that children with moderate levels of early life adversity demonstrated lower cortisol reactivity to laboratory stressors than did children with either low or high levels of adversity, providing additional evidence for curvilinear associations between early life stress and HPA axis regulation. A second study, using a sample of young adults, found a curvilinear effect in the opposite direction from that proposed by BSC theory and found in Gunnar et al.'s study. Engert and colleagues (2010) found evidence for an inverted U-shaped relation between retrospective self-report of levels of maternal care received in childhood and young adults' cortisol stress reactivity, such that stress-induced cortisol levels for low- and high-maternal care groups were lower than for those in medium-care group. Such divergent patterns found between studies may result from meaningful differences in developmental timing of physiological assessment, intensity of the stressors, and factors such as retrospective reporting of stressors vs. concurrent or prospective assessments. Both studies examine effects on reactivity to laboratory stressors, which may not generalize to daily levels of physiologic load that are more relevant to allostatic load. A third paper, a review by Macri et al. (Macri, Zoratto, & Laviola, 2011), summarizes evidence from laboratory rodent studies and suggests that the link between neonatal stress exposures and adult phenotypic reactivity follows a U-shaped, curvilinear relation. The conclusions of these three papers support, at the very least, further consideration of curvilinear associations between early life stress and HPA axis regulation.

Recent work from our laboratory provides some additional evidence. Using an ethnically diverse longitudinal sample of 338 kindergarten children, we examined the effects of cumulative contextual stressors on children's developing HPA axis regulation (Bush, Obradovic, Adler, & Boyce, 2011). Chronic HPA axis regulation was assessed using cumulative, multiday measures of cortisol in both the fall and spring seasons of the kindergarten year. Hierarchical linear regression analyses revealed that contextual stressors related to ethnic minority status, SES, and family adversity each uniquely predicted children's daily HPA activity and that some of those associations were curvilinear in conformation. Results showed that the quadratic, U-shaped influences of family SES and family adversity operate in different directions to predict children's HPA axis regulation such that children from both the low and high SES families demonstrated higher levels of daily cortisol than their peers from middle-SES families and children from families with moderate adversity demonstrated higher daily cortisol than did those at either end of the adversity continuum. Results further suggested that these associations differed for white and ethnic minority children, with the opposing patterns of findings potentially reflecting different biological responses to environmental adversity by subgroup or different ranges of exposure to the stressors within subgroups. In total, this study revealed that early childhood experiences contribute to shifts in one of the principal neurobiological systems thought to contribute to allostatic load, and findings suggested that analyses of allostatic load and developmental theories accounting for its accrual would benefit from an inclusion of curvilinear associations in tested predictive models.

A further consideration is that the preponderance of differential susceptibility research has examined the manner in which biology and context interact to predict psychopathology symptoms or diagnoses. More recently, we have investigated the manner in which "stress sensitive" alleles moderate the effects of early life adversity on stress physiology early in development—a phenotypic predictor of later development across a broad array of health outcomes. Exploring the established negative association between SES and chronic cortisol arousal in children,

Bush and colleagues found that both 5-HTTLPR and BDNF genotype moderated the effects of early life family SES on children's chronic daily cortisol arousal (Bush, Guendelman, Adler, & Boyce, 2013a, 2013b), such that children with the l/l genotype of the serotonin transporter or who are carriers of the BDNF met allele had the highest chronic cortisol levels when growing up in low SES homes, but the lowest levels when growing up in high SES homes. Strikingly, for s carriers and Val/val genotypes, SES did not affect chronic daily cortisol levels. Beyond providing additional examples of DNS (and contributing to the small literature demonstrating that l/l genotypes are most sensitive to some environments (see, for example, Davies & Cicchetti, 2014), this work highlights how susceptibility via one biomarker (genes) can influence stress sensitivity in other systems (HPA axis arousal).

Evidence of Differential Susceptibility Within Positive Environments

As a result of the field's focus on contextual risk for pathology over contexts that promote optimal development, the majority of studies reviewed above emphasize the negative impacts of adverse exposures or deprivation on children's neurobiology. These studies tell us little about whether enriched environments produce optimized neurobiological development of the same magnitude as that negatively affected by adverse environments. A few studies, however, do point to enhanced sensitivity to positive environments. One excellent example is the work by Knafo and colleagues (Knafo et al., 2011) who used a sample of 168 twin pairs of Israeli preschool-aged children to parse genetic and environmental effects and investigate whether the 7-repeat allele of the dopamine receptor D4 (DRD4) would confer enhanced sensitivity to positive parenting. They found that positive parenting predicted maternal-rated prosocial behavior, but only for 7-repeat carriers. Similar findings occurred in a Dutch study in which 7-year-old children who were securely attached to their parents had higher rates of experimentally induced sharing assessed by willingness to donate their recently earned money to charity, but only for 7-repeat carriers (Bakermans-Kranenburg & van IJzendoorn, 2011). Additional evidence can be found from a study that found that the highest levels of social integration within objectively coded high-quality childcare settings was demonstrated by the most temperamentally reactive toddlers (Phillips et al., 2012). Together, these studies suggest that a variety of indices of sensitivity allow for increased sensitivity to enriched or optimal environments, yet many more studies in this area are needed to discern whether the sensitivity to both positive and negative environments is similar in magnitude and frequency.

Studies of differential susceptibility to adversity also do not help us ascertain whether extremely enriched contexts might counteract detrimental effects of adversity. However, a new literature is pointing to evidence for enhanced sensitivity to interventions, which represent positive environments designed to ameliorate negative effects of context on trajectories of mental health.

The Bucharest Early Intervention Project, for example, is a novel study where institutionally reared Romanian children who had been abandoned in the first few years of life were randomized to either remain under institutional care or be placed in (relatively) enriched environments via in-home foster care placements (Nelson et al., 2007). It has provided compelling evidence for differential susceptibility to adversity and intervention effects (i.e., both negative and positive environments). Specifically, children with one of the more sensitive genotypes (in this study, the 5-HTTLPR s/s or BDNF Val66Met met-carriers) demonstrated the *lowest* levels of indiscriminate behavior in the enriched foster care environment and the *highest* levels in the continued institutionalization context (Drury et al., 2012). Children with either of the less sensitive alleles (in this study, 5-HTTLPR l-carriers or of BDNF val/val) demonstrated little difference in levels of indiscriminate behaviors over time and no group × genotype interaction. Strikingly, this pattern was amplified when GxGxE tests were conducted, revealing that the DNS effect was largest for children with both sensitive genotypes, relative to those possessing just one, and children with no plasticity alleles demonstrated no intervention effect on levels of indiscriminate behavior over time.

Additional evidence can be found in more typically developing samples in the United States. In a randomized controlled trial of 169 families, only highly irritable infants showed positive benefit from an intervention designed to improve attachment security (Cassidy, Woodhouse, Sherman, Stupica, & Lejuez, 2011). Likewise, in a randomized controlled trial of 985 low birth weight infants from the Infant Health and Development Program, Blair (2002) found that a comprehensive compensatory education intervention had a substantially stronger effect on cognitive functioning and externalizing behavior outcomes for infants with greater temperamental negativity (Blair, 2002). In addition, preliminary analyses of a longitudinal evaluation of a clinical intervention for school-aged boys with disruptive behavior disorder found that only those with high cortisol reactivity prior to treatment showed decreases in parent-rated aggression and oppositional behavior after

treatment (van de Wiel, van Goozen, Matthys, Snoek, & van Engeland, 2004). Bakermans-Kranenburg and colleagues (2008) also found that DRD4 7-repeat carriers were more sensitive to an intervention designed to increase maternal positive discipline within families struggling with or at risk for child externalizing behavior problems; not only were the intervention effects on decreasing externalizing behavior strongest for 7-repeat carriers, but the association was also graded such that the effects were largest when mothers had better adherence to the goals of increased positive parenting.

Particularly compelling is recent evidence from two randomized alcohol use prevention trials involving more than 900 African American youths presented by Brody and colleagues (Brody, Chen, & Beach, 2013). This group found that variation in dopaminergic (DRD2, DRD4, and ANKK1) and GABAergic (GABRG1 and GABRA2) genes predicted alcohol use across a 2-year period of adolescence such that genetically at-risk youth within the control condition displayed greater levels of alcohol consumption but genetically at risk youth assigned to the prevention condition showed the lowest levels of consumption. Strikingly, when adolescents were coded based on how many of the risk genes they possessed (a multilocus genetic score in this study) an interaction predicting longitudinal change in alcohol use revealed that youth carrying greater numbers of the risk genes showed the greatest increase in alcohol use if in the control condition but greater responsiveness to prevention (smaller increases in use) than carriers of zero or one risk gene. The large sample size and randomization increase confidence in these findings.

Intervention Effects on Susceptibility

In addition to thinking about differential susceptibility to interventions, it is important to consider how interventions might improve risk-associated phenotypic reactivity or sensitivity in a manner that affects later susceptibility to environment. Prospective research has found that parental responsivity during early childhood predicts adolescent cortisol reactivity to social stressors, even after adjusting for subjective appraisals of the stressor, other environmental risk factors, and current psychosocial functioning (Hackman et al., 2013). This points to interventions targeting parental behavior as potentially important for the shaping of neurobiological susceptibility to environment. Thus far, the limited empirical investigation of intensive interventions suggests that, although they may not be entirely reversible, some harmful effects of biological embedding of early adversity can be overcome. For example, promise for recovery through intervention can be found in the recent results of primate rearing experiments. Although peer-reared monkeys exhibited higher cortisol levels in infancy and in response to stress, relative to mother-reared monkeys, 16 months after monkeys were relocated to a large social environment consisting of infants from all experimental rearing conditions, rearing groups were indistinguishable from one another physiologically and behaviorally (Dettmer, Novak, Suomi, & Meyer, 2012), suggesting transition to more normative environments can allow for recalibration of systems over time. The Bucharest Early Intervention Project has also shown that early intervention to correct a deeply impoverished early environment can improve brain structure and function as well as cognitive and emotional capabilities (Sheridan, Fox, Zeanah, McLaughlin, & Nelson, 2012), suggesting the potential for catch-up brain growth in human children, even following extreme deprivation. Further results point to behavioral improvements as well, indicating that children in the foster care intervention demonstrated higher levels of positive affect and attention at both 30 and 42 months of age, and improved cognitive outcomes at age 42 and 54 months, compared with children who remained institutionalized (Ghera et al., 2009; Nelson et al., 2007). Children who were transitioned to foster care at earlier ages demonstrated the most marked improvements, suggesting sensitive periods for brain development. Studies of foster care children living in the United States have similarly provided evidence that psychosocial interventions may indeed modify children's disrupted biological systems, such as cortisol diurnal rhythms (Dozier et al., 2006; Fisher, Stoolmiller, Gunnar, & Burraston, 2007) and cortisol reactivity (Nelson & Spieker, 2013). For example, Nelson and Spieker found that an attachment promotion program with toddlers experiencing transitions in foster care placement led to increased cortisol reactivity (improvement in this context) in response to an experimental separation paradigm. There is also evidence that psychoeducation mixed with cognitive behavioral stabilizing group treatment can lead to decreases in levels of dorsal anterior cingulate cortex and left anterior insula activation to the Stroop task (thought to reflect selective attention and emotional regulation) for child abuse-related complex PTSD patients who previously demonstrated activation higher than that of matched controls (Thomaes et al., 2012). Together, these observed associations suggest some negative effects on neurobiology can be reversed or compensated for with early interventions, emphasizing the importance of both enrichment and adversity-reduction interventions in creating good

developmental environments for all children. Continued examination of intervention efforts with children exposed to early adversity and possessing stress reactivity phenotypes will broaden evidence for how contextual experience can shape the development of children's physiology and which phenotypes might be most capable of reversing ill effects on biology.

Vantage Sensitivity

In contrast to the diathesis–stress framework's emphasis on vulnerability to risk, Pluess and Belsky (2013) recently promoted a new construct of vantage sensitivity, which they argue can be distinguished from theoretically related concepts of differential-susceptibility and resilience, because it reflects variation in response to *exclusively* positive experiences as a function of individual endogenous characteristics (see Figure 3.1). They use this term to refer to the "bright side" of differential susceptibility in that some individuals are more sensitive and positively responsive to the environmental advantages to which they are exposed, be it security of attachment derived from sensitive parenting, prosocial behavior derived from supportive, healthy friendship networks, or academic achievement stemming from high-quality preschool or child care. This theoretical framework addresses some of the challenges that arise when attempting to examine certain combinations of individual characteristics and environments within a DNS framework. For example, from a DNS stance, a highly intelligent child might profit exceptionally from a high-quality education, but she may suffer disproportionately in a low-quality educational setting (perhaps due to being so smart that she disengages in the classroom and fails to learn); however a vantage sensitivity framework might allow for that child to have advantage in a good environment and no harm (unresponsive) to the adverse school environment, or even show protection from the adverse environment (increased resilience to adversity). In their review of recent empirical evidence for vantage sensitivity, they provide compelling examples featuring behavioral, physiological, and genetic factors as moderators of a wide range of positive experiences ranging from family environment and psychotherapy to educational intervention. We provide two illustrative examples here. First, in a large British cohort study, temperamentally reactive girls were more prosocial at age 6 if their fathers were highly involved in their care during early childhood, but nonreactive girls did not show any benefit of early father involvement on that outcome (Ramchandani, IJzendoorn, & Bakermans-Kranenburg, 2010). Second, Eisenberg and colleagues (Eisenberg et al., 2012) found that children high in baseline RSA activity reared in high quality home environments displayed lower aggression, whereas children characterized by low RSA levels did not benefit from the high quality environments. Pluess and Belsky pointed out in their review that much of the empirical work to date does not allow for true determination of whether individual phenotypes make one differentially susceptible to positive environments alone, because most studies with evidence for vantage sensitivity are not positioned to test whether those individuals are also more responsive to negative contexts. This situation of leaning on available data to support portions of a theory is a challenge for differential susceptibility more generally and improved study designs with breadth of measurement of contextual predictors and adjustment outcomes across negative and positive ends of those spectrums will greatly advance the field.

Cumulative Sensitivity to Environment?

Although research has spanned biological systems and often tests for DNS effects across several sensitivity markers concurrently, only recently have scientists begun to examine how sensitivities might be additive to create cumulative risk or advantage to environmental experience. In particular, Belsky and colleagues (Belsky & Beaver, 2011) have made efforts to advance this body of work through multigenic studies within larger samples, to test whether there are additive effects of purported plasticity genes. In the Add Health nationally representative sample of 1586 adolescents, they examined whether maternal parenting quality (including involvement, disengagement and attachment) predicted concurrent adolescent attentional, emotional, and behavioral self-regulation, assessed by questionnaires. Children in the sample were assessed for five gene polymorphisms with known associations with behavior and mood, including genes affecting dopamine availability and processing (DAT1, DRD2, and DRD4), the serotonin transporter gene (5-HTTLPR), and the MAOA gene, to test for cumulative sensitivity to parenting. Findings revealed that possessing increasing numbers of plasticity variants was associated with increasing sensitivity to parenting quality, such that maternal parenting quality was not associated with attentional and behavioral self-regulation for those carrying zero or one sensitivity alleles but predicted more and less self-regulation under, respectively, supportive and unsupportive parenting conditions, for those carrying two or more alleles. The pattern of findings suggested an additive effect such that the strength of the interactive association was greater with an increasing

number of sensitivity alleles. However, this effect was only found for males, and was not significant for females in this sample.

Of note, preliminary findings from our longitudinal sample of kindergarten children partially parallel this unique pattern of findings. Specifically, our findings (Allison, Bush, Adler, & Boyce, 2013) suggest that cumulative genetic sensitivity across several dopamine polymorphisms (DAT1, DRD2, and DRD4) predicts increasing severity of inattention and ADHD symptomatology later in the kindergarten school year, but only in males. However, this cumulative dopamine sensitivity variable did not significantly interact with family adversity to predict those symptoms. DAT1 alone, however, did interact with family adversity to predict inattention and ADHD symptoms in a manner consistent with the DNS theory. The variation in patterns of findings between the Belsky and Beaver analyses and those resulting from our preliminary analyses may be due to a variety of factors—a discussion of which highlights the complex challenge of establishing a body of evidence for cumulative sensitivity. First, we did not include two of the additional two sensitivity genes (5-HTTLPR and MAOA) used in their cumulative plasticity variable, as our interest was specifically in testing for cumulative effects within the dopamine pathway. Because studies rarely have exact replicates of variables for attempts at replications of findings, this sort of discrepancy will make it difficult to discern whether a specific genotype was driving the cumulative effect in a particular study and having multiple "risk" genotypes may just increase the odds that an individual possessed that particular variant. Second, we utilized different environmental variables (parenting vs. family adversity); although each are relevant exogenous influences on pathology, one measure may be more proximal for an individual child or more potent, and thus provide a better test of sensitivity to context. Third, our environmental variable had a limited positive range (lack of adversity does not necessarily imply a positive environment), and the parenting variable in the Belsky and Beaver study may have better reflected a broad range of experience in which to detect variability in response to environment. Fourth, there was an important difference in the ages assessed; the apparent cumulative sensitivity in adolescence may not manifest in a detectable manner by age 5, at least not in terms of ADHD symptomatology, which was relatively low in our community sample of young children.

Although not framed as cumulative plasticity, new findings from a sample of 120 preschool-aged children also appear to reveal how polygenic effects may add together to make individuals sensitive to environmental influences, for better or for worse. Pagliaccio and colleagues (2014) found crossover interactions such that children with greater numbers of genetic polymorphisms associated with risk of depression or higher cortisol had low hippocampal volume when they had histories relatively free of adversity but the highest hippocampal volumes when they had significant histories of adversity. The complex patterns of findings on children's hippocampal volume and risk for adjustment in the literature to date prevent us from interpreting this finding in terms of which children are better off, yet the crossover interactions found in that study provide additional data for consideration in the quest for understanding DNS.

Taking this cumulative plasticity approach is quite new, and additional work is needed to determine whether such conceptualizations and analyses will advance understanding of the etiology of developmental psychopathologies. Work such as that conducted by Brody and colleagues described above (Brody, Chen, et al., 2013), which revealed possession of greater numbers of susceptibility genes conferred increased risk for alcohol use across adolescence but greater sensitivity to a preventative intervention, is promising in this regard.

Although theoretically and statistically distinguishable from cumulative additive effects, three-way interactions among biological sensitivities and context, such as the GxGxE differential susceptibility findings reviewed earlier in this chapter, may also reflect a cumulative sensitivity or plasticity. Another example of this GxGxE effect can be found in additional work published by Brody and colleagues (Brody, Yu, et al., 2013). Within a sample of 315 African American youth, they found that those who possessed both the short (s) allele of the 5-HTTLPR gene and an allele of DRD4 with 7 or more repeats were most sensitive to the effects of the family environments on biology; whereas family environment had no effect on those who possessed none or just one of those sensitivity alleles. Specifically, individuals who experienced low levels of family support in adolescence were more likely to demonstrate high levels of allostatic load (a compilation of measures of HPA axis activity, blood pressure, and other biological markers of health) if they were both s-carriers and 7-repeat carriers. Cicchetti and colleagues have also found GxGxE effects in allostatic load models within a large multiethnic sample of 10-year-old children. Their findings revealed that maltreatment and CRHR 1 (corticotropin releasing hormone receptor 1) genetic variation affect cortisol regulation but that maltreatment and the joint effects of CRHR 1 TAT haplotype and 5-HTTLPR moderated

the effect of child maltreatment to predict internalizing symptoms (Cicchetti, Rogosch, & Oshri, 2011). Neither of these GxGxE studies presents findings that reveal the full spectrum of for-better-or-for-worse effects on adjustment due to their lack of differential susceptibility findings in better off family contexts or positive adjustment outcomes. However, they do reveal the ways multiple genes may simultaneously confer sensitivity to disadvantage via synergistic effects and point to the need for further multigene examination of sensitivity to context, particularly across positive and negative contexts and outcomes.

CONCEPTUAL AND METHODOLOGICAL ISSUES FOR EXAMINATIONS OF DIFFERENTIAL NEUROBIOLOGICAL SUSCEPTIBILITY

Impediments to Discovery

Given the difficulties of discovering biology–context interactions (Wachs & Plomin, 1991), and that the challenging factors discussed in the above section apply not only to searches for replication of cumulative sensitivity effects, but to replication of interaction findings more generally, it is all the more remarkable that such interactions are being increasingly identified and characterized in studies of human disease. GxE interactions are assessed as the differential risk effects of an exposure among individuals with different genotypes, or as the differing effects of a genotype among those who are heterogeneous with respect to exposure (Kraemer et al., 2001). As noted by McClelland and Judd (1993), field studies tend to underestimate the magnitude of interaction effects due to the nonoptimal distributions of the component variables, as the power to detect GxE interactions depends on the distributions and frequencies of the genotypes and exposures in the sample (for a discussion and examples see Caspi, Hariri, Holmes, Uher, & Moffitt, 2010). Interactions accounting for as little as 1% of outcome variance in field research may conceal a true R^2 many times that size that would be found using an optimal, experimental design. When demonstrated, biology–context interactions in human populations may disproportionately exist at the extremes of genetic and environmental variation (McGue & Bouchard, 1998). Mathematically, analyses of variance and related statistical tests often fail to identify nonadditive effects because they have much less power in tests of interactions than in tests of main effects (Wahlsten, 1990). Improved genetic research designs (Andrieu & Goldstein, 1998; Caspi et al., 2010; Dunn et al., 2011), along with statistical approaches that are more sensitive to interaction effects (Kraemer et al., 2001) and can simultaneously consider multiple genetic markers within an entire targeted region (e.g., Belsky, Moffitt, & Caspi, 2013; Yu et al., 2012), are abetting the discovery of complex interactions between and among biologically and environmentally based factors.

Single studies are likely to be capable of capturing only a portion of the underlying paradigmatic DNS interaction. As illustrated in Figure 3.2, which is adapted from a figure in our previous publication (Obradović et al., 2010), the observational window (indicated by the area within the lightly shaded square) for DNS effects shifts from study to study, and even within a particular study depending on the focus of specific publications. The observational window can shift depending on a variety of factors, including: *characteristics of the sample*, such as intentionally oversampling impoverished children or unintentionally having greater success enrolling and retaining upper SES families, which greatly influences the range and qualities of environmental exposures; *the outcomes of interest* and whether they have a positive or negative valence (such as prosocial behavior and externalizing problems respectively) or more of a continuum such as with effortful control, or whether studies are examining early phenotypic risk factors for later

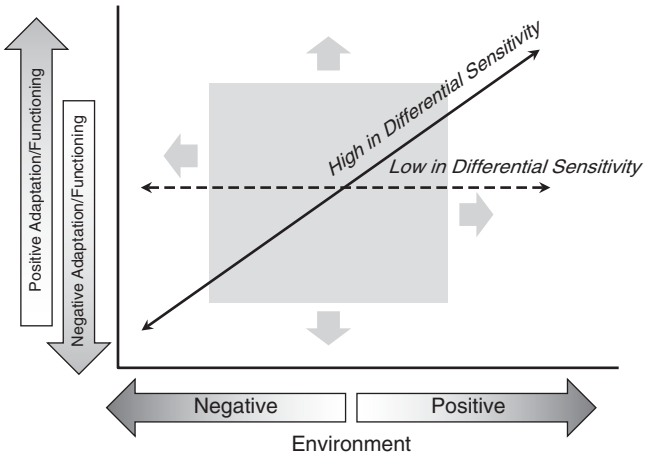

Figure 3.2 Conceptual model of the interactive effects between DNS and environmental influences, and the window of observation allowed by any one study design. Solid shaded gray area represents the window of observation by which any single study is capable of capturing a paradigmatic DNS interaction. The window can move in any direction, depending on study design and sample characteristics. *Source:* Figure adapted from previous work from our lab published in J. Obradović, N. R. Bush, J. Stamperdahl, N. E. Adler, & W. T. Boyce, Biological sensitivity to context: The interactive effects of stress reactivity and family adversity on socioemotional behavior and school readiness, *Child Development, 81*(1), 270–289, 2010. Adapted with permission from the authors.

pathology or examining extreme psychopathology (which can affect the strength of associations or the variability in your outcomes); *the measure of reactivity*, because some indices may have greater inter-individual variability, and some indices may be quite difficult to ethically elicit reactivity in, (such as purely sympathetic preejection period response in young children) which restricts the ability to detect highly reactive children; *the type of challenge or stressor used to elicit reactivity,* since some individuals may be particularly reactive to some types and not others (for example, perhaps highly stressed in contexts of social threat but not in those evaluating math performance); *developmental timing factors*, such as ways children's age or cognitive or biological development affect the capacity for studies to detect differences in phenotypic reactivity or adjustment outcome (e.g., some measures of physiological reactivity may not be appropriate early in development as the early development and functioning of those systems is not well understood); and a host of other possibilities.

For example, the observational window may shift to the left in studies of highly disadvantaged child populations or to the right in intervention studies. The window may shift downwards and flatten in studies of children with severe behavioral problems but cover more of the y axis in community samples of typically developing children with a broad range of functioning. Similarly, the slopes of the two component lines may be determined by the researchers' ability to capture the full range of stress reactivity responses, such as by truly activating the stress response system for reactive children or adequately sampling reactive and nonreactive genotypes, and thus distinguish between high and low reactive children. Failure to consider these factors in presentation of DNS findings, or in contexts when results fail to support DNS theory is an impediment to discovery, as it can lead to erroneous conclusions. It is critical, therefore, that developmental researchers examine and compare the interactive effects of stress reactivity and context across a range of outcomes and environmental influences and that the full scope of existing theories and literature be taken into account in the interpretation of such effects.

GxE Debate

As the cost of DNA testing has plummeted, an increasing number of tests of differential susceptibility are examining genetic polymorphisms as key biological plasticity factors. It is important to note that as enthusiasm for GxE studies in psychopathology has increased over the past decade, this has not occurred without controversy. The vast majority of GxE studies to date use the candidate gene approach, which focuses on associations between allelic variation within prespecified genes of interest and phenotypes or disease states. Candidate genes are most often selected for study based on a priori knowledge of the gene's biological functional impact on the phenotype or disease state being investigated. Strengths of these study designs often include: selection of both gene and environmental variables with plausible interactive biologic pathways; selection of an environmental variable with known association with the phenotype of interest; prospective and retrospective measurement of the environmental risk factor; and accepted and validated measures of the phenotype, based on *DSM-IV* (American Psychiatric Association, 2000; now *DSM-V*) criteria. Such an approach is thought to lead to accurate determination of true GxE effects.

On the other hand, candidate gene analyses, examining either main effects or a specific polymorphism's moderation of an environmental effect as in DNS models, have received criticism of late. GxE studies are notoriously difficult to replicate, and depending upon the methodology and comprehensiveness of an approach, meta-analyses have shown mixed evidence for GxE effects for even the most-studied candidate genes in psychopathology, such as the serotonin transporter polymorphism 5-HTTLPR (e.g., Karg et al., 2011; Risch et al., 2009). Such contrasting findings have advanced a robust debate among scholars, although studies with stronger methodological rigor appear more likely to replicate the original (Caspi et al., 2003) effects on depression. Additional rigorous work has extended these findings, suggesting that 5-HTTLPR confers sensitivity in the prediction of a variety of disease-related phenotypes such as hormone and inflammatory responses, brain wave patterns, and brain imaging results (Caspi et al., 2010). Recent years have led some from the field of genetics to argue that significant GxE results are likely to be the result of artifact or chance (see Rutter, Thapar, & Pickles, 2009), and that the smaller sample sizes required for these rich biological and environmental data analyses, inconsistency in which environments are selected for models, selective presentation of results, or publication bias may be inflating the appearance of a true effect. Proponents of this position often argue that genome-wide association studies (GWAS), which scan the entire genome for common genetic variation, are superior in that they avoid some of the bias problems within candidate-gene studies. Rather than beginning with a specific hypothesis about a candidate gene and psychopathology, as GxE researchers often do, whole-genome researchers typically begin with consideration of a particular disease, then examine the genomes of hundreds or thousands of people

exhibiting that disease to determine whether they possess specific genes or gene variants absent in disease-free individuals (The Psychiatric GWAS Consortium Steering Committee, 2008). This atheoretical approach is viewed by some to be more scientific, and when no genes materialize in GWAS analyses it is asserted that no genetic association exists for that disorder. However, in the decade following the decoding of the human genome, the mass of large-scale GWAS have found many promising leads, yet no clarity about causes or cures for the most prominent, heritable psychopathologies facing our society. Although genome-wide approaches to identify loci involved in GxE interactions have recently begun to appear, they have yet to establish significant GxE interactions in common or well-documented sensitivity alleles (Aschard et al., 2012), leading to increased skepticism for the GxE framework.

A crucial problem in this debate is that GWAS research is not able to test properly for DNS for a variety of reasons:

1. It is quite common that no significant main effects are found when true interactions exist, because crossover effects are masked due to the average level of outcome resulting from some individuals with the gene having very poor outcomes and others, also with the gene, having very good outcomes (see Rutter et al., 2009 for a discussion),
2. GxE effects of interest are not typically detectable in population-based whole-genome studies because such studies rarely examine environmental factors, and when they do it is often with one item, retrospective reporting, or other limiting methodologies, and
3. Very large surveys typically conducted for GWAS generally assess a particular categorical disease outcome, rather than a full continuum of positive and negative behaviors (such as emotion regulation), which is the hallmark of DNS (see Caspi et al., 2010 for a discussion of some of these and other issues).

Even well-designed genome-wide environmental interaction (GWEI) studies face a broad range of methodological and statistical challenges (see Aschard et al., 2012, for a review) before they can begin to unravel the complexities of GxE effects in human disease and behavior. Advancement in this debate will require a variety of approaches from all sides, including increased appreciation for replication, and inclusion of rich environmental variables in genome-wide association studies. As is crucial in all scientific endeavors, multiple research strategies are needed, and it is likely that both the GWAS approach and the candidate GxE approach will be informative and ultimately result in a synergistic or complementary understanding of these phenomena.

Is Reactivity or Susceptibility Maladaptive?

The identification of factors contributing to the activation and dysregulation of physiological systems designed to maintain the allostatic balance has been thought of as essential for the design of prevention and intervention efforts (Lupien et al., 2006). Indeed, the term *dysregulation* is widespread in the stress–reactivity and regulation literature—often without reference values for normative or healthy levels, and without consideration of the adaptive function of those organismic systemic changes. This promotes confusion about the meaning of physiologic resting and reactivity levels, the sources for variability in these measures, and interpretation of variability or changes in these values. However, in recent years, scholars have begun to consider that the alterations in individual biological systems in response to environmental adversity, although sometimes seen as harmful or maladaptive, may actually be an appropriate physiologic coping response to the organism's physical or social context. Thus, rather than being interpreted as a pathogenic response to negative experience, high reactivity would index heightened biological sensitivity to the quality of the environment, a characteristic with demonstrable adaptive features in certain rearing environments. Studies in rats and monkeys, for example, have revealed that negative neurobiological effects of low quality maternal care can actually contribute to adaptive physiologic and behavioral responses under future stressful conditions (Lyons, Parker, & Schatzberg, 2010; Oomen et al., 2010). Human children exhibiting muted or augmented reactivity in adverse contexts might be responding adaptively to chronic stressors, and although such physiological system modifications may do harm in the long run (e.g., allostatic load effects on pathology), they likely allow for improved functioning over the short term. Modifications such as enhanced amygdala reactivity to neutral stimuli (Tottenham & Sheridan, 2010) may also be a favorable response for children living in a high crime neighborhood, protecting one from physical harm albeit increasing risk for affective dysregulation. As such, variation in physiological outcomes sometimes found for minorities (e.g., Bush et al., 2011), relative to majority population levels, may be legitimately adaptive to contextual demands and might also reflect unique population characteristics that have other value for those populations (Garcia-Coll, Akerman, & Cicchetti, 2000).

Particularly when considering the evolutionary perspective of differential susceptibility, which we describe in more detail below (see also Belsky & Pluess, 2013), it may not be appropriate to think in terms of positive or negative outcomes, but rather alternative strategies by which organisms attempt to enhance their capacity for survival, given the ecological conditions in which they find themselves. Such a reactivity profile may work well in some setting but not others (e.g., crime-ridden neighborhood vs. classroom) and at some points in time but not others (e.g., successful in early childhood, but problematic as a child is expected to gain independence). Readers may also be interested in a new manuscript by Ellis and Del Giudice (2014) in which they outline the similarities and differences between the adaptive calibration model (ACM) and allostatic load models and articulate the value of long-term adaptive changes in biobehavioral systems, such as high reactivity phenotypes, that might otherwise be seen as dysregulated. Increased effort to discuss susceptibility factors and phenotypes with less deterministic wording and more context- and time-specific contingencies will likely prove to advance knowledge and prediction.

Evolutionary Thinking About Variation in Sensitivity

The origins, dimensions, and consequences of individual differences in phenotype are emerging as essential components in a full understanding of the biology of experience. Biology is teeming, of course, with both between- and within-species variation that bears convincing witness to the evolutionary uses of diversity, and elegant ethological and epigenetic work, such as that by Meaney (2010), McGowan and Szyf (2010), and Suomi (2006), reveals the adaptive benefits of phenotypic diversification. For example, the maternally and epigenetically regulated differentiation of rat pups' adrenocortical responsivity produces a range of low- to high-reactivity phenotypes, each of which may maximize survival and fitness within particular early life and later life environments (Weaver et al., 2004). Similarly, neither the aggressively uninhibited nor the shy, neophobic phenotypes of young rhesus macaques can be warranted as normal or optimal; rather, each has adaptive value within specific social and physical contexts (Cirulli et al., 2009; Stevens, Leckman, Coplan, & Suomi, 2009). What is salient and important about phenotypic variants is their capacity for enhancing fitness within the diversity of species-typical environments encountered. Human variation in sensitivity to social environmental influence is but one illustrative case.

Evolutionary arguments for the importance of these sensitivity polymorphisms or phenotypes suggest that the DNS gene variants with the greatest empirical support thus far (e.g., s/s allele of SERT, the 7-repeat of DRD4, and the Met allele of BDNF) appear to have emerged (most likely through mutation) and then rapidly expanded through humankind only within the past 100 millennia, now existing in up to 1/3 of the population (most likely through natural selection). It is thought that, due to population dynamics, the adaptive edge of some variants only holds if the trait remains within a minority of the population, as they become nonadaptive when common. For example, although the high sensation seeking and risk taking found in 7R DRD4 carriers in many studies may have helped drive human expansion around the globe, these traits are expensive in evolutionary terms, increase risk for negative outcomes, and would likely lead to societal failure if all members shared this phenotype (Matthews & Butler, 2011; Wilson, 1998). Thus, populations of individuals possessing the fullest range of phenotypic variation, at both the individual and group levels, are likely to have the best odds of adapting to the constantly varying social, physical, and chemical environment of our world. However, it is also important to note that evolutionary frameworks emphasize adaptations that will improve fit in terms of survival and ability to successfully reproduce into the next generations. Other fields interested in understanding human experience and life course trajectories emphasize the impact of those adaptations on mental and physical health, which may have a different time course (e.g., occurring well beyond reproduction) or occurring and affecting well-being despite not significantly changing reproductive trajectories. Thus, although evolutionary frameworks are quite important to a deepening understanding of DNS, they are only part of the equation when considering the broad range of processes and outcomes related to DNS.

Developmental Timing and DNS

It is clear that the relevance and strength of these interactive associations depend very much upon the developmental time at which they are examined. Thus, examination of this DNS phenomena is enhanced when one considers the central role of time—evolutionary, historical, developmental, neurogenomic, and neurophysiological—in determining phenotypic variation and whether it is adaptive (Boyce, Sokolowski, & Robinson, 2012). Much of the biological sensitivity to current social contexts has resulted from response predispositions established, selectively and epigenetically, through adaptations to the temporally distant environments of early hominids (Dubos, 1965; Nesse & Young, 2000). Social disparities in health—products, in part, of the social, economic, and health policies of

contemporary societies—wax and wane within historical time according to the era's dominant sociopolitical philosophies (Beckfield & Krieger, 2009; Krieger, 2001). Developmental time is uneven in its potency, intensity of change, and accessibility to environmental influence. Thus, for example, critical or sensitive periods exist for the acquisition of language and the discrimination of speech sounds in human infants (Weikum, Oberlander, Hensch, & Werker, 2012), and exposure to music can change auditory preferences in young mice through changes in prelimbic and infralimbic medial prefrontal cortex during an early critical period (Yang, Lin, & Hensch, 2012). It also appears that early trauma and early SES have a greater effect on adult pathology than does later experience of those phenomena (see, for examples Adler, Bush, & Pantell, 2012; Heim, Plotsky, & Nemeroff, 2004; Kittleson et al., 2006), because of both the increased biological sensitivity to experience that exists early in development and because of the greater impact on trajectories of experience that early experiences can have (see Cicchetti & Toth, 2009; Gunnar & Vazquez, 2006; Meaney, 2010).

Findings from animal research reveal evidence for the importance of neurogenomic time and neurophysiologic time, in that honey bees encode spatiotemporal mappings of foraging sites through differential gene expression signatures, allowing them to remember not only geographic locations of food but the circadian patterning of food availability (Naeger et al., 2011), and even fleeting social interactions between fish can trigger changes in neural firing and secretory action (Robinson, Fernald, & Clayton, 2008). Thus, at strikingly different levels of temporal resolution, time and timing appear to play crucial but not yet fully explored roles in guiding societal, organismic, and neurobiological responses to the conditions of early life (Boyce, Sokolowski, et al., 2012).

Work within the multidisciplinary field of developmental psychopathology requires the use of multiple levels of analysis, considered simultaneously, and the outcomes under study generally result from transactional, interdependent co-determination among multiple levels of influence (Gottlieb & Halpern, 2002). Of course, human development is more than an interaction term between a biological and an environmental variable, as it is dynamic and ever-changing (we now know, for example, that epigenesis continues throughout the life course). As we have tried to illustrate throughout this chapter, biological sensitivity to context is not just a cause but is an outcome as well, shaped by previous social contextual experiences. This critical latter element is not yet fully appreciated, especially outside of the field of developmental psychopathology. The cumulative history of the person determines in part the environmental contexts he or she finds him- or herself engaging with, reacting to, eliciting, or processing. Indeed, the organism reacts differently to the same environmental circumstance uniquely at different points in development, because it carries forward its history and the biological, cognitive and behavioral shaping that resulted from that history—thus engendering a slightly (or in some cases dramatically) different response to the same circumstances.

Prenatal Exposures

The prenatal environment is a relatively underexplored context and period that increasing evidence suggests plays a major role in DNS. As described already, susceptibility or plasticity can be shaped by the environment, and an organism's first environmental exposure occurs at conception. Although *nurture* is often thought of as a postnatal experience, animal and human studies building upon Barker's prenatal programming hypothesis (Barker & Sultan, 1995; Gluckman & Hanson, 2006) demonstrate that maternal stress hormones, nutritional cues, and other biological signals cross over the placental barrier to influence offspring phenotype, with the assumption that such information transfer is designed to support the optimal adaptation to the world into which the fetus will be born (for a review see Pluess & Belsky, 2011). For example, maternal psychosocial stress and stress hormone levels during pregnancy have been shown to predict infant birth weight (Worthman & Kuzara, 2005) (which has been linked to numerous neurodevelopmental outcomes, including difficult temperament (Pluess & Belsky, 2011)), child temperament (Davis et al., 2005) and behavioral recovery to a stressor (Davis, Glynn, Waffarn, & Sandman, 2011), HPA-axis regulation (Davis et al., 2011; Owen, Andrews, & Matthews, 2005) and stress-related gene methylation (Oberlander et al., 2008). Davis and colleagues (Davis et al., 2011) provide an excellent example of these effects in their finding that exposure to higher levels of maternal plasma levels of cortisol during the second and third trimesters of pregnancy predicted larger infant cortisol responses to the painful stress of a heel-stick procedure 24 hours after birth. Additionally, elevated levels of maternal cortisol early in pregnancy as well as prenatal maternal psychosocial stress throughout gestation predicted a slower rate of behavioral recovery to the heel-stick. Importantly, these findings could not be explained by socioeconomic status, child race or sex, or medical factors such as prenatal medical history, mode of delivery, or birth order.

These prenatal programming effects appear to last across development. For example, a prospective, longitudinal study of healthy mother-child dyads found that higher maternal cortisol in early pregnancy was associated

with larger right amygdala volume in female offspring at age 7 and that this effect partially mediated the association between maternal stress during pregnancy and girls' affective problems at age 7 (Buss et al., 2012). Additionally, these prenatal programming effects appear to last across development (e.g., Entringer, Kumsta, Hellharnmer, Wadhwa, & Wust, 2009). Such programmed physiological and behavioral phenotypes then moderate environmental effects on those offspring's developmental trajectories. It is intriguing to note that a fetus' own genetic sensitivity to environmental experience may make one fetus more sensitive to the uterine environment than another, adding a layer of DNS complexity to the understanding of the programming of DNS.

Researchers have begun to hypothesize about individual difference characteristics that make some more or less susceptible to the prenatal environment. For example, in a first examination of EEG data within a DNS framework, Fortier and colleagues (Fortier et al., 2014) recently postulated that asymmetry in alpha-activation of the frontal lobe may be a marker of DNS. They highlight that frontal EEG alpha-activation asymmetry has a moderately heritable basis, is present in utero, and fairly stable across the life course. Although the increased risk for negative affectivity in those with greater activation of the right hemisphere (right frontal asymmetry; RFA) might be seen as the more sensitive phenotype, the authors posited that the variability in positive and negative outcomes across the literature for those with greater activation in the left hemisphere (left frontal asymmetry; LFA) was evidence for that phenotype being the more susceptible to context. Indeed, the authors found that LFA individuals were sensitive to prenatal environment (reflected in low vs. normal birth weight) whereas RFA individuals were not. Specifically, LFA individuals who were normal birth weight (presumably reflecting optimal intrauterine conditions for development) evidenced the best mental health outcomes a decade later, and those who were extremely low birth weight (presumably reflecting adverse intrauterine conditions) evidenced the highest attention problems and withdrawn behaviors. Prenatal conditions reflected in birth weight had no association with later life problems for RFA individuals. The patterns of interaction found in this study reflect DNS for better and for worse outcomes.

New research is also attempting to span the prenatal programming of offspring reactivity literature with the DNS hypotheses. For example, a Swiss study examined the interplay between the prenatal environment, as indicated by maternal blood plasma cortisol levels in response to the Trier Social Stress test conducted late in pregnancy, and neonates' temperamental reactivity, as assessed by behavioral coding of newborns' neurological and behavioral reactivity to stimulation 10–14 days after birth (Bolten et al., 2013). Consistent with DNS theories, newborns that were most reactive demonstrated the best emotion regulation during the stressful Still Face Paradigm, if they had gestated in mothers with lower HPA axis reactivity, but they had the lowest emotion regulation scores if they were born to mothers with high HPA axis reactivity during pregnancy. Although newborn reactivity has been linked to maternal HPA axis functioning during gestation, these results point to the possibility that variability in newborn reactivity (presumably stemming from reactivity developed during the fetal stage) may also serve as a susceptibility factor to maternal reactivity in utero (and presumably her reactivity phenotype postnatally), in the prediction of developing emotion regulation. Another research group has also explored similar associations and find that infant's carrying the sensitive polymorphism of the 5-HTTLPR gene had higher levels of emotional dysregulation in early childhood if their mothers were depressed during gestation but the lowest levels of emotional dysregulation if their mothers had lower levels of prenatal depression (Babineau et al., 2015). These interaction findings held across multiple longitudinal time points and were robust to adjustments for postnatal factors such as maternal postnatal depression, but they are still limited by the shared reporter of maternal mood and offspring emotional regulation. Although both sets of these findings require replication and careful consideration of the timing of exposures and effects, they provide fodder for discussion of the complexity of the development and manifestation of DNS and highlight the opportunities for discovery when the prenatal period is examined.

BIOLOGICAL PATHWAYS LINKING EARLY LIFE DIFFERENTIAL SUSCEPTIBILITY TO LATER PSYCHOPATHOLOGY

Throughout this chapter, we have focused on the accumulating evidence for the manner in which biological sensitivity can moderate the effects of context on developing physiology and behavior. These findings add to the growing body of literature supporting a differential susceptibility model of biology × environment interactions in developmental psychopathology. It remains to be seen whether the differential effects on behavior are mediated by individuals' neurobiological changes, given the far less empirical evidence for biological processes linking early

adversity with subsequent psychopathology (Pollak, 2005). In rat and nonhuman primate studies, adverse early life exposures, such as maternal separation or low quality maternal care, have been shown to result in subsequent HPA axis, autonomic, and immune system changes in response to stress, as well as marked behavioral changes in adulthood such as anxious behavior, anhedonia, social dysfunction, predisposition to alcohol abuse, decreased appetite and sleep disruptions (Dettmer et al., 2012; Liu et al., 1997; Plotsky & Meaney, 1993; Provencal et al., 2012; Sanchez, Ladd, & Plotsky, 2001). Although animal research lends itself to the rigorous study of causal environmental effects on biology, it has limitations in its ability to model human experiences of early life stress or developmental psychopathology. On the other hand, researchers studying children with mental health problems find it challenging to incorporate biological assessment into their studies and to follow individuals for the long periods of time required to assess these life course processes. Burghy and colleagues provide a particularly useful study that bridges several of the concepts reviewed above (Burghy et al., 2012). Their findings suggest that stress exposure during infancy increases adolescent depression and anxiety and decreases amygdala-vmPFC resting-state connectivity via cortisol elevations in childhood. In a parallel fashion, the Buss et al. work reviewed above (Buss et al., 2012) found that stress exposure during gestation, via maternal circulating cortisol levels, was associated with greater affective problems, and this association was mediated in part by amygdala volume. Both studies also reveal important gender differences for this vulnerability to dysregulated affect, as well as developmental sensitive periods for these effects. The relatively small sample sizes of youth in both studies merits caution for generalization of the findings, but the rich breadth of longitudinal data, strong theory-driven hypotheses, and sophisticated statistical modeling in those studies make them exemplars of the advances being made in this area.

A Closer Consideration of Epigenetic Pathways

The work just reviewed spans several biological systems and levels of inquiry into neurobiological susceptibility. However, given the tremendous increase in attention given to the field of epigenetics over the past decade, and the promise it holds for understanding human development and disease, we examine that literature in more detail here. In short, epigenetics (from the Greek root *epi,* meaning upon or over) has been defined as "the structural adaptation of chromosomal regions so as to register, signal or perpetuate altered [gene] activity states" (Bird, 2007, p. 398). Epigenetic mechanisms change gene expression or activity through alterations in chromatin organization, but they do so without changing the genetic code of the DNA (Meaney, 2010). Thus, the epigenome can be viewed as a responsive overlay on the genome itself, and it possesses the potential to moderate the effects of genetic variation through up- and down-regulation of gene transcription.

Before we review evidence for such processes, it may be helpful to review some of the basic biology involved. Chromatin configuration is controlled by a physicochemical process in which chemical tags (i.e., epigenetic marks, such as methyl, acetyl, phosphate, or ubiquitin groups) are placed on or removed from the DNA or histone proteins. DNA methylation is the most highly studied and best characterized epigenetic mark. Methylation involves a direct covalent, chemical modification of a cytosine base lying sequentially adjacent to a guanine base (thus a *CpG dinucleotide*), and is catalyzed by a group of enzymes called DNA methyltransferases (DNMTs). CpG methylation can occur during any stage of the cellular life cycle and, depending upon genomic context, can impede or foster gene expression or leave it unchanged (Klengel, Pape, Binder, & Mehta, 2014).

Promoter DNA methylation (often in CpG islands, areas of the genome with comparatively high numbers of CpG dinucleotides) and gene body DNA methylation typically have contrasting associations with gene expression. High levels of promoter DNA methylation are frequently linked with diminished gene expression, but high levels of methylation in the gene body are more typically associated with increased gene expression (Jones, 1999; Kass, Landsberger, & Wolffe, 1997). DNA methylation is a relatively stable epigenetic tag, yet it has just recently become viewed as reversible and thus a potential mechanism of developmental plasticity (Wu & Zhang, 2014).

Epigenetics and the Mediation of Differential Susceptibility to Environmental Influence Interactions

All disorders of health and development can be seen as uniformly both genetic and environmental, in the sense that virtually all endpoints depend upon mutually interactive influences of both (Rothman & Greenland, 2005). The epigenetic marks and modifications controlling gene expression are gaining recognition as the molecular mechanisms underlying GxE interaction effects on developmental and mental health outcomes. Accordingly, these mechanisms constitute a tangible, physical nexus between environments and genes, between nurture and nature, between the exogenous and endogenous determinants of human development and psychological well-being.

Several recent leading edge discoveries support the perspective that *epigenetic processes* are molecular mechanisms for GxE at the population level. In a sample of 192 adults, Klengel and colleagues (Klengel et al., 2013) found that a functional polymorphism in the FK506 binding protein 5 (FKBP5) gene, an important functional, cytoplasmic regulator of the glucocorticoid receptor complex, interacted with childhood trauma exposure to predict the risk of developing stress-related psychiatric disorders in adulthood in a manner consistent with DNS. Although the interaction between FKBP5 and childhood maltreatment was known, their findings provide the first molecular evidence in humans that this type of GxE effect may be mediated via allele-specific, childhood trauma–dependent DNA demethylation in functional glucocorticoid response elements of FKBP5. Specifically, this research group found that demethylation was linked to increased stress-dependent gene transcription, followed by a long-term dysregulation of the stress hormone system and a global effect on the function of immune cells and brain areas associated with stress regulation. The authors suggest that, when occurring during developmentally sensitive periods, these epigenetic changes remain stable over time and further amplify the differential susceptibility to environment that the individual's genetic makeup originally bestowed upon it—particularly through long-term changes in the stress hormone system regulation and alterations in neuronal circuits. In turn, the early life demethylation event results in a consequent augmentation of risk for PTSD across the life course. Although gene expression is likely controlled by a variety of molecular mechanisms, only one of which is epigenetic marks, this empirically driven intersection of the fields examining genetic and epigenetic variation offers one groundbreaking account of how and under what conditions GxE interactions arise.

Work from the Holbrook lab (Teh et al., 2014) approached examination of this complex phenomena from the opposite direction. Their results demonstrate how neonatal human methylomes are affected by both unique intrauterine exposures and fixed genetic variation, resulting in GxE interactions during gestation. Specifically, within a sample of more than Singaporean newborns, the investigators found over 1,400 punctate genomic regions that were highly variable in methylation status across individuals—locations termed variably methylated regions (VMRs). Using birthweight as a proxy for environmental factors (e.g., nutrition, smoking, maternal depression, and maternal body mass index during gestation), they examined genetic and GxE origins of VMRs. Strikingly, GxE interactions were found to account for 75% of VMRs, through a combination of intrauterine environmental signatures on the fetal epigenome and the physicochemical effects of sequence variation on a CpG site's propensity for methylation. Of note, no VMRs were best accounted for by environmental linkages alone, independent of gene sequence variation. Allowing essentially the same inference as that made by Klengel and colleagues (2013), Teh et al.'s results reveal an increasingly convergent picture of how DNA sequence variation interacts with naturally occurring (and sometimes pernicious) variation in social environmental exposures at the molecular level, through chromatin modifications and other transcription regulatory processes, to produce complex developmental and health trajectories.

Kobor and colleagues provide additional recent data that sheds light on these complex epigenetic processes. Their series of studies examining allelic and epigenetic variation within human populations demonstrates that human populations possess highly divergent DNA methylation profiles and that the sources of divergences between populations involve differences in allelic frequencies and complex GxG and GxE interactions (Fraser, Lam, Neumann, & Kobor, 2012). Examining over 14,000 genes in 180 different cell lines from European and African samples, they found population-level differences in DNA methylation near transcription start sites in over a third of genes. Further analyses indicated that these methylation differences were mostly attributable to differences in allele frequencies. The Kobor lab's work augments the existing small evidence base for epigenetic dissimilarities between human populations (Krushkal, Tylavsky, & Thomas, 2011; Heyn et al., 2013; Moen et al., 2013) and points to the need for considering population heritage in epigenetic analyses but also for recognizing the manner in which population-level genetics drive variation in the epigenome.

Considered together, these three recent studies and related observations suggest that considerable developmental variation, particularly when it places individuals at risk for developmental psychopathology, may be linked to interactions between genetic and environmental differences. Moreover, they add to the emerging evidence implicating epigenetic processes as molecular-level mechanisms by which GxE interactions may occur. In light of these findings, it seems that the increasingly apparent *statistical* interactions identified between allelic variants and risk-engendering early social environments may be rooted in and attributable to differences in DNA methylation, post-translational histone modifications, or other epigenetic marks, which contribute to inter-individual

variation in the transcription of genes linked to pathological phenotypes or endophenotypes.

Variation in Epigenetic Marks as a Result of Differential Susceptibility to Context

A related, important question is whether epigenetic modifications, acquired as a consequence of early environmental signaling, might also be linked to differentially susceptible phenotypes. For example, researchers have studied large, differentially methylated regions centered upon the *NR3C1,* GR gene in the hippocampi of both rats and humans experiencing substantially different levels or forms of early parental care (Suderman et al., 2012). Suderman and colleagues found that the methylation profiles of both species were extensively different in individuals receiving high vs. low level (rats) or abusive vs. nonabusive (humans) early parental care. They also found many between-species commonalities in the specific, differentially methylated sites. Examining stressors associated with socioeconomic environment within a sample of African American youth from working poor communities, Beach and colleagues (Beach et al., 2014) found that cumulative socioeconomic adversity and the S-allele of the 5-HTTLPR, serotonin transporter gene interactively predicted promoter region methylation within a group of more than 200 genes associated with depression. Youth who were S-allele carriers demonstrated either the highest or lowest levels of depression-related gene methylation, depending upon levels of exposure to poverty-related stress. Recently, researchers have argued that the increased susceptibility of infants to infectious agents of disease may be due to differential methylation of immune-regulating and other developmentally salient genes (Strunk, Jamieson, & Burgner, 2013). Finally, the Binder laboratory work (Klengel et al., 2013) demonstrated a differential susceptibility of individuals bearing the AG/AA risk allele of the FKBP5 gene in that such individuals have either higher or lower rates of adult PTSD, conditional upon childhood exposures to sexual or physical abuse. Further, their work demonstrated that the molecular process by which this epidemiologically observed interaction occurs is mediated through DNA demethylation in the glucocorticoid response elements of FKBP5. These observations are among the first to show how chromatin modification and epigenetic marks may constitute the actual molecular mechanisms for a differential susceptibility to environmental conditions, yet much remains to be elucidated.

The proliferation of epigenetic publications and reports represents an epidemic of interest in this area, although the tremendous initial enthusiasm with which the work was greeted by the scientific community has more recently been tempered by increasing awareness of the limiting realities that commonly characterize the rapid emergence of new fields and technologies. Not only is it inappropriate to expect epigenetic processes to explain all biological phenomena, but sometimes they also fail to reliably explain phenomena within systems or questions it is most reasonable to assume they should. Yet, despite the need to face these scientific realities, the research domain holds at least implicit promise for illuminating one of the oldest and deepest mysteries of human experience (i.e., how individual susceptibility and social conditions work together)—at the behavioral, physiologic, neural, cellular and molecular levels—to initiate and sustain disorders of development, behavior, and health.

FUTURE DIRECTIONS

The body of work reviewed in this chapter is advancing at a rapid pace, and the opportunities for new research are vast and compelling. Although the developmental sequelae of early experience are well documented, current understanding of the individual-specific (moderated) manner in which those experiences get under the skin to affect psychopathology is quite limited, leaving much for the next generation to uncover.

A recent, potentially transformative shift in conceptualization of developmental psychopathology and funding for discovery may provide stimulus for this work. The National Institute of Mental Health's recent promotion of Research Domain Criteria (RDoC; Cuthbert & Insel, 2013; Insel et al., 2010) focuses on investigating the etiology and treatment of mental disorders as biological disorders that require advanced understanding of breakthroughs in genetics, physiology, and molecular, cellular and systems neuroscience. This movement away from diagnostic symptom criteria brings about additional reasons to increase attention to the range of ways variation in biology confers sensitivity to environment. As it is more likely that differential susceptibility to environments affects a broad range of physical and mental health phenotypes and outcomes (i.e., multifinality; Cicchetti & Rogosch, 1996), investigation of DNS is likely to benefit from this greater focus on intermediate phenotypes (heightened physiologic reactivity, patterns of epigenetic methylation, reactivity in regions of the brain, etc.) for a range of health outcomes, rather than predicting disease classifications.

As the fields reporting various forms of interactions between biologic predispositions and environments exponentially grow, what is now critically needed are programs of research examining the questions of how and by what mechanisms genes and early social contexts codetermine trajectories of behavioral and biological development. With respect to differences in complex behavior and its disorders, a focus on proximal, neurobiological processes must come strongly to the fore. With advances in neuroscience and human molecular genetics, next steps include identifying common variation in the genes and their expression that influence the functioning or availability of components in these stress–disease pathways. Illustrations of such approaches can be found in recent work within emerging imaging genomics (e.g., Hariri et al., 2005; Pezawas et al., 2005). A particularly groundbreaking example of progress in this realm that is specific to differential susceptibility research is the epigenetic work reported by Klengel and colleagues (Klengel et al., 2013) described earlier. Such sophisticated identification of molecular mechanisms for genotype-directed, long-term environmental reactivity is particularly informative, and further determination of how early in life such epigenetic modifications occur may elucidate the molecular origins of differential susceptibility and the deeper etiologies of developmental psychopathology.

Future work must also advance theory. For example, there is the need for research to determine whether these behavioral, physiological, and genetic markers of susceptibility to context constitute the same phenomena expressed at different levels of scale or complexity or represent different forms of susceptibility (Obradović & Boyce, 2009). To date, DNS studies typically focus on sensitivity in one level or system (albeit sometimes across various markers in that level), making it difficult to answer this question. Exceptions include work from our lab, such as that examining reactivity in both the HPA axis and within the parasympathetic nervous system to assess sensitivity to family adversity in the prediction of a variety of adjustment outcomes (Obradović et al., 2010). Although the patterns of findings in that study were cohesive across the biological systems and various outcomes, DNS interaction findings were not exactly replicated across the two biological systems. Although this might be the result of measurement or sample variability, such discrepancies suggest unique roles for sensitivity in each system, or at least unique timing for the role of sensitivity to context. In parallel, Belsky and Pluess's (2013) recent theory describing individuals as possessing plasticity phenotypes, rather than just system- or gene-specific plasticity, or acquiring cumulative plasticity, are important ideas demanding empirical testing and expansion.

A major impediment to uncovering the relations among adversity, biological sensitivities, and psychopathology is that the majority of behavioral and emotional pathologies are likely to result from constellations of aberrant biological systems, and multisystem studies and longitudinal analyses are rare. Considerable recent attention has been given to early adverse experience effects on the complex and varied neurobiology of depression (Bogdan & Hariri, 2012; Heim et al., 2004). For example, progressive effects on developing stress physiology might explain findings supporting the kindling hypothesis, in which an increase in spontaneous dysregulation or a lowering of the threshold for experiencing life stressors leads to easier triggering of depressive episodes (Monroe & Harkness, 2005). As precise, biologically plausible and multisystem models of psychopathology are developed (Pollak, 2005), our ability to seek and understand the manner in which early experience manifests as health and pathology will be greatly enhanced, as well.

To this end, some work from our laboratory and those of colleagues is beginning to indicate ways we might use simultaneous measurement of reactivity across the HPA, sympathetic and parasympathetic systems to better understand developmental psychopathology (Alkon et al., 2003; Bauer, Quas, & Boyce, 2002; Quas et al., 2014). In particular, Quas et al. found six distinctive patterns of cross-system reactivity in a multicohort sample of 664 children with anticipatory and stress reactivity measures across the parasympathetic and sympathetic nervous systems and the hypothalamic-pituitary-adrenal axis. Although the majority of children in their samples displayed moderate reactivity indicated by an average level of cross-system reactivity, five other patterns also emerged: parasympathetic-specific reactivity, anticipatory arousal, multisystem reactivity, hypothalamic-pituitary-adrenal axis specific reactivity, and underarousal. Of note, groups meaningfully differed in socioeconomic status, family adversity, and age, suggesting important roles for developmental timing and contextual exposures in the shaping of these anticipatory and reactivity profiles. Surprisingly little attention has been given to delineating precisely how these systems interact with each other when confronted with stress, and the Quas et al. findings highlight the importance of attention to this issue. The lack of attention to date may be due to the difficulty and cost associated with cross system data collection, particularly in children; however, it is likely also the result of the dearth of theory addressing this issue. For example, although much

argument has been made for the importance of multisystem models, theoretical models that argue for the existence and importance of cross-system patterns of physiological reactivity to challenge or stress have yet to elaborate on how more than two biological systems operate in conjunction with one another. For example, the influential work of Berntson, Cacioppo, and colleagues (e.g., Berntson, Cacioppo, Quigley, & Fabro, 1994) does not comment on the role of HPA axis activation in their detailed account of autonomic nervous system indices, despite the importance of the HPA axis arousal and regulation in the activation of other stress-response systems. Similarly, the work by Bauer and colleagues (Bauer et al., 2002) did not consider the regulatory function of the parasympathetic system. The Adaptive Calibration Model (ADM) described above (Del Giudice et al., 2011), makes progress in this regard in that it theorizes about varying patterns of baseline arousal and stress-induced activation of both branches of the ANS as well as the HPA axis; however data examining the 3-system patterns they propose is lacking. A primary reason for the varied findings across DNS studies (those published and those left in the file drawer) may be the lack of attention to responses across multiple systems. Increased theoretical and empirical attention to these simultaneously occurring physiological phenomena is likely to clarify DNS and will certainly advance understanding of the development of psychopathology given the importance of both main and interactive effects of physiological arousal on pathology.

Successful pursuit of advancement in the science of differential susceptibility within developmental psychopathology will surely also involve advanced methodology and more complex analyses. One example is that of Davies and Cicchetti (2014), who utilized structural equation modeling to test mediated moderation models to reveal that children's angry reactivity to maternal negativity partly accounted for the greater susceptibility of homozygous L carriers of the 5-HTTLPR polymorphism to variations in maternal responsiveness. Additional sophisticated approaches include those incorporating the perspective of complex adaptive systems (Galea, Riddle, & Kaplan, 2010). Traditional epidemiological strategies for understanding the health effects of social environmental factors involve the ascertainment of such factors' independent influences on a health end point through the use of multiple hierarchical regression models (Diez Roux, 2007). Although such an approach allows estimation of the isolated effects of single independent variables, it belies the reality that most human disorders are etiologically complex, with multiple interacting causes. Even detecting GxE interactions likely underserves the true complexity of pathogenic processes, because allelic variation in a single gene likely interacts with polymorphisms in several other genes and multiple dimensions of the environment may also interactively influence outcomes. In such circumstances—circumstances that may eventually prove to predominate in disease causation—the use of more sophisticated models and analytical tools will be required to understand the multiply interactive networks of risk factors involved in the ontogeny of disordered development and health. If so, one such approach with increasingly demonstrable efficacy is the use of complex systems analysis, involving descriptive inventories of system components, nonlinear mathematical modeling, and the construction of agent-based models of causal networks (Diez Roux, 2007; Galea, Hall, & Kaplan, 2009).

The apparent interaction between biological processes and contextual influences reviewed here points to the value of integrating biological measures into the design and evaluation of preventive interventions (Cicchetti & Gunnar, 2008). Moffitt (2013) elegantly articulated the need for and value of bringing stress–biology research and clinical intervention science together in the case of children exposed to violence, but the review and advocacy for the addition of a range of biomarkers to the study of violence-exposure interventions applies well across a variety of clinical contexts. Increasingly, the literature points to the potential for the inclusion of measures of HPA axis activation, inflammation, telomere length, gene expression, and epigenetic methylation. Given their increasing ease of collection and decreasing cost for assay, biological markers such as genotype and hair cortisol are beginning to prove useful for detecting who is most affected by interventions and whether those interventions affect biological systems related to later susceptibility. As costs go down for other neurobiological assessments, feasibility of using sophisticated biomarkers to advance our crafting and evaluation of interventions for psychopathology will improve, and the field will advance. Additionally, these endeavors, and the others described in this section should take account of the breadth of positive environments and buffering factors that operate across the life span, which will take us a step further in understanding healthy behavioral and emotional development.

Just as use of genetic information has played a major role in certain aspects of precision medicine (National Research Council, 2011), determination of sensitivity to context in conjunction with advances in technology, methodology, and biological discovery will enable a level of personalization in the prediction and treatment of psychopathology that was not previously feasible or

practical. It is likely that failure to assess for differential susceptibility in most environmental intervention trials (e.g., parenting, family, classroom, neighborhood) has led to erroneous or blunted conclusions about the efficacy of certain approaches and a misestimation of treatment effects. Although it would be ideal to provide all children with optimal or enriched environments, practicality often demands targeted interventions to those at greatest risk and those most likely to be sensitive to intervention, as well as clarity about which types of contextual interventions are most beneficial for whom, which is made more feasible as we better understand differential susceptibility. On the other hand, there are circumstances in which understanding sensitivity to environmental factors mandates a public health intervention that improves well-being for the entire population. For example, the discovery that certain individuals possess genetic variants that make them particularly susceptible to the harmful effects of lead exposure (Astrin et al., 1987) led to improved federal guidelines and regulations for lead-safe practices, thereby reducing exposure and toxicity risk for everyone. One can imagine how identifying individuals who are particularly susceptible to toxic effects of a variety of chemical and social exposures might promote public attitudes and policies that would limit risk for these individuals and their fellow community members.

CONCLUSIONS

A remarkable diversity of early, social environmental dimensions has been linked to important differences in mental and physical health, trajectories of development, and individual differences in behavior. As attention to differential susceptibility to those environmental dimensions grows, the capacity to place a finer, more exacting point on the specific kinds of environments that interact with particular variants of biological sensitivity will be important and likely illuminating. Indeed, studies examining the developmental biology of social experience show that we are on the cusp of providing deep mechanistic explications of the important, earlier insights of Waddington (1966), Gottlieb (1991) and others that organismic development is guided by the combined, interactive influences of biological predispositions and experiences.

Conducting scientific inquiry related to interactions between individually varying sensitivity variables and the range of environments we are exposed to requires consideration of a broad range of theoretical and analytic possibilities for those patterns of association. Such openness improves our ability to determine the true nature of these associations and better predict outcomes and optimal interventions. Rather than approaching these analyses with post hoc explanations for patterns of findings, researchers should endeavor to strongly consider the existing evidence base, evolutionary theories, and biological processes involved prior to developing hypotheses. However, if appropriate methods and statistics are used, post hoc analyses can disaggregate variability in responses to experiences and environments attributable to diathesis stress, differential susceptibility, vantage sensitivity, or some other form of host response singularity (e.g., Belsky, Pluess, & Widaman, 2013; Roisman et al., 2012). This approach has rarely been taken to date, but would greatly advance theories and evidence in this realm.

In conclusion, the information presented in this chapter supports several main points. First, the data support reframing the conventional focus on individual risk and resilience factors toward a conceptualization of developmental psychopathology that considers whether certain neurobiological factors confer differential susceptibility to both positive and negative environmental experiences. Second, there is a remarkable convergence among theories and supporting evidence from fields (e.g., pediatrics, developmental psychology, evolutionary anthropology, biological psychology) and scientific laboratories originally unknown to each other (e.g., the compelling work of Klengel et al. 2013, was conducted by researchers largely unfamiliar with the DNS literature) toward this same conclusion, suggesting a shared scientific value of this reframing. Additionally, beyond aiding an understanding of etiology of psychopathology, a DNS framework expands the possibilities for understanding biological and environmental factors contributing to the full range of behaviors across the life course as well as individual difference variables that predict intervention success. In reviewing this literature, we have hoped to stimulate a new generation of research illuminating the manner in which early life contexts interact with children's biological proclivities and biases to shape development and predict health and disorder. We hope that this work will support powerful insights into children's typical and atypical development, highlight clear opportunities for the prevention of psychopathology, and play a formative role in newly individualized approaches to precision medicine.

REFERENCES 157

INTRODUCTION

What is the most fruitful perspective from which to view developmental psychopathology? At present a major vantage point of our field, as embodied in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5;* American Psychiatric Association, 2013), is largely atheoretical and descriptive. Conceptually, it reifies psychopathological states as categorical entities that are modeled after discrete medical disorders (Kendler, 2012). To some extent this has been a serviceable and generative approach, well suited to today's medical marketplace. Leaving aside the inelegant unspecified designations, *DSM-5* also has a certain bureaucratic appeal with every disorder neatly in its place. The weaknesses of *DSM-5* are also readily apparent. Many of the criteria are no more than a reflection of the conventional wisdom of a committee of experts with limited empirical justification. Being categorical in nature, it largely ignores the dimensional properties of many syndromes and their intimate relationship with environmental factors and the individual's antecedent developmental history.

Perhaps most disappointing is its failure to provide a dynamic framework that would allow for a sensible dialectic with burgeoning areas of science including evolutionary biology, molecular genomics, environment-dependent epigenetic alterations of gene expression, systems and developmental neurosciences, neuroimmunology, ethology, child development, and cognitive and social neuroscience—to name a few. Despite these shortcomings there is an increasing recognition that there is a need to look beyond the proximal mechanisms that underlie specific disorders and to consider the distal evolutionary mechanisms that give rise to psychopathology (Stein & Neese, 2011). In this chapter the primary focus is on these emerging perspectives on how evolutionary processes may support the preservation of various forms of psychopathology.

GOALS OF EVOLUTIONARY EXPLANATIONS

The principal goal of an evolutionary perspective of psychopathology is to provide a coherent framework from which to view patterns of maladaptive behavior that are

persistent in human populations (Leckman & Mayes, 1998). In such an evolutionary framework, the issue of persistence appears to be paradoxical given the editing power of natural selection. Darwin's (1859) principle of natural selection posits (1) the existence of variation among individuals, (2) differential reproductive success for those individuals who exhibit traits that are useful in the struggle for life, and (3) differential inheritance of those factors that gave rise to the favorable traits. Why then would particular variations persist that place individuals at a reproductive disadvantage in the struggle for life? We also need to consider whether various forms of psychopathology are not truly maladaptive when viewed from an evolutionary perspective. As pointed out by Belsky and Pluess (2013), some forms of behavior that are generally considered to be psychopathological and maladaptive (e.g., impulsive, risky, antisocial) can be considered adaptive within certain conditions of adversity to the degree that they enhance an individual's reproductive fitness.

Before reviewing the proposed mechanisms, this chapter's position should be made clear. A major thesis of this review is that the improbable cascade of evolutionary events that has led to the emergence of our species and our particular set of conserved behavioral and mental capacities has also left us vulnerable to certain forms of psychopathology. By conserved behavioral and mental capacities, we refer simply to adaptive capacities that have contributed to our evolutionary success as a species. On reflection, this set of capacities includes such behaviors (and associated mental states) as purposive reaching and holding, feeding, locomotion, grooming, communication (gestures, species-specific vocalizations and language), alarm systems activated by perceived threats such as separation from an attachment figure, courtship and pair bonding, reproductive and parental behaviors, the formation of social dominance hierarchies, and our capacity to be resilient and adapt and thrive in novel and challenging environments—among many others.

Another fundamental aspect of this approach is to consider the developmental course of these conserved behavioral and mental capacities over the lifetime of the individual. Consideration of continuities and discontinuities between normality and psychopathology is a hallmark of developmental psychopathology (Cicchetti, 2006; Zigler & Glick, 1986). Consequently, in our examination of specific forms of psychopathology we will consider the developmental time course for the emergence of these conserved behavioral and mental capacities.

In line with this developmental perspective, it is becoming increasingly clear that changes in the transcriptional regulation of key developmentally expressed genes are major contributors to the evolution of our human species—especially the evolution of our brain and the emergence of brain-related disorders (Vallender, Mekel-Bobrov, & Lahn, 2008; Varki, Geschwind, & Eichler, 2008). Indeed, variation in regulation of gene expression during development, rather than variation in protein sequence, is almost certainly the dominant factor in human brain evolution (King & Wilson, 1975). Such changes are thought to have led to the creation of new combinatorial expression patterns during development and ultimately to the formation of distinct neuronal circuits. In this context the field of evolutionary psychology and psychopathology needs to take into account our rapidly expanding knowledge of the human genome and the organ specific transcriptomes (Barbosa-Morais et al., 2012; ENCODE Project Consortium, 2012), and the complexity of the neurodevelopmental programs required for cellular proliferation and circuit formation within the human brain (Kang et al., 2012).

Current estimates suggest that at least 80% of the human genome is functional. Our genome contains more than 20,000 protein-coding genes, more than 18,000 RNA genes as well as protein-bound regions, regions of histone modification and DNA methylation, and chromosome interacting regions (ENCODE Project Consortium, 2012). Many of these recently discovered regulatory elements are physically associated with one another and with expressed genes. A more complete understanding of their role should provide new insights into the specific mechanisms of gene regulation associated with neural development. A significant portion of these regulatory elements are likely to be associated with environmentally sensitive alterations in region-specific gene expression mediated by epigenetic mechanisms that take place during specific periods of development (Caldji, Hellstrom, Zhang, Diorio, & Meaney, 2011; Keverne, 2011; Pujadas & Feinberg, 2012).

Another advance in understanding how species with similar repertoires of protein-coding genes differ so markedly in their biobehavioral repertoires has come from an in-depth analysis of organ transcriptomes from vertebrate species spanning ~350 million years of evolution. These events likely have further contributed to the diversification of splicing and other transcriptomic changes that underlie the emergence of our species-specific bio-behavioral repertoire. For example, significant differences in alternative splicing complexity between vertebrate lineages has been documented with the highest complexity found in primates (Barbarosa-Morais et al.,

2012). However, other investigators have found that much of our uniqueness as a species comes from variations in regulatory elements in mammalian aligned regions rather than from primate-specific regions (Ward & Kellis, 2012).

The emerging picture of the intricate and dynamic complexity of the genetic programs associated with the development of the human brain is also worthy of note. Recent analyses of exon-level transcriptome and associated genotyping data, from multiple brain regions including several neocortical areas of developing and adult postmortem human brains, have found that over 80% of the more than 17,000 mostly protein-coding genes studied were expressed, and that 90% of these genes were differentially regulated at the whole-transcript or exon level across brain regions and/or time (Kang et al., 2012). Notably, many of the spatiotemporal differences detected were differently present prior to birth and included a number of genes that were sexually dimorphic in their patterns of expression (Kang et al., 2012). This study also identified in the developing and the adult human brain core gene co-expression networks associated with cellular proliferation, synapse and dendrite formation, and myelination. Moreover, because of functional redundancy of gene families in divergent biological processes, it is clear that the genetic and evolutionary origins of developmental disorders affecting behavior and emotions may be more systemic and polygenic in nature than is generally appreciated.

Ongoing studies comparing genomes across species as well as comparing spatiotemporal differences of gene expression should provide a clearer understanding of the transcriptional foundations of human brain development and evolution of language and other uniquely human traits (Johnson et al., 2009). Future studies of human postmortem brain material that include recently discovered regulatory elements in the human genome should allow investigators to generate expression trajectories of genes commonly associated with specific mental disorders. Likewise, large-scale experimental assays in multiple individuals, cell types, and populations have the potential to identify the role of the regulatory elements that are key to both human evolution and disease.

In an effort to integrate an interdisciplinary perspective on developmental psychopathology Killeen, Tannock, and Sagvolden (2012) have suggested that we consider Aristotle's four causes to explain how things come to be (Hocutt, 1974). The *formal cause* describes the pattern or form which is necessary for us to recognize something as a particular something. At present, criteria contained in the *Diagnostic and Statistical Manual* (DSM) and *International Classification of Diseases* (ICD) identify the specific requirements needed to diagnose mental disorders. The *material cause* is equivalent to the nature of the raw materials out of which something is made. Here it will be important to consider aspects of neural and somatic development occurring within specific environmental contexts—from the intrauterine environment to the social ecology of the caregivers and of the developing child (Rutter, 2008; Werner & Smith, 2001). The *efficient cause* identifies the triggers that cause something. Here again the individual's interactions with multiple environments is key. Examples include the unfolding complex somatic and emotional environment associated with child birth leading to postpartum depression or the recreational use of certain drugs—leading to addiction. Last, but not least, is the final cause, or *telos*, which is defined as the purpose, end, aim, or goal of something, and here we return to evolutionary accounts. With this Aristotelian perspective in mind the focus of this chapter is to understand why the evolution of our species' conserved behavioral and mental capacities has also left us vulnerable to certain forms of psychopathology. Although we focus on the final cause, it will also be important to consider the other three causes as well.

EVOLUTIONARY MECHANISMS THAT MAY ACCOUNT FOR THE EMERGENCE OF PSYCHOPATHOLOGY OVER THE COURSE OF DEVELOPMENT

As reviewed elsewhere in this volume (Chapter 1), evolutionary reasoning has played an increasingly prominent role in theoretical models that have been proposed to explain individual differences in behavior that emerge over the course of development. Several of these theoretical models were initially prompted by the limitations of biopsychosocial stress-diathesis models (Ingram & Luxton, 2005). While the concepts of resilience and adaptation remain useful concepts (Panter-Brick & Leckman, 2013; Chapter 6, Volume 4), other evolutionary-based theoretical models, including differential susceptibility and biological sensitivity to context, are gaining widespread use in both theoretical formulations and empirical studies of child development (Chapters 2 and 3, this volume). Likewise, efforts to integrate evolutionary science and neuroscience are being proposed that leave aside the prevailing taxonomy of mental disorders altogether and focus instead on the therapeutic importance of attachment solutions to the existential separation challenges that are inherent in life (Fricchione, 2011).

Stress–Diathesis Models: Resilience and Allostasic Load

In the early 1970s, Garmezy and his team at the University of Minnesota were focused on the risk and protective factors associated with the development of schizophrenia (Garmezy & Streitman, 1974). In this context, the concept of resilience emerged to describe the dynamic process involving positive adaptations within the context of significant adversity (Luthar, Cicchetti, & Becker, 2000). While adaption and resilience can be readily seen from an evolutionary perspective (Lasker, 1969), the initial formulations of these constructs in the field of developmental psychology typically did not explicitly invoke evolution as being an important determinant (Rutter, 1979). By the time McEwen and his colleagues introduced the term allostasis in the 1990s to describe how organisms can adapt to environmental challenges and obtain stability through change, an evolutionary perspective was firmly in place (McEwen & Stellar, 1993).

Differential Susceptibility and Biological Sensitivity to Context

The emergence of an evolutionary perspective led Belsky and colleagues to ask uncomfortable questions. For example, why would natural selection lead to the emergence of an individual that would respond to adversity by becoming putatively disturbed and dysregulated (Belsky, Steinberg, & Draper, 1991; Daly & Wilson, 1981)? Belsky et al.'s (1991) psychosocial acceleration theory was advanced to explain why behaviors such as early pubertal development, promiscuous sexual behavior, adolescent pregnancy, and limited parental investment in multiple offspring might make biological sense as a way to prepare for and insure the passage of genes from one generation to the next despite the likelihood of growing up in the context of environmental adversity. Subsequent work by Belsky, Boyce, and Ellis has led to several theoretical concepts including differential susceptibility and biological sensitivity to context (Belsky, 1997; Boyce & Ellis 2005). This evolutionary perspective has enriched the field of child development and led to a rich and expanding body of work that seeks to integrate scientific advances from a broad range of disciplines, from genetics and epigenetics to developmental neurobiology and neuroimaging to neuroimmunology. Although a comprehensive and critical exploration of this multifaceted field is well beyond the scope of this chapter, readers are referred to other chapters in this volume as well as to recent special issues of *Development and Psychopathology* (Ellis & Boyce, 2011) and *Developmental Psychology* as well (Ellis & Bjoklund, 2012). There are also several other excellent reviews and editorials (Belsky & Pluess, 2013; Leckman, 2014; O'Conner, Moynihan, & Caserta, 2014). It is also becoming increasingly clear that early adversity can have enduring detrimental effects on physical as well as mental health over the life course (Danese et al., 2009) and that early interventions have the potential to alter this unfortunate, but evolutionarily understandable, trajectory (Campbell et al., 2014; Heckman, Moon, Pinto, Savelyev, & Yavitz, 2010).

Separation Challenges and Attachment Solutions

Fricchione (2011) provided one of the most detailed and compelling accounts of biological foundations of the evolutionary need for attachment solutions, from the earliest single cellular organisms that appear to our vertebrate and humanoid lineage leading to the emergence of our species and our incredibly complex and plastic biobehavioral systems. Fricchione's conceptual framework relies heavily on attachment theory initially advanced by Bowlby (1969, 1973, 1980). In contrast to many evolutionary accounts that focus on the processes at work that lead to psychopathology, Frichonne relied on his evolutionary perspective to provide a theoretical foundation for his compassionate clinical care across the life span including the separation challenges that occur at the end of life.

EVOLUTIONARY MECHANISMS THAT MAY ACCOUNT FOR THE PERSISTENCE OF DISCRETE FORMS OF PSYCHOPATHOLOGY

In this section five evolutionary-based mechanisms that may account for the persistence of some forms of psychopathology are presented. Table 4.1 presents a list of these mechanisms along with short descriptions and putative examples. Interested readers may also wish to consult anthologies and book-length reviews of evolutionary psychology and psychopathology (Barkow, Cosmides, & Tooby, 1995; Baron-Cohen, 1997; Brüne, 2008; Buss, 2011; Marks & Nesse, 1994; McGuire & Troisi, 1998; Tooby & Cosmides, 1990).

Failure of *Conserved Patterns of Behavior* to Develop Normally

If we depend on the normal expression of specific genes at the correct time and place in the developing brain, then we remain vulnerable to events that can disrupt the

TABLE 4.1 Proposed Evolutionary Mechanisms

Proposed evolutionary mechanism	Description	Examples
Failure of conserved neurobehavioral systems to develop normally. If we depend on the normal expression of specific genes at the correct time and place in the developing brain, then we remain vulnerable to events that can disrupt the development of these neural circuits.	Any failure of a conserved neurobehavioral system will set an individual apart. Although most of the proximal causes for such deficit states are accidental or stochastic, these events (mutations or untoward epigenetic events) occur early and constrain subsequent CNS development. Many of the mutations that have been identified involve regulatory regions of the human genome and not conserved protein-coding regions per se. These mutations often affect an entire cascade of neurobiological systems	Disorders associated with intellectual disability (e.g., fragile X, Prader-Willi syndrome, Angelman syndrome), learning disorders and communication disorders; autism spectrum disorder; and childhood-onset schizophrenia
Dysregulation of conserved neurobehavioral systems	Some conserved neurobehavioral systems are highly plastic and only appear in response to particular environment perturbations or at particular points in development. Some of these are behavioral alarm systems. Inappropriate or expressive activation in response to potential threats or failure to shut down such systems following loss may lead to psychopathology.	Mood and anxiety disorders, obsessive-compulsive disorder
Differential susceptibility	In response to chronic adversity during prior generations as well as during embryonic, fetal and postnatal life, individual differences may emerge that promote putative maladaptive behaviors (impulsivity, poor inhibitory control, and antisocial acts). However, these maladaptive behaviors may be adaptive in the context of chronic environmental adversity by enhancing an individual's reproductive fitness despite the negative effects on the mental and physical health. The precise stochastic genetic, and epigenetic mechanisms that result in these individual differences and their impact of biobehavioral plasticity over the course of development have yet to be fully determined.	Increased susceptibility to develop behaviors associated with attention-deficit/hyperactivity disorder (ADHD); conduct disorder; antisocial behavior; and substance use disorders
Environmental shifts and the value of diversity at the population level	Historical shifts in the environment away from the primeval environment of adaptation may make some individuals stand out by displaying previously adaptive behaviors that are now out of place. Alternatively, there may continue to be advantages in reproductive fitness at the group level for the presence of individuals in the group who are drawn to novel stimuli, adventurous, variable in their response to the same stimuli and willing to take risks despite the potential negative impact on their own reproductive fitness.	ADHD
Co-optation of conserved neurobiological systems	Conserved neurobehavioral systems are highly dependent on specific neurobiological substrates. Some of these pathways can be co-opted or hijacked by exogenous substances, leading to addiction, behavioral dysfunction, and impairment.	Substance use and addictive disorders
Evolutionary arms races	Some conserved biobehavioral systems may have evolved in relationship to other species (e.g., parasites, predators) that were important members of the primeval environment of adaptation.	Some forms of acute onset obsessive-compulsive disorder: pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS)

Source: Adapted in part from J. F. Leckman & L. C. Mayes, Understanding developmental psychopathology: How useful are evolutionary perspectives? *Journal of the American Academy of Child and Adolescent Psychiatry, 37*, 1998, Table 1 (Leckman & Mayes, 1998).

development of these neural circuits which in turn can lead to the emergence of certain forms of psychopathology. In association with certain genetic mutations, characteristic phenotypes appear which reflect the loss or breakdown of *conserved patterns of behavior*. In some cases the reasons for persistence are clear; however, in many others the molecular mechanisms remain obscure. For many of these disorders there is a clear loss of reproductive fitness (Power et al., 2012). Four examples are briefly considered: fragile X syndrome, Prader-Willi and Angelman syndromes, autism spectrum disorder (ASD), and childhood-onset schizophrenia (COS).

Fragile X Syndrome

Fragile X syndrome serves as a good example of a single-gene disorder with a characteristic profile of strengths and weakness that generally follow a specific course over development (Hagerman & Hagerman, 2002; Chapter 2, Volume 3). Typically, males with fragile X syndrome have a characteristic phenotype with both physical

stigmata (long face, large ears, hyperextensible joints, and large testes) and cognitive-behavioral features (mental impairment with sequential processing deficits, dysarthric speech, motoric hyperactivity, anxiety and unstable mood, and social difficulties). Fragile X syndrome is the single most common cause for heritable intellectual disability. In addition, it is also the most widely diagnosed form of intellectual disability that leads to ASD (Hatton et al., 2006). This X-linked disorder is caused by an expansion of a trinucleotide CGG repeat (>200) on the promoter region of the *fragile X mental retardation* 1 gene (*FMR1*). As a result, the promoter region often becomes methylated which leads to a deficiency or absence of the expression of the FMR1 protein (FMRP) (McLennan, Polussa, Tassone, & Hagerman, 2011). The transcription failure is usually due to the presence of an unstable region of DNA in which a trinucleotide repeat sequence, (CGG)n, is amplified from fewer than 54 repeats in typically developing individuals to more than 200 repeats in affected males (Fu et al., 1991). Individuals in these families with more than 52 but less than 200 repeats have a premutation. Curiously, a premutation expands to a full mutation only when it is transmitted by a female so that daughters of a male with a premutation have only a premutation and remain unaffected. The genetic anticipation (progressively more individuals in a kindred are affected in successive generations) associated with this mutation accounts in large part for the persistence of this mutation in the population. Similar DNA amplification abnormalities and associated patterns of genetic anticipation within large kindreds have also been documented in several other autosomal disorders including Huntington disease (Walker, 2007). These disorders provide a clear example of how a mutation in a regulatory region can have a major impact on neural development.

Recent evidence suggests that the neuronal deficits in fragile X syndrome may occur in part due to the loss of translational constraint imposed by FMRP on transcripts for a number of synaptic proteins including neuroligin-3, neurexin-1, SHANK3, PTEN (Cowden syndrome), TSC2, and NF1 (neurofibromatosis type 1) (Darnell et al., 2011). Several of these genes including SHANK3 and NRXN1 have also been linked with ASD (State & Sestan, 2012). Also of note is that there are species-specific differences in the expression of FMR1 in the neocortex (Kwan et al., 2012) which in turn points to the potential limitations of animal model systems to explore the neuropathology of some neurodevelopmental disorders. From an evolutionary point of view this finding is consistent with the emerging knowledge that many of the genetic mutations responsible for human diseases occur in regulatory regions of the genome that are not conserved across other mammalian or primate species (Ward & Kellis, 2012).

Prader-Willi and Angelman Syndromes

Prader-Willi syndrome in conjunction with Angelman syndrome perhaps represents the best example of genomic imprinting in humans. Genomic imprinting is a phenomenon by which certain genes are expressed in a parent-of-origin-specific manner. It is independent of the classical Mendelian inheritance. Genomic imprinting is an epigenetic process that involves DNA methylation and histone modifications to achieve monoallelic expression without altering the protein-coding sequence. These epigenetic marks are established in the germline and are maintained throughout the somatic cells of an organism. Forms of genomic imprinting have been demonstrated in mammals as well as insects and flowering plants.

Prader-Willi syndrome is characterized by mild mental retardation, obesity, short stature, hypogonadism, and small hands and feet (Cassidy, Schwartz, Miller, & Discoll, 2012). Most commonly Prader-Willi syndrome is understood to involve the loss of a *paternally* imprinted stretch of five genes that encode polypeptides (MKRN3, MAGEL2, NECDIN, and SNURF-SNRPN) and a family of six paternal-only expressed small nucleolar RNA genes located on the proximal long arm of chromosome 15 (15q11.2-q13). There are three main molecular mechanisms that result in Prader-Willi syndrome: paternal deletion, maternal uniparental disomy and an imprinting defect. In 65–75% of the cases there is an interstitial microdeletion of the paternally inherited region on chromosome 15. In another 20–30% of cases, Prader-Willi is due to maternal uniparental disomy when the affected individual has two copies of chromosome 15, both of which are inherited from the mother. Maternal uniparental disomy has been shown to be associated with advanced maternal age (Gillessen-Kaesbach, Robinson, Lohmann, Kaya-Westerloh, Passargem, & Horsthemke, 1995). Finally, several forms of imprinting defects have been reported (Cassidy et al., 2012). Most of these defects arise from epigenetic causes while other individuals have a very small deletion (7.5 to >100 kb) in the promoter region of the SNRPN gene.

In contrast to Prader-Willi syndrome, Angelman syndrome is characterized by a severe intellectual impairment as well as a speech impairment characterized by the absence or the minimal use of words, epilepsy, puppet-like ataxic movements, prognathism, tongue protrusion, paroxysms of laughter, abnormal sleep patterns, and motoric

hyperactivity (Williams et al., 2006). Individuals with Angelman syndrome frequently exhibit socialization and communication deficits that meet the diagnostic criteria for ASD (Steffenburg, Gillberg, Steffenburg, & Kyllerman, 1996). Unlike Prader-Willi, Angelman's syndrome is due to the loss of expression of two *maternally* imprinted genes (*UBE3A* and *ATP10A*). These two loci are immediately adjacent to the Prader-Willi region on chromosome 15. UBE3A encodes an E3 ubiquitin ligase that is expressed biallelically in most tissues but is *maternally* expressed in almost all neurons (Mabb, Judson, Zylka, & Philpot, 2011).

One well-characterized substrate for UBE3A is the immediate early gene, Arc (activity-regulated cytoskeleton-associated protein). Arc is brain-specific and is rapidly upregulated in response to increases in neuronal activity. It is also required for learning and long-term memory (Greer et al., 2010). Angelman syndrome model mice, which carry a maternal Ube3a null mutation, recapitulate major features of Angelman syndrome in humans, including enhanced seizure susceptibility (Mabb et al., 2011). Interestingly, seizure or learning protocols induce abnormally elevated Arc expression in Ube3a knockout mice relative to wild-type controls (Greer et al., 2010), suggesting that UBE3A is required for Arc turnover in the brain during periods of increased synaptic activity. Excitatory neurotransmission onto neocortical pyramidal neurons has also been shown to be diminished (Wallace, Burette, Weinberg, & Philpot, 2012). These findings have resulted in an accelerating interest in UBE3A and its role in neural transmission. However, a number of critical gaps remain in our knowledge concerning UBE3A imprinting and its role in synaptic and circuit function.

A deeper understanding of Prader-Willi and Angelman syndromes will likely shed light on why mammalian development is characterized by the nonequivalence of parental genomes. There are a few hints from the animal literature that genomic imprinting has allowed mammalian species to alter the dosage of particular genes and sculpt their patterns of expression using non-Mendelian mechanisms. For example, results from mouse chimera studies suggest that the accumulative effects of paternally derived imprinted genes differentially influence hypothalamic and septal structures but not the cerebral cortex. Conversely, the accumulative effect of maternally derived genes is evident in the cortex, striatum, and hippocampus, but not the hypothalamus (Keverne et al., 1996). Perhaps the most compelling argument is that monoallelic expression (either maternal or paternal) provides a clear source of stability amidst the temporal and spatial complexity that characterizes the programming sequence associated with human CNS development (Keverne, 2011).

Autism Spectrum Disorder

Autistic behaviors have emerged as recognizable syndromes in the twentieth century based on the initial work of Kanner (1943), Asperger (1944), and Heller (1908). The current *DSM-5* diagnostic criteria for ASD focus on two symptom dimensions: (1) persistent deficits in social communication and social interaction across contexts, not accounted for by general developmental delays; and (2) restricted, repetitive patterns of behavior, interests, or activities (American Psychiatric Association, 2013).

At first glance ASD provides a clear example of a form of developmental psychopathology that involves a failure of conserved cognitive and emotional capacities to develop normally. Specifically, individuals with ASD are profoundly impaired in understanding the motives and mental states of other individuals. This impairment in their theory of mind extends into an understanding of one's own mental states as well as the mental states of others (Baron-Cohen, Leslie, & Frith, 1985; Chapter 4, Volume 3). Yet there are perplexing issues. Why does ASD persist in the face of such a potentially negative effect on reproductive fitness? What is the evolutionary explanation for why these two dimensions (social communication and highly restrictive interests or repetitive behaviors) co-occur together? Intuitively these aspects of behavior do not seem to be closely interrelated.

Some evolutionary explanations have approached this question. Most notably Baron-Cohen (2002) focused on the preponderance of males affected with ASD and proposed the extreme male brain theory of autism. This theory is based on the perspective that females on average have a stronger drive to empathize while males on average have a stronger drive to systemize. This theory is controversial, but it has led to an expanding body of empirical data focused on sex differences in brain structure and function and the potential role of fetal testosterone in influencing aspects of early brain development (Baron-Cohen, Lombardo, Auyeung, Ashwin, Chakrabarti, & Knickmeyer, 2011).

More recently, Reser (2011) examined the hypothesis that some genes associated with ASD did in fact enhance reproductive fitness due to the adaptive benefits of being cognitively suited for solitary foraging. According to this theory, individuals with subclinical ASD included ecologically competent individuals that could have been adept at learning and implementing hunting and gathering skills on their own. During times when nutritional resources were sparse, human groups may have had to

periodically disband. In such circumstances individuals adept in solitary foraging were at an advantage. Reser also speculated that the most severe cases of ADS may be due to assortative mating.

Evolutionary explanations also need to account for why children with ASD are much more commonly affected by a broad range of neurologic (e.g., epilepsy), neuropsychiatric, gastrointestinal and endocrine disorders (Chen, Chen, Liu, Huang, & Lin, 2009; Gurney, McPheeters, & Davis, 2006). The common neuropsychiatric and psychiatric comorbidities include stereotypic movement disorder, attention-deficit hyperactivity disorder (ADHD), obsessive-compulsive disorder (OCD), Tourette's syndrome, and mood and anxiety disorders and sleep disorders (Gurney et al., 2006; Matson & Nebel-Schwalm, 2007). Ultimately, many of these questions will be answered by our rapidly expanding knowledge of the genetic and epigenetic factors that regulate the spatiotemporal development of the human brain.

The neuropathogy associated with idiopathic ASD is variable although some structural and functional consistencies are emerging (Abrahams & Geschwind, 2008, 2010). Structurally, one well-replicated finding is that of accelerated postnatal growth in defined brain regions (Courchesne et al., 2010). There is also evidence of disrupted connectivity and laterality involving the frontal and temporal cortices, cerebellum, and amygdala (Eyler, Pierce, & Courchesne, 2012). Likewise, in response to viewing biological motion movements, children with ASD show differential patterns of activation compared with their unaffected siblings and typically developing controls (Kaiser et al., 2010). Biological motion refers to our evolutionarily conserved and robust visual sensitivity to the movements of other individuals (Blake & Shiffrar, 2007). The differential patterns of activation included prefrontal and temporal cortical regions as well as the amygdala and the fusiform gyrus (Kaiser et al., 2010). Intriguingly the unaffected siblings of the children with ASD also had unique patterns of functional activity in ventromedial prefrontal cortex and the right posterior temporal sulcus in response to biological motion. The authors speculate that since these regions have been previously implicated in aspects of social perception and social cognition (Adolphs, 1999), these regional activations may be *compensatory* in character such that these differential patterns might reflect a process through which brain function was altered over development to compensate for an increased genetic risk to develop ASD. In any case the social brain in its normal and dysfunctional states must be understood not in terms of specific structures but rather in terms of their interaction in large-scale networks (Kennedy & Adolphs, 2012)

Based on twin and family genetic studies, it is clear that ASD is highly heritable (Abrahams & Geschwind, 2008). A number of genetic mutations affecting single genetic loci have been described, including fragile X and Angelman syndromes. The number of single gene mutations associated with ASD phenotypes is increasing. One of the most well characterized disorders include Rett syndrome (Rett, 1966). Rett syndrome is one of the most common causes of ASD and intellectual disability in girls. It is characterized by early neurological regression that severely affects motor, cognitive and communication skills and is often associated with a seizure disorder. It is a monogenic X-linked dominant disorder related to mutation in MECP2, which encodes the methyl-CpG-binding protein MeCP2 (Smeets, Pelc, & Dan, 2012). Of interest MeCP2 deficiency in Rett syndrome causes epigenetic aberrations at the PWS/AS imprinting center that affects UBE3A expression (Makedonski, Abuhatzira, Kaufman, Razin, & Shemer, 2005). Among other single gene disorders, Novarino et al. (2012) recently identified inactivating mutations in the gene BCKDK (branched chain ketoacid dehydrogenase kinase) in consanguineous families with ASD, epilepsy, and intellectual disability. The encoded protein is responsible for phosphorylation-mediated inactivation of a branched-chain ketoacid dehydrogenase, causing individuals with homozygous mutations to display reductions in plasma branched-chain amino acids. Although the mechanism by which abnormal brain amino acid levels lead to autism, intellectual disability, and epilepsy is not fully understood, it likely involves the various biogenic amine pathways that underlie the dopaminergic, noradrenergic, serotonergic, and histaminergic pathways.

It is also becoming clear that in addition to single gene disorders that impact multiple neurodevelopmental pathways, rare and de novo point mutations and submicroscopic variations in chromosomal structure *contribute*, but in isolation do not cause, a considerable number of ASD cases. To date more than 100 susceptibility genes have been identified (Betancur, 2011; State & Sestan, 2012). They include synaptic adhesion molecules and postsynaptic density proteins including FMR1, SHANK3, and NRXN1 as well as chromatin modifiers (MECP2, CHD8), and DNA binding proteins (POGZ), ion channels (SCN2A), microtubule-associated proteins (KATNAL2), neurotransmitter receptors (GRIN2B), and phosphorylation-regulated tyrosine kinases (DYRK1A) (Jamain et al., 2003; Kwan et al., 2012; Neale et al., 2012;

O'Roak et al., 2011; Peça & Feng, 2012; Sanders et al., 2012; Sebat et al., 2007; Zachariah & Rastegar, 2012). In a recent exome sequencing of more than 340 children with ASD and one unaffected sibling Iossifov et al. (2012) estimated that there are at least 350 to 400 ASD susceptibility genes. In addition to rare and not so rare variants, it is also clear that common genetic variants likely account for substantial additive effects on ASD liability (Klei et al., 2012).

Returning to the question—why does ASD persist in the face of such negative effects on reproductive fitness—we can now say with certainty that the normal expression of many of these susceptibility genes at the correct time and place in the developing brain are crucial to our capacity to understand the mental states of the other. However, it is also clear that unaffected siblings who share some of these susceptibility genes also have modestly reduced fecundity as well. This is particularly true of brothers (Power et al., 2012). This raises further questions about the persistence of the disorder and perhaps the possibility that the presence of individuals with certain autistic-like traits might benefit society as a whole.

In addition, knowledge concerning the nature and timing of the relevant environmental insults that are associated with and increase the likelihood of ASD will also reveal further insights into the regulatory mechanisms that influence the emergence of our social and linguistic capacities over the course of development. For example, some of the strongest evidence indicates that advanced paternal age, especially for fathers over the age of 50 years; the immigrant status of the mother; prenatal nutrition; as well as pregnancy and birth complications, particularly gestational diabetes, can increase the risk of a child to develop ASD and related conditions including schizophrenia (Hamlyn, Duhig, McGrath, & Scott, 2013). The role of fetal levels of androgens (Lombardo et al., 2012) and events that can lead to activation of the fetal immune system early in life are also gaining increased attention (Crespi & Thiselton, 2011).

Schizophrenia, Particularly Childhood-Onset Schizophrenia

COS is variably defined by an onset of psychosis from age 12 to 18 years. Children with this condition have been identified and followed for decades (Asarnow, Tompson, & McGrath, 2004; Nicolson & Rapoport, 1999). The signs and symptoms of childhood/pediatric schizophrenia are nearly the same as adult-onset schizophrenia (Masi, Mucci, & Pari, 2006). Auditory hallucinations are the most frequent positive symptom, while visual and tactile hallucinations are rarer. The appearance of negative symptoms including emotional, cognitive, and behavioral abnormalities is often seen years before the onset of psychosis. In many instances the child has a history of delays in cognitive, language and motor development (Alaghband-Rad et al., 1995; Hollis, 1995). Indeed, cognitive abilities in the borderline to the intellectually disabled range have been reported in up to 20% of children with schizophrenia and ASD (Sporn et al., 2004).

A number of evolutionary theories have been advanced to account for the persistence of schizophrenia. For example, Brüne (2005) reviewed the available empirical evidence and concluded that, as in ASD, theory of mind is specifically impaired in schizophrenia and that many psychotic symptoms can be understood in light of a disturbed capacity in patients to recognize their own intentions, and to monitor others' intentions. Similarly, Burns (2006) advanced the hypothesis that the evolution of our social brain and other higher order cognitive abilities is also responsible for the evolution of schizophrenia. The overlap of the natural histories of COS and ASD as well as the overlap of the evolutionary theories advanced to account for the persistence of ASD and schizophrenia provides the rationale for the inclusion of COS and schizophrenia more broadly in this section of the chapter.

Structural brain imaging studies have documented an altered pace of neurodevelopmental trajectories in COS as well as in ASD. Specifically, in young adolescents with COS, there is increased velocity of gray matter thinning, which rectifies itself in parietal regions but partly persists in frontotemporal regions leading to the cortical deficit pattern similar to the one found in adult-onset schizophrenia (Gogtay, 2008; Rapoport & Gogtay, 2008). However, the trajectory of CNS development in COS differs from that seen in ASD.

Genetically, there is clear evidence that many of the same genes convey vulnerability for both ASD and schizophrenia (Talkowski et al., 2012). For example, Lin, Hrabovsky, Pedrosa, Wang, Zheng, & Lachman (2012) using transcriptome sequencing identified 801 genes in differentiating neurons that were expressed in an allele-biased manner. These genes included a number of putative schizophrenia and ASD candidate genes including several involved in synapse formation and function (NRG1, NRG3, NLGN1, NLGN4, and NRXN1). Overall, there was a modest enrichment for schizophrenia and ASD candidate genes among those that showed evidence for allele-biased expression. This again points to the possibility of parent-of-origin effects and the possible role of genomic imprinting in the transmission of schizophrenia and ASD in some families.

Knowledge concerning the nature and timing of the relevant environmental insults that are associated with the increased risk of developing schizophrenia also overlap with those implicated in ASD. There is strong evidence which indicates that advanced paternal age increases the risk for both disorders (Miller et al., 2011). Curiously this meta-analysis also documented a modestly increased risk for schizophrenia among the offspring of younger fathers (<25 years), but this increased risk was only seen among the male offspring. The immigrant status of the family as well as pregnancy and birth complications can increase the risk of a child to develop schizophrenia (Hamlyn, Duhig, McGrath, & Scott, 2013). Events that can lead to activation of the fetal immune system early in life are also gaining increased attention in schizophrenia research (Brown, 2011; Hsiao & Patterson, 2012).

Dysregulation of Conserved Behavioral Systems and Associated Mental States

Apart from developmental failure or distortion, another plausible mechanism that could account for the preservation of specific maladaptive phenotypes is the dysregulation of conserved behavioral patterns and associated mental states. Briefly, if normal behavioral patterns are initiated at an inappropriate time, are of too high an intensity, or are not turned off in a timely fashion, this could lead to a consistent phenotype of maladaptive behavior. A large number of psychiatric disorders have been suggested to be the result of such a mechanism. The list includes separation anxiety disorder (Bowlby, 1973), phobias (Marks, 1987; Mineka & Ohman, 2002), generalized anxiety disorder (Woody & Rachrnan, 1994), panic disorder (Klein, 1993; Nesse, 1989; Stein & Bouwer, 1997), OCD (Evans and Leckman, 2006), and major depression (Nesse & Williams, 1994). In many instances, these speculations rest on the plausible existence of innate alarm systems that are selectively activated when the brain detects danger in the environment (Marks & Nesse, 1994; Nesse, 1999). Here we consider mood and anxiety disorders as a general class. We then consider OCD as a specific example.

Mood and Anxiety Disorders

In *The Expression of Emotions in Man and Animals,* Darwin (1872) argued that anxiety and fear are evolved, adaptive responses evident in our mammalian ancestors. A strong case has been made that our ability to experience and outwardly manifest distress, fear, anxiety, and sadness provided selective advantages to our ancestors by altering aspects of appearance (including facial expressions and bodily cues), physiology, cognition, behavior and motivation. Key components of this conserved system appear very early in infant development and are distinctive elements of their behavioral repertoire (Gullone, 2000). Individual differences in the expression of distress, fear, anxiety, and sadness are closely linked to separation or the fear of separation from primary caregivers. For example, most infants experience a period of stranger anxiety around 8 to 12 months of age, marked by wariness or distress around new people (Waters, Matas, & Sroufe, 1975). Stranger anxiety is often followed by separation anxiety, which is usually evident by 10 to 18 months of age and is characterized by distress about being separated from the primary caregiver (Thompson & Limber, 1992). Here it is impossible to miss the fundamental importance of the infant's dyadic interactions with caregivers. Indeed, Bowlby's work from the 1950s on individual differences in human attachment behavior eventually led to a deep appreciation of the importance of evolutionary thinking about human development and the value of studying these phenomena across species (Bowlby, 1969, 1973, 1980; Hinde, 1987; Tinbergen, 2010).

Most anxiety disorders begin early in development, with a median age at onset of 12 years (Kessler, Avenevoli, Costello, et al., 2012; Merikangas et al., 2010). Almost one in three children suffers from an anxiety disorder at some point during childhood or adolescence (Merikangas et al., 2010). Mood disorders also affect a high percentage of adolescents and they are often preceded by an anxiety disorder (Merikangas et al., 2010; Silk, Davis, McMakin, Dahl, & Forbes, 2012). Epidemiological studies from across the globe also indicate that symptoms of anxiety and depression are not an all or none phenomenon; they have a dimensional character (Achenbach, Rescorla, & Ivanova, 2012). Indeed, a recent factor analytic study of the data from a population-based sample of adolescents found that mood and anxiety disorders are divided into two classes: (1) a *fear* class, including specific phobia, social phobia, panic disorder, and agoraphobia; and (2) a *distress* class, including separation anxiety disorder, posttraumatic stress disorder, generalized anxiety disorder, and major depression (Kessler, Avenevoli, McLaughlin, et al., 2012). High rates of comorbidity were seen within each of these two classes of disorders.

Viewed from an adult perspective a number of evolutionary hypotheses concerning mood and anxiety disorders have been advanced (Akiskal & McKinney, 1975; Andrews & Thompson, 2009; Forbes & Dahl, 2012; Hartley and Phelps, 2012; Nesse, 2009; Nettle, 2004; Price, Sloman, Gardner, Gilbert, & Rohde, 1994; Stein & Nesse, 2011;

Thornhill & Thornhill, 1989). Our capacity to detect and respond to potential threats and losses, customized to different developmental stages and differing social contexts are key elements of many of these hypotheses. Somatic symptoms of fever, pain, and coughing are presented as being analogous to the "psychic" pain and distress associated with depression and anxiety. In this model the psychic distress informs the sufferer that something needs to change in their interpersonal world and perhaps be avoided in the future. Nesse (2000) detailed the adaptive value of these symptoms in communicating to members of one's social group a need for help, a willingness to accept a lower social rank, as well as an increasing self-awareness that it may be useful to disengage from commitments to unreachable goals. In such situations, a depressed mood, pessimism, and lack of motivation may provide a fitness advantage by inhibiting otherwise futile or dangerous behavior. Similarly, Andrews and Thompson (2009) proposed the analytical rumination (AR) hypothesis that depression and related forms of mental distress are adaptive in that they provide a mechanism for the individual to engage in sustained analysis (rumination) of complex problems until a viable solution is reached. It is also worth noting that there is a fair amount of empirical evidence indicating an increased degree of assortative mating among individuals with mood disorders (bipolar disorder > major depression) which likely contributes to the persistence of some of these traits in the population (Mathews & Reus, 2001).

Most of these evolutionary hypotheses are not mutually exclusive. They also posit (or at least imply) that the neural mechanisms underlying these capacities can become dysregulated, leading to severe, chronic disabling and, at times, life-threatening symptoms and behaviors. The question then becomes how best to set the threshold for disorder and are there times when a "disorder" level impairment is normative and adaptive at a given developmental stage. While evolutionary theories may be useful in conceptualizing symptoms and disorders, population-based studies across age and gender groups and within diverse cultural and ethnic groups is a much more pragmatic and clinically useful approach.

Given their universality, it is likely that fundamental aspects of human neural development are closely interrelated with these unpleasant emotions. The available neurobiological studies of rodents, primates and humans have identified key components of the emotional regulation and fear circuitry that include the amygdala and regions of the prefrontal cortex (Blackford & Pine, 2012; Canteras, Mota-Ortiz, & Motta, 2012; Kupfer, Frank, & Phillips, 2012). Studies of depressed youth also have implicated these same brain regions as well as areas of the brain involved in reward processing, particularly in a social context (Silk et al., 2012).

Consistent with an evolutionary perspective, family, twin and adoption studies support an important role for genetic factors in the etiology of mood and anxiety symptoms and disorders (Hettema, Neale, & Kendler, 2001; Kendler, Gatz, Gardner, & Pedersen, 2006; Pawlby, Hay, Sharp, Waters, & O'Keane, 2009; Sullivan, Neale, & Kendler, 2000). These studies also consistently suggest that many of the genetic risk factors for mood and anxiety disorders are shared in common across these disorders (Kendler, Aggen, Knudsen, Roysamb, Neale, & Reichborn-Kjennerud, 2011; Kendler, Prescott, Myers, & Neale, 2003). However, efforts to identify specific genetic variants associated with an increased susceptibility to mood and anxiety disorders using large N genome-wide association studies (GWAS) have not been successful to date (Shyn et al., 2011). Despite this failure, it will be important to continue efforts to identify these susceptibility genes. Power et al. (2012) documented that siblings of patients with depression have significantly increased fecundity which more than compensated for the lower fecundity of affected individuals. This suggests that some of these susceptibility genes can increase an individual's reproductive fitness.

Efforts to identify gene by environment effects (GxE) with regard to mood and anxiety disorders have also been of great interest since the initial report by Caspi et al. (2003). They noted that a functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene (SLC6A4) moderated the influence of stressful life events on depression. In the initial report, individuals with one or two copies of the short allele of the 5-HTT promoter polymorphism exhibited more depressive symptoms, diagnosable depression, and suicidality in relation to stressful life events than individuals homozygous for the long allele. These findings have not been universally replicated, but the preponderance of the data from quantitative population genetics, neurobiological studies, and experimental studies in animals confirms the plausibility of their initial findings although the overall effect size may be modest (Caspi, Hariri, Holmes, Uher, & Moffitt, 2010).

Two approaches of considerable promise for future research are the emerging data from population-based samples of twins and efforts to begin to understand the role of epigenetic modifications that occur as a result of environmental adversities. First, the most convincing data concerning GxE effects have come from recent efforts

to examine the impact of environmental experiences on symptoms of anxiety and depression across the life span using longitudinal data from eight American and European population-based twin registries (Kendler et al., 2011). By modeling data from monozygotic (MZ) twin pairs of widely varying ages this group of investigators were able to reject the hypothesis that genetic influences alone can account for the relative stability of anxiety and depression across the life span. Based on their analyses of the individual trajectories, they determined that levels of symptoms increasingly diverged between the MZ twins from childhood to late adulthood based on their environmental experiences. Only in late adulthood (~70 years of age) did this divergence disappear.

Efforts to delineate the multiple and diverse epigenetic and neurobiological mechanisms by which environmental experiences shape the character and continuity of mood and anxiety disorders is also an important area for future study. It is increasingly evident that environmental experiences can lead to epigenetically mediated alterations in gene expression that likely influence an individual's vulnerability to depression and anxiety (Monk, Spicer, & Champagne, 2012). To date the strongest data from human and animal models concerns the epigenetic consequences of early adversity. For example, analysis of cord blood samples from infants born to depressed mothers indicated elevated levels of DNA methylation within the gene (NR3C1) that codes for the glucocorticoid receptor (Oberlander, Weinberg, Papsdorf, Grunau, Misri, & Devlin, 2008). At 3 months of age, these investigators assessed the infants' stress responsivity by examining their salivary cortisol levels. Levels of NR3C1 methylation in fetal cord blood were found to predict infant cortisol response to stress, suggesting a functional consequence of this epigenetic variation. Similar epigenetic changes have also been reported for the gene encoding the serotonin transporter (SLC6A4) (Devlin, Brain, Austin, & Oberlander, 2010). Although the meaning of these epigenetic changes in blood is unclear with regard to brain function, as epigenetic alterations can be tissue specific and even specific to particular brain regions (Provençal et al., 2012), animal models have convincingly demonstrated that exposure to prenatal stress can induce similar epigenetic changes in the most relevant brain regions as well as increased depressive-like behavior in adult animals (Mueller & Bale, 2008). Viewed from an evolutionary perspective these data suggest that we and our mammalian ancestors have evolved molecular mechanisms that permit some degree of programming so that the offspring may be better prepared for the environmental context in which their rearing will take place.

Obsessive-Compulsive Disorder

Dysregulation of otherwise adaptive behavioral patterns linked to specific environmental perturbations may also be readily evident in other forms of psychopathology. Although speculative, this list includes OCD. OCD has a lifetime prevalence of 2–3%, affecting all age groups across the globe (Ruscio, Stein Chiu, & Kessler, 2010). OCD is considered to be the fourth most common mental disorder and is frequently accompanied by family, social, school, and work dysfunctions (Ayuso-Mateos, 2006). Obsessive-compulsive (OC) symptoms, like symptoms of anxiety and depression are dimensional in character and evolutionary accounts for each of the symptom dimensions have been proposed (Evans & Leckman, 2006; Mataix-Cols, Rosario-Campos, & Leckman, 2005).

Obsessions are ego-dystonic, repetitive, and intrusive thoughts or images that are not simply excessive worries about real-life problems (American Psychiatric Association, 2013; Leckman et al., 2010). Classic examples include intrusive worries about cleanliness or about harm coming to close family members. Compulsions are repetitive behaviors (e.g., hand washing, checking, ordering) or mental acts (e.g., praying, counting, repeating words silently) that the person feels driven to perform in response to an obsession. These rituals usually need to be performed according to certain rules. Often there is a heightened sensitivity in the home environment to things not being "just right" in the way they feel, look, or sound (Leckman, Walker, Goodman, Pauls, & Cohen, 1994). This awareness that something is not just right is commonly associated with a sense of dread that something terrible is about to happen. Other OC symptom dimensions include preoccupations about symmetry and exactness and compulsions of ordering and arranging, doing and redoing, and counting (Leckman et al., 1997). Here again we may see the presence of an ancient alarm system that may have served well our hunter–gatherer ancestors as they struggled to survive in the face of predators and unsanitary conditions (Brüne, 2008; Feygin, Swain, & Leckman, 2006; Marks & Nesse, 1994).

Beginning in the second year of life, most normally developing children display a variety of intrusive thoughts, habits, and routines, some of which closely resemble the behaviors associated with OCD (Evans, Gray, & Leckman, 1999; Evans et al., 1997; Gesell, 1928; Leonard, Goldberger, Rapoport, Cheslow, & Swedo, 1990; Zohar & Felz, 2001). For example, in one large population-based study ($n \sim 1{,}500$), we found that parents reported that over half of the 2-year-olds were very aware of minute details, such as imperfections in toys and clothes (Evans et al., 1997).

Likewise, parents of 2-year-olds were also almost twice as likely to report that their child is very concerned with dirt, cleanliness, or neatness than were parents of 5-year-olds, and almost 7 times more likely than parents of children less than age 1. Finally, 63% of 2-year-olds were reported to arrange objects until they are just right compared with 4% of children less than 1 year of age and 41% of 5-year-olds.

For children less than 4 years of age, repetitive behaviors were positively related to the child's level of fearfulness in general as well as their fear of strangers (Evans et al., 1999). Interestingly, bedtime fears (fear of the dark, of monsters) were related to hoarding objects; fear of death was significantly associated with strong attachment to a specific object. For children older than age 4 years, a greater number of correlations emerged. Most notably, overall scores on the rituals inventory were related to bedtime fears. Just right behaviors were related to fears of contamination and fear of separation; and fear of death was positively related to repeats actions over and over, and arranges objects until they are just right (Evans et al., 1999).

As noted by Evans and Leckman (2006), these findings echo many of the theories of Erikson (1968), Werner (1957), and Winnicott (1958a) that children's rituals are associated with anxiety states brought on by the many fears and uncertainties that are common in childhood and that they bear some relationship to the presence or absence of attachment figures as a source of security and syncretic wholeness. These findings also emphasize the normal capacity that young children have to compare elements of the outside world with their existing mental representation to ensure that important aspects of their world are just right (Gesell, 1928; Piaget, 1962). This in turn recalls *les sentiments d'incompletude* (feelings of incompleteness) that Janet (1903) identified as the core problem for individuals with OCD at the end of the nineteenth century.

The initiation of parenting is another developmental stage that is normally characterized by intense harm-avoidant preoccupations and a heightened sense of responsibility accompanied by compulsive attention to issues of safety and cleanliness characterized by anxious intrusive thoughts and harm avoidant behaviors (Kim, Mayes, Feldman, Leckman, & Swain, 2013; Leckman, Mayes, Feldman, Evans, King, & Cohen, 1999; Winnicott, 1958a). The normally occurring emergence of these symptoms may well account for the increased risk of onset or exacerbation of OCD seen late in pregnancy and during the early postpartum period (Abramowitz et al., 2010; McGuinness, Blissett, & Jones, 2011). Viewed in the context of the historically high rates of infant mortality (Bideau, Desjardins, & Brignoli 1997) these observations are consistent with the hypothesis that the dysregulation of conserved behavioral patterns and associated mental states can contribute to the emergence of particular psychopathological outcomes.

Like the other anxiety disorders, OCD has been conceptualized as an imbalance between subcortical and cortical circuits. A relatively large and growing number of neuroimaging studies have examined both functional and structural correlates of OCD in both children and adults (Blackford & Pine, 2012). Functional imaging studies have consistently reported hyperactivity in the orbitofrontal cortex, anterior cingulate cortex, and caudate nucleus of individuals with OCD. Although these findings and the results of structural studies are not sufficient to establish causality, a relatively compelling case can be made that an imbalance in the cortico-basal ganglia-thalamo-cortical loops that specifically involve the orbitofrontal and the anterior cingulate cortices play a causal role in this disorder (Maia, Cooney, & Peterson, 2008).

Consistent with an evolutionary perspective, family, twin, and adoption studies have demonstrated that both genetic biological and environmental factors are important in the etiology of OCD (Pauls, 2010). Family-genetic studies published since the 1930s indicate that among first-degree relatives of OCD-affected children and adults there is a four- to tenfold OCD risk increase, respectively, as compared with relatives of controls. A review of twin studies concluded that obsessive-compulsive (OC) symptoms are heritable, with greater genetic influences in child-onset (45–65%), than in adult-onset OCD cases (27–47%) (Pauls, 2010). However, efforts to identify specific genetic variants associated with an increased susceptibility to OCD using large N GWAS have not been successful to date (Stewart et al., 2013).

In conclusion, the available data support the plausibility of the hypothesis that many OC symptoms appear normally during the course of development and confer some degree of reproductive fitness. It is only when there is some dysregulation of evolutionarily conserved neurobiological pathways that extreme variants appear and a diagnosis of OCD is warranted. While future genetic research, e.g., next-generation sequencing strategies, the study of rare variants), longitudinal epidemiological studies, particularly population-based twin studies (Kendler et al., 2011), and the development of valid animal models (Chen et al., 2010; Yaddanapudi et al., 2010) will continue to elucidate the relevant etiological pathways, it is difficult to imagine how specific evolutionary hypotheses concerning OCD can

be formally tested. Consequently, these hypotheses are best viewed as strategically important in the conceptualization of the study of psychopathology and the integration of data from across multiple disciplines.

Ancient Versus Current Environments and the Value of Diversity Within Populations

Another evolutionary explanation focuses on the changing nature of our environments. This viewpoint posits that much of our human behavioral equipment can be best understood in relationship to our primeval environment where we evolved as a species. As Bowlby (1969) pointed out, the property of being adapted entails a reference both to a specified outcome and to a specified environment. Thus as modern societies shift away from their agrarian pasts, certain behavioral traits might become less adaptive. That said, things never stay the same and the multiple environments in which we dwell are constantly changing. Global warming and climate change are emerging as a major challenge to our species while the near universality of virtual worlds via social media and the internet are now part of everyday life even for preschool children. Indeed, our capacity as a species to explore and adapt to novel environments is one of our most distinguishing traits—compared with other species (Morán, 2008). Work in this area also highlights another aspect of evolutionary theory—namely, in the struggle for life it is the reproductive fitness within societal groups that is selected for rather than any particular individual. With this perspective in mind, let us consider ADHD.

Attention-Deficit\|Hyperactivity Disorder

According to the *DSM-5*, ADHD is defined by a constellation of clinical features, including hyperactivity, inattention, and impulsivity (American Psychiatric Association, 2013). Children with ADHD are more likely to exhibit school behavior problems, academic underachievement, poor self-esteem, parent–child conflicts, and difficulties with peer acceptance (Abikoff, Gittelman-Klein, & Klein, 1977; Barkley, 1997; Erhardt & Hinshaw, 1994; Chapter 14, Volume 3). ADHD is a chronic disorder—as children age, become teenagers, and enter adulthood, they are more likely to engage in antisocial behaviors including substance abuse and criminal acts, as well as the persistence of attentional, familial, interpersonal, and occupational difficulties throughout their life span (Cherkasova, Sulla, Dalena, Pondé, & Hechtman, 2013; Klein & Mannuzza, 1991). These symptoms, and the compromised function they entail, should constitute strong evolutionary pressures that perhaps should have eliminated ADHD from the population within a few score generations. Yet ADHD is one of the most common psychiatric disorders in children and adolescents, with a worldwide prevalence above 5% (Polanczyk, de Lima, Horta, Biederman, & Rohde, 2007).

So why does ADHD persist in the face of such a potentially negative effect on reproductive fitness? Several evolutionary explanations have approached this question. For example, some have argued that in some instances the symptoms of ADHD are best viewed from the perspective of our ancestral environments that were unsafe, impoverished, and time critical. In such an environment there would be advantages to maintaining a response-ready versus a problem-solving attitude (Jensen et al., 1997; Urcelay & Dalley, 2012). Being distractible is perhaps better attuned to survival when every change in the environment could mean a threat or an opportunity. Acting on impulse may have left few opportunities for questioning later, but it has undeniable survival value in dangerous environments. Other potential advantages for ADHD-like symptoms include: alertness to novel stimuli; willingness to depart from local environments predisposed to high levels of prenatal and perinatal stressors, and potential positive founder effects upon discovery of novel, resource-rich environments.

Among the many attempts to explain the persistence of ADHD, Killeen, Tannock, and Sagvolden (2012) provided the most current and comprehensive review as they consider the four causes of ADHD and point to the vast interdisciplinary literature from brain structure, electrophysiology, and neuropsychology to the role of neurotransmitters and genes. Specifically, interconnections between attention-regulating subsystems in temporal, parietal, and prefrontal cortices are likely involved in many cases of ADHD (Arnsten, Berridge, & McCracken, 2009). The prefrontal cortices, in particular, play a top-down inhibitory function by regulating emotions and behaviors, sustaining attention, and by screening out distracting stimuli. In this context, it appears that cortical development lags in children with ADHD compared with their peers (Shaw et al., 2007).

Family, twin, and adoption studies also indicate that ADHD is highly heritable with heritability estimates consistently around 0.8 (Faraone & Mick, 2010). A large number of candidate genes have been and continue to be evaluated. Historically, much of the focus has been on genes involved in the synthesis and processing of biogenic amines. However, large scale GWAS have yet to identify convincingly any common genetic variants associated with increased susceptibility to ADHD (Neale et al.,

2010). It appears likely that the genetic vulnerability to ADHD is mediated by multiple generalist genes each of small effect. In considering GxE, it is clear that perinatal risk factors such as birth trauma, anoxia, and prematurity can contribute to the risk of a child developing ADHD (Barry & Gill, 2007). It will also be important to examine how adverse environments characterized by low parental responsivity, high and critical expressed emotion, under stimulation, harsh or coercive disciplinary techniques, conflictual parental relationships, and low socio-economic status, can shift early brain development and neural systems more toward ADHD-like outcomes. Moving forward, the possibility that these risk factors operate through epigenetic mechanisms is an important set of molecular mechanisms to consider (Mill & Petronis, 2008). It is also worth noting that some individuals with ADHD are more likely to engage in risky sexual behaviors that may lead to their having more children with multiple partners (Flory, Molina, Pelham, Gnagy, & Smith, 2006; Hosain, Berenson, Tennen, Bauer, & Wu, 2012). These empirical observations are also consistent with the growing literature of differential susceptibility. As noted earlier in this chapter, in some adverse environments impulsivity, risk taking, and frank antisocial behavior may be adaptive to the degree that they enhance an individual's reproductive fitness (Belsky & Pluess, 2013).

The findings of an innovative computational modeling study undertaken by Williams and Taylor (2006) are also consistent with differential susceptibility. Briefly, they attempted to simulate the potential evolutionary benefits for groups when they have in their midst a minority of individuals who were highly variable, i.e., unpredictable, in their risk-taking approaches to secure food resources within changing environments. They initially constructed five groups of ten individuals. Nine of the individuals were programmed to be very predictable. Information about the availability of local foods was shared within each of the groups. Ninety per cent of the matings were programmed to occur outside the individual's original group. In the simulation each of the offspring who had one of the five brittleness genes were randomly selected from the two parents, and in 10% of matings one of the five genes randomly mutated. Whenever the overall population exceeded 200, a group was randomly selected for elimination. Individuals started reproducing at age 10, and life span was limited to 50 years. When groups exceeded 20 individuals, they split into two groups. They then simulated the ability of two interventions to alter the reproductive fitness of the groups. These were the rate of environmental change and the relationship between an individual's predictability and rate of reproduction. They found that increased environmental variability produced a small, but definite and reversible reduction in population predictability. Given the parameters used in their simulations, they concluded that there is a class of tasks (group exploration tasks) in which unpredictable behavior by a minority of individuals optimizes results for the group. Characteristics of these tasks were risk taking, because its cost is borne mainly by the individual, and information sharing, because its benefits increase with group size. More importantly they found that a reproductive bias favoring the unpredictable individuals helped populations cope with rapid environmental change, without imposing major cost during periods of stability. In contrast, when they programmed in a reproductive bias favoring predictable individuals, they observed an opposite effect on reproductive fitness. Despite the obvious limitations of reducing ADHD to a single behavioral characteristic—unpredictability—the use of computational modeling may prove useful in evaluating other evolutionary hypotheses for ADHD and other forms of developmental psychopathology. This perspective is also consistent with the widely held view that the factors that shape human development do so in a probabilistic rather than a deterministic fashion (Belsky & Pluess, 2013).

Co-optation of Neurobiological Systems Associated With Establishing Salience and Reward

Perhaps the most compelling evolutionary explanation to be considered in this chapter relates to substance abuse and addictive disorders. Here it comes down to how our brains are built. If we rely on specific genetic pathways, neurotransmitters, and circuits to establish what is salient and rewarding in our world, then exogenous agents that affect these neurobiological systems may well have effects that are sufficiently maladaptive to be labeled a form of psychopathology.

Substance Use Disorders and Addictive Disorders

Drug abuse and addictive disorders including pathological gambling exact an enormous emotional, medical, and financial toll on societies across the globe in the form of the loss of an individual's potential to contribute to society, loss of employment, crime, and family disintegration, in addition to medical complications in the case of an overdose (Anthony, Warner, & Kessler, 1994; Le Moal, 2010; Chapter 18 and 19 Volume 3). Considered together, alcohol, tobacco, and illicit drug use are implicated in

over 12% of mortality worldwide. Their use constitutes the leading cause of preventable death (World Health Organization, 2009a, 2009b).

Addiction is a chronic, relapsing disorder that has been characterized by the impulsive and compulsive need to seek and consume the drug (craving); an inability to control intake leading to intoxication; and the emergence of a distressed emotional state, e.g., dysphoria, irritability, during periods of withdrawal when access to the drug is prevented (Koob & Volkow, 2010). Animal and human studies have identified widely distributed neural circuits that mediate each of the three stages of the addiction cycle. Remarkably, virtually all substance use disorders engage many of the same neural circuits. As reviewed by Koob and Volkow (2010), key elements of the reward and salience mesolimbic dopamine pathways are structures that once activated can lead to a cascade of neuroadaptations in the ventral striatum (i.e., a brain region that includes the nucleus accumbens core and shell and some nuclei of the olfactory tubercle) that receives projections from the ventral tegmental area and prefrontal cortex. Once addiction has been established, multiple interconnected brain regions are involved in craving including the orbitofrontal and other regions of the prefrontal cortices, as well as the insula, basolateral amygdala, and hippocampus.

Although many individuals are exposed to nicotine, alcohol, and drugs of abuse, only a subset becomes addicted. Although the genetic contribution to risk for addiction is approximately 50%, the specific genetic variants have yet to be identified (Goldman, Oroszi, & Ducci, 2005; Kendler, Myers, & Prescott, 2007). One probable explanation for this failure is that the relevant sequences do not lie within the protein coding regions of these genes but rather in the recently discovered regulatory elements which are physically associated with one another and with expressed genes. Since an individual's susceptibility to drug use and addiction is strongly influenced by the psychological and social context in which drug exposure occurs, and since these genomic regulatory elements can be modified by environmental exposures, it is not surprising that the search for key transcription factors, as well as efforts to identify the molecular events that can regulate transcription through modifications of DNA and chromatin structure in specific brain areas have become a major focus for research (Robison & Nestler, 2011; Wood & Lipovich, 2012). For example, Robison and Nestler (2011) recently reviewed some of the multiple mechanisms by which drugs of abuse can alter the expression of key transcription factors, i.e., proteins that, in response to cell signaling pathways, bind to specific sequences of DNA to increase or repress the expression of downstream genes. Their review focuses on four specific transcription factors: ΔFOSB, cyclic AMP-responsive element binding protein (CREB), nuclear factor-κB (NF-κB), and multiple myocyte-specific enhancer factor 2 (MEF2) and their roles in addiction. They also usefully reviewed the current state of knowledge concerning various epigenetic mechanisms including histone tail modifications which alter the accessibility of genes within their native chromatin structure to the molecules needed for transcription, DNA methylation which can have enduring effects on gene expression as well as non-coding microRNAs. MicroRNAs are found in all mammalian cells and serve as post-translational regulators that bind to complementary sequences on target mRNAs to repress translation, thus silencing gene expression. Like histone modifications and DNA methylation, expression of microRNAs can alter gene transcription in the absence of any change to the DNA coding sequence. It is reasonable to anticipate that as future insights on transcriptional and epigenetic mechanisms of addiction accumulate, a more complete understanding of how addictive substances modify specific neural circuits will emerge. Hopefully this in turn will contribute to the identification of new targets for the treatment of addictive disorders.

In sum, addiction and substance use disorders provide a compelling example of how our evolutionary history has left us vulnerable to certain forms of psychopathology (Nesse & Berridge, 1997). Specifically, the conserved neural circuitry involved in reward processing and salience determination in vertebrate species can be co-opted or hijacked by exogenous substances, leading to addiction and associated behavioral dysfunction and impairment.

An Evolutionary Arms Race: Infections and Autoimmunity

At first glance, the mention of infectious processes in a listing of evolutionary mechanisms might seem odd. However, our long-standing evolutionary relationship with bacterial and viral pathogens and the endless arms race between our species (theirs and ours) has probably done much to shape aspects of our genome and so our vulnerability to disease (Chapman & Hill, 2012; Dawkins, 1987; Dawkins & Krebs, 1979). In psychiatry these effects include post-infectious autoimmune disorders that have neuropsychiatric sequelae such as Sydenham's chorea (Husby, van de Rijn, Zabriskie, Abdin, & Williams, 1976; Kiessling, Marcotte, & Culpepper, 1993; Swedo et al., 1989).

PANDAS

Swedo and coworkers (1998) described a group of children with PANDAS characterized by the sudden overnight onset of OCD as well as at least two other neuropsychiatric symptoms (i.e., anxiety, emotional lability, irritability, aggression or oppositional behavior, behavioral regression, deterioration in school performance, sensory or motor abnormalities including motor or vocal tics, and somatic signs and symptoms like sleep difficulties, enuresis, and urinary frequency) in children who had been previously developing normally. Currently, the predominating theory to explain the pathophysiology behind PANDAS is molecular mimicry whereby antibodies formed to target Group A beta-hemolytic streptococci (GABHS) also targets proteins in the cells of the basal ganglia.

However, since the introduction of PANDAS as a clinical entity, it has been a source of a fair amount of controversy, partly stemming from how the original PANDAS criteria have been interpreted by subsequent teams of investigators (Singer, Gilbert, Wolf, Mink, & Kurlan, 2012; Swedo, Leckman, Rose, 2012). Despite this controversy cogent models of disease pathogenesis have been put forward in which the neurotransmitter dopamine is influencing the functional status of the immune system (Besser, Ganor, & Levite, 2005; Kipnis et al. 2004; Sarkar, Basu, Chakroborty, Dasgupta, & Basu, 2010) and that antibodies directed against GABHS can increase the amount of dopamine released and affect the functional status of dopamine receptors (Kirvan, Swedo, Heuser, & Cunningham, 2003; Kirvan, Swedo, Kurahara, & Cunningham, 2006; Murphy, Kurlan, & Leckman, 2010).

Additional clinical, translational, and basic science investigations are needed. Strikingly, animal models are again providing a proof of concept for PANDAS as a clinical entity (Birmberg et al., 2012; Yaddanapudi et al., 2010). For example, GABHS infections can trigger the production of cross-reactive antibodies that not only lead to some of the same neurologic and behavioral symptoms in the originally infected mice, but also evoke symptoms when they are passively transferred from donor to wild-type mice. Expanding these investigations to evaluate the effects of a variety of infectious agents and other immune stimulants would be useful, particularly if the animal models can be used to evaluate potential therapeutic interventions.

From an evolutionary perspective since humans are the only known natural host for GABHS, the persistence of Sydenham's chorea and PANDAS in our species is attributable to our continued vulnerability, as a species, to this pathogen that has made its permanent home in our bodies.

Other Evolutionary-Based Explanations

Several other evolutionary-based accounts of psychiatric disorders have been proposed. They include the limited power of natural selection to eliminate mutations, particularly recessive mutations, if their adverse effects on reproductive success are modest. This may be particularly germane for mild or late-onset disorders. For example, in Huntington's disease the initial symptoms do not appear until after many of the affected individuals have had offspring.

In contrast, inbreeding and consanguineous marriages which are commonplace in many cultures do have the potential to disrupt neurodevelopmental pathways and cause early onset neuropsychiatric disorders. A recent example, cited above, concerns inactivating mutations in the gene BCKDK in consanguineous families with ASD, epilepsy, and intellectual disability (Novarino et al., 2012). The heterozygote carriers of this mutation develop normally and their reproductive fitness is not otherwise affected. However, individuals can develop this syndrome when the mutation is transmitted within extended families so some descendants are homozygous for the same mutated recessive gene.

CONCLUSIONS AND CRITIQUE

The study of evolutionary principles suggests that many of the mental and neurodevelopmental disorders encountered by professionals working with infants, children, and adolescents (e.g., clinical psychologists, pediatricians, primary care clinicians, child and adolescent psychiatrists, social workers, teachers) are likely to persist despite their being associated with a reduction in reproductive fitness. In many instances their ultimate causes are built into the genetic and neurobiological mechanisms that underlie highly conserved features of our basic behavioral and cognitive repertoires. While we usually confine our discussion of these conserved features to humanoid, primate, or mammalian lineages, the fossil record is clear that some of the most defining events in our neurobiological history date back more than 500 million years with the emergence of our first chordate ancestors. Examination of the cranial endocasts of our earliest vertebrate ancestors indicate that by 480 million years ago they already had the major divisions of the central nervous system (CNS): telencephalon, diencephalon, mesencephalon, metencephalon, myelencephalon, and spinal cord as well as olfactory capsules, orbital cavities, a hypophysis, labyrinths, and the exit

foramina for the 10 cranial nerves (Miklos, 1993; Karen, 1970). Remarkably, our CNS is simply a variant on the same theme.

A second point focuses on the intrinsic population-based nature of evolution. Variation within populations is an essential ingredient for natural selection (Pujadas & Feinberg, 2012). This is true at each level of understanding from linear arrays of genes in genomes, to populations of molecules within cells, to collections of neurons, to organized behavioral repertoires, and even to collections of people in social communities. Several corollaries to this point are also apparent. First, at each level it appears that any single function can usually be carried out by more than one configuration of units or individuals. For example, many genes are pleiotropic with many functions. These functions can overlap with one another so that the loss of one gene can be made up by another (Finch & Rose, 1995). Similar arguments are possible at each of the other levels as well. Second, there is the potential for pleiotropy at more proximate levels. For example, central oxytocin pathways appear to play an important role in the initiation of a wide range of complex behaviors from pair bonding and sexual activity to uterine contractions during delivery and milk release during nursing. In the body, oxytocin is synthesized in the heart, thymus, gastrointestinal tract, as well as reproductive organs. The distribution of the oxytocin receptors in both the brain and periphery is even more far-reaching and its expression is subject to changes over the course of development. Oxytocin receptor expression is also sensitive to changes in the external environment and the internal somatic world. The net result is a vast, complex, and developmentally sensitive bio-behavioral system (Gordon, Martin, Feldman, & Leckman, 2011). Other elements include sensory inputs, the salience, reward, and threat detection pathways, the hypothalamic-pituitary-gonadal axis, and the hypothalamic-pituitary-adrenal stress response axis.

A third inescapable lesson from the study of evolutionary mechanisms is the importance of the environment (ancestral, intrauterine, and the infant's early nurturing environment) in shaping our genome and its capacity to be programmed to maximize adaptation and diversity. For each proposed mechanism some aspect of the environment, past or present, is playing or has played a crucial role. Perceived threats to survival, emotional attachments to others, the availability of drugs of abuse, the existence of reservoirs of beta-hemolytic streptococci, are just a few examples.

A fourth point concerns the self-organizing character of these bio-behavioral systems—namely, that they have the capacity to modify and reorganize in response to new environmental perturbations and to settle into one or a few modes of organization (Thelen & Smith, 1995). Behaviorally this is seen throughout the animal kingdom as we tend to settle into familiar habits. Indeed, one way of conceptualizing some forms of psychopathology is to consider them to be a reflection of individuals getting stuck in a restricted set of otherwise normal behaviors. Examples include the washing and cleaning rituals of some forms of OCD or the motor stereotypes seen in individuals with ASD. The basis for this fractal property of evolution (the ability of populations to self-organize regardless of the temporal or spatial scaling) remains speculative, but it would seem to be a requirement for evolution to have occurred in the first place.

A fifth conclusion concerns the incomplete nature of evolutionary explanations. They may provide a plausible explanation of why certain vulnerabilities persist within human populations, but they do not account for why a particular individual is affected. Here the study of individual differences and of particular developmental histories is required. Special attention should be directed at events occurring early as they can constrain the later development of the CNS (Edelman & Tonini, 1995). Models of pathogenesis of early-onset disorders must embrace both developmental and evolutionary perspectives.

Finally, we must acknowledge that although some of these evolutionary accounts have a certain degree of face validity (co-optation of conserved neurobiological systems, evolutionary arms races) many of the evolutionary accounts discussed above are speculative and largely untestable. Given the historical nature of the proposed accounts, the fragmentary fossil record, and the limits of paleobiology to document brain evolution, we must admit that the actual course of these events remains inexplicable. While computational models may be useful in establishing the plausibility of some of these mechanisms, many of these accounts may be justly characterized as just so stories that provide explanations that cannot be disproved. We must be content then with (1) their heuristic value to raise questions concerning data already available to us, (2) their ability to provide a framework for the integration of new knowledge from a broad range of scientific disciplines, and (3) their value to clinicians.

Future Prospects

The conceptual framework underlying emerging models of brain evolution and development provides a powerful framework for understanding aspects of disease

pathogenesis in developmental psychopathology. This framework is consistent with the pioneering efforts of investigators such as Baldwin (1902), Bowlby (1969, 1973), Darwin (1872), Ekman (1982), and Waddington (1977) among others who have applied evolutionary and developmental principles to the study of normal variation or psychopathology. Although progress has been slow, due in part to the scope and complexity of the emerging scientific knowledge base, incremental progress can be anticipated that should enrich and refine our emerging models of disease pathogenesis. Future progress is likely to follow in the wake of powerful and promising technologies in genomics, epigenomics, neurodevelopment, neuroimmunology, longitudinal neuroimaging, computational modeling, and information processing, as well as taking greater advantage of population-based registries.

Despite the relative failure of most GWAS it is clear that many rare genetic variants acting alone or together can be lethal for the normal emergence of species-typical behavioral patterns (as may occur in some forms of ASD). Despite many disappointments, it is reasonable to expect the eventual identification of multiple alleles of major and minor effect that act in concert (co-action) that contribute to a number of heritable disorders including some forms of intellectual disability, dyslexia, ASD, schizophrenia, Tourette's syndrome, and antisocial behavior (Bentley et al., 2013).

Future translational work with animal models should focus on the role that genes and/or environmental factors play in the development of circuits that regulate specific physiological and behavioral outcomes. This emphasis on circuit formation, as a fundamental unit for understanding behavior, is distinct from current approaches of modeling psychiatric illnesses in animals (Kaffman & Krystal, 2012). The work over the past several decades of Capecchi and his team at the University of Utah on the role of homeobox genes on development provides a clear illustration of this point. Homeobox genes are a class of regulatory genes that act primarily as transcription factors in the promoter regions of the genome. They are also known as master control genes because of the key role they play in the control of embryonic development along the longitudinal axis of the developing embryo from head to toe in all multicellular animals from fruit flies to humans. Capecchi and his team have for some time been pursuing the systematic analysis of the mouse homeobox genes by monitoring the animals' somatic and behavioral phenotypes after a specific homeobox gene was knocked out. In 2002, Capecchi and his team knocked out the Hoxb8 gene. Remarkably, although this gene is anatomically expressed no higher than the lumbar region of the developing embryonic spinal cord, all of the Hoxb8 (–/–) mice displayed excessive grooming behaviors leading to hair removal and skin lesions (Greer & Capecchi, 2002). Why did this behavioral phenotype emerge? Eight years later, they provided the answer. The Hoxb8 cell lineage is associated with the bone marrow-derived microglia that migrates into the brain during embryonic development from the yolk sac (Chen et al., 2010). The conclusion is clear: a behavioral disorder, with some resemblance to trichotillomania, is associated with mutant microglia in the brain. The role of microglia in normal brain development and circuit formation has also become increasingly clear given their active surveillance of synaptic activity and their capacity to prune presynaptic inputs based on their level of neural activity (Schafer et al., 2012).

This brings us to another conclusion, namely, that we still have a great deal to learn about the role of the immune system and its role interconnecting the brain and body as well as its interface with other bio-behavioral systems. Based upon our limited knowledge, one can safely predict that additional stories will emerge that will strengthen the link between psychoneuroimmunology and stress response, maternal bonding, and sexual behaviors, as well as salience and reward pathways. Recently, data also suggest that the immune system will play a role in modulating feeding behavior and energy homeostasis, and perhaps even in the multi-directional microbiome-gut-brain network (Poutahidis et al., 2013). All of which point to the importance of the central role the immune system plays at the dynamic interface of physical and mental health (see Leckman, 2014).

Although animal model systems may permit the testing of the effectiveness of novel pharmaceutical agents as well as a deeper understanding of how the expression of these particular alleles constrains the developing nervous system (Andersen & Navalta, 2011), species differences and ethical constraints place a natural limit on the testability of evolutionary and developmental explanations of human psychopathology. The recent finding for the various ENCODE studies concerning the many differences in noncoding regulatory regions of the human genome compared with other species reinforce the view that animal models will always be incomplete.

Our ability to genotype accurately individual patients with regard to known vulnerability alleles as well as regulatory regions of the human genome may lead to more accurate clinical predictions of course, outcome, and treatment response. Similarly, the results of neuropsychological, neuroimaging, and other biological studies may become more interpretable by classifying patients according to their respective genotypes (Bansal et al., 2012).

For developmental neurobiologists the ongoing studies comparing genomes across species as well as comparing spatiotemporal differences of gene expression should provide a clearer understanding of the transcriptional foundations of human brain development (Johnson et al., 2009; Ward & Kellis, 2012). Future studies of human postmortem brain material that include recently discovered regulatory elements in the human genome should also allow investigators to generate expression trajectories of the interactive genes present in large-scale networks.

Future progress may also depend on the refinement of psychopathological phenotypes and endophenotypes. Psychopathological states vary in their complexity and are often best seen as multidimensional composites. The Research Domain Criteria project launched by NIMH in 2009 seeks to implement this strategy by defining basic dimensions of functioning (such as the fear circuits or working memory) to be studied across multiple units of analysis, from genes to neural circuits to behaviors, cutting across disorders as traditionally defined (Cuthbert & Insel, 2010).

Finally, there is the need to continue to examine the factors and mechanisms that promote and weaken resilience particularly among individuals experiencing significant adversity (Cicchetti & Toth, 2009). Resilience is an evolutionarily conserved trait that supports reproductive fitness. Consequently gaining a deeper understanding of the factors that contribute to resilience is an important area of continuing research in the area of developmental psychopathology. Given the multi-finality in developmental processes and the diversity of ways in which individuals respond to and interact with vulnerability and protective factors at each ecological level, continuing longitudinal efforts are needed to understand the complex matrix of the individual's biological and psychological organization and its response to adversity over the course of development (Cicchetti, 2013). Thus far, it is clear that an individual's resilience resides in a broad range of genomic, epigenomic, neural, neuroendocrine, and behavioral mechanisms, but more work is needed (Grigorenko & Cicchetti, 2012; Karatoreos & McEwen, 2013; Chapter 8, this volume). From an evolutionary perspective, although certain genetic variants may confer an increased vulnerability in the face of adversity, such as maltreatment, it is equally probable that other variants at the same locus may serve a protective function against environmental insults (Belsky, Jonassaint, Pluess, Stanton, Brummett, & Williams, 2009; Cicchetti & Blender, 2006). There is also evidence, in the case of maltreated children, while some genetic variants had a negligible effect for the maltreated group in predicting resilience, the same genotype contributed to higher resilient functioning in non-maltreated children (Cicchetti & Rogosch, 2012).

Clinical Implications

The present conceptualization of neurodevelopment and the factors that selectively influence its course has important implications for the prevention, treatment, and care of individuals with various forms of developmental psychopathology. The identification of risk factors, both environmental and genetic, is likely to lead to screening procedures and preventive interventions such as public health programs aimed at reducing lead exposure in children. This conceptualization emphasizes the environment as a crucial factor in designing treatment interventions. Identifying features in the home and educational environments that will allow children to build on their strengths and improve their adaptive capacities should continue to be a major priority for research (Leckman, 2013). Advances in our understanding of those components of the environment that are most crucial for resilience and sustaining successful adaptations will doubtless refine interventions designed to prevent and treat various forms of psychopathology (Panter-Brick & Leckman, 2013; Rutter, 2013).

Finally, aspects of this approach may permit a deeper empathetic understanding of individuals with early onset disorders. For example, if some forms of OCD bear some relationship to the mental states associated with highly conserved behavioral repertoires typically encountered in expectant parents (intrusive worries about some misfortune befalling the fetus or infant), it should be easier for clinicians to have a deeper emotional empathy for the anguish a patient is experiencing if they can relate the patient's symptoms to emotional experiences in their own lives as parents and members of extended families (Kim et al., 2013; Leckman & Mayes, 1998; Leckman et al., 1999).

Although these models can appear to be reductionistic approaches that neglect the inner worlds of children, some of the emerging models of mental development (Edelman & Tononi, 1995; Fricchione, 2011) are fully compatible with the rich, dynamic complexity of intrapsychic states that we encounter in ourselves, in the consulting room, in our families, and throughout our social ecological systems.

INTRODUCTION

Early life adversity is a well-documented risk factor for developmental psychopathology. While there is no substitute for directly studying human populations with early experience-related high risk for developmental psychopathology (e.g., maltreated children, children adopted from orphanages; Ehlert, 2013; Neigh, Gillespie, & Nemeroff, 2009; Teicher, Tomoda, & Andersen, 2006), animal studies offer a unique opportunity to understand the basic neurobiological and developmental underpinnings of these disorders at a level not possible in humans (Kaufman, Plotsky, Nemeroff, & Charney, 2000). This includes understanding the underlying cellular and molecular mechanisms involved and critical sensitive periods. A better understanding of the neurobiological mechanisms underlying increased risk for developmental psychopathology has led not only to more targeted research and clinical questions in human studies, but also to the inception of effective interventions and preventative therapies. If we can determine what is changing, when, and how, and the specific subsequent alterations in behavior, we would be able to design treatments aimed at specific processes and developmental time points. An important, but often overlooked, step in this process is to have a strong understanding of the normative patterns of neurobehavioral development not only in children, but also in the animal models being used (Machado & Bachevalier, 2003), which requires models and experiences with ecological validity. Understanding each species' typical experiences and developmental trajectories provides the critical context in which to place outcomes associated with disruptions of neurobehavioral systems early in life, such as those that occur in response to early life adversity. Thus, the goal of this chapter is not only to describe animal models of developmental psychopathology, but to also present what is known about species-typical development of biological systems thought to play an especially strong role in developmental psychopathology and how these developmental processes compare to those in humans.

Clinical studies have identified a series of irregularities in structure and function of specific neural circuits

We thank the members of the NIMH-funded Early Experience, Stress and Neurobehavioral Development Center (P50 MH078105) for the stimulating discussions that influenced some of the views presented here. This work was supported by grants P50 MH078105, K18 MH105098 and F31 MH086203 from the National Institute of Mental Health (NIMH), grants HD055255 and HD077623 from the National Institute of Child Health & Human Development (NICHD) and grant NR014886 from the National Institute of Nursing Research (NINR). The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIMH, NICHD, NINR or the National Institutes of Health. The project was also supported by the Office of Research Infrastructure Programs/OD P51OD11132 (YNPRC Base grant). The YNPRC is fully accredited by the Association for the Assessment and Accreditation of Laboratory Care, International.

related to developmental psychopathology (De Bellis, 2005; De Bellis, Baum, et al., 1999; De Bellis, Keshavan, et al., 1999; Drevets, Gadde, & Krishnan 2011; Teicher, Andersen, Polcari, Anderson, Navalta, & Kim, 2003; Tottenham & Sheridan, 2009), and thus the focus of much animal research has targeted how these regions mature. They include the prefrontal cortex (PFC), particularly the ventromedial PFC (vmPFC: medial and orbital areas), and subcortical limbic structures that communicate with it, including the amygdala and hippocampus (Bale et al., 2010; Pryce et al., 2005; Sanchez, Ladd, & Plotsky, 2001; Veenema, 2009). These corticolimbic circuits play very important roles in emotion regulation and control of the stress response, including the activity of the neuroendocrine hypothalamic-pituitary-adrenal (HPA) axis (Herman, Ostrander, Mueller, & Figueiredo, 2005; Herman et al., 2003; Ulrich-Lai & Herman, 2009). Exposure to elevated levels of circulating stress hormones due to repeated activations of the HPA axis is thought to be one of the primary biological mediators of the increased risk for developmental psychopathology associated with early life adversity (Doom & Gunnar, 2013). Our knowledge of the developing HPA axis is still growing, but thanks in great part to animal models we are beginning to understand how perturbations of this system contribute to increased risk for developmental psychopathology. Other mechanisms involved, including inflammation, changes in gut microbiota and epigenetics will also be reviewed in this chapter, but we will focus on the HPA axis in the next section.

HPA Axis: Development and Regulation in Humans and Animal Models

It is important to have an understanding of normative developmental patterns in both humans and animal models to be able to accurately translate research between species. Thus, we begin this section with a brief description of normative development of the HPA axis in humans and some commonly used animal models. Typically developing human newborns are able to activate the HPA axis in response to stressors, but do not exhibit a mature circadian cortisol rhythm. However, they do show two peaks of cortisol about 12 hours apart that are independent of the time of day (Gunnar, 1992). Some studies have reported an adult-like circadian cortisol rhythm emerging as early as 2 weeks of age while others were unable detect a mature rhythm until 3 months of age (Price, Close, & Fielding, 1983; Santiago, Jorge, & Moreira, 1996). At about 3 months of age, there is also a decrease in the cortisol response to physical examinations, an effect that continues throughout the first year of life (Gunnar, 1992) and is paralleled by decreases in basal cortisol (Tollenaar, Jansen, Beijers, Riksen-Walraven, & de Weerth, 2010). This period of apparent stress insensitivity is thought to mirror the stress hyporesponsive period (SHRP) described in rodents and may be dependent on the quality of the caregiving provided (Gunnar & Quevedo, 2007).

In rodents, the SHRP is characterized by a quiescent HPA axis, evidenced by both an inability to mount a cortisol response to stressors that are effective in activating the axis at other ages, and by failure to suppress circulating cortisol levels in response to challenge with the synthetic glucocorticoid (GC) dexamethasone, suggesting insensitivity to the inhibitory effects of high levels of GCs observed in adults (Sapolsky & Meaney, 1986; Vazquez, 1998). Given the broad effects of GCs on homeostasis and gene expression, the purpose of this hyporesponsive period is thought to be to maintain the low level of GCs necessary for normative brain growth and development (Sapolsky & Meaney, 1986). There is strong evidence that maternal presence plays a major role maintaining these low GC levels during the SHRP and that the mother regulates the development of the pup HPA axis and fear systems, as well as their transition out of the SHRP. During the first couple weeks of life rat pups will not mount a corticosterone response to a stressor in the presence of the dam, but when removed from her they are able to show stress-induced elevations in corticosterone (Moriceau & Sullivan, 2006; Stanton, Gutierrez, & Levine, 1988; Stanton, Wallstrom, & Levine, 1987). More recent research into this phenomenon has shown that a sensitive period for attachment learning in rodents coincides with the low corticosterone levels associated with the SHRP, at the same time that fear learning is turned off (Sullivan & Holman, 2010). Interestingly, the transition from this early sensitive period when attachment (approach) learning is turned on but fear (avoidance) learning is turned off to the next developmental period when the pup starts exploring and fear is turned on seems mediated by the presence of higher levels of corticosterone acting on the amygdala, as shown by elegant manipulations of the corticosterone system during this time by Sullivan and colleagues (Moriceau, Roth, Okotoghaide, & Sullivan, 2004; Moriceau & Sullivan, 2004; Sullivan & Holman, 2010). Thus, in the early period, when maternal presence is paired with an aversive stimulus (i.e., foot shock) attachment and proximity seeking behavior (i.e., odor preference) is induced in pups due to the suppression of corticosterone release and subsequent suppression of amygdala activation by the dam, while in her absence elevated corticosterone activates the amygdala resulting in fear and avoidance behavior (Moriceau & Sullivan, 2006). Similarly, in nonhuman primates and humans there is also evidence that the period of relative stress hyporesponsivity described earlier is dependent on the quality of parental care, and may extend through childhood (Gunnar & Fisher, 2006;

McCormack, Newman, Higley, Maestripieri, & Sanchez, 2009), which is consistent with the hypothesis that GC levels need to be tightly regulated during brain development to support typical maturational processes. This is also supported by alterations in the stress response and brains of humans exposed to early life stress (Gunnar & Quevedo, 2008; Loman & Gunnar, 2010; Tarullo & Gunnar, 2006).

The role of salient social interactions, such as caregiving in infancy and peer relationships during adolescence, in regulating a developing human's response to stressors has been demonstrated in many studies. In infants, sensitive and responsive parenting is able to decrease levels of cortisol elicited in response to a mild stressor (Albers, Riksen-Walraven, Sweep, & de Weerth, 2008). The developmental trajectory of this ability of caregiving to buffer the stress response is exemplified by a child's response to inoculations over the first year and a half of life. In the presence of a parent 2, 4, and 6 month old infants show increases in cortisol; however, as early as 12 months old and to at least 18 months, this increase is no longer detectable when the parent is present (Jansen, Beijers, Riksen-Walraven, & de Weerth, 2010). The neurobiological mechanisms that underlie this ability have yet to be completely elucidated, but emerging evidence suggests some likely candidates (Hostinar, Sullivan, & Gunnar, 2014). The hormone oxytocin, induced by caregivers and with some anxiolytic and antistress properties (Cardoso, Ellenbogen, Orlando, Bacon, & Joober, 2013), is one possible route. Another may be through recruitment of brain regions linked to safety signal learning, including the vmPFC, as suggested by a recent report where viewing of one's mother's face resulted in changes in functional connectivity between the amygdala and the vmPFC that was accompanied by an increased ability to regulate affect in children, but that did not work in adolescence (Gee et al., 2014). Exactly how these safety learning mechanisms change over time is unknown, although recent evidence suggests that the caregiver's ability to modulate offspring's stress response may decrease in adolescence (Hostinar, Johnson, & Gunnar, 2014). Other changes in stress physiology taking place during adolescence include an increase in basal HPA activity, with increased stress reactivity also being reported in some studies (Gunnar, Wewerka, Frenn, Long, & Griggs, 2009). Sex differences in HPA axis function are not apparent in childhood but begin to be reliably measured around adolescence, with girls having higher cortisol levels than boys (Gunnar et al., 2009; Reynolds et al., 2013).

The development of the HPA axis in nonhuman primates follows a similar pattern as that described for humans, making them ideal model organisms when attempting to model complex sequelae related to stress physiology. The presence of a basal HPA diurnal rhythm has been reported in infant rhesus monkeys, but it still appears to be immature at 5 months of age (which is the equivalent to 18–24 months in humans), with high cortisol levels early in the morning but only a slight decline from morning to afternoon, followed by a steep decline from afternoon to bedtime—around sunset for animals housed outdoors (Raper, Bachevalier, Wallen, & Sanchez, 2013). By the juvenile stage (starting around 12 months, equivalent to 4 years in humans) cortisol sharply declines between morning and afternoon, and between afternoon and night, demonstrating an adult-like diurnal pattern of cortisol secretion (Barrett, Noble, Hanson, Pine, Winslow, & Nelson, 2009; Raper et al., 2014; Sanchez et al., 2005). Although there is no solid evidence of a true SHRP in rhesus monkeys, socially familiar cues, specifically the presence of a nurturing mother, do buffer the HPA axis stress responses in infant macaques (McCormack, Newman, Higley, Maestripieri, & Sanchez, 2009; Sanchez, 2006). Thus, as described for humans, nonhuman primate mothers also function as external regulators of infant HPA axis activity, serving as strong social buffers that prevent stress-induced activations to potential threats. In contrast, highly rejecting, abusive, and low protecting rhesus mothers fail to buffer their infants' HPA axis stress responses (McCormack, Newman, Higley, Maestripieri, & Sanchez, 2009). This highlights the importance of early social experiences, in particular the role of nurturing caregiving, on the development of the HPA axis across different mammalian species, as well as the utility of animal models to study the role of adverse caregiving on the etiology of early life stress-induced developmental psychopathology.

The mammalian HPA axis is regulated by different neural pathways that transmit specific information about exteroceptive (psychological, environmental) and interoceptive threats (hemorrhage, infection, pain) to the hypothalamic paraventricular nucleus (PVN) (Herman et al., 2003; Herman et al., 2005; Ulrich-Lai & Herman, 2009). Psychological/emotional stressors are processed by brain regions that include corticolimbic structures such as the vmPFC, amygdala, and hippocampus, which convey information about threatening stimuli to the PVN via indirect projections, and undergo massive prenatal and postnatal developmental changes in mammals, making them particularly vulnerable to adverse early social experiences (Andersen, 2003). These brain regions, as well as their connectivity, have a protracted development. Recent research has focused on the development of vmPFC-amygdala circuits and its relevance for the development of the HPA axis and emotional regulation. One successful approach to disentangle the complex interplay of interconnected structures that develop together within

a brain circuit is to lesion one of the regions and observe what happens to the other parts of the circuit during development using animal models. For example, although in adult nonhuman primates the amygdala plays a stimulatory role on the HPA axis, so that lesions of the amygdala result in blunted HPA axis reactivity (Kalin, Shelton, & Davidson, 2004; Machado & Bachevalier, 2008), without effects on basal HPA axis activity (Kalin et al., 2004; Machado & Bachevalier, 2008; Norman & Spies, 1981; Sapolsky, Zola-Morgan, & Squire, 1991), recent studies by our group showed that when the amygdala is lesioned during the neonatal period (around 2 weeks of age) alterations in both HPA axis reactivity and basal function result, with lesions being associated with heightened—instead of blunted-basal and stress-induced HPA axis reactivity during infancy and the juvenile period (Raper, Bachevalier, et al., 2013; Raper, Wallen, Sanchez, et al., 2013; Raper, Wilson, Sanchez, Machado, & Bachevalier, 2013; Raper et al., 2014). These findings suggest that the amygdala may have a paradoxical inhibitory influence on HPA axis activity in primates during development, switching later on to have a stimulatory role on cortisol release. Both adult and neonatal lesions of these limbic circuits result in similar alterations in emotional reactivity though (Kalin et al., 2004; Machado & Bachevalier, 2008; Machado, Emery, Capitanio, Mason, Mendoza, & Amaral, 2008; Machado, Kazama, & Bachevalier, 2009; Raper, Wallen, et al., 2013; Raper, Wilson, et al., 2013), which combined with the differential effects of lesion timing on the HPA axis highlights the need for further carefully thought out experiments to pinpoint the underlying neural mechanisms.

The previous findings in nonhuman primates support emerging evidence of developmental switches in the role the amygdala plays in the regulation of stress and fear responses in humans, where amygdala functional coupling with PFC seems to switch from positive (i.e., when the amygdala is active so is the PFC) during early childhood to a more adult-like negative coupling during the adolescent transition (Gee, Humphreys, et al., 2013). This developmental switch from positive to negative coupling between PFC and amygdala could have a potentially important functional role, as it has been associated with stronger emotional regulation (Gee, Gabard-Durnam, et al., 2013). The findings from our studies using neonatal amygdala lesions in infant rhesus monkeys are consistent with this evidence, supporting an intriguing role of developmental switches in the amygdala's role in emotional and stress regulation.

Altogether, this evidence highlights the need to challenge the assumption that developing systems will be affected in the same ways as their mature counterparts. Thus, while the study of developmental psychopathology in humans is somewhat limited to observing the correlational relationships between environmental influences, alterations in brain structure and function during development, and the emergence of psychopathology, animal models, both rodent and nonhuman primate, allow for very precise and ingenious manipulations of the developing organism's environment, as well as the organism itself (e.g., neuroendocrine stress systems, brain circuits), providing invaluable information regarding possible biological, neurodevelopmental, molecular and system level mechanisms.

RODENT MODELS OF DEVELOPMENTAL PSYCHOPATHOLOGY

Rodent models include mostly mice and rats, and are some of the most commonly used model organisms in biomedical research. They allow for precise manipulations of neural systems and a level of experimental control not possible in humans and even in nonhuman primate studies. A full description of the natural history and ecology of rodents used in biomedical research is beyond the scope of this chapter, but has been reviewed for mice elsewhere (see Fox, Barthold, Davisson, Newcomer, Quimby, & Smith, 2006), although not for other species (e.g., rats). One notable difference between the early environment in rodents commonly used for research and that of a human infant is that rodents are altricial, born at a much earlier developmental stage than primates (equivalent to the end of the second trimester) and in litters, so that pups are not only exposed to their mothers, but also to their siblings. This allows for valuable within- and between-litter comparisons not possible in humans (except perhaps in the case of twin studies), but may also represent conceptual challenges when trying to understand the underlying mechanisms of developmental changes. Although there are obvious differences between rodents and humans, there are also certainly commonalities in neurodevelopmental patterns and physiology that make them strong animal models.

Prenatal and Postnatal Development: Critical Periods

Extensive research has been conducted on the plasticity of the prenatal and postnatal periods in the rat and mouse. Nearly 6,000 peer reviewed research papers have been indexed in the U.S. National Library of Medicine and it is beyond the limits of this chapter to recount all of the findings here. Many of the models and early findings of manipulations during the prenatal period and postnatal period are thoroughly detailed elsewhere (Marco, Macri, & Laviola, 2011; Molet, Maras, Avishai-Eliner, & Baram, 2014; Sanchez et al., 2001). Here we will briefly define the major models of prenatal and postnatal stress used in

the field to study mechanisms leading to developmental psychopathology and highlight the systems that have been reported to be affected. Finally, we will summarize some of the recent work examining the potential reversibility of early stress effects and explore the evidence that suggests that these early life stressors create an inherent susceptibility to insults later in life.

Common Models of Prenatal Stress

Although a wide range of stressors are employed with rodents including both psychological and physical stressors, those applied prenatally need to be moderate enough so that to they do not cause reabsorption of the pregnancy. Because of this concern, most stressors applied prenatally in the literature are of a psychological nature and typically do not include massive physical challenges such as temperature manipulations or forced physical activity like swimming. Several of the widely used paradigms are summarized herein, but there is a great deal of variability among research groups and the descriptions in this chapter are not exhaustive, as our focus is mainly in postnatal experiences.

Repeated Restraint

Repeated restraint has been commonly used as a model of prenatal stress. Restraint is generally facilitated through the use of plastic restraining devices sold for use in collection of unanaesthetized blood samples. These devices have sufficient numbers of holes to allow for heat exchange and guard against hyperthermia and are designed to confine the rodent such that it cannot make head to tail turns but the chest wall is in no way compressed so that breathing is unencumbered. Restraint devices are available in a variety of sizes such that larger sized restrainers can be used as pregnancies progress and the rat's abdominal circumference increases. The most common paradigm for prenatal restraint stress involves exposing the pregnant dam to restraint three times a day for 30–60 minutes under bright lights during the final week of gestation (days 14–21) (Bowman, MacLusky, Sarmiento, Frankfurt, Gordon, & Luine, 2004; Herrenkohl & Whitney, 1976; Kinsley & Bridges, 1988; Szuran, Pliska, Pokorny, & Welzl, 2000; Weller, Glaubman, Yehuda, Caspy, & Ben-Uria, 1988). Also reported in the literature are variations on this model in which the dam is exposed for a longer duration of restraint (2 hours) once a day for the final week of gestation (Wiggins & Gottesfeld, 1986). Although much less frequently reported, some research groups have also used this paradigm during early gestational periods (days 7–10 postconception; Glavin, 1984) or even throughout the duration of the pregnancy (Rojo, Marin, & Menendez-Patterson, 1985). An extensive number of publications exist which demonstrate that the application of repeated restraint stress alters both the offspring behaviors with relevance to psychopathology and related neurotransmitter systems. But, the main issue is the ecological validity and translational value for human prenatal conditions of this stress model.

Despite that caveat, repeated restraint stress of the dam results in intriguing alterations of multiple neural systems and behaviors relevant to psychopathology and neuropsychiatric disorders. As with many perturbations during development, the results are not necessarily uniformly negative or positive, reminding us that most of these developmental changes are a result of adaptations to the early environment. In one report of repeated prenatal restraint, although the offspring developed the previously described phenotypes of increased anxiety-like and depressive-like behaviors, they also demonstrated a resistance to chemically induced seizures (Marrocco et al., 2012). These findings highlight the adaptability of the developing brain, which in this instance were attributed to alterations in glutamatergic signaling (Marrocco et al., 2012). Prenatal restraint stress also alters attentional processing in offspring, renders the pups more susceptible to additional stress challenges after parturition (Burton, Lovic, & Fleming, 2006), and leads to modifications in responsiveness to psychostimulant drugs such as cocaine (Kippin, Szumlinski, Kapasova, Rezner, & See, 2008). As one might expect, prenatal restraint stress also causes robust alterations in the HPA axis both in terms of output of corticosterone and signaling within the hypothalamus and pituitary. More recently abundant evidence has emerged that supports the claim that the effects of prenatal restraint stress are not uniform and vary depending on the sex of the offspring (Garcia-Caceres, Diz-Chaves, et al., 2010; Garcia-Caceres, Lagunas, et al., 2010; Louvart, Maccari, & Darnaudery, 2005; Louvart, Maccari, Lesage, Leonhardt, Dickes-Coopman, & Darnaudery, 2006; Louvart, Maccari, Vaiva, & Darnaudery, 2009) and genetic factors such as gene polymorphisms (C. Kinsley & Svare, 1987; Lovic et al., 2013; Schroeder, Sultany, & Weller, 2013; van den Hove et al., 2011).

Noise

Noise stress is an easily delivered and potent inescapable stressor, sometimes delivered in combination with other stressors, as will be discussed in the next section. One common model of noise stress is exposure to 85- to 90-decibel

noise for 1 hour daily during the last week of gestation (Kim et al., 2006; Sobrian, Vaughn, Ashe, Markovic, Djuric, & Jankovic, 1997). In some cases, noise (880 Hz; 77 decibels) is applied to the pregnant dam for 15 minutes per day during midgestation (days 10–18) and the rat is also exposed to forced swim for 15 minutes per day (Nishio, Kasuga, Ushijima, & Harada, 2001). Given that forced swim is a very physically demanding stressor, this is not frequently used in gestational stress studies, but some groups have had success, meaning that the pregnancy is not compromised. A very common combination with noise stress is the addition of intense light, based on the ecology of most rodent species used in research, which are nocturnal animals, and therefore photophobic. This model has been published extensively (Fride & Weinstock, 1989; Kay, Tarcic, Poltyrev, & Weinstock, 1998; Weinstock, Matlina, Maor, Rosen, & McEwen, 1992). Noise stress has been reported to impact both somatic and cognitive outcomes in the offspring (Kay et al., 1998; Nishio, Tokumo, & Hirai, 2006; Sobrian et al., 1997), but overall less research has been conducted with these noise models than with either prenatal restraint stress or the combination of stressors used in the chronic mild stress paradigm described in the next section.

Chronic Mild Stress

Chronic mild stress (CMS), also referred to as chronic variable stress (CVS), is the pseudorandom exposure to multiple mild stressors over a series of days. Frequently the battery of stressors includes: restraint, noise, bright light, light cycle disruptions, dirty bedding, wet bedding, cage tilt, and crowding. There is a high degree of variability among research groups and there is no standard set of individual stressors in the CMS battery that is universally applied. The general principle of CMS is that these stressors represent daily hassles or unpredictable mild stressors that will trigger a stress response but are unlikely to result in habituation or severe physical detriment. CMS was first reported by Willner (Willner, Towell, Sampson, Sophokleous, & Muscat, 1987) and variations of CMS during gestation have been reported in the literature over the past decade with the first report appearing in 1998 (Secoli & Teixeira, 1998). The precise effects of CMS/CVS on offspring outcome are highly dependent on the timing of the gestational stress exposure (Mueller & Bale, 2006) and some effects of prenatal CMS/CVS may be mediated by influences on maternal behavior (Bourke, Capello, et al., 2013). CMS during gestation also increases startle responses, a metric associated with anxiety, in male (Hougaard, Mandrup, Kjaer, Bogh, Rosenberg, & Wegener, 2011) and female offspring (Kjaer, Wegener, Rosenberg, & Hougaard, 2010). In some cases the cognitive deficits in offspring exposed to prenatal stress can be improved with antidepressant exposure (Abdul Aziz, Kendall, & Pardon, 2012). Although prenatal CMS/CVS has been demonstrated to also alter neuronal dendritic spine density in cortical regions of the adult offspring, there is less evidence that this manipulation modifies amphetamine responses (Muhammad & Kolb, 2011). The high variability in behavioral and neurological effects of CMS/CVS during pregnancy are likely due to the wide variety of stressors used to compose the CMS/CVS paradigm among laboratories and the range of gestational days to which the paradigm is applied. When considering CMS/CVS, or any prenatal stressor, it is important to consider the neural processes involved in the neuropsychiatric disorder of interest and design the paradigm to best target the development of these systems.

Diet and Immune Challenge as Models of Prenatal Stress

In addition to the classic prenatal challenges of psychological and physical stress, more recently it has been established that both dietary challenges and immune challenges during gestation can result in neural and behavioral manifestations that are reminiscent of psychopathology. The additional strength of these models is that they have more ecological validity and translational relevance for human pregnancy. High fat diet during gestation has been shown to further impair the changes in both dopamine signaling and the HPA axis response that normally result from prenatal stress exposure (Naef, Gratton, & Walker, 2013; Vucetic, Kimmel, Totoki, Hollenbeck, & Reyes, 2010). Further, high fat diet leads to delayed physical and neural development, increased aggression, and depressive-like behaviors in the offspring (Giriko et al., 2013). A different model using protein restriction during pregnancy also results in neural and behavioral deficits. Offspring of protein-restricted dams during pregnancy demonstrate deficits in memory, elevations in depressive-like behavior, and deficits in neurogenesis (Godoy et al., 2013) when assessed in adulthood. Given the profound energetic demands of development during gestation and the survival needs that drive adaptation to the environment, diet is a robust signal for the developing organism that garners lasting changes in neurobiology and behavior and some of these may contribute to the development of psychopathology depending on the adult environment.

In terms of immune challenges during pregnancy, several rodent models have been used to examine the consequences of pathogens on later offspring development. For example, prenatal exposure to lipopolysaccharide

(LPS) results in depressive-like behaviors and reduced neurogenesis in the offspring (Lin & Wang, 2014). In an alternate model of maternal immune activation using the immunogenic agent Poly I:C, the pregnant dams' physiologic response to the challenge predicted behavioral changes in the offspring. Thus, dams that gained weight after the immune challenge gave birth to offspring with normal behavioral responses to amphetamine challenge, locomotor activity, and prepulse inhibition, while those that lost weight postimmune challenge had offspring with abnormal behavioral responses in these metrics (Missault et al., 2014). These findings suggest that the developmental alterations resulting by these (and other) early insults are complex and highly dependent on many maternal physiological factors, including her metabolic state. Not only that, but there is strong evidence that an important mechanism mediating the impact of psychological prenatal stress on offspring development involves immune activation. As shown by Bronson and Bale (Bronson & Bale, 2014), prenatal stress results in placenta inflammation, which mediates behavioral alterations in the adult offspring, in particular locomotor hyperactivity—which reflects brain dopaminergic dysregulation—and that were prevented by maternal treatment with nonsteroidal anti-inflammatory drugs during gestation. This literature linking maternal stress with proinflammatory states and the variety of prenatal immune challenge protocols being used in rodent models have been recently compared and contrasted (Meyer, 2014). Given the growing recognition that immune activation during pregnancy contributes to the etiology of psychopathology in the offspring, including the recent evidence that stress-induced activation of proinflammatory pathways in the placenta and stress-induced changes in maternal vaginal microbiome (Bronson & Bale, 2014; Howerton & Bale, 2012) mediate prenatal stress programming effects on offspring behavioral development, rodent models of gestational immune stress are proving critical to understand this early programming and to test treatment options for human patient populations.

Rodent Models of Postnatal Stress

Multiple postnatal stress paradigms have been used in the literature and most capitalize either directly or indirectly on manipulation of the powerful dam-pup relationship. One of the reasons behind the broad use of these models is based on the remarkable developmental changes in HPA axis regulation during the early postnatal period, which includes the thoroughly characterized transition to the HPA axis hyporesponsive period, as well as the critical role of the dam as an external regulator of pup behavior and physiology. This maternal regulatory role is not only evident for the pup neuroendocrine stress responses, but for the development and regulation of fear responses (Rincon-Cortes & Sullivan, 2014; Sanchez et al., 2001). The most well-known mechanisms mediating the effects of maternal care on offspring neurobehavioral development have been reviewed elsewhere (Howell & Sanchez, 2011; Sanchez et al., 2001) and are not the focus of this chapter. They include (1) feeding regulation of the pup's heart rate through milk actions on gatrointestinal receptors, (2) tactile stimulation via licking, grooming, nursing and retrieving, which stimulates sensory pathways that modulate the activity and development of limbic emotional circuits involving amygdala function, and also (3) epigenetic modifications such as DNA methylation changes in many genes, including GR, estrogen receptor, neurotrophic factors (e.g., brain derived neurotrophic factor: BDNF) and other brain proteins that regulate synaptic development (e.g., protocadherins), which altogether cause long-term genomic programming effects that seem part of extensive and coordinated biological responses to adapt to the environment, and that can be transmitted to future generations through epigenetic modifications in the germ line. While multiple postnatal stress paradigms exist in the literature, the two most commonly used with strong implications for behavior and neurobiology relevant to developmental psychopathology are reviewed next.

Maternal Separation

Maternal separation is a long-standing postnatal stress manipulation that has appeared in a variety of forms. The first apparent report of maternal separation was in 1969 by La Barba and colleagues (La Barba, Martini, & White, 1969) and the paradigm consisted of separation from the dam for 21 hours/day for 18 consecutive days beginning 24 hours after birth. Each separation period lasted for 6 hours with a 1 hour feeding period in which the dam was returned to the pups. This rather extreme paradigm has been replaced by a relatively standard model of 180 minutes of daily separation (maternal separation; MS) on postnatal days 2–14 that was originally described by Plotsky and Meaney (Plotsky & Meaney, 1993). This model has a much higher ecological validity than the previous longer separations as it is based on the fact that rat mothers in the wild leave the litter in the nest for short periods of time to forage, but when food sources are scarce, that time can increase to 2–3 hours (Fleming, 1986). As previously reviewed (Molet et al., 2014; Sanchez et al., 2001), this separation paradigm has robust and long lasting effects

on both behavioral and neurobiological endpoints with implications for developmental psychopathology, including increased anxiety/fear, stress reactivity and anhedonia. The effects of maternal separation have been shown to be mediated not really by separation-induced stress activation in the pups, but mostly by alterations in the dam's maternal behavior following reunion after these prolonged separations, which becomes disorganized and harsh (Huot, Gonzalez, Ladd, Thrivikraman, & Plotsky, 2004).

Maternal Abuse of Pups Induced by Impoverished Environment

A recent rodent model of adverse caregiving induces abusive and neglectful maternal behaviors by reducing the bedding of the cage where the rat dam lives with her litter. This simple manipulation triggers drastic alterations in the mother's behavior, which becomes very disorganized, and includes trampling the pups and carrying them around in a very rough manner. This impoverished environment model developed by Baram and colleagues (Avishai-Eliner, Gilles, Eghbal-Ahmadi, Bar-El, & Baram, 2001; Brunson et al., 2005; Gilles, Schultz, & Baram, 1996; Ivy et al., 2008), directly affects maternal behavior by manipulating the nesting environment and without separating the pups from her, leading to dysfunctional nurturing as well as physically abusive behaviors in the dam (Ivy, Brunson, Sandman, & Baram, 2008 Rice, Sandman, Lenjavi, & Baram, 2008; Roth & Sullivan, 2005). This paradigm induces cognitive and emotional alterations in the offspring (Baram et al., 2012), including the emergence of a behavioral phenotype later in life that includes depressive-like behavior as well as disrupted HPA-axis and amygdala function (Rincon-Cortes & Sullivan, 2014). Some of these behavioral and emotional alterations seem, at least in part, mediated by reduced BDNF expression in the PFC via epigenetic modifications (DNA methylation changes) in the BDNF gene (Roth, Lubin, Funk & Sweatt, 2009). Altogether this body of literature underscores the critical role of competent and nurturing parental behavior for proper neurobehavioral development of the offspring across mammalian species and points to some of the underlying biological and molecular mechanism involved.

Plasticity and Susceptibility of Adverse Early Life Experiences

The high degree of plasticity early in life in terms of both brain and behavior can work either for or against the ultimate adaptive development of an organism. Thus, if the immature animal grows in a generally positive environment, with a nurturing mother and environmental enrichment, following early life adversity some effects of the stressor exposure can be mitigated. However, if an additional challenge is experienced, commonly referred to as a double-hit, then the outcome for the organism could be highly maladaptive and lead to overt somatic or behavioral deficits and potentially psychopathology. Models of either reversal of early insults by enrichment or further insult have begun to be applied in the laboratory setting with rodent models. Thus, alterations in synaptic proteins that are created by maternal separation have been reported to be reversible through exercise exposure, a type of enrichment, in early adulthood (Dimatelis et al., 2013). In addition, housing of maternally separated rat offspring in enriched environments postweaning was sufficient to prevent the manifestation of anxiety-like behaviors that were evident in maternally separated offspring that were not afforded the benefit of postweaning enrichment (Vivinetto, Suarez, & Rivarola, 2013). Similarly, both the HPA axis over-activation and deficits in play behavior that are induced by prenatal stress can be reversed by housing in an enriched environment during adolescence (Morley-Fletcher, Rea, Maccari, & Laviola, 2003). Conversely, exposure to LPS followed by repeated restraint in early development creates a more profound anxiety-like phenotype than either manipulation in isolation (Walker et al., 2009). Prenatal immune challenge also creates a susceptibility to restraint stress applied in the juvenile period such that mice exposed to both challenges develop deficits in prepulse inhibition and dopaminergic signaling. This susceptibility can be prevented by treatment with alphalipoic acid during the juvenile period (Deslauriers, Racine, Sarret, & Grignon, 2014), which is an antioxidant essential for aerobic metabolism. This suggests that factors in the diet can palliate the deleterious impact of stress. Thus, dietary modifications during stressor exposure during pregnancy (such as fish and coconut oil) can improve the behavioral phenotype of the offspring (Borsonelo, Suchecki, Calil, & Galduroz, 2011). However, there are also negative diet by stress interactions such that rats who have been exposed to stress prenatally are more susceptible to the negative effects of a high fat and high sugar diet in adulthood (Paternain, de la Garza, Batlle, Milagro, Martinez, & Campion, 2013).

Puberty: The Perfect Storm

Major depressive disorder (MDD) can have devastating consequences; it can be particularly detrimental if it develops during adolescence because it interrupts the

development of social skills and causes potentially life-long alterations in physiology and behavior. The incidence of depression in the child and adolescent population is rapidly increasing in prevalence with an estimated rate of 8% near the beginning of adolescence and 25% by the end of adolescence (Kessler, Avenevoli, & Ries Merikangas, 2001). Furthermore, an adolescent episode of an anxiety or depressive disorder is associated with a two- to threefold increased risk for adult affective disorders (Pine, Cohen, Gurley, Brook, & Ma, 1998). Subthreshold depression during adolescence produces an increased risk of adult depression and suicidal behaviors similar to that of individuals who meet the criteria for major depression during adolescence (Fergusson, Horwood, Ridder, & Beautrais, 2005; Leuner, Mendolia-Loffredo, Kozorovitskiy, Samburg, Gould, & Shors, 2004). Finally, treatment plans for adolescents suffering from MDD are based largely on adult studies, and are not as efficacious in adolescents as they are in adults. The mechanisms of these differences are not understood but may be linked to the rapid physiological changes that occur during puberty and the concomitant demands on energy availability.

Although ketones are a significant fuel source prenatally, glucose is the quintessential cerebral fuel source for the majority of the life span (Clarke & Sokoloff, 1994). In the resting state, the adult brain uses approximately 20% of whole-body glucose for brain metabolism (Cremer, 1982). While the cerebral demand for glucose is clearly substantial in the adult, the requirement is heightened during development. In fact, the demand for brain glucose is 3–4 times higher in children and adolescents, with as much as 80% of whole-body glucose utilization being demanded by the brain (Cremer, 1982). This substantial allocation of energetic resources is particularly remarkable in light of the substantial peripheral demands during childhood and adolescence for overall growth and maturation of the reproductive organs. The introduction of additional energetic demands during this life phase, in the form of stress, can be energetically costly and cause developmental delays (Laugero & Moberg, 2000).

In addition to the demands of growth, there are dramatic and dynamic changes in sex steroids during puberty, and sex differences in physiology and behavior become more robust at this life phase. The precise timing of growth demands, sex steroid changes, and stress appear to result in a situation where intersectionality is important. Studies suggest that the timing of puberty influences the impact of stressful life events in humans (Ge, Conger, & Elder, 2001) and similar findings have been reported for rodents. Exposure during development appears to be fundamentally different than exposure in adulthood. Exposure to a single stressor episode postweaning in rats, close to the time of the onset of puberty, increases anxiety-like behavior following a single stressor in adulthood, to a greater degree than exposure to two stressors in adulthood (Avital & Richter-Levin, 2005). Exposure to chronic variable stress during puberty enhances the acoustic startle response both at the end of puberty and in adulthood (Maslova, Bulygina, & Popova, 2002), and short-term exposure (3 days) to a psychogenic stressor (predator odor and elevated platform) during puberty produces sustained changes in fear-related behavior (Toledo-Rodriguez & Sandi, 2007). Finally, chronic stress exposure during adolescence results in sustained depressive-like and anxiety-like behaviors that are still evident in adult female rats but not male rats further suggesting that the hormonal milieu interacts with other demands of puberty to cause variable outcomes (Bourke & Neigh, 2011).

Defining Adolescence in the Rodent

As in humans, adolescence in rodents is difficult to precisely define and definitions can vary depending on the endpoint in question. Adolescence is loosely defined as PND 22–59 with less certainty placed on the ends of the time zone as the pubertal process is subject to environmental influence. Factors to consider when defining adolescence are social changes, sex steroid changes, and neurogenesis changes. In regard to social behavior, it is commonly accepted that infancy and early childhood in the rodent ends at weaning (PND 21) and adulthood begins at PND 60 (Beckman & Feuston, 2003; Marty, Chapin, Parks, & Thorsrud, 2003). This milestone is marked by development of social and motor behaviors which allow the rat/mouse to be independent of the mother including food seeking, reaching, play fighting, and maturation of sensory systems (Whishaw & Kolb, 2005).

When using sex steroids to define adolescence, the peripubertal period is generally divided into three phases governed by the maturation of the sex organs: (1) early puberty (PND 22–35), which ends prior to the beginning of sexual organ maturation (i.e., vaginal opening in the female and balanopreputial separation in the male); (2) midpuberty (PND 35–49), which ends with the completion of sex organ maturation and the origination of sexual behavior; and (3) late puberty/early adult (PND 49–60), characterized by additional neurodevelopmental changes and cognitive behavioral changes (McCormick & Mathews, 2007; Spear, 2000).

In regard to the third criteria, neurogenesis, while it is well described that neurogenesis occurs in humans

(Eriksson, Perfilieva, Bjork-Eriksson, Alborn, Nordborg, Peterson, & Gage, 1998), developmental changes in neurogenesis have been best characterized in rodent species. Androgens and estrogens are known to influence neurogenesis (Galea, 2008; Galea, Spritzer, Barker, & Pawluski, 2006; Li & Shen, 2005; Tanapat, Galea, & Gould, 1998) and more than twice the number of newly dividing cells in the brain are described during puberty as opposed to in adulthood (Cameron & McKay, 2001). Although many of the newly divided cells die in both the adolescent and adult brain, new cells can be retained if the animal is exposed to learning around the time of the birth of the new cells (Leuner et al., 2004). This process was first described in adults (Leuner et al., 2004), but has also been identified in adolescents (Curlik, Difeo, & Shors, 2014). Given the greater number of cells that are born in the adolescent brain, this may predispose the adolescent brain to be more likely to retain new information than the adult brain. In the context of psychopathology, this is a potentially interesting mechanism to explain why adolescent individuals exposed to the exact same traumatic event as adults are more likely to develop posttraumatic stress disorder (PTSD). An illustration of this phenomenon is the Ehime Maru sea accident in which 78% of adolescent survivors developed PTSD and only 12% of adults developed PTSD (Maeda, Kato, & Maruoka, 2009).

Common Rodent Models of Stress During Puberty

Because of the limitations associated with conducting experiments in human subjects, animal models are invaluable in understanding the pathologic consequences of stress. Although rats cannot be queried to determine their affective state and are unlikely to experience depression in the sense that humans do, it is possible to study similar behavioral patterns and neurochemical phenomena in rodents. The neurobiology of rats is very well characterized and careful behavioral assessment can identify patterns of behavior that parallel depressive/anxiety-like behaviors in humans (Whishaw & Kolb, 2005). A multitude of preclinical studies have demonstrated that early life stressful experiences, such as maternal deprivation, exert both acute and long-term effects on neuroendocrine, cognitive, and behavioral systems (Gutman & Nemeroff, 2002; Weinstock, 2007). Consistent with the clinical literature, early life stress-induced changes in affective-like behavior and the HPA axis are more prevalent in female rats than male rats (Weinstock, 2007). Laboratory animals exposed to stressful conditions during development manifest adverse short and long-term cognitive dysfunction and abnormal behavior associated with alterations of the normal physiology and genetic regulation of the stress response (Gutman & Nemeroff, 2003; Ladd, Huot, Thrivikraman, Nemeroff, Meaney, & Plotsky, 2000). Although prenatal and postnatal stress have been studied for several decades, studies of stress during puberty are more recent. Many of the stressors employed during adolescence function off of principles of isolation and aggression. Social isolation in mice is profoundly detrimental and causes prolonged changes in aggressive behavior and neurogenesis (Ibi et al., 2008). Social stress exposure during puberty alters the formation of agonistic behaviors in both male and female golden hamsters (Taravosh-Lahn & Delville, 2004; Wommack, Taravosh-Lahn, David, & Delville, 2003). Finally, social stress during puberty can alter subsequent stress responses (McCormick & Mathews, 2007), behavior (Barnum, Pace, Hu, Neigh, & Tansey, 2012; Bourke et al., 2013; Bourke & Neigh, 2011; McCormick, Smith, & Mathews, 2008), neuroanatomy (Weathington & Cooke, 2012; Weathington, Hamki, & Cooke, 2014), and increase substance abuse behaviors in animals (Ferris & Brewer, 1996; Ferris, Messenger, & Sullivan, 2005; McCormick, Robarts, Gleason, & Kelsey, 2004). Here we will describe several of the most commonly published models of adolescent stress currently used in rodents, as well as the most relevant findings in each model.

Social Isolation

Isolation can be a powerful stressor in social animals regardless of the species. Although individual housing has profound health and behavioral effects on adult rodents, the positive influences of social housing have been mostly reported in the context of recovery from brain injury and peripheral wound healing (DeVries, Craft, Glasper, Neigh, & Alexander, 2007). However, in the context of development, social isolation has strong effects even in the absence of an additional physical challenge such as an injury. For example, a history of isolation housing starting in early puberty (postnatal day (PND 22) significantly increases the vulnerability to cocaine self-administration in adulthood. These data suggest that social isolation during puberty alters the development of reward brain circuits, predisposing the organism to greater drug abuse potential later in life.

The specific effects of timing of social isolation during puberty is another current research question. An interesting approach to these social isolation stress paradigms involves starting the isolation towards the end of early puberty (PND 30) and to regroup the rats following the isolation. One such approach confines the isolation to

just 5 days after PND30, returning the rats to group housing at PND 35. Although a very succinct period of isolation, this manipulation results in striking behavioral alterations in the forced swim test and elevated plus maze suggesting elevated anxiety- and depressive-like behaviors, as well as reductions in synaptic neuroplasticity (Leussis & Andersen, 2008). Furthermore, the reductions in synaptic plasticity are still evident when assessed weeks later, in adulthood (Leussis, Lawson, Stone, & Andersen, 2008). Extending the time of isolation to PND 30–50 results in further alterations in the HPA axis both at the level of output (corticosterone) and in terms of central neuronal changes (Weintraub, Singaravelu, & Bhatnagar, 2010). In addition, this prolonged separation paradigm results in sex-specific alterations in behavior and brain endpoints such that both males and females exhibit alterations following the separation, but the patterns are distinct (Weintraub et al., 2010). If the window of isolation is extended even further, PND 30–60, alterations in social learning are also observed. Thus, when tested for social recognition with a conspecific, mice that were group-housed their entire life performed better than mice housed alone from PND 30–60, independently of whether or not the isolated mice were returned to social groups for several weeks before they were tested (PND 80) (Kercmar, Budefeld, Grgurevic, Tobet, & Majdic, 2011). Altogether, this body of recent research highlights the strong long-term impact that even brief periods of social isolation during adolescence have on brain and behavioral development, emphasizing the important role of social relationships during this developmental period for humans.

Restraint Stress

Although the ecological and ethological validity of this model is questionable, restraint stress has been one of the most commonly used stressors used in rodent research. Plastic restraints commonly used for collection of blood samples are commercially available, and placement in a restrainer will generate a robust HPA axis response (Neigh, Bowers, Pyter, Gatien, & Nelson, 2004). Restraint is sometimes applied as a single acute stressor to challenge the HPA axis and examine the physiology of the activated state and in other cases is used as a repeated chronic stressor with multiple daily exposures. The range of days used in chronic restraint stress paradigms vary widely and can occur anywhere from days to multiple months. Repeated restraint was one of the first stressors applied in the context of adolescence and there is a wealth of data regarding the response of the adolescent rat to both acute and chronic restraint. Acute restraint increases anxiety-like behavior in the elevated plus maze as compared to adult rats exposed to the same restraint paradigm (Slawecki, 2005). Five days of repeated restraint (90 minutes/day) cause increased social anxiety in adolescent rats and the HPA axis response to restraint did not habituate as efficiently in adolescent as it did in adult rats (Doremus-Fitzwater, Varlinskaya, & Spear, 2009). Similar divergences in effects of repeated restraint on HPA axis function between adolescents and adults have also been reported by other research groups (Lui et al., 2012). Ten days of restraint (1 hour/day) from PND 25–35 caused increased basal corticosterone and increased cocaine-induced locomotion (Lepsch, Gonzalo, Magro, Delucia, Scavone, & Planeta, 2005). Restraint during adolescence has also been demonstrated to alter ethanol-induced behaviors differentially from similar exposure in adulthood (Acevedo, Pautassi, Spear, & Spear, 2013; Varlinskaya, Truxell, & Spear, 2013; Willey & Spear, 2013). Neural function and morphology are also impacted by chronic restraint stress during adolescence with reports of reduced neurogenesis in females, but not males, (Barha, Brummelte, Lieblich, & Galea, 2011), enhanced hypothalamic glutamatergic transmission in males (Kusek, Tokarski, & Hess, 2013), evidence of lower synaptic transmission in the prelimbic cortex (Negron-Oyarzo, Perez, Terreros, Munoz, & Dagnino-Subiabre, 2014), and alterations in conditioned fear behaviors (Zhang & Rosenkranz, 2013).

While restraint is a frequently used stress paradigm during adolescence, this approach has some limitations. For restraint to serve as an effective stressor, the rodents generally have to be individually housed. While this does not discount the value of restraint as a stressor, it is important that investigators acknowledge that they are using a combination of restraint and the more chronic stressor of isolation, which has strong developmental effects on brain, behavior, and physiology. This fact has strong implications for the interpretation of findings, particularly for translation to humans. Another concern is that rodents have the ability to habituate to restraint stress (Gray, Bingham, & Viau, 2010), which may create a situation in which the investigator is actually documenting the effects of habituation to a repeated stressor as opposed to the effects of chronic stress. Again, this does not necessarily invalidate the use of restraint as a chronic stressor, but it is essential to understand and differentiate which phenomenon is being studied to adequately and accurately interpret the experimental findings. Finally, repeated restraint has been criticized due to its lack of ethological relevance (Figueiredo, Bodie, Tauchi, Dolgas, & Herman, 2003) as this is not a stressor that a rodent would likely encounter

repeatedly in its natural environment and therefore the resulting physiological and behavioral processes may be contrived. Given these concerns and limitations of restraint as a model of chronic adolescent stress, additional stress paradigms have been recently generated that use more ethologically relevant stimuli or combine restraint with additional stressors.

Social Instability Stress

An adolescent stress approach that combines social isolation with instability is the social instability stress model. In this model, the rodent is isolated for one hour and then returned to a social group containing unfamiliar conspecifics. Social instability stress applied for 16 days during puberty (PND 30–45) has many behavioral, cognitive, emotional, and neural consequences. For example, it increases the risk for addiction, as shown by alterations in the locomotor effects of nicotine, with more pronounced neural correlates in male than female rats (McCormick & Ibrahim, 2007). In contrast, females appear to be more sensitive to deficits in spatial memory, which are paralleled by reduced hippocampal cell proliferation following social instability stress. Assessment of memory in an object spatial location task demonstrated that although female rats exposed to social instability had similar spatial memory to control rats shortly after the social stress paradigm in adolescence, their memory was impaired in adulthood (McCormick, Nixon, Thomas, Lowie, & Dyck, 2010). Some similar behavioral effects were also found in males exposed to social instability stress during adolescence, with memory appearing to be intact at the end of adolescence but a deficit in spatial memory evident in adulthood (McCormick, Thomas, Sheridan, Nixon, Flynn, & Mathews, 2012). Although social instability stress resulted in fewer newly generated cells in the hippocampus of females, the study design did not allow for the assessment of causation or determination of whether fewer cells were born or fewer cells survived (McCormick et al., 2010). The effects of social instability stress also extend to fear conditioning, with adolescent males (Morrissey, Mathews, & McCormick, 2011) and females (McCormick, Merrick, Secen, & Helmreich, 2007) exposed to this social stress during adolescence showing deficits in fear conditioning that could not be replicated when adult animals of either sex were exposed to the same chronic stressor. Collectively, these data highlight the plasticity of the brain and behavior in adolescent animals in response to exposure to complex social stressors and demonstrate the potential for these effects to be both delayed in onset, adolescence-specific, and enduring.

Social Defeat Stress

Social defeat is a robust and ethologically relevant stressor that has been applied to adult male rodents for over three decades (Van de Poll, De Jonge, Van Oyen, & Van Pelt, 1982). More recently, this stress paradigm has begun to be applied to adolescent rodents. Although there is a broad range of precise experimental designs, the protocols typically involve using large adult male Long Evans rats as an aggressor against an adolescent rat (either male or female). The adult aggressor is frequently housed with a female rat to increase territorial behavior. The female is removed from the cage prior to the defeat episode. A partially obstructive barrier that divides the cage in half but allows exchange of olfactory and visual cues is placed in the center of the home cage of the aggressor and then the adolescent experimental rat is placed on the opposite side of the barrier. After a short period of acclimation (generally 5–10 minutes, depending on the specific laboratory protocol), the barrier is removed and the adult and adolescent are allowed to freely interact. There is a large degree of laboratory specific variation for how long the interaction lasts, but after a predetermined period of time or a specific number of pins, the rats are separated by the barrier and remain in visual and olfactory contact for an additional exposure period (30 minutes to 24 hours depending on the lab).

Social defeat stress is a powerful stressor with high ecological and ethological validity with demonstrated wide range of effects in both male and female adolescents following exposure. Males exposed to social defeat for the entirety of puberty develop depressive-like behavior in the forced swim test and anhedonic behavior, and these effects are only partially reversible by either fluoxetine or a CRF antagonist (Bourke, Glasper, & Neigh, 2014). The demonstration of depressive-like and anxiety-like behavior following chronic adolescent social defeat has been replicated by multiple research groups with varying defeat parameters and in both rats and mice (Bourke et al., 2014; Huang et al., 2013; Iniguez et al., 2014; Vidal, Buwalda, & Koolhaas, 2011; Weathington, Arnold, & Cooke, 2012). The impact of chronic social defeat stress also impacts neural function and structure (Coppens et al., 2011; Watt et al., 2014; Weathington et al., 2012). Further, these changes in neural endpoints appear to have implications for drug abuse (Burke, Forster, Novick, Roberts, & Watt, 2013; Burke, Watt, & Forster, 2011; Novick, Forster, Tejani-Butt, & Watt, 2011), nicotine use (Zou, Funk, Shram, & Le, 2014), and alcohol consumption (Rodriguez-Arias et al., 2014). Finally, consistent with the effects of the previously discussed adolescent stress exposures, exposure to adolescent social defeat

causes impairments in spatial memory (Novick, Miiller, Forster, & Watt, 2013). Altogether, these recent findings support the validity of this model as an emerging model of social stress during adolescence, which some research groups argue could potentially serve to model bullying and physical abuse during human adolescence.

Chronic Mixed Modality Stress

Some stress paradigms in the literature use a combination of multiple types of stressor exposures to avoid habituation to a specific stress stimulus or situation. A classic example of this strategy is the use of the chronic unpredictable stress model which consists of pseudo-random exposures to multiple types of stressors including restraint, isolation, extended light cycle exposure, damp bedding, cage tilt, cage crowding, and other rodent-specific stress manipulations. A less variable model that has been more recently used with adolescent rats is the chronic mixed modality stress model. This model combines isolation housing, social defeat, and restraint exposures. The isolation component of the stressor begins at PND 35 and then social defeat and restraint exposures occur over 12 days in midpuberty (PND 37–48) with a single exposure a day. This paradigm causes robust and long-lasting depressive-like and anxiety-like behaviors in females and increased body mass (Bourke & Neigh, 2011), and exaggerated inflammatory responses in males (Pyter, Kelly, Harrell, & Neigh, 2013). The combination of these individual stressors provides a context-rich stress paradigm that may have more pervasive effects than any one stressor given repeatedly. However, this is a newer stress paradigm and it has not yet been determined whether it also has implications for drug addiction-related behaviors, physiology or learning and memory.

Predatory Stress

In the wild, rats and mice have multiple predators and exposure to a predator or cues signaling the presence of a predator can be used to elicit a robust stress response. For both rats and mice, cat or cat-related signals and fox-related signals are frequently employed as predatory stressors, and they are now being applied during adolescence. For instance, in a study comparing adolescent and adult rat exposure to cat odor, adolescent rats were exposed to cat odor on PND 38–42 and adult rats were exposed on PND 60–64. Three weeks later, all adolescent and adult rats were assessed and the findings indicated that the adolescent rats were more impacted in terms of HPA axis response, anxiety-like behavior, and social behavior, than adult rats exposed to the predatory stress paradigm (Wright, Muir, & Perrot, 2012). In a separate study, adolescent rats were subjected to 12 alternate days of cat fur exposure from PND 33 to 57. During exposure, adolescent rats demonstrated defensive huddling (all rats in the cage congregating away from cat fur) and reduced weight gain over the days of exposure. However, when the long-term effects of this experience were examined in adulthood, the rats exposed to cat fur actually showed reduced passive coping in the forced swim test (commonly interpreted as reduced depressive-like behaviors, although the actual functional meaning of these behaviors are a matter of debate in the field) and increased social behaviors, perhaps suggesting resilience (Kendig, Bowen, Kemp, & McGregor, 2011). It is important to note that these rats were not housed in isolation and the social housing may have provided social buffering from the repeated stress, again highlighting the powerful effect of positive social relationships during adolescence.

An additional predatory stress model that is specific to mice, is the use of a rat as the predator. In this paradigm, a mouse is placed in a four inch plastic activity ball and then the ball is placed in the home cage of a pair of adult male Long Evans rats. The rats typically engage in physical interactions with the activity ball with the mouse housed inside. In this paradigm the mouse is exposed to the smell and sight of the rat as well as the unpredictable physical movement of the rats manipulating the activity ball. Although no physical injury is experienced, this predatory stress paradigm initiated during adolescence has been shown to increase anxiety-like and depressive-like behaviors as well as measures of inflammation (Barnum et al., 2012). The pro-inflammatory phenotype induced by this intense stressor exposure is even more potent than a chronic mild stress paradigm (Barnum et al., 2012; Burgado et al., 2014). However, the robust effects of these stressful exposure may not be specific of adolescence because effects of the same stressor have also been demonstrated when the predatory stress is applied in adulthood (Burgado et al., 2014).

Brain Injury during Adolescence as a Model of Psychopathology

Sports-related traumatic brain injury (TBI) is a significant public health concern in the US and the incidence has risen with estimates as high as 3.8 million cases in the US each year (Langlois, Rutland-Brown, & Wald, 2006). The number of child and adolescent emergency room visits for sports-related TBI have more than doubled in the past decade (Mitka, 2010) and the majority of this increase is attributable to adolescent sports-related TBI (Graves, Whitehill, Stream, Vavilala, & Rivara, 2013). TBI is associated with a myriad of somatic

and psychological pathologies (Losiniecki & Shutter, 2010) and the long-term consequences of adolescent TBI are often overlooked (Graves et al., 2013; Ives, Alderman, & Stred, 2007). Further complicating the effects of adolescent TBI is the immature nature of the central nervous system. One example is the HPA axis, which undergoes substantial changes during adolescence, making this developmental stage a time of particular HPA axis susceptibility such that modifications to the HPA axis have profound and prolonged effects that are distinct from similar insults during adulthood or even early childhood (Avital & Richter-Levin, 2005; Bourke & Neigh, 2011; Greco, Hovda, & Prins, 2013, 2014; Maslova et al., 2002; McCormick & Mathews, 2007; McCormick et al., 2008; Pyter, Kelly, Harrell, & Neigh, 2013; Toledo-Rodriguez & Sandi, 2007). Adolescents are also susceptible to second-impact syndrome. Second-impact syndrome is rare in adults, but in adolescents, a second impact before complete resolution of the original injury, can lead to serious neurologic injury and death due to prolonged neuroinflammation and edema (Bruce, Alavi, Bilaniuk, Dolinskas, Obrist, & Uzzell, 1981; Cantu, 1995; McCrory & Berkovic, 1998). Even in the absence of a secondary injury, the prolonged neuroinflammation following TBI in an adolescent can cause profound changes, including possible dysregulation of the HPA axis. This is significant as the consequences of a dysregulated HPA axis response have been well documented in paving the way for a myriad of diseases including neurodegeneration and may underlie the progression of TBI-associated pathologies (Barnum et al., 2012; Bourke, Harrell, & Neigh, 2012; Bourke, Raees, Malviya, Bradburn, Binder, & Neigh, 2013; DeVries et al., 2007; McEwen, 1998, 2000, 2001, 2008; McEwen & Seeman, 1999; Neigh et al., 2009; Neigh & Nemeroff, 2006). Because of the clinical relevance of studies of TBI and evidence of developmental TBI involvement in the development of psychopathology, researchers have begun to focus on laboratory animal models of adolescent TBI, and potential treatments. This is a relatively new area of research with most studies focused on somatic outcomes. To date, research in adolescent rats has demonstrated implications of either single or repeated concussive injury on pituitary function (Greco et al., 2013, 2014) and sexual dysfunction (Greco et al., 2014). Much more work has been completed in adults with demonstrations of TBI-induced anxiety-like and depressive-like behaviors (Jones, Cardamone, Williams, Salzberg, Myers, & O'Brien, 2008; Pandey, Yadav, Mahesh, & Rajkumar, 2009; Rodgers et al., 2014) and deficits in learning and memory (Gorman, Shook, & Becker, 1993; Shear, Galani, Hoffman, & Stein, 2002; Sweet, Eakin, Munyon, & Miller, 2014). Given the general susceptibility of the adolescent brain to injury and the high incidence of TBI in adolescents, it will be important to extend these studies of TBI to its impact on adolescent neurobehavioral development.

NONHUMAN PRIMATE MODELS OF DEVELOPMENTAL PSYCHOPATHOLOGY

Nonhuman primates are more closely related to humans phylogenetically than rodents while still allowing for experimental manipulations not possible in studies investigating humans directly, making them crucial when studying the neural mechanisms of developmental psychopathology (Gibbs et al., 2007). Rhesus monkeys are a nonhuman primate species commonly used to study the neurobehavioral effects of early experience due to several advantages. In the wild they live in large troops made up of several multi-generational female-headed families and a few immigrant adult males, resulting in a complex social environment. They also have well-developed brains that closely resemble humans' in respect to organization and neurochemistry (Barbas, 2000; Croxson et al., 2005; Reep, 1984; Thiebaut de Schotten, Dell'Acqua, Valabregue, & Catani, 2012), particularly regarding the PFC, which is very different in primates versus rodents (Öngür & Price, 2000; Preuss, 1995; Preuss & Goldman-Rakic, 1991a, 1991b). Stress physiology, including the regulation and development of the HPA axis, as well as the distributions of glucocorticoid receptors (GR) and corticotropin releasing factor (CRF) receptors are comparable in rhesus monkey and human brains, particularly regarding their high expression in PFC (Pryce, 2008; Sanchez, Young, Plotsky, & Insel, 1999, 2000; Seckl, Dickson, Yates, & Fink, 1991), suggesting that some effects of early life adversity on the developing brain induced by elevations in stress hormones and neuropeptides (e.g., GCs and CRH) could be similar in both species. Neuromaturational processes also occur with similar temporal and anatomical patterns in humans and monkeys, although over a condensed period of time in monkeys (approximately 1:4 years, monkey to human age) (Diamond, 1991; Gibson, 1991; Huttenlocher & Dabholkar, 1997). To provide a translational framework on which to place the findings from nonhuman primate studies presented in the following sections we will first present a brief overview of normative nonhuman primate brain development as it relates to human brain development.

Primate Brain Development: Sensitive Periods

Early adversity is thought to be so detrimental because it occurs at a time of rapid developmental changes in the brain, creating windows of vulnerability in which adverse experience can be encoded (Andersen, 2003; Knudsen, 2004; Rice & Barone, 2000). In both developing monkey and human brains cellular processes (e.g., synapse formation, pruning, and dendritic changes) are revealed by gross region specific decreases in gray matter (GM) and increases in white matter (WM) due to pruning of synaptic connections and myelination of axons (Lenroot & Giedd, 2006; Malkova, Heuer, & Saunders, 2006). Although early reports in humans of GM volume changes with age suggested linear decreases (Reiss, Abrams, Singer, Ross, & Denckla, 1996), more recent studies of GM volumes describe a region-specific inverted U shape during development (that is, an initial developmental increase that, after reaching a postnatal peak, follows a developmental decrease), with frontal and parietal GM peaking at 12 years of age, temporal GM peaking at 16 years, and occipital GM continuing to increase through 20 years (Giedd, 2004; Giedd, et al., 1999). These developmental patterns suggest region-specific sensitive periods, with some lasting for several years as a result of protracted developmental trajectories (Andersen, 2003). More detailed analyses of longitudinal data suggest that cortical maturation (i.e., GM loss) occurs in low-order regions (e.g., regions that process visual or somatosensory stimuli) prior to the association cortices that integrate this sensory input such as portions of the temporal and frontal cortices (Gogtay et al., 2004). Cortical development also seems to follow the maxim "ontogeny recapitulates phylogeny," with phylogenetically older regions such as the piriform and entorhinal cortex maturing before evolutionarily newer regions such as the inferior temporal cortex and PFC (Giedd, 2004; Gogtay et al., 2004; Shaw et al., 2008). These data suggest the specific brain regions undergo increased developmental changes early in life, and those with protracted developmental trajectories, including regions such as the PFC, may be particularly vulnerable to environmental insult, and thus may contribute to developmental psychopathology.

In monkeys the elimination of axons occurs both prenatally and postnatally in a region specific manner that coincides with the emergence of related behavioral and cognitive functions, with some regions such as the corpus callosum (CC) not reaching adult axon numbers until postnatal day 60 (LaMantia & Rakic, 1990). In both monkeys and humans myelination begins in some regions prenatally (e.g., motor cortex) but it takes place postnatally in most other cortical regions and continues in association areas, namely temporal, prefrontal and parietal regions, into early adulthood (Gibson, 1991). Thus, cerebellar, temporal and prefrontal tract myelination occurs massively during childhood, with the cerebellum achieving adult levels of myelin between 3 and 6 months of age in monkeys and 1 to 2 years in humans, while WM of commissural and association tracts only reach adult levels of myelination at 3.5 years in monkeys (equivalent of 14 years in humans, peripuberty) and around 20 years in humans (Gibson, 1991). This suggests that commissural and association tracts, which are important for integrating information between brain regions, such as the uncinate fasciculus (UF), a WM tract connecting PFC with temporal regions and the last WM tract to myelinate in humans (Lebel, Walker, Leemans, Phillips, & Beaulieu, 2008), are particularly sensitive to critical aspects of maternal care as well as early adverse experiences because of their protracted development. This, combined with the important role the UF plays in emotion and stress regulation (Kim et al., 2011) via prefrontal–amygdala connectivity (i.e., prefrontal top-down control on amygdala reactivity to threat) suggest that adverse early experience-related alterations in the development of these networks are a likely neurobiological mechanism contributing to developmental psychopathology.

Much of what we know about the rapid structural development that occurs early in life in the amygdala comes from studies of rhesus monkeys. The amygdala is composed of several heterogeneous nuclei that differ in cellular composition, connectivity, and function, which is why it is often referred to as the amygdaloid complex. Development of the amygdala in rhesus monkeys follows nuclei-specific patterns. The medial nucleus (which is involved in sensory processing) is near adult size at birth, while the lateral and basal nuclei, which are involved in emotional processing and learning, increase in volume from birth through 3 months of age (Chareyron, Lavenex, Amaral, & Lavenex, 2012). The volume of the central nucleus (which has direct connections to the autonomic nervous system, and is involved in modulating the stress response through these connections) is about half of adult size at birth and continues to increase beyond one year of age, during the juvenile period (Chareyron et al., 2012). These nuclei specific patterns are reflected in a postnatal increase in total amygdala volume, which occurs at the highest rates during the first 4 months of life (Payne, Machado, Bliwise, & Bachevalier, 2010). Thus different amygdala nuclei, and the specific functions and behaviors that they support,

may be vulnerable at specific times during development. Numbers of oligodendrocytes in the amygdala increase in parallel with the increase in amygdala volume after 3 months of age, while neuronal size, astrocyte number, and neuron number do not change (Chareyron et al., 2012). This suggests that the increase in amygdala volume is not only due to neuronal changes, but also in the glia that produce the myelin in WM, and that these cells may also be vulnerable to early life adversity. This also suggests that WM in amygdala circuits supporting specific behaviors may be affected by early life stress. For example, in monkeys, amygdala afferents from portions of temporal cortex that relay visual information mature at week 3 when an animal first begins to respond appropriately to social cues, while efferents from these same temporal regions to orbital PFC do not become mature until 2 months when curiosity and frustration become apparent (Machado & Bachevalier, 2003). Thus, early adverse experiences in primates, particularly alterations in proper maternal care, occurring during the first few weeks of life may interrupt the ability to process social information, while adversity occurring during the second month of life might affect detection of stimuli salience and, therefore, exploratory behaviors. The complexity of the interplay of timing of these adverse experiences and neurodevelopment is one challenge the field of developmental psychopathology faces, and one in which nonhuman primate models may be especially informative given the similarities in neurobehavioral development highlighted earlier.

Although there is still much to be learned about normative neurobehavioral development, we are beginning to appreciate the importance of first understanding how these brain circuits and processes develop under species typical conditions when trying to disentangle the many factors that contribute to developmental psychopathology. During normative development drastic changes occur at the cellular, molecular, structural, functional, and systems levels in brain networks that have been consistently linked with developmental psychopathological symptomatology. It is this rapid maturation early in life that is thought to make these regions sensitive to environmental influence (Andersen, 2003). Therefore, several nonhuman primate models of early adversity and social stress have been used to study these effects, and to determine the underlying mechanisms of these experiences on the brain and behavior (Kalin & Shelton, 2003; Machado & Bachevalier, 2003a; Nelson & Winslow, 2008; Parker & Maestripieri, 2011; Sanchez, 2006; Sanchez et al., 2001; Stevens, Leckman, Coplan, & Suomi, 2009), which will be reviewed in the next sections.

Social Deprivation and Nursery Rearing

Arguably the most salient experience for a newborn primate is the relationship with its primary caregiver. Thus disruption of species typical early interaction with the primary caregiver, either through experimental manipulations or as sometimes occurs in nature, can serve as potent paradigms for studying the neurobiological underpinnings of developmental psychopathology. Studies of the effect of this type of early life stress (ELS) began in the 1960's with Dr. Harry Harlow's seminal work using experimental manipulations of the early rearing environment to model ELS including rearing in partial social isolation. Removing the vast majority of social interactions typically experienced by young primates resulted in severe behavioral and social deficits including stereotypies, self-injurious behavior, inability to read social cues or develop normal social relationships (including maternal behavior), and hyperaggressiveness (Suomi, Harlow, & Kimball, 1971). Rearing in complete social isolation led to similar outcomes, but with increased severity of developmental outcomes, and also included increased fear and anxiety (Seay & Gottfried, 1975). Alterations in the HPA axis have also been reported in this model (for review, see Sanchez et al., 2001), and recently several studies have reported evidence supporting possible genetic mechanisms mediating individual vulnerability to the severity of outcomes (i.e., gene-by-environment interactions that highlight strong effects of the serotonin transporter and monoamine oxidase A gene polymorphisms) as well as ELS-induced epigenetic alterations (Barr et al., 2003, 2004; Newman et al., 2005; Provençal et al., 2012). One recent study looked at whether levels of cortisol accumulated in hair (a measure of chronic glucocorticoid exposure) were related to anxious behavior and early experience in the form of peer-rearing. This study found that animals reared in the nursery were more anxious and had higher levels of accumulated cortisol (Dettmer, Novak, Suomi, & Meyer, 2012). These manipulations of the early social environment have been invaluable in understanding the importance of social stimuli on socioemotional and physiological development, but these are all somewhat artificial paradigms with limited ecological and ethological validity (except for extreme cases of social deprivation in children, such as orphanage rearing), which are complemented by other early adversity models discussed in the following sections.

Experimental Alterations in Maternal Care

Maternal separation has also been used to model developmental psychopathology in both New and Old World

nonhuman primates, including rhesus monkeys, squirrel monkeys (*Samiri sciureus*), and common marmosets (*Callithrix jacchus*). In rhesus monkeys, separation from the mother is a potent stressor for infant monkeys that leads to increased activity, vocalizations, and HPA axis activations (Bayart, Hayashi, Faull, Barchas, & Levine, 1990; Harlow, Harlow, & Suomi, 1971). Maternal separation has been related to decreased left dorsolateral PFC activation, as well as increased right dorsolateral and right ventral temporal/occipital lobe activation, effects related to concurrent elevations in plasma cortisol concentrations (Rilling, Winslow, O'Brien, Gutman, Hoffman, & Kilts, 2001). Repeated maternal separation in infancy has been related to alterations in stress responsivity including increased cortisol reactivity in females and flattened diurnal cortisol rhythms, as well as increased acoustic startle responses (i.e., reflecting increased anxiety) later in life (Sanchez et al., 2005). These effects are predicted by both exposure to chronically elevated levels of stress hormones and impaired maternal care following mother–infant reunion after the separation (Sanchez et al., 2001). Cameron and colleagues have gone one step further and looked at the long-term effects of complete maternal deprivation on infant behavior as a function of when the mother and infant are separated. The primary findings of these studies are consistent with those reported in children. That is, rhesus infants separated from their mothers at earlier ages (beginning at 1 week of life) showed the most detrimental effects (O'Connor & Cameron, 2006). These effects included social disturbances and alterations in fear behaviors that appeared to depend on the timing of separation. For example, animals that were separated at 1 week of age did not seek comfort when anxious, while those separated later at 1 month of age did seek comfort but were hypervigilant to social cues (O'Connor & Cameron, 2006). These adverse early experiences were also related to alterations in both PFC and amygdala (O'Connor & Cameron, 2006).

Marmosets are useful model organisms when studying the effects of alterations in early caregiving for a few reasons: (1) they are small, making them logistically easier to work with; (2) they are biparental; and (3) they typically give birth to twins, allowing for twin experimental designs to tease apart genetic versus experiential effects. Studies using marmosets have demonstrated the importance of considering parental factors when studying the effects of adverse early experience (Dettling, Schnell, Maier, Feldon, & Pryce, 2007). For example, in a model using parental-infant separation consisting of daily separations between days 2 and 28 (Dettling, Feldon, & Pryce, 2002a, 2002b), the adolescent animals that experienced parental separation showed decreases in GR mRNA, hippocampal growth-associated protein-43 (GAP-43) mRNA, serotonin 1A receptor (5-HT_{1A}R) mRNA and binding ([^{3}H]WAY100635), and increased vesicular GABA transporter mRNA in the hippocampus (Arabadzisz et al., 2010; Law et al., 2008). They also showed decreased levels of the dendrite-enriched protein spinophilin in the subgenual anterior cingulate cortex (Law, Pei, Feldon, Pryce, & Harrison, 2009). Increases in both urinary norepinephrine and dopamine, along with increased systolic blood pressure have also been reported (Pryce, Dettling, Spengler, Spaete, & Feldon, 2004; Pryce, Dettling, Spengler, Schnell, & Feldon, 2004), and these physiological alterations may be related to alterations in both the physiological and behavioral responses to stress reported (Dettling et al., 2002a, 2002b). Cognitive effects of this adverse early experience include increased sensitivity to perceived loss of control, reduction in reward motivation, impairments in behavioral inhibition, and impairments in reversal learning (Pryce, Dettling, Spengler, Spaete, et al., 2004; Pryce, Dettling, Spengler, Schnell, et al., 2004). All of the aforementioned studies corroborate the importance of parental care in neurobehavioral development, and support the involvement of several systems in the etiology of development psychopathology including the HPA axis, the PFC, and subcortical brain regions such as the amygdala and hippocampus.

The aforementioned nonhuman primate models have certainly demonstrated the critical role of the early social environment (including the mother and the father, in biparental species like humans) on primate neurobehavioral development, but they are based on artificial experimental manipulations (maternal deprivation since birth, repeated mother infant separations), which these species may not otherwise experience in the wild (e.g., in contrast to rats, rhesus monkey mothers don't leave their infants behind to forage), making it difficult to interpret their developmental consequences, as well as determining the generalizability and ethological relevance of the biological mechanisms involved for the human experience. Thus, we now discuss the complementary information provided by more naturalistic nonhuman primate models with stronger ecological and ethological validity.

Variable Foraging Demand

The variable foraging demand model contrasts the previously described models in that it was specifically developed as an ethologically valid model of early life adversity that exploits species typical behavior (i.e., foraging for food).

This model was first developed by Leonard Rosenblum and colleagues and consists of variable, and most importantly, unpredictable, availability of food (i.e., periods of intense foraging alternated with periods of free access to food), and has been used to study disruption of the early social environment in bonnet macaques (*Macaca radiata*) (Rosenblum & Paully, 1984). It is important to point out that even under conditions where the mother had to spend more time foraging enough food was available to maintain her and her infant's health. Thus, this manipulation does not involve malnutrition, but alters maternal behavior by reducing the amount of time spent responding to infant solicitations for care (Rosenblum & Paully, 1984). These alterations in mother–infant interactions resulted in several behavioral alterations in the infants including increased clinging to the mother, reductions in exploratory and play behavior, as well as behavioral disturbances such as despair-like behaviors involving self-clasping (Andrews & Rosenblum, 1994; Rosenblum & Paully, 1984). At 2.5 years of age animals raised under high foraging conditions showed decreases in affiliative behaviors and reductions in reactivity in response to a mildly threatening stimulus (Andrews & Rosenblum, 1994; Rosenblum, Forger, Noland, Trost, & Coplan, 2001). Long-term behavioral alterations in the infant also include social incompetence, increased fearfulness, increased social subordination, and both behavioral and physiological hyperresponsiveness to stressful stimuli (Andrews & Rosenblum, 1994; Coplan et al., 1996).

This environmentally induced change in mother–infant interactions does not only result in the behavioral alterations described already, but also alters neurobiological development. For example, behavioral and hormonal responses to neurochemical manipulation using the alpha2-adrenergic agonist clonidine, the alpha2-antagonist yohimbine, and the mixed serotonin 2C/1B receptor agonist m-chlorophenylpiperazine were reported in infants raised under the high foraging demand condition as compared to those raised under low foraging demand (Rosenblum, Coplan, Friedman, Bassoff, Gorman, & Andrews, 1994; Smith, Coplan, Trost, Scharf, & Rosenblum, 1997). The high foraging demand animals also had elevated levels of CRF and somatostatin, as well as monoamine metabolites including the serotonin metabolite 5-hydroxyindoleacetic acid (5HIAA), the dopamine metabolite homovanillic acid (HVA), but reduced levels of cortisol compared with those raised under low foraging demand (Coplan et al., 1996, 1998, 2001). The increase in CSF CRF in high foraging demand offspring was due to higher levels found in those carrying the short allele of the serotonin transporter polymorphism, paralleling findings in maternally separated animals (Coplan, et al., 2011). In vivo imaging studies of these animals in adulthood have reported reductions in corpus callosum area, hippocampal and temporal gyrus volumes, the neuronal viability marker N-acetylaspartate in the anterior cingulate and medial temporal lobe (reflecting signs of neuropathology in these brain regions), as well as reductions in tract microstructural integrity of the anterior limb of the internal capsule (Coplan et al., 2010; Jackowski et al., 2011; Mathew et al., 2003). Just as the previously described models that involved more invasive manipulations of maternal care, this more ecologically and ethologically valid model points to the involvement of similar brain regions in the alterations associated with changes in mother–infant interactions. They also provide evidence that specific neurochemical systems and brain regions not traditionally thought to play an active role in developmental psychopathology, such as white matter tracts, may also contribute to the etiology of developmental psychopathology.

Social Subordination

Nonhuman primates live in highly structured societies that provide unique opportunities to model human socioeconomic status (SES), particularly during development (Hackman, Farah, & Meaney, 2010). Rhesus monkeys, for example, live in societies organized by a strict dominance hierarchy that functions to maintain group stability (Bernstein, 1976; Bernstein, Gordon, & Rose, 1974). This is true of other nonhuman primate species as well, such as cynomolgus macaques (*Macaca fascicularis*), another species of Old World monkey often used when studying the effects of social subordination (Shively, Laber-Laird, & Anton, 1997; Shively, Register, Friedman, Morgan, Thompson, & Lanier, 2005). An animal's place within the hierarchy determines its access to resources, such as food and mates (Sade, 1967). These matrilineal hierarchies are maintained through contact and noncontact aggression and threats of aggression from dominant to subordinate animals (Bernstein, 1976; Bernstein & Gordon, 1974; Bernstein et al., 1974). The defining feature of social subordination is the presentation of submissive behaviors from subordinate animals in response to agonistic interactions with dominant animals (Bernstein, 1976; Bernstein & Gordon, 1974; Bernstein et al., 1974). These agonistic encounters are unpredictable, and often unprovoked, increasing uncertainty and stress in subordinates (Silk, 2002). This presumably reduces a subordinate animal's sense of control over the social and physical environment. Infant rhesus monkeys acquire the relative rank of their

mothers within their social group (Sade, 1967), a process thought to be attributable to latent observational learning as well as harassment from higher ranking females (Holekamp & Smale, 1991). Thus, infants of low ranking mothers are subject to the pressures of their rank beginning very early in development. While we know social subordination affects pubertal timing (Wilson, Bounar, Godfrey, Michopoulos, Higgins, & Sanchez, 2013; Wilson, Gordon, & Collins, 1986; Zehr, Van Meter, & Wallen, 2005), an effect that is associated with increased emotional reactivity in these animals (Wilson et al., 2013), the subordinate phenotype is less well understood in developing monkeys. It is important to recognize that this form of social stress is experienced throughout the life of the animal, and not just during early life, which is a main difference between this and other animal models used to study the underlying neurobiological mechanisms of stress-related developmental psychopathology, apart from the different adverse experience in comparison to animal models of disrupted maternal care. Consequences of this unpredictable, continual harassment in adult females include stress-related phenotypes, such as HPA dysregulation, evidenced by hypercortisolemia and impaired GC negative feedback (Jarrell, Hoffman, Kaplan, Berga, Kinkead, & Wilson, 2008; Kaplan et al., 2010; Michopoulos, Higgins, Toufexis, & Wilson, 2012; Shively et al., 1997). Subordinate animals receive higher rates of aggression and lower rates of affiliation (Michopoulos et al., 2012). It is interesting then to note that these two behaviors were the best predictors of increased cortisol in subordinates found in a meta-analysis of several primate species (Abbott et al., 2003). Thus, social subordination in rhesus monkeys is a well-established nonhuman primate model of chronic psychosocial stressor exposure, with high ethological validity. This model has been used to study the adverse effects of chronic social stress on a broad range of adult behavioral, neuroendocrine, neuromodulatory, immune and health outcomes (Gust et al., 1991; Kaplan, Adams, Clarkson, Manuck, Shively, & Williams, 1996; Kaplan et al., 2010; Michopoulos, Berga, Kaplan, & Wilson, 2009; Morgan et al., 2002; Paiardini et al., 2009; Tung et al., 2012); however many of these studies were performed on experimentally derived groups, meaning that animals from a single rank were taken and used to form new groups under well-controlled conditions, or animals were raised in nurseries beginning in infancy. While this approach can answer many valuable questions about the effects of chronic psychosocial stress on adult animals, it is not an ideal design when trying to answer questions relating to the effects of ecologically valid and species-specific adverse early experiences. Given the success of this model in studying effects of chronic social stress in adults, though, recent investigations are just now beginning to focus on the effects of this chronic stressor during development. For example, a recent study by our group examined the effects of social status on WM microstructure development during the juvenile period and found increased microstructural integrity in prepubertal subordinate animals in frontal (motor and sensorimotor regions) and prefrontal WM (Howell. Godfrey, et al., 2014). In this study animals with higher fractional anisotropy (increased cortical WM structural integrity) in cortical regions involved in emotional and sensory processing were observed to be also more submissive in their home social groups and more emotionally reactive (fearful) during a standardized emotional reactivity task (the Human Intruder Paradigm) (Kalin & Shelton, 1989), suggesting that increased integrity in these cortical WM regions is related to increases in socially adaptive behavior (i.e., exhibiting submissive behavior and more emotional reactivity if you are a subordinate) (Howell, Godfrey, et al., 2014). Future studies will need to address genetic versus experiential contributions to these outcomes.

Infant Maltreatment

Child maltreatment is not a uniquely human phenomenon, but has also been reported in both wild and captive populations of nonhuman primate species, including macaques, baboons, and marmosets (Brent, Koban, & Ramirez, 2002; Carroll & Maestripieri, 1998; Johnson, Kamilaris, Calogero, Gold, & Chrousos, 1996; Maestripieri, 1998; Maestripieri & Carroll, 1998; Maestripieri, Wallen, & Carroll, 1997; Troisi & D'Amato, 1984; Troisi, D'Amato, Fuccillo, & Scucchi, 1982). In macaque species infant maltreatment is an adverse early experience that includes two comorbid types of behavior in the mother that both result in overt signs of infant distress (vocalizations, tantrums, etc.): (1) physical abuse in which the mother exhibits aberrant violent behaviors towards the infant that cause pain and distress (drags, crushes, sits on, or roughly grooms the infant) and typically occur during the first 2–3 months of life, and (2) high rates of infant rejection early in life, which consists of pushing the infant away when it solicits contact with the mother (Maestripieri, 1998; Maestripieri & Carroll, 2000; McCormack, Sanchez, Bardi, & Maestripieri, 2006). Infant physical abuse has been more widely studied and characterized in the literature. It occurs within specific families, and by cross-fostering females born to control mothers to abusive mothers and observing their behavior with their own infants, Maestripieri and colleagues were able to

show that this type of infant maltreatment is experientially passed from generation to generation (Maestripieri, 2005; Maestripieri & Carroll, 1998; Maestripieri, Megna, & Jovanovic, 2000). Abusive mothers will often abuse successive infants, and primiparous mothers show higher rates of both abuse and neglect (Maestripieri & Carroll, 1998). Using sophisticated statistical methods Maestripieri and colleagues showed that physical abuse was not triggered by infant signals, such as crying, although abusive mothers were less likely to respond positively to their infants' cries (Maestripieri, Jovanovic, & Gouzoules, 2000), possibly leading to alterations in vocal emotional communication later in life (Jovanovic & Maestripieri, 2010).

Studies using this animal model have identified several alterations in the HPA axis associated with this adverse early experience, including increases in both basal and stress levels of cortisol, as well as blunted ACTH responses to a CRF pharmacological challenge that reflects down regulation of CRF receptors in the pituitary (Koch, McCormack, Sanchez, & Maestripieri, 2014; McCormack et al., 2003; Sanchez, 2006; Sanchez, McCormack, Grand, Fulks, Graff, & Maestripieri, 2010). Altogether these findings suggest that maltreatment is a stressful experience that results in elevated activity of the HPA axis, including a likely hypothalamic CRF overproduction that causes pituitary downregulation of its receptors. Socioemotional alterations include increased emotional reactivity, comparable to those seen in maltreated children (Howell, Grand, et al., 2014; McCormack et al., 2006; Sanchez & Pollak, 2009). Infant rejection was associated with decreases in brain serotonin and dopamine metabolite levels, and rejection and low serotonin function were, in turn, associated with increased activity of proinflammatory pathways (Maestripieri, Higley, Lindell, Newman, McCormack, & Sanchez, 2006; Maestripieri, McCormack, Lindell, Higley, & Sanchez, 2006; Sanchez et al., 2007), an interesting finding given that other studies have found modulation of some maltreatment related outcomes by serotonin transporter gene polymorphisms. For example, abused infants carrying a short (risk) allele showed increased vulnerability to exhibit increased anxiety and alterations in the HPA axis than abused infants with the long allele (McCormack et al., 2009). Delays in social development including delayed independence from the mother and less exploration and play have also been reported in this model (Maestripieri & Carroll, 1998; Maestripieri, Jovanovic, et al., 2000). The increased emotional reactivity caused by infant maltreatment persists throughout the juvenile and adolescent periods (Howell, Grand, et al., 2014). Recent neuroimaging studies have reported a positive correlation between amygdala volume and abuse rates received by the animals during infancy, as well as negative correlations between infant basal cortisol (collected at 1 month of age, when abuse rates were highest) and juvenile WM integrity in tracts important for behavioral and emotional regulation (Howell, Grand, et al., 2014; Howell et al., 2013). These findings parallel long-term consequences found in maltreated humans, supporting the construct validity of this model to gain understanding of the mechanisms underlying the poor developmental outcomes associated with this adverse early experience in humans.

Stress Inoculation Model: the Important Issue of Timing of Early Adverse Experiences for Resilience Versus Vulnerability to Psychopathology

In contrast to the evidence presented in this chapter that early adverse experiences (prenatal and postnatal stress, immune/inflammatory challenges, and disruptions in the mother–infant bond) are strong risk factors for developmental psychopathology, there is an interesting body of literature showing evidence that moderate stress at specific times of development actually has the opposite effect. That is they increase resilience when the individual faces challenges later in life. Most of the evidence for this phenomenon in nonhuman primates comes from studies in squirrel monkeys showing that manageable mild stress exposure at specific developmental times (weaning) may actually be protective, allowing the animal to better adapt to environmental challenges (Lyons & Parker, 2007; Lyons, Parker, & Schatzberg, 2010; Parker, Buckmaster, Schatzberg, & Lyons, 2004). This phenomenon has been termed *stress inoculation* and has been most extensively studied by exposing young squirrel monkeys during weaning (around 16 weeks of age, when they are no longer as dependent on maternal care) to mild intermittent stress consisting of separation from the mother and social group for 1 hour, once a week for ten weeks. Although rodent studies suggest that the quality of maternal care upon reunion following a prolonged (3 hours) mother-pup separation is altered and constitutes the critical factor in the increased risk for developmental psychopathology in the offspring, the stress resilience observed in the stress inoculation model does not seem to be caused by changes in maternal care (Parker, Buckmaster, Sundlass, Schatzberg, & Lyons, 2006). Although seemingly contradictory to everything presented so far, both the resilience outcomes and the lack of maternal mediation on the effects could be explained by the fact that these infants are in a later developmental stage (weaning), and are less dependent on maternal care. These studies have shown several

positive behavioral outcomes related to stress inoculation including increased exploratory behavior in adolescence and enhancements in inhibitory control of behavior lasting into early adulthood (Parker, Buckmaster, Justus, Schatzberg, & Lyons, 2005; Parker, Buckmaster, Lindley, Schatzberg, & Lyons, 2012). The HPA stress response also seems to be better calibrated to handle challenges, as evidenced by reductions in basal levels of stress hormones and the ability to mount a comparable neuroendocrine response to a moderate stressor as compared to animals that had not been inoculated (Parker et al., 2005; Parker et al., 2012). Neurobiological effects of this early experience include alterations in PFC morphology and GC receptor distributions in regions related to alterations in reward related-learning, but without accompanying effects on the hippocampus (Lyons, Afarian, Schatzberg, Sawyer-Glover, & Moseley, 2002; Lyons & Schatzberg, 2003; Patel, Katz, Karssen, & Lyons, 2008). These studies highlight how important the timing of the experience is in determining risk and resilience for developmental psychopathology (Parker & Maestripieri, 2011).

CONCLUSIONS

Animal models, both rodent and nonhuman primate, are indispensable when trying to determine the underlying biological mechanisms of developmental psychopathology. These models have led to significant progress in our understanding of not only maladaptation and dysfunction as it relates to developmental psychopathology, but by utilizing more ethologically valid models they have also begun to provide the normative developmental and ecological context necessary to draw meaningful conclusions. Animal models also allow us to compare and contrast findings to gain an even deeper understanding of the specific role of the early environment and caregiving in neurobehavioral development. Despite the many evolutionary, developmental, neurobiological, behavioral, and ecological differences between rodents, nonhuman primates, and humans, some striking cross-species parallelisms have emerged in studies of developmental psychopathology. These include developmental alterations of PFC and limbic regions like the amygdala and hippocampus in the etiology of developmental psychopathology, as well as the complex interplay between these regions as they change across development resulting in specific sensitive periods and windows of vulnerability. Shifting research paradigms to use more naturalistic and ethologically valid animal models has highlighted the unique role of competent and sensitive early caregiving in mammalian neurodevelopment. These paradigm shifts have also provided compelling evidence that there is a strong evolutionary, adaptive purpose for the developmental changes triggered by early life adversity, which are advantageous as they prepare the offspring to live in a harsh and challenging environment, but also result in significant and costly poor developmental outcomes. Animal models will remain invaluable as the field of developmental psychopathology moves towards understanding even more complex mechanisms involving epigenetic modifications and transgenerational transmission of experience-sensitive behaviors.

Translational Implications

The goal of translational research using animal models of developmental psychopathology is to understand the biological mechanisms, predictors, developmental processes, and critical periods by which early adversity gets under the skin, resulting in life long alterations. More recently the field has moved towards understanding resilience factors and developing interventions to positively impact human populations with developmental psychopathology. But, as in all translational animal research, it is difficult to definitively quantify its impact. We are just beginning to understand the neurobiological underpinnings of dysfunctions that cut across species and suggest highly conserved phenomena, which is the first step in designing effective treatments and preventative therapies. The work presented here has identified key biological mechanisms (not only the classical stress hormones, but inflammatory processes, epigenetic modifications and alterations in gut and vaginal microbiomes), brain regions and early experiences that are now being targeted to not only treat children at risk, but to ideally prevent symptoms from developing altogether (see Gunnar & Fisher 2006 for review).

As highlighted in the previous examples from animal research, and from the expansive body of human literature that has been built over the past century, the primary caregiver is especially important in shaping the development of the neurobehavioral repertoire of a child. Thus, one striking translational consequence of animal research since the seminal studies by Harlow (1958) and other work in animals that led to attachment theory (Ainsworth, 1969, 1979; Bowlby, 1958) is to encourage and emphasize warm and sensitive caregiving in our society, as especially critical early in life. This has led to the development of interventions and therapies that significantly improve child outcomes, such as educating the primary caregiver on how to properly and attentively care for their child.

One such intervention developed by Dozier and colleagues stemmed directly from some of the animal work finding alterations in the HPA axis in response to disruption of the caregiver–offspring relationship described already. Based on the evidence in animal models that HPA axis dysfunction is part of the etiology of developmental psychopathology, the explicit goal of this intervention was to normalize HPA axis function among children in foster care. In this intervention caregivers were shown how to provide an environment for their child that encourages development of the child's ability to regulate their emotions and behaviors, as well as teaching the caregiver how to interpret the child's difficult behaviors (Dozier, Higley, Albus, & Nutter, 2002). This intervention resulted in the normalization of cortisol levels, as well as improved behavioral outcomes (Dozier et al., 2006; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008), constituting a beautiful example of how animal research can directly inform strategies to improve the lives of children facing early life adversity.

Another example of the direct impact of research using animal models of developmental psychopathology to improve outcomes in children early in life is the emphasis on skin-to-skin contact and tactile stimulation, or kangaroo care, often prescribed to parents of low birth weight babies and babies being treated in the neonatal intensive care unit (NICU; Jefferies 2012). This strategy was supported by rodent work that demonstrated tactile stimulation of pups, both via naturally high rates of maternal licking and grooming as well as experimental stroking of pups, was related to neurodevelopmental changes in the brain, including arousal–amygdala pathways, that were related to improved performance on several behavioral tasks (Kaffman & Meaney 2007; Richards, Mychasiuk, Kolb, & Gibb 2012). Kangaroo care has been shown to decrease infant mortality, illness, and infection, and also to improve cardiorespiratory and temperature stability, sleep organization, and neurodevelopmental outcomes (Head 2014; Jefferies 2012). This practice is a prime example of how animal research can be used to not only understand the mechanisms underlying developmental psychopathology but also to develop interventions, as described in the previous example, and even to prevent these poor outcomes.

Future Directions

Translation of findings from animal models into direct treatments and applications that can be used to positively impact affected human populations is a challenge for researchers in all health related disciplines, but it is particularly problematic for mental and behavioral health, which has been the focus of recent discussions (see Insel, 2007). In addition to these challenges, the field of developmental psychopathology has a unique challenge because the human population involved is undergoing massive normative changes in brain, behavior, physiology and social relationships on which psychopathology is superimposed. Without a clear understanding of normative development and pathology in humans and in each animal species being utilized as a model organism it is difficult to know exactly how to model human conditions and experiences. An important way to address how to model processes that translate to humans is to consider the natural history of each species, both the commonalities that suggest direct translation to humans (as exemplified by some of the animal work on maternal care highlighted earlier), and the differences that highlight possible specializations (as shown by the wonderful work explaining maternal control over the stress response in rodents during specific developmental times). This idea of ecological validity has been a recent discussion target for research using animal models (or model animals, as Dr. Thomas Insel emphasizes in a recent article (Insel, 2007), and we think it is critical for translation. Another point we want to emphasize as we reach the closing remarks of this review is that the best way to accomplish advances in the future is through interdisciplinary collaborations that allow us to understand human phenotypes and experiences to design studies with model animals that tap into similar constructs or developmental processes (see the Research Domain Criteria published by the National Institute of Mental Health; Cuthbert & Insel, 2010), also termed *reverse translation*, to then apply what we learn with animal models to guide human studies. This would allow for direct comparisons of results in human and animal studies, and through these direct comparisons a much clearer idea of underlying mechanisms and translational value of the animal model.

The question of how early experience is translated to epigenetic changes is currently being investigated in parallel in both humans and animal studies. Due to an explosion in biotechnological capabilities to study the mind-bending complexity of genetic regulation, we are beginning to appreciate how deep early experience can get under the skin, not only of the individual, but how these changes can be transmitted to future generations (Anacker, O'Donnell, & Meaney, 2014; Kundakovic & Champagne, 2014). Work showing epigenetic alterations (heritable traits not due to changes in the DNA sequence itself) related to

early experience, including variations in maternal care in rats (Champagne & Curley, 2009; Weaver et al., 2004) and nursery rearing in nonhuman primates (Dettmer & Suomi, 2014), are leading the way for in depth neurobiological studies that go beyond the immediate impact of early adversity on the individual's neural systems to expand our understanding of how that experience also causes changes at the molecular level, not only in somatic cells, but in the germ line, supporting the transgenerational transmission of phenotypes and memories. Consistent with other approaches and findings presented already, epigenetic modifications of genes and brain regions involved in the stress response have been identified in both animal models and humans (Anacker et al., 2014; McGowan et al., 2009). Using these techniques other cellular systems, including those involved in synaptogenesis, have been implicated in the brain's adaptations to early adversity, providing new targets for future research. This is still a nascent field that is opening new avenues of research into the neurodevelopmental mechanisms of early life adversity underlying developmental psychopathology.

New and fast advances are being made in other fields in addition to epigenetics which are impacting the way we understand how early experiences shape neurobehavioral development. The new emphasis on the gut-brain axis, for example, highlights the powerful role that something once thought to be static and unrelated to central nervous system functioning, the gut microbiome, plays in the control of neural processes and how early experiences can change this interaction, leading to developmental alterations in neurotransmitter function, such as the serotonin system (Cryan & Dinan, 2015). The role of the vaginal microbiota during birth, which is extremely sensitive to prenatal stress (Jašarević, Rodgers, & Bale, 2015), is to inoculate the neonate's gut with commensal microbiota shown to be important in neurobehavioral development (Borre, O'Keeffe, Clarke, Stanton, Dinan, & Cryan 2014). This is not only a growing field in the study of developmental psychopathology but is of particular relevance for the current review because much of the evidence for the role of the gut microbiota in normative neurobehavioral development comes from studies of animal models (i.e., germ-free animals raised without any microbiota; Clarke, O'Mahony, Dinan, & Cryan, 2014). These animals show alterations in the behavioral and physiological stress responses, as well as alterations in socioemotional behavior (Clarke, et al. 2014). Based on this evidence, physicians are now inoculating babies delivered via cesarean section with their mother's vaginal microbiota (De Jesus-Laboy et al., 2014). By incorporating measures of the gut and vaginal microbiome and other related physiological systems, and molecular techniques including epigenetic methods, we are now expanding our understanding of the complex etiology of developmental psychopathology to the systems biology level.

These are very exciting times of change, both technological and conceptual, that are opening opportunities to advance our understanding and potential for intervention and prevention of developmental psychopathology. We are able now more than ever to study the etiology of developmental psychopathology using multiple levels of analysis, all the way from the molecular to the behavioral level. Animal models have been instrumental in identifying some of the systems and underlying neurodevelopmental mechanisms involved in the brain's responses to early life adversity, but there is still much more for us to learn from them. The future of developmental psychopathology animal research is taking shape, and brings much hope for the development of efficacious treatments and preventative therapies. By combining knowledge gained in animal models and human studies with the ever-expanding frontiers of science and engineering, such as nanotechnology, the brain–machine interface, and biofeedback research (revolutionary technological and conceptual advances in the way we can manipulate the brain to treat behavioral and mental disorders), there is great potential for alleviating the burden of early life adversity and developmental psychopathology.

THE ROLE OF EARLY NUTRIENT DEFICIENCIES IN THE DEVELOPMENT OF PSYCHOPATHOLOGIES

Background

The influence of early nutrition on the developing brain has been a scientific issue over the past century (Susser & Stein, 1994). However, popular culture has recognized the importance of early nutrition in children's health dating back to Roman times. The Nobel Prize–winning author Pearl S. Buck wrote about the devastating effects of starvation on young children in her 1931 classic book *The Good Earth*. In this novel, the first daughter of the main character is born at the height of a severe famine. Buck implies the significant malnutrition the child endured early in life resulted in devastating brain damage, leaving her profoundly retarded. While such a profound effect likely overstates the case, the role of undernutrition and malnutrition in developmental psychopathology has strong scientific basis. It is the goal of this chapter to review and update the evidence for this science and to highlight the importance of a developmental psychopathology perspective for studying this complex issue.

Our species comes from a long history of inadequate access to food and thus malnutrition is generally conceptualized as undernutrition. Undernutrition can be global when there is an overall lack of nutrition (as occurs in famine) or specific, as in the absence of specific nutrients in an otherwise sufficient diet. More recently, the term *malnutrition* has taken on a broader meaning more consistent with its literal roots: bad nutrition. In this conceptualization, overnutrition is also a risk to somatic and brain development and, like undernutrition, could be due to a global excess of nutrients or the presence of toxic amounts of a specific nutrient. Indeed, risk from nutrients represent a U-shaped curve, where the lowest risk and greatest efficacy are from a range of nutrient sufficiency, while deficiency or excess confer risks to developing systems such as the brain.

Specific conditions such as phenylketonuria (PKU), where there is an excess of the amino acid phenylalanine due to a genetic inability to metabolize the amino acid, illustrate the importance of nutritional factors in brain development. If not addressed, PKU can result in mental retardation (Huttenlocher, 2000; Sullivan & Chang, 1999). The build-up of this amino acid during brain development results in a toxic reaction leading to brain damage (Huttenlocher, 2000). Reports hypothesizing a nutritional origin of some forms of mental retardation first appeared in the early 1950s when researchers noted high amounts of phenylketones in the urine of some mentally retarded individuals (Huttenlocher, 2000). Subsequent investigations linked PKU to various neuropathologies including diffuse

white matter changes and reduced dendritic branching (Huttenlocher, 2000). Specific genetic disorders resulting in deficiencies of micronutrients (such as copper in Menkes disease), regional geographic deficiencies of trace elements (such as iron, iodine and selenium), the presence of inhibitors of nutrients from the diet (all divalent metals including zinc, copper and iron) and low prenatal levels of maternal nutrients (such as folate and iron) have all been linked to severe neurological abnormalities or intellectual deficits (Hibbard & Smithells, 1965; Lozoff, 1989; Pharoah, Buttfield, & Hetzel 1971; Prohaska, 2000; Shim & Harris, 2003; Yi-Ming, 1996).

The famines and food shortages throughout Europe during the Second World War created an interest in studying the changes in psychological and physiological functioning caused by general undernutrition (Keys, 1946; Pollitt, 1988). Although many of the outcomes were chronicled as alterations to adult behaviors, it is pertinent in our context because (1) children likely exhibit similar, if not greater, psychological consequences and (2) by affecting the psychological state of their caregivers, parental malnutrition may exert indirect effects on children regardless of their nutritional status (Brozek, 1990).

In a more controlled scientific approach to the general malnutrition question, Keys and colleagues (at the University of Minnesota) exposed 36 healthy adult males to 6 months of semistarvation followed by 3 months of controlled rehabilitation (Franklin, Scheile, Brozek, & Keys, 1948; Keys, 1946). Results indicated that during the period of semistarvation the participants became lethargic, apathetic, less sociable, uninterested in sexual activity, less alert (except with regard to hearing), and depressed (Franklin et al., 1948; Keys, 1946). Although the participants complained about changes in mental alertness and inability to think cogently, researchers noted no decreases on tests of memory or intellectual ability (Franklin et al., 1948; Keys, 1946). The participants in the study exhibited unusual behaviors involving food such as compulsive gum chewing and coffee/tea drinking (up to 40 packs of gum a day and 15 cups of coffee a day), souping (i.e., the practice of drinking the liquid in soup and then refilling the bowl with hot salted water and repeating the process before eating the vegetables in the soup), and unusual eating habits including novel spice concoctions, hoarding of food, and doting over every last piece of food on the plate (Franklin et al., 1948). Many of the participants greatly increased their daily consumption of water and either began smoking or substantially increased the amount they smoked (Franklin et al., 1948). Finally, participants displayed numerous physiological reactions such as decreased sensitivity to heat, increased sensitivity to cold, edema, skin discoloration, and reduced hair growth (Franklin et al., 1948).

During the controlled rehabilitation phase, participants were initially irritable and easily frustrated (Franklin et al., 1948). These effects were short-lived; however, weight gain and sexual interest did not immediately return to prestarvation levels. In fact, participants did not reach their prestarvation weight and level of physical fitness until almost a year after the conclusion of the semistarvation phase (Franklin et al., 1948).

These findings are important because they indicate in adults periods of substantial undernutrition result in demonstrable acute but reversable alterations in behavior, physiology, and mood (Franklin et al., 1948; Keys, 1946). The reversibility of these symptoms suggests, in adults, behavioral changes occur secondarily to acute changes in neurotransmitter systems, as opposed to neuronal structure, induced by the nutrient deficiency. Research in humans and animals show dietary manipulations result in rapid changes in behavior and concentration of specific neurotransmitters (Fromentin, Gietzen, & Nicolaidis, 1997; Gietzen & Magrum, 2001; Phillips, Oxtoby, Langley, Bradshaw, & Szabadi, 2000; Pierucci-Lagha et al., 2004; Riedel, 2004). The developing brain of the child is at greater risk for the effects of undernutrition and these may not be as amenable to rehabilitation, thus resulting in long-term of lifelong behavioral abnormalities. The child's brain is at greater risk for residual abnormalities (after the nutritional burden is lifted) because in contrast to the adult brain, malnutrition likely impacts neuroanatomic organization in addition to neurotransmitter systems during periods of sensitive or critical periods of regional brain development (Winick & Rosso, 1969). While neurotransmitter recovery may seem more likely to occur, disordered neuroanatomical organization in childhood is more difficult to overcome because of sensitive periods of development (Wachs et al., 2014).

To test this question of long-term risk of psychopathology following early life global malnutrition, Stein et al. (1972) used a natural experiment to investigate whether prenatal exposure to famine in the Dutch hunger winter of 1944–1945 adversely affected intellectual abilities in a sample of 19-year-old males. In September 1944 the Netherlands cooperated with allied forces in an attempt by British paratroopers to force a bridgehead over the Rhine River (Stein et al., 1972, 1975; Susser et al., 1998). The attempt failed, and in retaliation the Nazi army imposed a trade embargo on Holland. Unfortunately, when the army lifted the embargo, previous railroad strikes and a severe

winter that had frozen the shipping channels resulted in serious food shortages in much of Western Holland. At the height of the famine, daily food rations could be as low as 450 kilocalories per person, a quarter of the standard amount. The most significant period of the famine began in November 1944 and lasted until allied armies crossed the Rhine and liberated Holland in May 1945. The severity of famine was indicated by a sharply increased death rate in the affected cities (many of these deaths were attributed to starvation), substantial (up to 25%) loss in body weight, and the occurrence of physical signs associated with severe malnourishment such as osteomalacia and hunger edema (Stein et al., 1972, 1975).

This event was unique because it occurred at a specified time and place in a population which before and after famine had good nutrition, there was good reporting on food rations provided to the population, and excellent public health records allowed researchers to divide individuals into groups of varying exposures based on birth date and birth location. This natural experiment has generated numerous investigations on the effects of prenatal famine exposure on a multitude of psychological and medical variables.

Stein et al. (1972) grouped individuals into six birth cohorts based upon their intrauterine exposure to famine: (1) individuals born before the beginning of the famine; (2) individuals prenatally exposed to famine in the third trimester only; (3) individuals exposed to famine in the middle 6 months of gestation; (4) individuals conceived during the famine and exposed in the first and second trimesters; (5) individuals conceived during the famine and exposed during the third trimester only; and (6) individuals conceived and born after the famine occurred. Stein and colleagues used Raven Progressive Matrices scores gathered at age 19 during military induction testing to compare these cohorts with control cohorts born during the same time frame in similarly sized cities not affected by the famine. The researchers failed to find significant declines in average IQ or increases in the rates of mild or severe mental retardation in the four groups prenatally exposed or in the one group exposed postnatally. Because many births occurred at home, the researchers could not evaluate the influence of prenatal famine exposure on the birth weight of the entire cohort; however, a subsample of births occurring in hospitals in the famine and control cities indicated no relationship of birth weight to IQ at age 19.

These findings cast doubt on the assertion that maternal malnutrition alone results in significantly declined intellectual abilities. However, the authors emphasize that their findings should not be generalized to chronically malnourished populations where the mother is likely to be malnourished before and after parturition, the child is at high risk for postnatal nutritional deficits, or deficiencies in specific trace nutrients are common. The authors suggest their findings reveal either a high degree of protection afforded to the developing child in utero or the considerable resilience of many children in the face of prenatal insult.

Over the years, many people have speculated that nutrition acutely affects behavior (e.g., sugar increases activity levels). Although careful research has not substantiated this particular assertion, there are many clearly documented short-term effects of specific nutrients (or substances) on behavior (Beyth & Baratta, 1996; Fernstrom, 2000; Fishbein & Pease, 1994; Lieberman, 2003). These acute effects are not the topic of this paper. Rather, the discussion focuses on the effects of generalized malnutrition or specific micronutrient deficiencies on the developing brain during fetal life, infancy and childhood and how these insults may contribute to the later emergence of psychopathology.

Before beginning the discussion in detail, it is important to define several terms. First, in this chapter *early undernutrition* refers to nutrient restriction occurring prenatally (sometimes even prior to conception) or in the first few years of postnatal development (prior to age 3). Second, *undernutrition* refers to a general reduction in macronutrient intake, also known as protein energy malnutrition (PEM). Nutritional deficits can be characterized by PEM, by deficits in specific micronutrients such as iron (Fe), Zinc (Zn), or iodine (I), or by both, as is often the case. Most of the extant research concerns PEM/undernutrition, and this will be the focus of the first section of this paper; however, each of the three micronutrients is discussed in the second half of the chapter because of their high prevalence rates around the world and their profound impact on early brain and behavior development.

An unambiguous definition of what constitutes psychopathology has proven elusive (Lilienfeld & Marino, 1999; Meehl, 1979; Spitzer, Fleiss, & Endicott, 1978; Wakefield, 1993, 1999), but is not necessary here. We will use major mental disorders as listed in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, *Fifth Edition* (*DSM-5*; American Psychiatric Association, 2013) as constituting a large subset of psychopathology pertinent to this discussion. Most research relevant to this review examines schizophrenia and schizophrenia spectrum disorders, internalizing disorders (such as major depression and anxiety disorders), and externalizing problems (such as

attention-deficit/hyperactivity disorder and antisocial personality disorder).

Basic Principles

When examining the effects of nutritional deficiencies on the developing brain and the role these may play in the genesis of psychopathology, it is important to keep in mind several core principles. First, brain development occurs in overlapping but dissociable stages, and each of these stages may be uniquely vulnerable to injury (Honig, Herrman, & Shatz, 1996; Monk, Webb, & Nelson, 2001; Morgane et al., 1993; Teicher, Andersen, Polcari, Anderson, & Navalta, 2002; Wachs et al., 2014; Webb, Monk, & Nelson, 2001). These stages include neurulation, neurogenesis, proliferation, migration, differentiation, synaptogenesis, myelination, apoptosis, and synaptic pruning (Andersen, 2003; Monk et al., 2001; Webb et al., 2001). Disturbances in some of these processes are associated with neurobehavioral deficits—as in the nonverbal impairments and psychiatric symptoms seen in the leukodystrophies—or the hypothesis that aberrant synaptic connections play a role in the etiology of autism and schizophrenia (Innocenti, Ansermet, & Parnas, 2003; Keller & Persico, 2003; Percy & Rutledge, 2001; Rosebush, Garside, Levinson, & Mazurek, 1999; Van Geel, Assies, Wanders, & Barth, 1997).

Some of the initial processes of brain development (e.g., neurulation and neurogenesis) occur during a single early period whereas other later stages (e.g., myelination, apoptosis, and synaptic pruning) occur independently at different times in various brain regions (Monk et al., 2001; Webb et al., 2001). Thus, a brain structure or region will have its own time course through which development proceeds. Moreover, certain highly metabolic brain regions such as the hippocampus are more vulnerable to injury than other regions (Walsh & Emerich, 1988). Ultimately, the result of any insult to the developing brain depends on the time of onset of the insult and what developmental processes are occurring/brain structures are actively developing at that time, how innately vulnerable these processes/structures are to injury—a factor driven largely by the relationship between metabolic demand and blood supply—and the magnitude of the insult (i.e., the severity and duration of the injury). Thus, a specific nutrient deficiency can have different effects on the developing nervous system, largely dependent upon these variables. (Adams et al., 2000; Georgieff & Rao, 2001; Kretchmer, Beard, & Carlson, 1996; Morgane et al., 1993; Pollitt, 1996; Wachs et al., 2014). In this context, it is worth highlighting that the timing of rapid development of certain "major" systems spans fetal and early postnatal life. The hippocampus, which is so central to discriminative recognition memory, undergoes its most rapid differentiation between 32 weeks gestation and 18 months postnatal age. Myelination, a mediator of speed of processing throughout the nervous system, also begins in earnest around 32 weeks gestation and proliferates rapidly until approximately 3 years of age. The dopamine neurotransmitter system, which is integral to reward, motivation and attention, starts to develop in mid-gestation and is solidly regulated by 3 years of age. Each is particularly sensitive to common nutrient deficiencies of pregnancy and young children such as protein malnutrition, iron deficiency and fatty acid deficiencies. Not only is there concern about the primary functions mediated by these three systems, but also proper function of these primary areas during development is key for establishing connections to more distal areas (e.g., frontal cortex) and for the efficiency of integrated circuits in mediating complex behaviors (e.g., prepulse inhibition).

A second important principle underlying the current discussion is the concept that abnormal behavior (as in psychopathology) is the efferent expression of brain activity, and changes in neuroanatomy, neurochemistry, and neurophysiology can result in alterations in behavior (Brower & Price, 2001; Moffitt, 1993; Moffitt & Caspi, 2001; Nestor, Kimble, Berman, & Haycock, 2002; Pennington & Ozonoff, 1996; Raine, 2002). Thus, early malnutrition may lead to the expression of cognitive deficits or abnormal behavior stemming from alterations in fine neuroanatomy (delicate structures such as dendritic arbors and white matter tracks), neurochemistry (disturbances in neurotransmitter systems), or neurophysiology (the functioning of ion channels and specific receptors) (Arnold, 1999; Benes & Berretta, 2001; Bowley, Drevets, Öngür, & Price, 2002; Fuglestad et al., 2008; Konradi & Heckers, 2003; Molnar, Potkin, Bunney, & Jones, 2003). Although specific findings (e.g., white matter abnormalities or increased receptor density in a certain region) are sometimes difficult to replicate in new samples, disturbances in these three broad domains are consistently associated with various forms of psychopathology (Dwork, 1997; Flecher, 1998; Jones, 1997).

The last core principle running through this discussion is the concept that genes will likely prove to be the single most important long-term determinant of behavior; however, their expression can be modified (repressed or activated) by interaction with the environment (Bunney et al., 2003; Jacobs et al., 2002; Murphy et al., 2001; Rutter, Pickles, Murray, & Eaves, 2001; Rutter & Silberg, 2002; Slutske et al., 1997; Wachs et al., 2014). Environmental influences causing anomalous neurological development

(such as chronic and severe neglect or toxicity) can have especially salient and long-term effects (Barone, Das, Lassiter, & White, 2000; Castle et al., 1999; Schettler, 2001; Wachs et al., 2014; Weiss, 2000). Similarly, nutrition is an important environmental factor that can affect the developing brain (Fuglestad et al., 2008; Georgieff & Rao, 2001; Morgane et al., 1993; Morgane, Mokler, & Galler, 2002; Wachs et al., 2014).

This does not imply that environmental insults such as malnutrition have uniform effects on people of differing genetic characteristics. It is likely that individual differences in the capacity to maintain homeostasis in response to challenges (thereby allowing for reasonably normal development) and in—at present—poorly explicated concepts such as neurological integrity, plasticity, and resilience are genetically or experientially determined, and such factors likely modulate the effects of environmental challenges such as undernutrition (Bhutta & Anand, 2002; Engle, Castle, & Menon, 1996; Morgane et al., 1993; Nelson, 2000a; Sapolsky, 2001; Wachs et al., 2014; Walker et al., 2011).

Furthermore, it is rarely the case that undernutrition exists independently of other risk factors such as maternal stress, genetic predisposition, poverty, and dangerous living conditions (e.g., poor sanitation or in the presence of toxins such as lead) (Guesry, 1998; Pollitt, 1969; ; Pollitt et al., 1996; Schettler, 2001; Snodgrass, 1994; Stein & Susser; 1985; Tanner & Finn-Stevenson, 2002; Trope, Lopez-Villegas, Cecil, & Lenkinski, 2001). Pollitt (1969) reported that in developing countries children with the greatest nutritional deficits had the poorest living conditions (i.e., lack of running water or adequate plumbing, cramped housing, and large families). Thus, malnutrition may generally exert its effects by acting in concert (additively or synergistically) with other risk factors (Guesry, 1998; Morgane et al., 1993, 2002; Stein & Susser, 1985; Zeskind & Ramey, 1981). For example, Caspi and coworkers (2002) found that abused children with a genotype leading to higher levels of a neurotransmitter metabolizing enzyme (monoamine oxidase) displayed lower rates of antisocial behavior. The authors interpreted these findings to be evidence of a gene/environment interaction in which the genotype influenced an individual's response to a particular environmental stimulus. It is possible that analogous mechanisms or interactions could be at work in determining the outcome of early malnutrition.

Overview

The current chapter endeavors to examine the effect of early nutritional deficits on brain development and the role this may play in the emergence of psychopathology. We will begin the discussion by examining the possible link between early nutritional insults and the development of psychopathology in the context of those studies that have specifically researched this question. After this, we will step back and delve into other investigations that assess the effects of early malnutrition on broader issues such as cognitive development in humans and developmental neurobiology. These factors are important because they characterize a developmental path (resulting from early malnutrition) in which psychopathology may exist as part of the milieu or which may increase an individual's risk for the later development of mental illness. Finally, the chapter will conclude with a brief hypothetical discussion of potential causal mechanisms that may account for the relationship between early nutritional insults and the later development of psychopathology.

Studies on Psychopathology Related to Early Life Nutrition

Studies in this section are presented with regard to the spectrum of psychopathology they examine. Thus, studies investigating the effects of early malnutrition on schizophrenia or schizophrenia spectrum disorders, neurodevelopmental disorders (e.g., attention-deficit/hyperactivity disorder [ADHD], autism), externalizing disorders such as conduct problems and antisocial behavior, and internalizing disorders (e.g., depression) are discussed. Krueger and colleagues (in addition to other researchers) have proposed the broad dimensions of externalizing and internalizing to capture more accurately the structure of common mental disorders (Krueger, 2002; Krueger, Caspi, Moffitt, & Silva, 1998; Krueger, McGue, & Iacono, 2001). These dimensions are used in the current discussion for clarity and succinctness.

Despite numerous investigations into the cognitive effects of malnutrition on children, most of the research dealing with the effects of malnutrition on the development of psychopathology concerns individuals older than eighteen. This is a significant shortcoming of our knowledge in this area because many psychiatric disorders will likely prove to have developmental origins. Thus, it is probable that these conditions have perceptible manifestations during childhood and adolescence. Similarly, early malnutrition may influence the developmental course (e.g., age of onset, severity, or progression) of psychiatric disorders. Moreover, malnutrition may be expected to exert more powerful immediate effects upon the developing brain—thereby suggesting the effects of malnutrition may be more salient in individuals younger than 18.

Thus, children affected by early nutritional deficits may display additional or significantly different behavioral effects than mature adults (Keys, 1946). Furthermore, it is possible that some of the cognitive manifestations of undernutrition (discussed later) may have resulted from impairments secondary to various psychiatric symptoms such as inattention or anxiety.

Much of the information regarding the relationship between early malnutrition and later psychopathology comes from data collected on cohorts prenatally exposed to famine during the Dutch hunger winter of 1944–1945 and the later Chinese Great Leap Forward famine of 1959–1961 (Brown & Susser 2008; Brown et al., 1996; Butler, Susser, Brown, Kaufmann, & Gorman 1994; Hoek, Brown, & Susser, 1998; Lumey, Stein, & Susser, 2011; McGrath, Brown, & St Clair, 2011; Song, Wang, & Hu, 2009; St Clair et al., 2005; Susser, Hoek, & Brown, 1998; Xu et al., 2009). As discussed previously, Stein et al. (1972) found no evidence suggesting decreased intellectual abilities or increased rates of severe or mild mental retardation following prenatal famine exposure. However, years later, Susser (the son of the original investigators) and his collaborators revisited the famine data to examine if individuals with a history of prenatal famine exposure exhibited higher rates of psychopathology in adulthood (Brown, Susser, Lin, Neugebauer, & Gorman, 1995; Brown et al., 2000; Hulshoff-Pol et al., 2000; Insel et al., 2008; Neugebauer, Hoek, & Susser, 1999; Susser et al., 1996; Susser & Lin, 1992).

Several major admonitions regarding these natural experiment should be pointed out. First, the amount of food redistribution in families is not known (Stein et al., 1972). Thus, pregnant women who occasionally received greater rations might have been supplied more calories via sacrifice of other family members (Stein et al., 1972, 1975). Second, although probably not substantially significant, it is not known how much individuals supplemented their diets with other materials, which may have actually contained toxins (Stein et al., 1972, 1975). Third, except for records indicating profession of father within the Dutch sample, there is no information regarding familial background. Finally, because many of the births occurred at home, it is impossible to gather information on birth or gestational complications, which along with maternal infection and stress may play etiological roles in the emergence of behavioral deficits and psychopathological conditions (Anand & Scalzo, 2000; Brown, Cohen, Greenwald, & Susser, 2000; Brown & Susser, 2002; Brown et al., 2000; McNeil, Cantor-Graae, & Weinberger, 2000; Teicher et al., 2002). Regardless of these essentially unavoidable imperfections, the studies discussed below provide valuable insights regarding the possible role of prenatal malnutrition in the emergence of later psychiatric disorders. Moreover, the consistency of the findings from the two episodes serves to support the contention that early exposure to severe prenatal nutritional deprivation increases the risk for later development of various psychopathologies.

In an initial 1992 study of the Dutch sample, Susser and Lin found that women, but not men, exhibited an increased prevalence of schizophrenia following prenatal exposure to famine in the first trimester. However, they obtained these results through a broad inclusion criteria (that is, first trimester of gestation during periods of low food rations), and review of admission records to psychiatric hospital units from 1978 to 1989. Thus, they based exposure on a single criterion that may not have completely captured children who experienced the highest levels of exposure. Furthermore, individuals were at least 32 years old at the start of the review period. This age tends to be past the age that most males have their first psychotic episode; therefore, it is likely many men would have already made initial psychiatric contact prior to this age and were not re-hospitalized during the review period (Brown et al., 1996).

In a more extensive follow-up investigation, Susser et al. (1996) used stringent inclusion criteria to define a maximal exposure cohort. The inclusion criteria for the other cohorts were the same as in the 1992 study. However, they defined the maximal exposure cohort to include only those individuals conceived at the height of the famine. This cohort consisted of individuals born when the general population exhibited increases in adverse health effects and new births demonstrated excess congenital malformations (which according to Stein, et al. (1975) are associated with severe prenatal starvation). These criteria ensured that the researchers dealt exclusively with the maximally exposed cohort (e.g., the cohort that underwent the most significant early insult due to the famine). These restrictions led to the identification of a cohort born between October 15, 1945 and December 31, 1945 (Hoek et al., 1996, 1998; Susser et al., 1998). The authors extended the period of record review back to 1970, thereby more accurately reflecting lifetime history of psychiatric admission.

Based upon these data, the researchers found a significantly increased prevalence of schizophrenia in both males and females of the maximal exposure cohort. This cohort displayed a prevalence rate for schizophrenia nearly two times higher than that of the unexposed cohort. Further, the other exposed cohorts did not differ in prevalence rate from the unexposed cohort. Susser et al. demonstrated

these findings using a narrow and a broad diagnostic definition of schizophrenia. Individuals within the maximal exposure cohort had mothers malnourished during the periconceptional phase, and their prenatal famine exposure occurred early in pregnancy, generally entirely within the first trimester.

Using magnetic resonance imaging, Hulshoff-Pol and colleagues (2000) found increased brain abnormalities (specifically focal white matter hyperintensities) in a subgroup of individuals from the maximal exposure cohort (Hulshoff-Pol et al., 2000). They showed that individuals from this cohort diagnosed with schizophrenia evidenced reduced intracranial volume compared to non-exposed individuals with schizophrenia and non-diagnosed individuals with the same level of famine exposure. The authors speculated that the decreased intracranial volumes observed only in the famine exposed individuals with schizophrenia resulted from an interaction between genetic risk factors and early brain stunting caused by gestational malnutrition—eventually resulting in the development of schizophrenia. They concluded that exposure to famine early in gestation is associated with increased focal brain abnormalities—possibly secondary to specific micronutrient deficiencies. In some individuals, these aberrations may result in a higher risk for developing schizophrenia. The researchers urge discretion when examining their findings, stressing they obtained the results using a limited number of participants and other confounding factors could not be completely taken into account. Nevertheless, these data provide an initial glimpse into specific structural brain changes present following severe first trimester malnutrition.

Another study by the same group expanded their inquiry to determine if males conceived at the height of the hunger winter evidenced increased prevalence of schizophrenia spectrum personality disorders (SSPD)—as defined by *ICD-6* (Hoek et al., 1996). This study used methodology similar to the aforementioned study. Thus, the authors compared the maximal exposure cohort (see Susser et al., 1996, for a description of this cohort) to an unexposed cohort and a cohort with first trimester exposure but without maternal malnutrition at the time of conception. The authors obtained data regarding the diagnosis of SSPD from military induction records; thus, males only are represented. This maximal exposure group demonstrated a higher prevalence of SSPDs. This increase appeared to be unique to SSPDs because the three groups did not differ from one another in the prevalence of psychoneurosis (i.e., general anxiety). They noted that this relationship remains consistent when estimated SES is taken into account. However, the authors hasten to point out that despite the increased risk in the maximal exposure group, relatively few individuals actually met criteria for SSPD in the entire study. Furthermore, they cautioned that despite the apparent care taken in making these diagnoses, no formalized diagnostic system existed at the time of these evaluations. To some extent, this caution should be applied to both of the studies previously discussed.

Using information obtained from birth and medical records in a population-based cohort born between 1924 and 1932 in Helsinki, Finland, Wahlbeck, Forsén, Osmond, Barker, and Eriksson (2001) reported on the relationship between factors indicative of prenatal undernutrition and the later development of schizophrenia. This study found that children born to mothers with a low body mass index (BMI) prior to parturition, who were born with small placentas and were below-average length and weight at birth, had an increased risk of developing schizophrenia in adulthood. Furthermore, this study indicated that, independent of other predictors, children thin at 7 years of age had an increased risk for developing schizophrenia in later life. The data also indicated that children short at birth who remained lean during childhood had a fourfold risk of developing schizophrenia. The authors observed no differences in the risk for schizophrenia between groups of varying SES, replicating findings from other studies.

These results are consistent with the hypothesis that fetal and childhood factors (specifically undernutrition) play a role in the pathogenesis of schizophrenia. However, given the relatively low and consistent prevalence of schizophrenia within the population and the relatively high rate of early malnutrition, it may be more plausible to conjecture that early nutritional deficits act as predisposing or triggering circumstances. This study suggests malnutrition statistically increases the risk for later development of schizophrenia.

Wahlbeck and colleagues suggest, in their sample, nutritional status (based upon maternal BMI, birth length, and slenderness in childhood) is independent of SES; however, they provide no evidence to bolster this claim. Thus, it is impossible to discern (given the information available) if these measures reflect actual undernutrition, or are simply corollaries of low SES or a genetic diathesis that increases risk for schizophrenia.

Similar results were obtained in later studies using a cohort of individuals affected by the Great Leap Forward famine occurring in China between 1959 and 1961. In the initial study with this cohort, St Clair and colleagues (2005) found that in the most affected province, the adjusted risk of developing schizophrenia increased from 0.84% for

those born in 1959 to 2.15% and 1.81% for those born in the height of the famine in 1960 and 1961 respectively. A later investigation by Xu and colleagues (2009) confirmed these increases using a cohort from a different region of China. This study found that this result appeared largely driven by individuals from a rural population suggesting that the increase was observed in only the most affected areas (Xu et al., 2009).

Taken together, these studies suggest that the prevalence of schizophrenia and schizophrenia spectrum disorders increases in individuals who are exposed to severe generalized malnutrition early in gestation. The findings of Wahlbeck et al. (2001) also provide evidence that schizophrenia is (either directly or indirectly) related to suboptimal growth in utero through early childhood.

Hoek et al. (1998) speculated about potential mechanisms to explain the findings of their group. First, they noted that it was unlikely that this finding was related solely to nutritional restriction because if such a correlation existed, one would expect to find significantly higher rates of schizophrenia and schizophrenia spectrum disorders in developing countries that commonly have serious food shortages. Rather, it is more likely that the increased prevalence was related to a restriction in a specific micronutrient, stating that these types of deficiencies are frequently observed in both developed and developing areas. For example, early iron deficiency (a very common micronutrient deficiency in both developed and developing countries) causes impairments in prepulse inhibition (PPI) in rodents (Pisansky et al., 2013). PPI is considered a reliable endophenotype of schizophrenia (Swerdlow, Braff, & Geyer, 2000), suggesting that early iron deficiency is a plausible mechanism for the development of psychosis in some circumstances (Pisansky et al., 2013). These initial findings underscore the importance of additional research using animal models of specific micronutrient deficiencies occurring at circumscribed times during brain development that reflect a proposed pathophysiology of a disorder—for example, migration defects in schizophrenia secondary to folate deficiency.

This approach could be useful in elucidating the effects of micronutrient deficiencies on neuroanatomy, neurochemistry, and neurophysiology; however, it would fall short in illustrating possible behavioral correlates because there are currently no irrefutable animal models of mental disorders, especially schizophrenia. Finally, Hoek and colleagues (1998) stated, their findings could have resulted from the increased level of birth complications and morbidity associated with early birth found in the most affected famine cohort. They noted that areas less affected by the famine experienced similar increases in obstetric complications without the concomitant rise in schizophrenia spectrum disorders, making this potential confound less problematic.

Neugebauer and colleagues (1999) again used the Dutch famine data to investigate possible relationships between prenatal nutritional restriction and the subsequent development of antisocial personality disorder (ASPD). The researchers used diagnostic information regarding ASPD from Dutch military induction records. According to the authors, Dutch psychiatrists considered ASPD to include a constellation of behaviors such as aggression, history of criminal activity, disregard for the truth, impulsivity, volatile temperament, unreliability, and interpersonal difficulties. Furthermore, psychiatrists categorized individuals under the subclassifications of violent or nonviolent ASPD.

Individuals exposed to severe malnutrition in utero during the first or second trimesters had an increased risk for the emergence of later ASPD (specifically violent ASPD) compared to either unexposed individuals, individuals with only moderate levels of caloric restriction, or individuals severely malnourished in the third trimester alone. Malnutrition remained predictive, even after they included other proven or potential risk factors (e.g., low social class, low IQ, or large sibship size) for ASPD in multiple regression equations. The authors comment that the most likely explanation for this pattern of results is the lack of a particular unspecified micronutrients during this critical period of brain development. They argued that similarities in infant morbidity between cases and noncases, specificity of time and place of the findings, and the lack of third trimester effects indicate severe malnutrition (during the first and second trimester) supersedes other environmental insults. However, they also proposed a possible mechanism in which malnutrition potentiates preexisting genetic or environmental vulnerabilities.

Additional research with the Dutch cohort indicates that exposure to the famine during the first trimester of gestation is associated with an increased risk of development of an addictive disorder in adulthood (Franzek, Sprangers, Janssens, Van Duijn, & Van De Wetering, 2008). These investigators did not find any evidence of increased risk for those individuals with exposures limited to the second or third trimesters, although those individuals with first trimester exposure during the peak of the famine continued to be at increased risk despite reintroduction of adequate nutrition during the remainder of their gestation. Of note, this effect appeared to hold only in males and was not observed in females with exposures during similar times in development.

Using a cohort of low birth weight (LBW) children, Breslau, Chilcoat, Johnson, Andreski, and Lucia (2000), examined the relationship between LBW, soft neurological signs, and subsequent intellectual/behavioral functioning at ages 6 and 11. Soft neurological signs refer to a number of various subtle neurological abnormalities in sensory, motor, and integrative skills that do not significantly impact an individual's overall functioning but may still result in suboptimal abilities in these domains (Breslau et al., 2000). Importantly, soft signs are not thought to reflect focal brain damage, but rather a diffuse neurological pathology resulting from a variety of sources including genetic anomalies such as microdeletions or mosaics (Breslau et al., 2000). Furthermore, studies have linked soft neurological signs to early malnutrition and deficits in IQ and behavioral functioning (Breslau et al., 2000; Galler, Ramsey, Solimano, Kucharski, & Harrison, 1984).

Breslau et al. (2000) observed a relationship between LBW and the occurrence of soft neurological signs in which LBW children are nearly twice as likely to exhibit soft signs as normal birth weight (NBW) children. The researchers found a linear relationship between LBW and the frequency of soft signs. Thus, the lower a child's weight at birth, the more likely the child was to display soft signs. Moreover, the data indicated children evidencing soft signs consistently performed below average on tests of intellectual abilities regardless of birth weight; however, LBW children tended to score lower on the IQ test in general, thus indicating additive influences. They also found a relationship between soft signs in both LBW and NBW children and the occurrence of learning disorders (at age 11) and the occurrence of internalizing problems at six and eleven. In the LBW group, the investigators found a relationship between soft signs and the occurrence of externalizing behaviors including attention problems at age 6 but not at age 11.

Even though this study did not strictly deal with nutritional deficits, it is interesting because LBW and soft signs may be associated with undernutrition. This is particularly germane to the Breslau et al. (2000) study because many of the participants, especially those within the LBW group, lived in urban settings and came from low SES backgrounds and thus had an elevated risk for prenatal or postnatal malnutrition. Regardless of the nexus between LBW and soft neurological signs, the findings suggest LBW children may be at increased risk for reductions in IQ, learning disabilities, internalizing problems, and, when younger, externalizing difficulties including attention deficits. The reason for the apparent evaporation of differences in the externalizing domain may be increased levels of externalizing behaviors exhibited by the control groups (Moffitt, 1993), or the beneficial effects of behavioral/medical interventions.

In a follow-up to their 1986 study (to be discussed in a subsequent section of the chapter), Galler and Ramsey (1989) assessed a group of previously malnourished Barbadian children for symptoms of hyperactivity. Using parent and teacher reports, they found increased levels of hyperactivity and distractibility. These relationships remained consistent after taking into account environmental factors such as parental involvement, parental career/knowledge of the world, stability of the home environment, number of siblings, and quality of living conditions (e.g., quantity of modern conveniences and durability of dwelling construction). Furthermore, these results concur with earlier findings (Galler, Ramsey, Solimano, & Lowell, 1983), which suggested increased attention difficulties in previously malnourished children between 5 and 11 years of age. The current study revealed an increased prevalence of speech difficulties in the formerly malnourished children as noted by teacher report. However, difficulties with socialization, emotional reactivity, and immaturity previously observed in these children (Galler, Ramsey, Solimano, & Lowell, 1983) were not seen in the current investigation. According to the authors, this may have resulted from slight changes in the assessment tools (necessary to reflect the older age of the children) or interventions targeted at ameliorating some of the effects of early malnutrition. If the latter is the case, it is meaningful because it suggests some aspects of early malnutrition (e.g., social skills) may be more amenable to educational interventions than others (e.g., attention problems) (Galler & Ramsey, 1989). However, it is possible that effects such as emotional instability are more characteristic of younger children who were previously malnourished and would disappear in older children regardless of interventions (Galler & Ramsey, 1989). A shortcoming of this study is the researchers' failure to control for intellectual abilities. Thus, it is unknown if the increased attention problems observed in the experimental group are a unique aspect of undernutrition in the first year of life, or rather are a corollary of the lower intellectual skills previously reported in these children (Galler et al., 1986). In a long-term follow-up investigation, Galler and colleagues (Galler, Bryce, Waber, Zichlin, Fitzmaurice, & Eaglesfield, 2012) determined that those individuals previously malnourished continued to experience increased symptoms of attention problems in adulthood. This investigation used both self-report and computer-based assessments of attention difficulties and demonstrated that

the impact of early malnutrition was not attenuated by environmental factors in childhood and that self-report of attention concerns was not influenced by childhood intellectual abilities.

Other recent studies by this same group (Galler, Bryce, Waber, Medford, Eaglesfield, & Fitzmaurice, 2011; Galler, Bryce, Zichlin, Fitzmaurice, Eaglesfield, & Waber, 2012) found a relationship between a history of protein-energy-malnutrition in the first year of life and attenuated executive skills via parent report, peer directed aggression when the cohort was relatively young, and the development of conduct problems via self-report as the cohort aged. These investigators stated that findings indicated continuity between the reports of the youth and earlier obtained teacher reports (Galler, Bryce, Waber, et al., 2012). Results suggested a relative decrease in parent reported peer aggression as the children aged and also showed that the later emergence of conduct problems was partly mediated by other factors such as childhood IQ and home environment.

Although not as robust as the findings in schizophrenia, the studies discussed already imply that prenatal as well as postnatal malnutrition predisposes individuals for exhibiting a variety of externalizing behaviors. It is intriguing to speculate whether the brain is susceptible to insults causing externalizing behaviors for a longer period during development, or if there are distinct etiologies of externalizing disorders, potentially linked to disruptions at various stages of brain development. Nevertheless, this handful of studies provides an impetus for future investigations on the role of malnutrition and other neurobiological risk factors in the etiology of externalizing problems.

Brown and colleagues investigated the relationship between prenatal famine exposure and the later development of affective disorders (affective psychosis and neurotic depression) (Brown, Susser, Lin, Neugebauer, & Gorman, 1995). The researchers defined affective psychosis and neurotic depression in accordance with ICD-9 definitions. Thus, individuals with affective psychosis displayed disturbances in mood (either depression or mania) accompanied by mood congruent delusions, whereas individuals with a diagnosis of neurotic depression displayed disturbances in mood (including symptoms of depression or anxiety) but evidenced no psychotic symptoms. They formed the groups by matching birth date and location with psychiatric admission records from 1978–1991.

Prenatal exposure to famine in the second trimester increased the risk of developing affective psychosis in later life; however, the authors did not find increased risk of affective psychosis resulting from first or third trimester famine exposure. These results remained significant when sex was taken into account; however, there was a significant interaction between sex and second semester famine exposure. Thus, males but not females appeared to be at greater risk for developing affective psychosis after second semester famine exposure—whereas females had higher prevalence rates in general. The data indicated no increased risk of neurotic depression following prenatal famine exposure in any trimester or in either sex.

A possible reason for the disparity between the diagnostic categories may be that (when compared to neurotic depression) affective psychosis represents a more severe mood disorder with a greater risk of hospitalization. Furthermore, neurotic depression may be more likely triggered by life stressors and thus differences between groups could be submerged by random variation in the population. A limitation of this study is that females usually begin exhibiting mood symptoms in adolescence. Therefore, effects of prenatal famine exposure may be observed in females if the researchers reviewed earlier hospital admission records. Additionally, Brown and his collaborators caution, their findings may not represent increased prevalence of affective psychosis, but rather may reflect increased need for hospital admission or delayed onset of symptoms in prenatally famine-exposed males. Nevertheless, these results suggest that males are at greater risk for developing serious mood disorders following significant mid-gestational malnutrition.

In a follow-up to their 1995 study, Brown and colleagues (2000) greatly increased their sample size by obtaining new diagnostic records. The researchers focused on unipolar and bipolar depression requiring hospitalization. Exposure to famine during the second and third trimesters related to increased hospital admissions in both males and females with unipolar and bipolar depression. The authors indicated that this effect was particularly robust if exposure occurred in the third trimester only. These results extend the findings of the 1995 study, and suggest prenatal famine exposure predisposes adults to develop serious mood disorders requiring hospitalization and characterized by either depression or mania/hypomania.

Another more recent study with the Dutch cohort indicated increases in depressive symptoms in adulthood among those individuals whose mothers were exposed to famine prior to gestation (i.e., in the preconceptual period; Stein, Pierik, Verrips, Susser, & Lumey 2009). The authors also found decreases in self-reported quality of life among this cohort. Interestingly, differences in depressive scores did not appear dependent on trimester of exposure during pregnancy (Stein et al., 2009).

Thompson and colleagues examined the relationship between low birth weight and the incidence of depression in old age (Thompson, Syddall, Rodin, Osmond, & Barker, 2001). These investigators used data obtained from individuals born between 1920 and 1930 in the English county of Hertfordshire and who still lived in the area in the early 1990s. The authors assessed all of the participants for depressive symptoms using two measures (a self-report questionnaire and a semistructured interview), and simultaneously asked about confounding factors such as SES, recent loss, general illness, and coronary heart disease (CHD).

This study found a relationship between birth weight and depression in late life so that the lower a child's birth weight, the greater the risk for developing late life depression. The findings were more robust in males and remained significant when the researchers statistically controlled for other complicating factors such as illness, SES, and bereavement. When they specifically took into account the occurrence of chronic heart disease (another risk factor for late life depression) the relationship grew stronger. The researchers that indicated males with low birth weight but high weight at one year exhibited the highest risk for late life depression; conversely, males with above average birth weight and comparatively low weight at one year exhibited the lowest risk for late life depression. They conjectured that this pattern indicated poor prenatal nutrition followed by compensatory growth and good prenatal nutrition followed by a regression to the mean respectively. Because this study focused on current and not early life depression, the results should not be generalized to depression occurring outside of old age. The authors hypothesized their findings provided support for aberrant fetal programming (see the conclusion section of this paper) caused by undernutrition as the major factor contributing to the future development of depression. Conversely, Waber et al. (2011) using the Barbadian cohort demonstrated that the direct relationship between depressive symptoms and early malnutrition was significantly attenuated when intellectual abilities were used as a covariate.

In summary, severe prenatal undernutrition appears to increase the risk for developing internalizing disorders (specifically mood disorders). However, it is unclear if the role of postnatal undernutrition significantly increases the risk of depressive disorders once other contributing variables (e.g., cognitive functioning) are taken into account. It is interesting that the risk period for exposure to malnutrition in the externalizing and internalizing domains may be later than for the schizophrenia spectrum disorders. The stages of brain development affected during these periods of vulnerability concur with research on the neurological sequelae of these various psychopathologies, and support the timing of onset and duration of insult hypothesis. For example, the research presented already on schizophrenia strongly suggests malnutrition exerts its effects in early stages of CNS development, neural tube formation, or initial neuronal migration, all of which have been implicated in the etiology of schizophrenia (Arnold, 1999; LaMantia, 1999; Rioux, Nissanov, Lauber, Bilker, & Arnold, 2003; Susser, Brown, Klonowski, Allen, & Lindenbaum, 1998). The later period of vulnerability observed in externalizing and internalizing disorders suggests malnutrition disrupts later processes of brain development such as neurotransmitter formation, late stage migration, or gliogenesis. Abnormalities in these processes have been implicated in the etiology of externalizing and internalizing disorders (Bowley et al., 2002; Cotter, Pariante, & Everall, 2001; Jenihe et al., 1996). Further, some conditions (such as schizophrenia) may be associated with a relatively acute injury, whereas behavioral disturbances in the externalizing and internalizing domains may be associated with insults extending over longer periods.

The investigations undertaken with the Dutch and Chinese famine cohorts and similar samples suggest early severe malnutrition, even if relatively brief in duration, increases the risk for the later development of mental disorders. Furthermore, this effect is not a general increase in vulnerability, but rather appears to depend on the timing and duration of the nutritional insult. Because the Dutch famine studies lack confounds such as social class, deprived environments, parental education, and extended postnatal malnutrition (which frequently accompany early malnutrition) they cannot be generalized to a chronically malnourished population. However, they provide strong support for the unique contribution of severe prenatal undernutrition in the emergence of later psychopathology.

Few studies have addressed the role of postnatal or prenatal–postnatal malnutrition in the development of psychopathology, even though it is clear from the National Collaborative Perinatal Project data base from the United States that prenatal malnutrition followed by postnatal failure to thrive has profound effects on IQ at 7 years of age (Pylipow et al., 2009). The lack of data on an effect of prenatal–postnatal malnutrition on psychopathology is particularly disheartening because postnatal malnutrition is common throughout the world, and, as discussed later in the studies on cognition, it is likely postnatal malnutrition is associated with deficits that differ from those of prenatal malnutrition.

The previous discussion suggests that early malnutrition may lead to the later development of psychopathology. Moreover, the expression of a particular psychopathology

likely depends on when the insult occurred (e.g., prenatal vs. postnatal or first verses second and third trimester). Another contributing factor (discussed in greater detail in the concluding remarks section) is that malnutrition may exert its maximal affect if it occurs concurrently with another insult such as stress or toxicity. Now that a plausible link has been established, it is necessary to take a step back in order to examine what may underlie the development of these conditions. We will first examine human studies that have been designed to determine if early malnutrition results in adverse effects on cognitive/intellectual development.

It is necessary to note that human protein energy malnutrition or undernutrition rarely exists without concomitant micronutrient deficiencies (Gorman, 1995; Kretchmer et al., 1996). Whether long-term effects are due to global or specific key nutrient undernutrition (e.g., iron, zinc) remains an interesting research question.

HUMAN STUDIES OF NUTRITION AND COGNITIVE DEVELOPMENT

One of the shortcomings of research on humans is it is difficult to control all potentially relevant variables, sometimes even known confounds. This limitation is particularly vexing in epidemiological research regarding the long-term consequences of early malnutrition. For example, as previously discussed, early malnutrition rarely occurs independently of other risk factors such as poverty and environmental stress (Engle et al., 1996; Pollitt, 1969; Stein & Susser, 1985; Tanner & Finn-Stevenson, 2002; Wachs et al., 2014). Although there are statistical techniques that can help compensate for this co-morbidity, one must still be careful when making inferences regarding experimental interventions or the interplay of particular risk factors. Secondarily, many studies using a population-based design are unable to account for other known or conjectured risk factors such as genetic predisposition, parental education, maternal stress, chaotic home environment, or other complicating physical factors such as toxin exposure, infection, or birth complications (Grantham-McGregor, 2002; Pollitt, 1969; Wachs et al., 2014). These caveats are not indictments of these types of studies, because what such studies lack in elegant controls they often make up for in direct relevance. However, the limited control over potential third variables should be kept in mind when evaluating such studies.

There are numerous studies detailing the effects of early malnutrition on human cognitive development (Fuglestad et al., 2008; Georgieff & Rao, 2001; Gorman, 1995; Park et al., 2011; Pollitt, 1988; Walker et al., 2011). Many of these studies were conducted in developing countries where malnutrition (or perhaps more frequently, undernutrition) is likely chronic and may span all of development—from the periconceptional phase to adolescence and young adulthood (Grantham-McGregor, 2002; Pongcharoen et al., 2012; Walker et al., 2011). Given the growing minority and immigrant populations of developed countries such as the United States and the fact that a vast portion of children worldwide suffer from early malnutrition, a careful consideration of these studies is warranted—even for those primarily interested in industrialized populations (Pollitt, 1994). Furthermore, knowledge of successful nutritional interventions in developing countries may help to improve current U.S. government programs such as the Women, Infants and Children (WIC) program (Pollitt, 1994; Tanner & Finn-Stevenson, 2002). It is useful to review this literature in this chapter in order to provide insight into the broad behavioral effects of early malnutrition. Further, research has linked intellectual/cognitive deficits with various types of psychopathologies (Moffitt & Caspi, 2001). Although this link may not be causal, these conditions (i.e., cognitive abilities and psychopathology) may nonetheless be connected.

Studies on neurocognitive outcomes of children who suffered early malnutrition are presented in three sections: studies concerning prenatal malnutrition and effects of low birth weight (where the fetus is protected from certain environmental factors such as poverty), studies on postnatal or combined prenatal and postnatal malnutrition, and studies examining the effects of nutritional interventions with malnourished populations.

LBW children (<2500 grams) or small for gestational age (SGA) births at term gestation are usually the result of intrauterine growth retardation (IUGR), which is frequently associated with fetal PEM (Georgieff & Rao, 2012). Although nutritional deficits in SGA babies can result from poor maternal nutrition, they can also result from other gestational or fetal problems such as maternal hypertension or genetic disorders (Georgieff & Rao, 2012).

Numerous studies have examined the neurocognitive functioning of SGA children (Georgieff, Hoffman, Pereira, Bernbaum, & Hoffman-Williamson, 1985; Low et al., 1982; Pollitt, 1996; Pylipow et al., 2009; Stein et al., 1972). Strauss and Dietz (1998)—using data from the National Collaborative Perinatal Project—compared the intellectual performance and visual-motor skills of IUGR children to their same sex non-IUGR siblings and normal birth weight children (without IUGR siblings). These researchers demonstrated that IUGR infants are usually born to shorter women who weigh less than the average female. Furthermore, this study revealed that normal birth

weight siblings of IUGR children were typically smaller than other normal birth weight children—although they were not considered SGA. The authors found that, at seven years of age, formerly IUGR infants with a head circumference significantly below normal or less than their siblings' evidenced reduced intellectual capacity and visual-motor skills compared with normal birth weight children. However, the performance of IUGR children did not significantly differ from their non-IUGR siblings—although the data trended in this direction.

These findings suggest that reduced birth weight is a phenomenon considerably influenced by genetic factors—although it is possible the normal birth weight siblings were malnourished, albeit at a lesser level than their SGA siblings. Additionally, statistically correcting for genetic and environmental agents suggests IUGR alone does not substantially contribute to the reductions in cognitive abilities noted in other studies. However, these data indicate IUGR infants born with significantly decreased head circumference differ from the normal birth weight population, other IUGR children without reduced head circumference, and their siblings in terms of their intellectual and visual-motor skills at 7 years of age.

Low and colleagues (1982) failed to find a relationship between IUGR and cognitive deficits. Results of their study indicated that IUGR children remained smaller than their peers at 6 years of age; however, the data revealed no significant long-term effects of IUGR on cognitive, motor, sensory, or language abilities. The IUGR group exhibited higher rates of certain difficulties (such as increased language difficulties and a slightly higher fail rate in senior kindergarten), but these differences did not reach statistical significance.

The authors admitted that the small IUGR male sample may have limited statistical power to detect delays in language skills, and they rightly point out that all of the children in this study were full-term, preventing generalization to preterm IUGR infants. Furthermore, this study did not assess specific neurocognitive functions (e.g., attention and recognition memory) that, because of their mediation by the hippocampus, might be more susceptible to prenatal insults such as IUGR. It is also possible that intervening environmental factors (such as a quality home environment) attenuated deficits in IUGR children. Another explanation rests on the fact that the authors meticulously matched the IUGR and control groups on factors such as obstetric complications, newborn characteristics, socioeconomic variables, and status at one-year follow-up; thus, factors potentially contributing to the reduced cognitive performance of IUGR children in previous studies might have been eliminated in the present investigation. Moreover, although not expressly stated in this paper, it is probable that the children in both IUGR and control groups received adequate postnatal nutrition.

Other studies expressly examined the effects of decreased head growth and caloric restriction on cognitive skills (Georgieff et al., 1985; Harvey, Prince, Bunton, Parkinson, & Campbell, 1982). Winick and Rosso (1969) demonstrated that children dying of severe malnutrition in the first year after birth evidence reduced brain DNA content—indicative of fewer neuronal and glial cells. Reduced head growth secondary to reduced cell numbers is an important variable to consider because microcephaly (severely reduced head size) is linked to neurodevelopmental disorders such as fetal alcohol syndrome (FAS). Furthermore, some investigators have correlated small head circumference at birth with greater risk for developing psychiatric disorders such as schizophrenia (Archibald et al., 2001; Bracha, Torrey, Gottesman, Bigelow & Cunniff, 1992; Kunugi, Takei, Murray, Saito, & Nanko, 1996). While reduced head growth is not associated with development in a specific brain region, it may be an indirect indicator of general brain maturation (Pollitt, Mueller, & Leibel, 1982).

Georgieff et al. (1985) showed that small for gestational age (SGA) infants and appropriate for gestational age (AGA) infants experiencing a prolonged period of postnatal caloric deprivation (due to medical complications) exhibited reduced rates of catch-up head growth. As would be expected, SGA infants began showing this reduced growth rate after sustaining a shorter period of caloric deprivation. The reduced rates of catch-up growth in these infants resulted in smaller head circumference at one year, head growth curves that (although broadly within the normal range) continued to be less than optimal, and in the most severely affected infants below average motor development scores.

Harvey and colleagues found that children born SGA with intrauterine head growth that slowed prior to 26 weeks gestation obtained lower scores on tests of perceptual and motor skills at 5 years of age (Harvey et al., 1982). Furthermore, SGA children with normal head growth performed at the same level as controls in these and other cognitive domains. The researchers combined the two SGA groups and evaluated performance strictly in terms of birth weight, ignoring rate of head growth; they determined that (taken as a single group) SGA children did not perform significantly differently from controls. Although this study did not deal with frank undernutrition, these results are an interesting corollary to the findings of

Georgieff et al. (1985) because they indicate that early rate of head growth may have a long-term impact on certain cognitive abilities.

Again using the Dutch cohort, a recent investigation by de Groot and colleagues (2011) found no evidence for any significant decreases in intellectual functioning in adulthood when compared to sibling controls and a geographically similar population born outside of the years of famine exposure. The authors indicated that although their findings did not indicate notable declines in IQ among the famine exposed group, their results could not completely rule out a role for early gestational famine exposure in decreasing intellectual abilities. Another study using this adult cohort found evidence for decreases in selective attention among males and females exposed to famine during the early portion of gestation (de Rooij, Wouters, Yonker, Painter, & Roseboom, 2010). The authors speculated that these findings may indicate premature signs of aging in the famine exposed individuals.

Although not entirely consistent in their findings, these studies suggest that SGA infants—especially those with decelerated rates of intrauterine head growth—and children who have lower birth weights compared to siblings are at higher risk for developing subtle but detectable neurocognitive difficulties. The findings from studies of frank malnutrition with the Dutch sample are somewhat equivocal, but highlight the likely role of early malnutrition in continued cognitive difficulties into late adulthood (de Groot et al., 2011; De Rooij et al., 2010). Those with first trimester exposure appear to be the most vulnerable.

The mechanism behind these effects is unknown although some interesting speculations can be made by results of a study from Tirosh, Gaster, Berger, Cohen, & Scher (2000). These investigators showed that birth weight and head circumference of typically developing children positively and significantly correlated with activity level and mobility in infancy. Prenatal malnutrition in the absence of other risk factors has not been convincingly demonstrated to result in long-term decreases in cognitive abilities, and it remains unclear how meaningful any deficits will be as previously malnourished children age (Guesry, 1998; Pollitt, 1996; Stein et al., 1972; Stein & Susser, 1985). The relationship noted by Tirosh et al. (2000) is important because it suggests that babies born with low birth weights are less active and less able to explore their environment, thereby potentially reducing mental stimulation—which human and animal studies indicate is necessary for basic cortical organization and development (Black, 1998; Nelson, 1999). Researchers theorize environmental stimulation is also critical for the development of other more complex cognitive skills (Black, 1998; Nelson, 1999; Nelson, 2000; Wachs et al., 2014).

It is necessary to qualify these assertions. First, it is quite likely that the SGA infant is affected by the internal and external environments into which she or he is born, for example, by factors like maternal substance use, stress, or genetic constitutions; postnatal nutritional factors; and birth complications such as premature birth, hypoxia, maternal infections, etc. Therefore, the ultimate effects of SGA are likely graded on a continuum, depending upon the combination of other vulnerabilities and assets possessed by the child (Engle et al., 1996; Stein & Susser, 1985).

Second, SGA infants are a heterogeneous group, and it is plausible that different etiologies of IUGR have different effects on neurological development (Black, deRegnier, Long, Georgieff, & Nelson, 2005). Finally, evidence suggests that prenatal malnutrition (especially if endured early in pregnancy) can occur without resultant low birth weight (Heasman, Clarke, Stephenson, & Symonds, 1999; Lumey, 1998). Lumey (1998) determined that prenatal malnutrition restricted to the first trimester resulted in compensatory placental growth without subsequent reductions in birth weight at term. For this reason, normal birth weight does not necessarily assure adequate prenatal nutrition, particularly during the sensitive period in the first trimester.

Many children, despite being born appropriate for gestational age (AGA), may have sustained neurological insults due to prenatal malnutrition. These children as well as SGA children may be more vulnerable to further nutritional deprivation or other environmental insults (Berkman, Lescano, Gilman, Lopez, & Black, 2002; Galler & Ramsey, 1987, 1989; Galler, Ramsey, & Forde, 1986; Ivanovic et al., 2000, 2002; Liu, Raine, Venables, Dalais, & Mednick, 2003). It is therefore difficult to dissociate the precise effects of prenatal malnutrition because the populations typically studied may not represent all prenatally malnourished individuals.

In a series of papers, Galler and colleagues (Galler & Ramsey, 1987, 1989; Galler, Ramsey, Solimano, & Lowell, 1983; Galler, Ramsey, Solimano, Lowell, & Mason, 1983; Galler et al., 1986) described the consequences of moderate to severe malnutrition sustained by Barbadian children in the first year of life. Galler et al. (1986) showed that (despite apparently so-called successful nutritional rehabilitation) previously malnourished children continued to exhibit lower performance on tests of intellectual abilities up to 8 to 14 years postmalnutrition. In this study, researchers administered to participants the Wechsler Intelligence Scale for Children–Revised (WISC-R), (Galler et al.,

1986), and the participants' mother completed a questionnaire assessing living circumstances, education, family relationships, and caregiver contact, among other factors. Consistent with previous evaluations (Galler, Ramsey, Solimano, Lowell, & Mason, 1983), results indicated that previously undernourished children had lower overall intellectual abilities and performed below controls (matched on birth weight, medical illnesses other than malnutrition, age, sex, and handedness) on the verbal and performance subscales of the WISC-R. The researchers observed no sex differences or sex-nutrition interactions, except (regardless of early nutritional status) females outperformed males on the Freedom from Distractibility index.

The study reported a significant correlation between scores on the WISC-R and environmental factors (e.g., poverty and maternal employment) (Galler et al., 1986). However, early malnutrition remained significant when the authors statistically adjusted for these influences. Conversely, environmental factors remained significant when the authors statistically adjusted for early nutritional status. The significant influence of environmental factors on test performance at these older ages is interesting because this was not found in previous investigations with this cohort (Galler, Ramsey, Solimano, Lowell, & Mason, 1983). The authors concluded that a history of malnutrition continues to play a role in intellectual deficits at least into adolescence. However, as a child matures, the effects of an early nutritional insult may be overcome or attenuated by other environmental factors. Thus, the findings suggest that appropriate interventions may be effective in combating some of the intellectual impairments incurred after early malnutrition.

Using this same cohort, Galler and Ramsey (1987) found that previously malnourished children younger than 14 displayed deficient performance on Piaget's tests of conservation. These differences were not entirely accounted for by IQ—suggesting these tasks assess slightly different cognitive domains. Contrasting to the persisting differences on measures of IQ, previously malnourished children performed equivalent to controls by age 14. This pattern is similar to that observed in the Galler et al. (1986) study in that it suggests that effects of an early nutritional insult, initially very salient, grow less robust with time. However, in a recent study, Galler and colleagues (Galler, Bryce, Waber, Zichlin, Fitzmaurice, & Eaglesfield, 2012) determined that at a 40-year follow-up, children who experienced PEM early in life demonstrated decreased earnings and reduced socioeconomic status in adulthood. The investigators acknowledged that the relationship became less robust once cognitive abilities were included in the model although the affect persisted (Galler, Bryce, Waber, Zichlin, Fitzmaurice, & Eaglesfield, 2012). this suggests early malnutrition can have long-lasting detrimental effects despite adequate provision of nutrition thereafter.

Another series of papers by Ivanovic and collaborators (2000, 2002) investigated the effects of severe early malnutrition on scholastic achievement, IQ, and brain morphology in Chilean high-school graduates. Formerly undernourished and never undernourished high-school graduates of low SES participated in this study. Researchers found that individuals with a history of early malnutrition obtained lower full-scale IQs (as assessed by the Wechsler Adult Intelligence Scale [WAIS]), lower scores on a scholastic aptitude test containing verbal and numerical items, and reduced brain volume on magnetic resonance imaging (MRI). The IQ results remained consistent across verbal and nonverbal domains in both sexes, whereas the brain volumetric difference—though significant in both sexes—emerged much more strikingly in males.

In a subsequent study with a similar population, Ivanovic et al. (2002) evaluated two groups of young adults with mean IQs of about 125 and 91, respectively. Both groups included individuals of high and low SES. They assessed participants with the same battery as in the 2000 study—adding intellectual testing of both parents. The researchers verified the occurrence of malnutrition in the first year of life by reviewing hospital records.

Results indicated that, regardless of SES, children with higher IQs had greater brain volumes, higher maternal IQ, better prenatal nutrition as indexed by birth weight, no evidence of postnatal nutritional deficits, and higher scholastic achievement. Maternal IQ, brain volume, and postnatal nutrition significantly related to young adult IQ. Early malnutrition rarely occurred within the high SES, low IQ group; however, this group evidenced lower maternal IQ when compared to the high SES, high IQ group. Conversely, 64% of individuals with low SES and low IQ had a history of early malnutrition, and this group, in general, had maternal IQs lower than the other three groups. Additionally, the researchers showed individuals within the low IQ group had similar maternal IQ, scholastic achievement, and brain volume. This led the authors to conjecture that these findings are typical correlates of low IQ.

Liu et al. (2003) assessed the effect of malnutrition at age 3 upon cognitive skills at age 3 and again at age 11 while attempting to statistically control for various psychosocial risk factors (e.g., living circumstances, parental education, age of mother at time of birth, presence of mental illness in the mother, and number of children living in the home).

Study participants included children living in the island of Mauritius and enrolled in the Mauritius Child Health Project—a prospective longitudinal study of children's physical and psychological health. At three years, children were assessed for several indicators of malnutrition: angular stomatitis, kwashiorkor, sparse fine hair, and anemia. These indicators are associated with deficiencies in vitamin A and B_2; protein, zinc, and copper; protein energy, zinc, and iron; and iron, respectively. The researchers considered a child malnourished if he or she displayed one or more of these four indicators. Assessments at age 3 included subtests from the Boehm Test of Basic Concepts—Preschool Version. Assessments at age 11 included: subtests from the WISC, Trails A & B (tests of executive functions), and a test of basic reading skills.

Results indicated that children malnourished at 3 years displayed overall intellectual and verbal cognitive deficits and continued exhibiting these deficits at age 11. Moreover, at age 11 these children exhibited deficits in nonverbal abilities, scholastic skills, reading abilities, and executive functioning. They found that even though malnourished children tended to have lower parental education and higher scores on measures of social stress, the effects of malnutrition remained significant when these factors were statistically adjusted for in the analysis. Additionally, this study reported a dose–response (i.e. monotonic) relationship between indicators of malnutrition and cognitive skills, as assessed by the WISC. Thus, children with three of four indicators of malnutrition at age 3 had IQs approximately 15 points below the mean, children with two indicators had IQs nine points below the mean, and children with one indicator had IQs only three points below the mean.

Anemia at age 3 years was the most significant indicator relating to lower cognitive performance at ages 3 and 11. The researchers acknowledged that they did not obtain nutritional information at age 11. Hence, it is possible these results could be explained by current or chronic malnutrition. Furthermore, the authors did not examine birth records. Therefore, factors such as birth weight or prenatal complications may have influenced the results. Nonetheless, this is a strong experimental design supporting the hypothesis that postnatal malnutrition has repercussions for later cognitive functioning. It also suggests trace nutrients such as iron are particularly important in the manifestations of malnutrition.

The unique impact of postnatal malnutrition and its relationship with other risk factors on cognitive development remains unknown. In general, the studies presented earlier suggest postnatal malnutrition is associated with discernable decreases in intellectual abilities (Berkman et al., 2002; Galler & Ramsey, 1987; Galler et al., 1986; Liu et al., 2003). Even though this assertion appears supported by the extant data, cautions similar to those detailed in the section regarding prenatal malnutrition still apply. For example, many of the studies did not directly assess potential confounding factors commonly associated with early malnutrition such as parental IQ, biological risks (birth complications, childhood diseases, or environmental toxins), and social variables (e.g., a chronically neglectful or understimulating environment; Berkman et al., 2002; Guesry, 1998; Liu et al., 2003; Pollitt 1969, Stein & Susser, 1985). Nevertheless, a majority of the studies reviewed indirectly assessed important variables and controlled for these variables in the subsequent analyses (Berkman et al., 2002; Galler et al., 1986; Galler & Ramsey, 1987; Liu et al., 2003) allowing us to be fairly confident in the assertion that postnatal malnutrition exerts deleterious effects on the developing brain. Indeed, the effect seems to have a particular sensitive period in the first postnatal year. Growth velocity prior to 1 year of age (but not afterward) predicts IQ at 9 years of age (Pongcharoen et al., 2012).

The studies leave open the question of amelioration of the effects of early malnutrition on the developing brain. Several studies addressing this point are now considered.

Studies that examine amelioration of early malnutrition investigate either strictly nutritional or combined environmental/nutritional interventions (Joos, Pollitt, Mueller, & Albright 1983; Lien, Meyer, & Winick, 1977; Pollitt, 1996; Raine et al., 2001; Raine, Mellingen, Liu, Venables, & Mednick, 2003; Winick, Meyer, & Harris, 1975; Zeskind & Ramey, 1981). The individuals in these studies are usually assumed to suffer from postnatal malnutrition although many of the investigations did not explicitly rule out the possibility of prenatal nutritional restriction.

Pollitt and his collaborators (1993) described a nutritional intervention in four rural Guatemalan villages (Pollitt, Gorman, Engle, Martorell, & Rivera, 1993). Beginning at various times during development (e.g., before conception, during gestation, throughout lactation, and into childhood), this project provided pregnant mothers and their children with either a high-protein, high-calorie drink known as Atole or a low-protein, low-calorie drink known as Fresco. The researchers fortified both beverages with trace minerals. Individuals in two villages received the Atole drink and individuals in the others received Fresco.

Children of low SES whose mothers received Atole during gestation and until at least age 2 outperformed their peers on tests of information processing, mental

ability, academic skills, and progressed further in school than children receiving Fresco. Low SES children with shorter and later (beginning at or after age 2) periods of exposure to Atole also benefited (scoring higher on tests of numerical and reading abilities and progressing further in school than their peers), although these findings were less striking. These results are interesting because they argue for a stable, long-term improvement in intellectual, academic, and cognitive skills resulting from prenatal through postnatal nutritional supplementation in undernourished populations. Moreover, they imply that supplementation has the greatest impact and benefit on low SES individuals, perhaps because it delivers help to the children who, without it, would have fared worst. They also illustrate the differential vulnerability (or plasticity) of the brain depending on the timing of the insult and intervention.

Using data from the Mauritius health project, Raine et al. (2001) investigated the effects of an enriched educational environment on orienting and physiological arousal (measured by electroencephalography). In this study, experimenters matched children based upon psychophysiological characteristics at age 3 and randomly assigned participants to an enriched preschool or to a standard preschool educational experience on the island of Mauritius. The enriched preschool employed various types of enriching experiences including well-balanced meals, education about nutrition and hygiene to parents and children, encouragement of imaginative play, interactive conversational skills, socialization, exercise, and regular field trips. Furthermore, parental involvement was highly encouraged, timeout discipline was used instead of corporal punishment, and the children's health was carefully monitored. The enriched experiences lasted for two years, at which time the children began grade school in typical classrooms.

Results indicated the enriched preschool experience related to increases in orienting and physiological arousal at age 11. The authors speculated that these findings provided evidence of improved information processing or accelerated neurological maturation in children enrolled in the enriched preschool. They acknowledged that, given the multi-factorial nature of the enriched experience, it was impossible to surmise which component or components explained these results although research suggests both nutritional and educational enrichment have unique effects on cognitive development (Grantham-McGregor, Powell, Walker, & Himes, 1991; Grantham-McGregor et al., 2014; Wachs et al., 2014). The results may be partially explained by long-term changes in parental or child behavior caused by the early preschool experience. For example, the parental education and increased parental involvement encouraged by the preschool may have been built upon and maintained after the child began grade school. Thus, the findings may represent the consequence of being raised in a more stable, lower stress home environment and not by neurological alterations directly induced by the preschool experience. Regardless, these findings suggest that long-term alterations in physiological parameters—considered to reflect neuronal processing (Williams et al., 2000)—secondary to environmental enrichment and nutritional supplementation (Grantham-McGregor et al., 2014). These results are fascinating because reduced orienting and arousal responses are associated with various types of psychopathology (Banaschewski et al., 2003; Perry, Felger, & Braff, 1998; Schnur et al., 1999).

The studies illustrate the potential benefits of nutritional supplementation and combined nutritional/environmental enrichment in chronically undernourished populations. However, undernourished children are frequently born with other genetic and environmental risks (Guesry, 1998; Pollitt 1969; Stein & Susser, 1985). This begs the question: can comprehensive environmental enrichment rescue a child with multiple risk factors including malnutrition (Grantham-McGregor et al., 2014)?

Winick et al. (1975) and Lien et al. (1977) addressed this question by investigating the intellectual performance of Korean children who suffered early malnutrition (prior to the age of 2), but were subsequently adopted into homes in the United States. Winick and colleagues (1975) showed that even the most severely malnourished children (below the third percentile for height and weight at or before age 2) made significant advances in their physical and intellectual development after adoption. Specifically, in middle childhood the previously malnourished children attained heights and weights above the standard for Korean children (although they continued to be smaller than American children). Furthermore, these children achieved IQ scores within the average range (mean of 102) and demonstrated academic performance comparable to their American peers.

The researchers suggested that these scores were substantially greater (in excess of 40 points) than would be expected if these children remained in restricted environments. Importantly, this study showed a significant difference between the IQs of previously malnourished adopted children and those of adopted children with no history of malnutrition (mean IQ of the latter group was approximately 112). Winick and colleagues conjectured these differences were partially genetic (the parents of undernourished children being more likely to have lower

intellectual abilities), or a consequence of the nutritional deficits (i.e., the previously malnourished children had not been able to benefit as much from the adopted environment). Unfortunately, it is difficult to disentangle these possibilities without an assessment of parental IQ or a sibling design in which the other sibling was not malnourished.

Lien et al. (1977) examined the roles of malnutrition on the cognitive development, growth, and academic achievement in Korean children adopted later in childhood (between 2 and 5 years of age). The researchers again found that severely, moderately, and nonmalnourished adopted children attained weight and height above standards for Korean children but below those of American children. However, they found that severely malnourished children attained IQ scores significantly lower than American children and their nonmalnourished adopted peers. Results also indicated that severely malnourished late adoptees had academic achievement scores below their American classmates and their late adopted peers.

The effect of nutritional deficits on academic performance remained significant when age of adoption and age of placement with the adoption agency were taken into account. (This analysis was not completed on the IQ information because of the relatively small number of cases with this information provided.) Interestingly, the authors found a significant effect for age of adoption on academic performance, but no evidence relating academic performance to duration of malnutrition or for an interaction between any of these factors. Secondary factors (e.g., behavioral or emotional concerns) may explain both later age of adoption and below average performance on IQ and academic tests, but more would have to be known about a child's preadoptive history to completely discount this confound.

These two studies provide evidence for improved cognitive and scholastic performance following severe malnutrition in adopted children removed from pathological environments. However, the results of the second study suggest there is a critical period in which environmental enrichment will be maximally beneficial and after which recovery is either slowed or attenuated.

We have seen that environmental enrichment (of varying degrees and types) is able to ameliorate some of the detrimental effects of malnutrition on cognitive skills; however, a subsequent question asks, would enrichment contribute to a reduction in psychiatric correlates of malnutrition? This is especially interesting because, based upon the discrepant findings of Stein et al. (1972) and Susser et al. (1996) with regard to the effect of prenatal famine exposure on cognitive deficits and schizophrenia, it appears likely that psychopathological conditions may be more sensitive to diffuse neurological disruptions than cognitive abilities, which themselves appear more sensitive than current measures of neuropathology.

In a follow-up to their 2001 study, Raine et al. (2003) address the previous question. This study reported that children who experienced the enriched preschool environment exhibited significantly fewer conduct problems and schizotypal personality traits at age 17, and reduced self-reported levels of criminal offending at age 23. Court records of criminal offenses trended toward fewer offenses in the enriched group, but this did not reach conventional levels of statistical significance. Furthermore, the data showed significant interactions between environmental enrichment and early nutritional status. Thus, individuals with poorer nutritional status assessed at 3 years of age (see Liu et al., 2001) prior to the enriched preschool intervention demonstrated significant benefits from the program. Specifically, in addition to the results presented before, the undernourished group evidenced reduced interpersonal deficits at age 23 when compared to undernourished nonenriched controls. Subsequent analyses to account for psychosocial risk factors (see Liu et al., 2001) and physiological factors at age 3 revealed no moderating effects or changes in the results.

The authors argue that their findings indicate long-term behavioral benefits of enriched environmental experiences, and a particularly striking long-term improvement in functioning of previously malnourished children. They acknowledge the aspects of the enriched preschool experience contributing the most to the observed differences cannot be identified. However, they contend that the improved nutrition offered by the preschool likely played a role, especially with regard to the children who had previous nutritional deficits. This hypothesis is consistent with the findings of other research studies indicating a unique effect of nutritional supplementation on cognitive development (Grantham-McGregor, 2014; Grantham-McGregor et al., 1991).

Research indicates that environmental enrichment moderates the effects of malnutrition, albeit through direct supplementation or combined nutritional and educational enrichment. Some questions remain as to how permanent and significant these effects are, but certain data indicate if undertaken early in development and for a sufficient duration the beneficial effects of environmental enrichment can become stable and long lasting (Lien et al., 1977; Pollitt, 1996; Raine et al., 2001; Winick et al., 1975). However, it would be naïve to assume that all

insults, regardless of severity or genetic diathesis, can be completely alleviated by high quality schools, nutritional supplementation, and supportive parenting (Lien et al., 1977; Pollitt, 1996). No matter the interventions employed, one cannot help but suspect that some conditions remain resistant to complete amelioration. At the same time, the inherent adaptability and plasticity of the nervous system, both in children and adults, attests to the fact that some improvement in many conditions is possible, given proper stimulation (Huntley & Jones, 2002; Nelson, 1999). For example, the studies described by Pollitt (1996) suggest that in malnourished, low SES populations, nutritional supplementation alone can have a long-term ameliorative impact on cognitive functioning. Furthermore, the reports by Lien et al. (1977), Winick et al. (1975), and Zeskind and Ramey (1981) give hope that even individuals with risk factors across multiple domains can profit from quality environmental circumstances. Essentially, plasticity exists; however, recovery from early insults such as malnutrition is likely to be incomplete.

In summary, the studies discussed in this section indicate early malnutrition has discernable effects upon cognitive skills throughout all periods of brain development (gestational and postnatal). However, research also suggests that there is potential for catch-up brain growth and improved intellectual and behavioral development if nutritional needs are restored. Additionally, other studies suggest that educational and environmental manipulations may also contribute to improved outcomes following early malnutrition. It is possible that some of the manifestations of malnutrition reported in this section (e.g., reductions in intellectual and certain cognitive abilities) may have resulted from impairments secondary to various psychiatric symptoms such as inattention or anxiety. However, with the exception of the Galler and Ramsey (1989) study these two factors appear to have not been measured concurrently. At this point, the discussion will again move down another level and focus on findings which shed light upon the effects of early malnutrition on the structure and function of the developing and mature brain.

NEUROBIOLOGY OF NUTRITIONAL EFFECTS: EVIDENCE FROM BENCH SCIENCE

Early Life Macronutrient Undernutrition

Many studies link early undernutrition to disturbances in neurotransmitter development and function and to neuroanatomic abnormalities including fine structures (e.g., dendritic spines) and specific regions such as the hippocampus (Almeida, Tonkiss, & Galler, 1996b; Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Morgane et al., 1993; Morgane et al., 2002; Wauben & Wainwright, 1999; Wiggins, Fuller, & Enna, 1984). These are important factors to consider because changes in brain morphology and physiology caused by malnutrition may be similar to the biological alterations observed in various psychopathologies (Brown et al., 1996).

Neurotransmitters and their receptors are important determinants of brain development before they become a critical part of the information processing activities of neurons (Benes, Bolte-Taylor, & Cunningham, 2000; Berger-Sweeney, 1998; Bonhoeffer & Yuste, 2002; Fernandez-Ruiz, Berrendero, Hernandez, Romero, & Ramos, 1999; Franciosi, 2001; Heine, 1999; Ma et al., 2000; Nguyen et al., 2001; Retz, Kornhuber, & Riederer, 1996; Van Kesteren & Spencer, 2003; Whitford, Dijkhuizen, Polleux, & Ghosh, 2002). Thus, if early malnutrition disturbs the balance of neurochemical systems, it could result in structural or behavioral alterations (Alvarez et al., 2002; Wauben & Wainwright, 1999; Wiggins et al., 1984).

Disruption of neurotransmitter systems due to early malnutrition could directly or indirectly affect brain development (Wauben & Wainwright, 1999). That is, a neurotransmitter may directly induce a developmental process (e.g., GABA in promoting proliferation of neuronal progenitors, acetylcholine's involvement in apoptosis, serotonin's role in synaptogenesis, and glutamates regulation of dendritic spine formation; Nguyen et al., 2001). Therefore, if early malnutrition greatly reduces or augments neurotransmitter concentration, normal processes may not occur, or may occur in an abnormal fashion (Wauben & Wainwright, 1999). Alternatively, a neurotransmitter may be responsible for modulating other neurotransmitters, growth factors, or signaling molecules (e.g., cytosolic calcium levels, immediate early gene expression, or the mitogen-activated protein kinase cascade), which in turn regulate other developmental processes (Wauben & Wainwright, 1999). All of these downstream events could be disrupted by abnormal neurotransmitter concentrations resulting from malnutrition (Evrard, Marret, & Gressens 1997; Wauben & Wainwright, 1999).

The amino acids tryptophan and tyrosine are precursors of the neurotransmitters serotonin and dopamine, respectively (Benes et al., 2000; Wauben & Wainwright, 1999). The blood brain barrier contains transporters for these amino acids, which are not directly synthesized in the brain (Wauben & Wainwright, 1999). Therefore, adequate dietary intake is essential in order to maintain proper central nervous system (CNS) concentrations

of these compounds. Serotonin is involved in neuronal proliferation, differentiation, glia formation, and synaptogenesis (Gaspar, Cases, & Maroteaux, 2003; Morgane et al., 1993; Okado, Narita, & Narita, 2001; Wauben & Wainwright, 1999).

Hernandez-Rodriguez & Manjarrez-Gutierrez (2001) found increased tryptophan uptake across the blood brain barrier and serotonin synthesis within the brain of gestationally malnourished rats. They observed these differences through weaning, and the increased serotonin synthesis continued after nutritional rehabilitation and normalization of tryptophan uptake. Based upon these animal studies and human research suggesting analogous patterns of plasma tryptophan ratios, these researchers postulated similar outcomes are likely in human infants suffering from prenatal malnutrition (see Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001, for review).

Manjarrez et al. (2003) conjectured the increased concentration of serotonin observed in undernourished animals results in a desensitization of the serotonergic system secondary to chronic overactivation (Manjarrez, Manuel, Mercado, & Hernandez, 2003). Prenatally malnourished adult and adolescent rats also displayed decreased serotonin uptake sites, decreased serotonin fiber density, and enhanced serotonin release following hippocampal stimulation (Blatt, Chen, Rosene, Volicer, & Galler, 1994; Chen, Tonkiss, Galler, & Volicer, 1992; Mokler, Galler, & Morgane, 2003). In addition, prenatally and postnatally malnourished animals exhibit deficits in adaptation of the serotonergic system in response to chronic stress (Almeida et al., 1996; Mokler et al., 2003). Other studies indicate that a history of PEM decreases extracellular dopamine in the medial prefrontal cortex of adult rats and alters both dopamine and serotonin release in the cortex and hippocampus (Mokler, Torres, Galler, & Morgane, 2007). Together, these results suggest that prenatal malnutrition can lead to long-lasting or even permanent alterations of the serotonergic system—potentially contributing to the later development of psychopathology (Benes et al., 2000; Fishbein & Pease, 1994; Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Manjarrez et al., 2003).

Pre/postnatally undernourished animals also demonstrate reduced reactivity to pharmacological manipulations of the catecholaminergic system (Almeida et al., 1996; Chen, Turiak, Galler, & Volicer, 1997; Soto-Moyano et al., 1999). For example, early malnourished animals showed an attenuated response to dopamine agonists that induced stereotyped motor behaviors, reduced sensitivity to catatonic symptoms caused by dopamine antagonists, and a developmental delay in the induction of hypoactivity after administration of an adrenergic agonist (clonidine) (Almeida et al., 1996; Bredberg & Paalzow, 1990; Goodlett, Valentino, Resnick, & Morgane, 1985). Other studies show decreased concentrations of dopamine and epinephrine receptors in specific brain regions of animals exposed to early undernutrition (Almeida et al., 1996; Wiggins et al., 1984).

Almeida and colleagues (1996) conjecture these modifications are an adaptive response to initially high levels of catecholamines during brain development in undernourished animals. However, findings of increased sensitivity to the hypothermic effects of apomorphine (a dopamine agonist) but decreased sensitivity to the hypothermic effects of clonidine suggest a more complex picture in which pre/postnatal malnutrition has a differential impact on various subtypes of catecholaminergic receptors and on receptors within certain brain regions (Almeida et al., 1996; Brioni & Orsingher, 1987). For example, using a mild (8%) protein depleted diet, Soto-Moyanoa and collaborators found increased norepinephrine release and neuronal density only within the occipital cortex of prenatally malnourished rats (Soto-Moyanoa et al., 1999). Again, early malnutrition appears to cause alterations within the catecholaminergic system regardless of the precise dietary manipulation.

Prenatally malnourished animals exhibit reduced sensitivity to the effects of benzodiazepines (BZs) (Almeida et al., 1996; Masur & Ribeiro, 1981; Tonkiss et al., 2000; Tonkiss, Trzcinska, Shultz, Vincitore, & Galler, 2000). This class of drugs potentiates the actions of the inhibitory neurotransmitter GABA (Almeida et al., 1996). Researchers observed long-term changes in sensitivity to BZs, similar to those found in the serotonergic system, during malnutrition and following nutritional rehabilitation (Almeida et al., 1996; Tonkiss et al., 2000).

Tonkiss and coworkers (2000) studied spatial learning in prenatally malnourished rats following administration of the GABAergic agonist chlordiazepoxide (CDP) at 30 and 90 days after birth. They found prenatally malnourished animals responded less than control animals to a high dose of CDP at both 30 and 90 days of age, but at 90 days the previously malnourished animals displayed greater sensitivity to a lower dose of CDP when compared with well-nourished controls. A possible reason for these differential responses may be that the drug exerts certain effects (e.g., anxiolytic versus amnesic) at high and low doses respectively. The researchers concluded that differences between the GABAergic system of malnourished and well-nourished animals resulted in differential responses to

CDP depending on age of administration and particular dosage of the drug.

Researchers have linked early malnutrition to reduced levels of GABA transmitter and increased binding of GABA and BZs to the GABA receptor complex within the CNS of rodents (Almeida et al., 1996). It is probable the alterations in GABA binding and concentration underlie the attenuated responses to BZs, and result from permanent changes in this neurotransmitter system directly caused by early malnutrition (Almeida et al., 1996; Chang, Galler, & Luebke, 2003). Again, changes in this system appear consistent across dietary manipulations, ages, and strains of animals used; therefore, they likely represent actual effects of early malnutrition and are not simply a byproduct of a specific experimental design (Almeida et al., 1996). Changes in the developing GABA system are significant because GABA is a very active transmitter in early cortical development (Ben-Ari, 2002; Davies et al., 1998).

Early malnutrition is associated with lower sensitivity to drugs acting on the opiate system; however, studies showing specific receptor changes have not been completed (Almeida et al., 1996). Similarly, studies indicate reduced cholinergic function within the early malnourished rats (Almeida et al., 1996). Specifically, differences in muscarinic receptor density, binding, and developmental course within different brain regions are seen in previously malnourished rats (Almeida et al., 1996). However, too few studies have been completed to draw firm conclusions regarding the effect of early malnutrition on the cholinergic system with relevance to possible behavioral effects (Almeida et al., 1996).

Tonkiss, Almeida, & Galler (1998) used an operant procedure to show that prenatally undernourished female rats displayed sensitivity to the blockade of glutamate receptors with an N-methyl-D-aspartate (NMDA) antagonist (MK-801). The NMDA receptor is a type of glutamate receptor highly concentrated in the hippocampus and is thought to play a critical role in learning and memory (Cui et al., 2004; Nakazawa et al., 2003; Roesler et al., 2003). Tonkiss and coworkers trained rats to a stable level of performance on a differential reinforcement of low-rates (DRL) task. On this particular DRL schedule, animals did not receive a reward unless they separated their responses by at least 18 seconds. After attaining a stable performance, the researchers administered MK-801 at various doses. Results indicated the performance of prenatally malnourished female, but not male, rats was disrupted after MK-801 administration. This experiment is interesting because it is one of the few studies to examine sex differences in generalized prenatal malnutrition. Although speculative, the increased sensitivity to NMDA blockade in prenatally malnourished females may be the result of loss or dysfunction of NMDA receptors in the hippocampus of these animals (Salinas, personal communication). This explanation is consistent with histological findings in other neurotransmitter systems showing decreased concentrations of various receptor types following nutritional insults (Almeida et al., 1996; Wiggins et al., 1984).

Alternatively, Fiacco and colleagues (Fiacco, Rosene, Galler, & Blatt, 2003) reported that prenatally malnourished rats displayed persistent increases in the concentration of kainate receptors (another type of glutamate receptor) within the CA3 subregion of the hippocampus—a region implicated in recognition memory (Fiacco et al., 2003; Lee & Kesner, 2003). These differences persisted through 220 days of age, but they did not emerge until 30 days after birth. Furthermore, Palmer, Printz, Butler, Dulawa, and Printz (2004) found evidence of increased NMDA receptor binding in the striatum of prenatally protein malnourished animals, but they observed no differences in NMDA receptor binding in the hippocampus or dopamine receptor binding in the striatum. These studies suggest that changes in the glutamate system occur in rats secondary to prenatal malnutrition; however, more studies need to be completed to specify the precise nature of these changes across brain regions, age, sex, and subtypes of glutamate receptors.

The aforementioned research indicates that early malnutrition appears to perturb an animal's responsiveness to pharmacological manipulation of various neurotransmitter systems (Almeida et al., 1996). Many studies show decreased receptor density for several types of neurotransmitters (dopamine, epinephrine, serotonin, acetylcholine, and GABA (Almeida et al., 1996). Researchers postulate that this represents an aspect of homeostatic functioning in early malnutrition in that down-regulation of receptors occurs in response to higher-than-normal levels of neurotransmitter during development (Almeida et al., 1996; Manjarrez et al., 2003). In addition, malnourished animals show decreased adaptations of the serotonergic and opioid systems in response to stress—possibly indicating permanently altered system dynamics (Almeida et al., 1996; Mokler et al., 2003). Essentially, malnutrition may exert its effects upon neurochemistry not solely by affecting a single neurotransmitter system, but rather by perturbing the intricate balance between systems in the developing brain.

The changes in neurotransmitter systems described here appear to alter how an animal reacts and interacts with its environment. Therefore, if similar biochemical changes

occur in the developing human brain, one could speculate these perturbations will also result in modifications of behavior (Almeida et al., 1996). These behavioral changes may represent interesting correlates of certain forms of psychopathology (Almeida et al., 1996). For example, Almeida et al. (1996) reported on a study that found, when compared to well-nourished controls, postnatally malnourished animals exhibited an anxiolytic reaction similar to that of panic disorder patients after chronic administration of either a tricyclic antidepressant or a monoamine oxidase inhibitor. Furthermore, numerous studies have linked dysfunction of neurotransmitter systems to the expression of various forms of psychopathology (Fishbein & Pease, 1994; Kaufman, Plotsky, & Nemeroff, 2000; Konradi & Heckers, 2003). In addition to effects on the organization of developing neurotransmitter systems, malnutrition affects structures within the brain such as the hippocampal formation. This brain region is particularly susceptible to a wide range of early insults and is implicated in various types of psychopathology (Arango, Kirkpatrick, & Koenig, 2001; De Bellis et al., 2000; Harry and Lefebvre-d'Hellencourt, 2003; Heckers et al., 1998; Kimura, Reynolds, & Brien, 2000; Korte, 2001; Laakso et al., 2000, 2001; Walsh & Emerich, 1988).

Early malnutrition results in decreased serotonergic innervation to the hippocampus due to decreased projections from the median raphe nucleus (Morgane et al., 2002). However, as noted previously, early malnutrition results in increased serotonin release within the hippocampal formation proper. The authors propose the disruption in input and local neurotransmitter concentration within the hippocampus leads to increased GABAergic activity in select inner neurons (Chang et al., 2003; Mokler et al., 2003; Morgane et al., 2002). Subsequently, this results in more inhibition of certain hippocampal regions, thereby potentially affecting information outflow and integration (Morgane et al., 2002).

Malnutrition results in deficits in long-term potentiation (LTP; Jordan & Clark, 1983), which is considered a candidate mechanism for learning and memory processes (Bliss & Collingridge, 1993; Kandel & Schwartz, 1982; Martin & Morris, 2002). Early PEM also effects LTP within the entorhinal cortex and decreases release of brain derived neurotrophic factor within the CA1 region of the hippocampus (Hernández et al. 2008). Other studies suggest perturbations of hippocampal inhibitory mechanisms produce asynchronous activity of neuronal networks—potentially leading to decreased hippocampal plasticity (Morgane et al., 1993). Jordan and collaborators suggested that malnutrition induces changes at the level of hippocampal synapses (Jordan, Howel, McNaughton, & Heatli.e., 1982). A recent study by Matos and colleagues (2011) found that a history of early malnutrition in a rodent model resulted in impaired cell proliferation in the dentate gyrus of the hippocampus. Early malnutrition appears to disturb hippocampal function through a variety of mechanisms (Morgane et al., 2002).

Early PEM is associated with a reduction in dendritic spine density and with abnormal spine morphology in the hippocampus, cerebral cortex, and cerebellum (Benítez-Bribiesca, De la Rosa-Alvarez, & Mansilla-Olivares, 1999; Fiala, Spacek, & Harris, 2002). A dendritic spine is a plastic structure frequently found in the cortex and is thought to play an important role in stimulus encoding and information processing (Bonhoeffer & Yuste, 2002; Coss & Perkel, 1985; Fiala et al., 2002; Segal, 2001; Whitford et al., 2002). Malnutrition may result in anomalies of spine number and shape of pyramidal cells within cortical layers three and five and CA3 region of the hippocampus and of granule neurons within the dentate gyrus (Fiala et al., 2002). Cerebellar granule cells, Purkinje cell spines, and giant spines are reduced in early malnutrition (Fiala et al., 2002). These findings are important because research indicates dendritic spine abnormalities exist in conditions such as mental retardation (Fiala et al., 2002).

The previous discussion supports the assertion that early malnutrition can result in distinct changes in brain neurochemistry and delicate morphology (Almeida et al., 1996; Fiala et al., 2002). However, the process of brain development is likely significantly protected (through various homeostatic and placental mechanisms) from many harmful environmental influences. This being said, the developing organism can only compensate so much before long-term changes in the chemical composition or structural organization of the developing brain result. The precise nature and extent of these changes may vary between individuals, although some general patterns (e.g., elevation of neurotransmitter concentrations and pathological dendritic spine formation) likely exist.

Although specific pathological mechanisms explaining behavioral changes are unclear, developmental alterations of neurochemistry, neurophysiology, and brain morphology resulting from early malnutrition implicate candidate mechanisms that could account for behavioral deficits. Research indicates that chronic changes in various neurotransmitter systems can affect levels of growth factors, gene expression, functioning of other transmitter systems, and the ability to acquire certain types of learning (Dudman et al., 2003; Kesslak, Chuang, & Berchtold, 2003; O'Donnell, Stemmelin, Nitta, Brouillette, & Quirion,

2003; Paule et al., 2003). Researchers have identified all of these factors as necessary components of typical central nervous system development (Acampora, Gulisano, & Simeone, 1999; Bar & Goffinet, 1999; Black, 1998; Cirulli, Berry, & Alleva, 2003; Cowan, 1998; Lyons et al., 1999; Nelson, 2000b; Rutter & O'Connor, 2004; van Kesteren & Spencer, 2003). Therefore, significant or persistent dysfunctions in these systems (secondary to early malnutrition) may contribute to abnormal neurological development. Work by Gietzen and others reveals that reductions of specific amino acids result in altered gene expression and changes within various neurotransmitter systems (Blevins, Teh, Wang, & Gietzen, 2003; Gietzen & Magrum, 2001; Gietzen, Ross, Hao, & Sharp, 2004; Jousse et al., 2004; Truong, Magrum, & Gietzen, 2002). These cascading effects provide a plausible mechanism for the effect of macronutrient malnutrition on neurobiology and behavior—i.e., malnutrition causes decreases in important neurotransmitter systems, thus resulting in changes in growth factor concentration and in gene expression, eventually leading to modifications of behavior.

The discussion here has focused on generalized caloric restriction/macronutrient deficiency. The reason for this emphasis is practical in that this is where many researchers have concentrated their efforts. However, as noted in the introduction, certain micronutrient deficiencies are associated with deviant brain development. Therefore, although little research exists directly linking specific micronutrient deficiencies to psychopathological outcomes, it is important to review briefly some of the extant research concerning the effect of specific micronutrient deficiencies on brain development.

Early Life Micronutrient Undernutrition

As stated previously, it is common for deficits in micronutrients to accompany generalized protein energy undernutrition (Gorman, 1995; Kretchmer et al., 1996); conversely, it is possible to have deficits in specific micronutrients without concomitant caloric or protein restriction (Brozek, 1990; Georgieff & Rao, 2001; Fuglestad et al., 2008). The latter scenario is more common in developed versus developing countries (Brown et al., 1996). As discussed already, Brown and colleagues (1996) postulated deficiencies in specific micronutrients (such as folate) more fully explain the findings within the Dutch hunger winter cohort. Numerous studies have repeatedly allied early deficits of iron, zinc, and iodine with aberrant brain development and decreased cognitive skills—thus this brief discussion focuses on these elements (Georgieff & Rao, 2001; Kretchmer et al., 1996; Wachs et al., 2013; Yi-Ming, 1996).

Some studies have stressed the necessity of adequate levels of other micronutrients (such as vitamin B-6, selenium, manganese, copper, and choline) for proper neuronal development; however, they have been studied less extensively, especially with regard to human brain development and cognition (Castano et al., 1997; Craciunescu, Albright, Mar, Song, & Zeisel, 2003; Fisher, Zeisel, Mar, & Sadler, 2002; Fuglestad et al., 2008; Groziak & Kirksey, 1990; Guilarte, 1989, 1993; Keen et al., 1999; McCullough et al., 1990; Prohaska, 2000; Watanabe & Satoh, 1994; Yi-Ming, 1996; Zeisel, 2000). However, several studies have linked decreased periconceptional folate concentration to the development of neural tube defects in the progeny of some individuals (Czeizel & Dudas, 1992; Hibbard & Smithells, 1965). Brown et al. (1996) conjectured an association between prenatal folate deficiency and the development of schizophrenia. Furthermore, investigators have observed lower folate levels in depressed adults, but the etiology or significance of these reductions (i.e., if they represent a symptom or contributor to depression) is unknown (Alpert & Fava, 1997).

Iron

Iron deficiency is one of the most common forms of undernutrition in the world (Lozoff, 1989). Its postnatal cause is chronic undernutrition or consumption of foods low in dietary iron combined with loss of gastrointestinal blood (which contains iron) due to intestinal infestations. This etiology is found primarily in developing countries. Neonatal iron deficiency is also caused by maternal gestational iron deficiency, usually found in developing countries and by conditions such as maternal diabetes or IUGR in developed countries (Georgieff & Rao, 2001; Petry et al., 1992; Siddappa et al., 2007). A significant body of work has connected early iron deficiency (ID) to disturbances in myelination, neurotransmitter systems, metabolism, and hippocampal morphological development (Beard, 2003; DeUngria et al., 2000; Jorgenson, Wobken, & Georgieff, 2003; Kwik-Uribe, Gietzen, German, Golub, & Keen, 2000; Lozoff, 1989; Lozoff & Georgieff, 2006; Roncagliolo, Garrido, Rao, Tkac, Townsend, Gruetter, & Georgieff, 2003; Walter, Peirano, & Lozoff, 1998).

Furthermore, behavioral studies with animals have shown perinatal ID results in impaired performance of hippocampally dependent tasks, lower environmental reactivity, and decreased motor skills (Carlson, et al., 2010; Felt & Lozoff, 1996; Schmidt, Waldow, Salinas, & Georgieff, 2007). Studies conducted with ID infants and

children have revealed deficits in motor skills, sensory processing, recognition memory, visuospatial abilities, language skills, inhibitory control, set-shifting, planning, attention, and academic performance—some of which may persist after iron repletion (Lozoff et al., 2003; Lozoff, Jimenez, Hagen, Mollen, & Wolf, 2000; Lukowski et al. 2010; Nelson, Wewerka, Borscheid, DeRegnier, & Georgieff, 2003; Roncagliolo et al., 1998; Stoltzfus et al., 2001). Lozoff and colleagues (2003) demonstrate that ID children are less socially interactive, display more inefficient information processing, and exhibit reduced activity in their physical environment. Thus, they propose ID infants are less likely to receive sufficient environmental stimulation (Lozoff et al., 2003).

There is well documented evidence that ID in children has a significant influence on cognitive development and intelligence, however there are more recent associations with ID and childhood and adolescent-onset psychiatric disorders. It has been postulated that the alterations in monoamine transmitters and abnormal myelination associated with ID may be related to several psychiatric disorders (Chen et al. 2013). Numerous studies have reported the association of iron deficiency anemia (IDA) with unipolar depressive disorder (Bodnar et al. 2005; Yi et al. 2011; Lozoff et al. 2000). In a longitudinal cohort study of 191 participants, those with IDA in infancy exhibited more depression, anxiety, social problems, and attentional problems later in life (Lozoff et al. 2000; Lukowski et al. 2010). Results of a study of 192 female medical students found the mean ferritin was significantly lower in students with depression than in healthy students (Sharitpanaahi et al., 2007).

Although studies of iron deficiency and the pathophysiology of ADHD, autism, and schizophrenia have been somewhat inconsistent, there have been several important associations demonstrated. Cortese et al. used magnetic resonance imaging to demonstrate that children with ADHD had significantly lower brain iron levels in the thalamus compared to healthy controls (Cortese et al., 2008). An increased risk of ADHD in ID was also shown in a meta-analysis by Tan et al. in 2011. In a study of 96 children with autism spectrum disorder (ASD) by Latif et al., there was an increased prevalence of ID as analyzed by serum ferritin in children with ASD. Up to 30 percent of the children with ASD had significant ID (Latif et al., 2002). Insel et al. studied a population-based cohort born from 1959–1967 and identified that maternal iron deficiency may be a risk factor for schizophrenia spectrum disorders among offspring in adulthood (Insel et al., 2008). Another population-based study in Denmark has identified a similar increased risk of schizophrenia spectrum disorder with maternal iron deficiency (Sorensen et al., 2011). All of these research studies support the emerging evidence that iron deficiency early in life may lead to long-lasting neural and behavioral changes in children.

Iron has been documented to be important in socio-emotional development and therefore ID may lead to alterations in the development of emotion regulation. Mechanisms for ID leading to emotion dysregulation were reported by Phillips et al. (2006) and Stein et al. (2009). Due to ID induced changes in the dorsal and ventral prefrontal cortices, the limbic circuitry, and the hippocampus, ID has been plausibly associated with bipolar disorder, anxiety disorder, and tic disorders. Again in the Lozoff cohort, 25 year follow up demonstrated a direct path for chronic iron deficiency and more detachment and dissociation as adults (Lozoff et al., 2013). Although direct causality between IDA and psychiatric disorders is difficult to prove, the repeated associations identified in these studies warrants further investigation into causality and comorbid effects of ID and psychiatric disorders.

Iodine

Iodine is a necessary for maintaining adequate brain thyroid status. In the late 1990s, estimates indicated that approximately one billion people in the world were at risk for iodine deficiency (Yi-Ming, 1996). Severe maternal iodine deficiency in the preconception period (usually attributed to hypothyroidism) is associated with the development of severe mental retardation secondary to endemic cretinism (Pharoah et al., 1971). Moreover, moderately iodine deficient children display minor (but significant) increases in reaction time and decrements on neuropsychological measures of verbal information processing, attention, and visual-motor integration (Fenzi et al., 1990; Lombardi et al., 1995). These studies suggested that the differences were time-limited and amenable to amelioration with iodine therapy. Additionally, periconceptional injection of iodized oil in at risk populations is effective in attenuating the incidence of endemic cretinism and subsequent mental retardation (Pharoah et al., 1971). Conversely, prolonged childhood iodine deficiency may lead to lower achievement motivation and decreased learning speed, both of which become more striking with increasing age (Tiwari, Godbole, Chattopadhyay, Mandal, & Mithal, 1996). Again, no investigations have specifically examined any possible connections between early iodine deficiency and the development of mental illness (with the well-established connection between maternal iodine deficiency and mental retardation being the exception).

Zinc

Zinc is an important component of many enzyme systems and has been localized to presynaptic vesicles within limbic and cortical regions of the brain (Frederickson & Danscher, 1990; Johnson, 2001; Tuormaa, 1995). Zinc deficiency is associated with growth retardation and impaired hippocampal functioning (Sandstead et al., 1998; Tuormaa, 1995). Zinc is also critical for axonal transport and proliferation during neuronal development (Tuormaa, 1995). Animals made zinc deficient early in gestation commonly experience fetal reabsorption or spontaneous abortion (Tuormaa, 1995). Zinc deficiency in latter gestation or lactation results in decreased forebrain and hippocampal size as well as reductions in total cell numbers (Duamah & Russell, 1984; Tuormaa, 1995).

Some researchers have linked zinc deficiency to increased hyperactivity, apathy, lethargy, sleep problems, poor appetite, aggression, and irritability (Tuormaa, 1995). Others have hypothesized that maternal zinc deficiency during gestation results in permanent alterations of neurological development, which may eventually manifest as psychiatric or neurological conditions (such as schizophrenia, autism, epilepsy, and Parkinson's disease) (Johnson, 2001). Lower serum zinc levels have been demonstrated in unipolar depression (Maes et al., 1994; Manser et al., 1989; Nowak et al., 2005). The severity depression has been negatively correlated with the serum level of the zinc ion as well (Nowak et al., 1999, 2005; Schlegel-Zawadzka et al., 2000). Despite the potential seriousness of zinc deficiency, a study by Sandstead and colleagues (1998) reported that zinc-deficient children showed improved neuropsychological test performance after 10 weeks of zinc supplementation, leaving open the possibility of successful zinc rehabilitation.

Summary of Micronutrient Deficiencies

Overall, data indicate that specific micronutrient deficiencies can affect brain growth, cognitive development, and behavior. Nevertheless, adequate experiments explaining how deficits in these specific micronutrients result in the development of psychopathology (with the exception of mental retardation) have not been conducted. Examples of this approach would include DNA microarray, proteomic, and metabolomic assessments of targeted brain regions or processes (e.g., myelination, migration) following specific timed nutrient deficiencies. The expectation would be to identify genes and gene products that mediate neuronal form and function. For example, studies investigating the hypothesized connection between prenatal folate deficiency, potential migration defects, and the later development of schizophrenia could be addressed using such an approach. Studies of this kind are particularly important, given the significant number of individuals (in both developed and developing countries) affected by early micronutrient deficiencies, both apart from and in combination with generalized malnutrition.

FUTURE DIRECTIONS

A major issue that future research should specifically address is the significance (i.e., magnitude of the effect) of malnutrition in the development of psychopathology. Thus, does early malnutrition independently increase the risk for the development of psychopathology, or is it merely one of many important factors that when combined have a deleterious effect? Similarly, the developmental psychopathology constructs of equifinality (i.e., different developmental pathways leading to the same outcome) and multifinality (i.e., the same precipitating event resulting in numerous developmental trajectories) need to be explored with regards to early malnutrition (Cicchetti & Toth, 2009). For example, it is possible that individuals exposed early in life to less than ideal nutritional circumstances may have different psychopathological or resilient outcomes depending on their genetic predispositions, rearing environments, or level of nutritional supplementation (multifinality). Alternatively, the same psychopathological outcomes could be contributed to by more than one type of nutritional deficiency (equifinality).

Explaining how early malnutrition exerts negative effects on the developing nervous system is also a critical direction for future investigations. Possible neuropathogenic mechanisms of early malnutrition can be broken down into direct and indirect effects. Direct effects refer to those that are the primary result of malnutrition and are considered to underlie the subsequent pathology (e.g., disrupted neurotransmitter function, brain morphology, or myelination). These primary effects could potentially work through direct nutrient contact with DNA promoter regions (as seen with zinc) or at any other post-transcriptional regulatory sites. Indirect effects refer to effects that may potentiate other pathological processes or conditions associated with a pernicious outcome, for example where the nutrient deficiency affects pregnancy integrity, maternal stress levels, or maternal parenting style. Other indirect effects could occur through nutrient deficiency effects on metabolism that in turn influence fetal programming of brain development. It should be noted

that none of the aforementioned mechanisms has been irrefutably linked to the development of psychopathology. They are merely presented here as possibilities to be considered; however, investigating all of these potential mechanisms would be fruitful grounds for future scientific inquiry.

Future research will need to take the knowledge gained at the regulatory level and apply it to physiologic studies at the systems level. For example, many studies have associated disturbances in various neurotransmitter systems (e.g., monoamenergic and glutamatergic) with psychiatric disorders including schizophrenia, depression, and anxiety (Fishbein & Pease, 1994; Kaufman et al., 2000; Konradi & Heckers, 2003). Furthermore, evidence indicates that early malnutrition (or deficiencies in micronutrients such as iron) results in alterations in the development and eventual functioning of certain neurotransmitter systems (Hernandez-Rodriguez & Manjarrez-Gutierrez, 2001; Manjarrez et al., 2003; Tran et al., 2013; Unger et al., 2012). Although it is difficult to speculate on a specific causative mechanism, prolonged increases in neurotransmitter concentrations yielding diminished receptor density or augmented neurotransmitter uptake may significantly alter the neurochemical milieu affecting the functioning of the entire nervous system (Almeida et al., 1996; Pisansky et al., 2013; Wauben & Wainwright, 1999). Additionally, some have postulated neurotransmitter systems interact with each other during development (Benes et al., 2000). Thus, perturbations in one system due to malnutrition may affect the developmental course of other systems (Wauben & Wainwright, 1999). For example, researchers have conjectured that changes within the glutamate, GABA, and norepinephrine systems interact with and contribute to the disregulation of the dopamine system observed in schizophrenia (Friedman, Temporini, & Davis, 1999; Goldman-Rakic & Selemon, 1997; Laruelle, Kegeles, & Abi-Dargham, 2003; Syvalahti, 1994). In addition, dysregulation of certain neurotransmitter systems may adversely affect dendrite formation, gene expression, and neurophysiological functioning all of which would be appropriate avenues to explore in animal models and in human neuroimaging studies (Gietzen et al., 2004; Jousse et al., 2004; Ma et al., 2000; van Kesteren & Spencer, 2003).

The hypothesized relationship between malnutrition and hippocampal dysfunction and between hippocampal dysfunction and psychopathology suggests that this circuit plays a role in the emergence of psychopathology following early nutritional deficits (Pisansky et al., 2013). As highlighted previously, researchers have connected early deficits of protein/protein energy, iron, or zinc to hippocampal malformation and dysfunction (DeUngria et al., 2000; Jorgenson et al., 2003; Morgane et al., 2002; Schmidt et al., 2007; Tuormaa, 1995). This specific brain structure is noteworthy because it has been implicated in various types of psychopathology including schizophrenia, alcohol abuse, antisocial behavior, and anxiety/depression (Brown, Rush, & McEwen, 1999; De Bellis et al., 2000; Heckers et al., 1998; Heim & Nemeroff, 1999, 2001; Korbo, 1999; Korte, 2001; Laakso et al., 2000, 2001; Rajkowska, 2000). However, it is not known whether the hippocampus plays a direct causal role, if it modulates other structures involved in the pathogenesis of the disorder (e.g., frontal lobe structures), or if disruption in this region represents more generalized brain atrophy (Graham, Heim, Goodman, Miller, & Nemeroff, 1999). Moreover, it is possible that although affected, the hippocampus itself is not the crucial contributor to a deviant behavioral outcome. Rather, it is possible that hippocampal dysfunction disrupts projections to/from other brain structures thus deranging the functioning of a wider cortical network (Pisansky et al., 2013).

Another effect of early nutritional deficits (specifically resulting from iron deficiency and essential fatty acid deficiency) is disrupted myelination (Kwik-Uribe et al., 2000; Roncagliolo et al., 1998). This is of note because researchers have reported the occurrence of aberrant white matter structures in various psychiatric disorders (e.g., schizophrenia, mood disorders) (Cotter et al., 2001; Davis et al., 2003; Molnar, Potkin, Bunney, & Jones, 2003; Öngür, Drevets, & Price, 1998). Again, the relationship between the observed white matter abnormalities and the behavioral phenotypes of the disorder are currently unknown; however, they deserve note and future scrutiny because it is conceivable the white matter changes are causally linked to psychopathology (Jones, 1997).

Maternal stress is an example of a more indirect effect that may partly explain the role of malnutrition in the emergence of mental disorders (Monk et al., 2013) and clearly deserves attention from future investigations. For example: more than likely, chronic malnutrition rarely occurs in the absence of significant maternal stress (Gorman, 1995). Therefore, malnutrition could potentiate the effects of maternal stress or vice versa. Moreover, there are clear interactions between stress and nutrition where maternal stress affects who she absorbs and distributes nutrients to the fetus (Monk et al., 2013). The pervasiveness of maternal stress during the Second World War makes it unlikely that this factor alone can account for the pattern of deficits observed in the Dutch famine studies. Nevertheless, maternal stress cannot be ruled out

as a factor contributing (either additively or synergistically) to these findings. Similarly, malnutrition of the child or infant likely occurs along with malnutrition of the mother. Thus, as suggested by the studies of Keys and colleagues (Franklin et al., 1948; Keys, 1946), significant malnutrition affects the psychological functioning of the mother and presumably her ensuing interactions with her child. Therefore, some of the consequences observed following malnutrition could partly result from disordered mother-child interactions (Moffitt & Caspi, 2001). The magnitude of the effects on maternal-child and maternal-fetal interactions—independent of other environmental/biological influences—remains unclear but deserves greater scrutiny by researchers (Moffitt & Caspi, 2001; Monk et al., 2013). However, if the maternal behavior is severely abusive or pathological to the point of being unable to provide the minimal physical, perceptual, and social stimulation required for normal brain development, then a deviant outcome compounded by malnutrition is likely (Guesry, 1998; Jaffee, Caspi, Moffitt, & Taylor, 2004; Raine, Brennan, & Mednich, 1994, 1997; Stein & Susser, 1985; Tully, Arseneault, Caspi, Moffitt, & Morgan, 2004).

The Developmental Origins of Adult Health and Disease (DOHaD) theory states that early intrauterine environment programs the fetus in gestation (Barker, 2001). This mechanism is regarded as an adaptive response helping the fetus to react during gestation to particular stressors such as malnutrition (Barker, 2001; Oliver et al., 1999; Seckl, 1998). This theory argues that these adaptive changes become liabilities when the environmental challenge is no longer present (Barker, 2001; Oliver et al., 1999; Seckl, 1998; Gluckman and Hanson, 2004). Barker and colleagues have invoked this fetal programming hypothesis to explain the relationship between retarded intrauterine growth and the later development of coronary heart disease (Barker, Forsén, Utela, Osmond, & Eriksson, 2001). More recently, researchers have used the fetal programming hypothesis to explain their findings of a link between fetal undernutrition and the later development of depression (Thompson et al., 2001) and reduced cognition (Pylipow et al., 2009). Thus, fetal programming in response to malnutrition could account for many of the descriptive findings regarding prenatal undernutrition; however, a precise mechanism for these alterations is still unknown (Seckl, 1998).

Another potential indirect effect connecting early malnutrition to the development of psychopathology is the decreased cognitive abilities observed in numerous studies. As discussed already, research indicates postnatal malnutrition can result in long-term reduction of intellectual abilities and cognitive skills (e.g., attention) (Galler & Ramsey, 1987, 1989; Galler et al., 1986). These findings are important because intellectual ability measures obtained in middle childhood are highly stable into later life (Deary, Whalley, Lemmon, Crawford, & Starr, 2000; Deary, Whiteman, Starr, Whalley, & Fox, 2004). Other research indicates that low intelligence is an independent predictor of lifetime psychiatric contact in that lower intellectual capacity results in a significantly increased risk for developing psychiatric difficulties including conduct problems and antisocial behavior (Moffitt, Gabrielli, Mednick, & Schulsinger, 1981; Walker, McConville, Hunter, Deary, & Whalley, 2002).

Jacobs and others (2002) found that although childhood cognitive ability and childhood psychopathology are predicted by independent genetic factors, a third genetic factor along with (unspecified) non-shared environmental factors predicts both. Thus, if postnatal malnutrition results in decreases in IQ sustained through middle childhood, these are likely permanent and may in turn lead to increased psychiatric contact. These results may be subtle and relatively small on the individual level. However, slight perturbations in the population IQ will greatly impact the number of individuals classified as mentally retarded and requiring social support services, thus increasing the financial cost to society (Tanner & Finn-Stevenson, 2002). Moreover, reductions in population IQ and specific cognitive skills (such as verbal reasoning) may increase the number of individuals requiring psychiatric support services and engaging in impulsive/delinquent behaviors (Arseneault, Moffitt, Caspi, Taylor, & Silva, 2000; Moffitt et al., 1981; Stevens, Kaplan, & Bauer, 2001; Stevens, Kaplan, & Hesselbrock, 2003).

Finally, early nutritional deficits may make an individual more vulnerable to insults (e.g., hypoxia) that are associated with the development of psychopathology (McNeil et al., 2000; Zornberg et al., 2000). Rao et al. (1999) provided some evidence for this hypothesis by showing prenatally iron deficient juvenile animals sustained more damage to the hippocampus following a hypoxic ischemic insult. Moreover, Fechner and colleagues showed that children admitted to hospital suffering from kwashiorkor exhibited decreased plasma antioxidant levels (Fechner et al., 2001). Decreased antioxidant concentrations likely make these children more susceptible to neuronal damage/death after traumatic injuries such as anoxia or hypoxia-ischemia (Buonocore, Perrone, & Bracci, 2001; Zauner, Daugherty, Bullock, & Warner, 2002).

Similarly, compared with well-nourished children, malnourished children are more susceptible to cell damage and exhibit decreased DNA repair following an injury (Gonzalez et al., 2002). Gietzen and colleagues (1996)

observed that rats with essential amino acid deficiencies displayed heightened seizure vulnerability. Furthermore, research suggests maternal zinc deficiency exacerbates the effects of prenatal alcohol exposure (Flynn et al., 1981).

The previous findings suggest that a nervous system already compromised by malnutrition is more vulnerable to additional insults such as toxin exposure or chronic stress. As discussed in the section on neurobiology, there is a potential for malnutrition or any early insult to alter the fundamental organization or structure of the developing brain. While these modifications may prove beneficial in the short-term (e.g., by conserving energy or reallocating resources) they may prove detrimental in the future—possibly by decreasing behavioral or cellular plasticity (Gluckman & Hanson, 2013).

Thus, malnutrition could serve as a catalyst disrupting normal development, but it may not have an enduring effect, unless occurring proximally with another insult. Furthermore, the consequences of early malnutrition may not be revealed until a future stressor tries the plasticity of the system. This model is analogous to the diathesis–stress theory of mental disorders. In this model, undernutrition could be the stress (second injury) whereas the diathesis (initial damage) could stem from a genetic vulnerability or from other already-present environmental risk factors. Conversely, early malnutrition and its effects could be present first, so that a later infection, toxin exposure, or hypoxic/ischemic event would tip the scales toward an undesirable outcome. As discussed in the introduction, another variable to consider in this system is an individual's ability to maintain homeostasis in response to a challenge. This model may explain some of the discrepant findings in the literature. That is, it posits that each individual has his or her own threshold of how much damage via malnutrition (or other environmental insults) he or she can endure before exhibiting an aberrant phenotype. It also hypothesizes that malnutrition exerts its maximal effect if it occurs in the context of an already compromised system. Again, this is merely a hypothesis and it should be rigorously tested (including the formulation of models that strive to describe this threshold in terms of numerical relationships and which factors are the best predictors of eventual outcome).

TRANSLATIONAL IMPLICATIONS

Studying the impact of early nutritional deficiencies is well-suited to a translational approach because of the various environmental and genetic confounds that are best addressed through multiple levels of analysis. The research reviewed supports the hypothesis that time of onset, dose, and duration of nutritional insults and interventions play critical roles in determining the nature and extent of any deficits (Morgane et al., 1993; Pollitt, 1996; Walker et al., 2011). However, what is not known is how much each of these three factors uniquely contributes to the eventual neurobehavioral outcome. The challenge lies in conjecturing plausible and testable mechanisms for these interactions and deriving maximally precise predictions of which factors contribute in which ways to the eventual outcomes.

Disentangling the various issues at the root of this question highlights the importance of a translational approach that incorporates techniques from basic neurobiology, animal behavioral studies, cognitive and brain-imaging studies with children, and longitudinal, epidemiological studies of affected populations. For example, neurobiological models (concerned with cellular and molecular mechanisms) can inform the development of animal models used to understand behavioral and cognitive correlates. These models would be based on extant relationships between form and function in the brain that are conserved across species and would lend themselves to experimental manipulation. Although there are no convincing animal models of psychopathology, animal studies designed to manipulate time of onset, dose, and duration of early malnutrition would help to understand the relative role of these components on neurochemistry, neuroanatomy, and some basic behavioral constructs (e.g., reward/punishment sensitivity, autonomic arousal, inhibitory control). Using neuroimaging and postmortem techniques, these findings could then be extended to human populations, and combined with evolving knowledge of the neurologic basis of psychopathology may provide insight into the relationship between early malnutrition and the development of mental illness.

Further, these basic studies would be complimented by studies on human participants including longitudinal investigations of the impact of nutrient deficiencies (similar to the types of studies that have already been conducted but with more sophisticated measures of cognitive functioning that are based on current models of brain and cognitive development). Studies with child participants should also include statistical models that seek to explain population and subpopulation relationships among environmental factors to help parse the unique contribution of early nutritional deficiencies. Because criteria for the diagnosis of mental disorders is somewhat arbitrary and may be somewhat culturally determined, a possible way of examining this issue across settings may be to investigate more biological markers of mental disorders (such as dexamethasone suppression in depression or reward/punishment

sensitivity in externalizing disorders). Although the specificity and sensitivity of these types of measures is far from perfect, this approach may provide a useful tool for examining the base rate of psychopathology in undernourished populations—where the current diagnostic system may be less effective for determining the presence or absence of a disorder. This type of a multidisciplinary, multiple levels of analysis approach is the essence of developmental psychopathology and appears very timely given the new emphasis on funding studies that examine psychopathology through the lens of basic neurobiological mechanisms (i.e., the Research Domain Criteria initiative from the National Institute of Mental Health in the United States; Morris, Rumsey, & Cuthbert, 2014).

CONCLUDING REMARKS

The research reviewed in this chapter indicates that malnutrition is associated with disturbances in neurotransmitter systems necessary for normal neuronal maturation, morphological changes in delicate brain structures and reductions in brain growth. Functional behavioral disturbances include deficits in cognitive abilities and an increased risk for psychiatric disorders including schizophrenia and other psychopathological conditions such as externalizing behaviors and internalizing difficulties. These form and function effects persist across various models of malnutrition in animal studies and across demographic factors (country of origin and social class) in human investigations. However, the problem of early malnutrition is significant for both developed and developing countries; thus additional research is necessary to better explicate the long-term consequences of this condition.

The question is not whether severe malnutrition (i.e., starvation) leads to adverse outcomes, because it is obvious that beyond a certain threshold of caloric restriction conception becomes unlikely, miscarriage is inevitable, and death eventually results if adequate energy intake is not restored (Coad, Al-Rasasi, & Morgan, 2002; King, 2003; Stein et al., 1972). Rather, the question that future research should address is: given a limited supply of energy, protein, or specific micronutrients, is an individual at an increased risk for developing psychopathology? Complicating the picture, available research suggests generalized malnutrition rarely exists without micronutrient (iron/zinc) deficits, decreased parental intellectual abilities, deficient psychosocial stimulation, chronic childhood illness, or unsanitary living conditions (Guesry, 1998; Ivanovic et al., 2002; Pollitt, 1969; Stein & Susser, 1985). Even in the case of the Dutch hunger winter, the population was not free from significant wartime and famine induced stress. Therefore, it is difficult to discern if there is a unique contribution of early malnutrition to the development of psychopathology, and what, if any, is the relationship between malnutrition and other risk factors (i.e., mediational, additive, or synergistic).

Early malnutrition appears to be a topic very well suited to the field of developmental psychopathology as it easily lends itself to a multidisciplinary, translational approach. That is, to adequately understand and ameliorate the impact of early nutritional deficiencies on development of psychopathology researchers will need to draw from techniques of basic science (neurobiology and biochemistry) as the foundation, translational research (e.g., using animals to model various paradigms of malnutrition), and finally comprehensive human investigations which include measures of motor, perceptual, cognitive, intellectual abilities, and objective measures of personality and psychopathological symptoms. These human studies should also endeavor to match participants (or otherwise statistically control for) potential confounds such as SES, parental education/IQ, familial history of mental illness, toxin exposure, and living circumstances. Although costly and difficult to conduct a human study which could incorporate all of these components, a study of this kind would provide valuable data which could greatly augment our understanding of the long-term effects of early malnutrition and specify how this condition interacts with other risk factors.

The potential for various gene-environment interactions may explain the relative effectiveness of nutritional intervention programs in developing countries compared to the often modest benefits shown by similar endeavors in countries such as the United States (Pollitt, 1996; Grantham-McGregor et al., 2014). That is, in developing countries, the population is likely to be chronically undernourished but may not exhibit elevated rates of psychopathology, and parents might provide a stable home environment. Conversely, in developed countries, individuals at risk for early malnutrition are more likely to have genetic and additional environmental risk factors—increasing their chance of expressing a deviant phenotype (Grantham-McGregor et al., 2014). This is merely a speculation and is not intended to minimize the potential impact of early malnutrition or the need to address this issue, but rather to emphasize the idea that many malnourished children (especially in developed countries) possess other substantial risk factors such as poverty, unstable home environments, deficient psychosocial stimulation, and

genetic propensities, which may complicate intervention efforts. Again, designing efficient, beneficial interventions is another area that future studies should explore. Implementing successful interventions in countries such as the United States will likely entail carefully designed, targeted procedures (e.g., ensuring proper prenatal care and nutrition, encouraging breastfeeding and parental involvement, better parental and childhood nutrition education, proper vaccinations and postnatal nutrition) that begin early and aim to treat the gestalt of the circumstances and not merely a single destructive component of the milieu (Ramey & Ramey, 1998; Wachs et al., 2014).

The study of G-E correlation reflects a central premise in developmental psychopathology—the idea that individuals create their own environments, either by evoking some response from the people around them or by actively selecting certain experiences. Thus, G-E correlations can be thought of as a special case of person–environment correlations, highlighting the fact that the individual characteristics that drive this active construction are partially genetic in origin (Defries & Loehlin, 1977). The process by which individuals elicit certain reactions from others, manipulate their environments, selectively attend to features of their environments, or niche-pick their environments on the basis of personality, abilities, or other individual characteristics is what perpetuates and amplifies individual differences in these phenotypes (Caspi & Moffitt, 1995).

From a developmental psychopathology perspective, this process by which person–environment correlations (and the genetic influences that underlie them) drive development is inherently interesting. G-E correlations are additionally relevant to the study of developmental psychopathology, however, because of their implications for understanding causal processes. The goal of social and clinical science is to understand the causes of normal and abnormal development. Features of the environment, ranging from environmental toxicity to relationships with family members, romantic partners, and peers are hypothesized to be among the causes of multiple disorders. The possibility, however, that G-E correlations confound observed effects of exposures or experiences on outcomes is a major challenge to causal inference (D'Onofrio & Lahey, 2010; Foster, 2010; Rutter, 2007). Our goal in

this chapter is to define genotype–environment correlations and then describe efforts to (1) detect and assess the impact of genotype–environment correlations using adoption and twin designs, (2) describe the implications of genotype–environment correlations for understanding developmental processes, (3) describe the evidence for genotype–environment correlations from molecular genetic studies, and (4) use genotype–environment correlations under certain restrictive conditions to make causal inferences about environmental exposures.

GENOTYPE–ENVIRONMENT CORRELATION: DEFINITIONS

Genotype–environment correlation (rGE) refers to genetic differences in the exposure to a particular environment (Kendler & Eaves, 1986; Plomin, DeFries, & Loehlin, 1977). Genotype can be defined as those features of an organism that are encoded in DNA sequence. Environment is defined as the context in which an individual develops over time, including family, neighborhood, peer, school, and work contexts, among others. *Environment* describes not only structural features of these various contexts (e.g., family structure or the percentage of neighborhood residents living below the poverty threshold) but also process-level features (e.g., the quality of parent–child relationships, the amount of praise or criticism provided by teachers). Thus, like other phenomena that are studied in developmental psychopathology, G-E correlations reflect multiple levels of influence on the developing person, with those influences encompassing on the one hand the genes that get outside the skin to increase (or reduce) exposure to specific experiences and, on the other hand, the reciprocal effect of those experiences on a person's affective, behavioral, or cognitive tendencies. Moreover, the study of G-E correlation in the context of developmental psychopathology crosses disciplinary boundaries, requiring that researchers develop expertise in quantitative or molecular behavioral genetics as well as expertise in social epidemiology, clinical science, and development.

Genotype–environment correlation can arise from the causal effects of genotypes as well as from other processes. For example, natural selection and genetic drift give rise to ancestral differences in genotype both within and between populations. Genetic markers for population ancestry will therefore correlate with any environmental and phenotypic features that vary by ethnic group. For example, exposure to malaria-bearing mosquitos over many generations may have caused the higher allele frequency among individuals of African ancestry for the sickle cell hemoglobin (HbS) allele, a recessive mutation that causes sickle-cell anemia, but confers resistance against malaria (Aidoo et al., 2002). In this way, HbS genotype has become associated with the malarial environment. These spurious associations are particularly common in the presence of recent population admixture, and are a potential source of confounding in genetic association studies.

In terms of causal processes that give rise to genotype–environment correlations, psychologists, and psychiatrists commonly refer to three different categories (Figure 7.1). *Passive genotype–environment correlation* refers to the association between the genotype a child inherits from his or her parents and the environment in which the child is raised. In other words, the existence of passive genotype–environment correlation creates the possibility that observed associations between the child's environment and the child's cognitive, behavioral, or physical outcomes are confounded by the genotype shared by parents and children. For example, because parents who have histories of antisocial behavior (which is moderately heritable) are at elevated risk of abusing their children, maltreatment may be a marker for genetic risk that parents transmit to children rather than a causal risk factor for children's conduct problems (DiLalla & Gottesman, 1991; Eaves, Prom, & Silberg, 2010). As another example, reading aloud to young children may be predictive of children's verbal ability because children inherit this capacity from verbally adept parents who tend to enjoy reading to children and have the time to do it.

Evocative (or reactive) genotype–environment correlation refers to the process by which an individual's genotype evokes or elicits some response from the environment. Evocative genotype–environment correlations tend to be behaviorally mediated, meaning that genotype influences an individual's behavior and the behavior is what generates a reaction from others with whom the individual interacts (Jaffee & Price, 2007). For example, although arguing with a spouse may cause someone to become depressed, it is equally plausible that individuals who are highly neurotic and prone to depression tend to provoke arguments with significant others (or other stressful life events), calling into question the direction of the effect (Kendler & Gardner, 2010). In other words, evocative genotype–environment correlations are evidence of heritable person effects on the behavior of others in their milieu.

Active (or selective) genotype–environment correlation refers to the association between an individual's genetic propensities and the environmental niches that individual selects. In other words, active genotype–environment

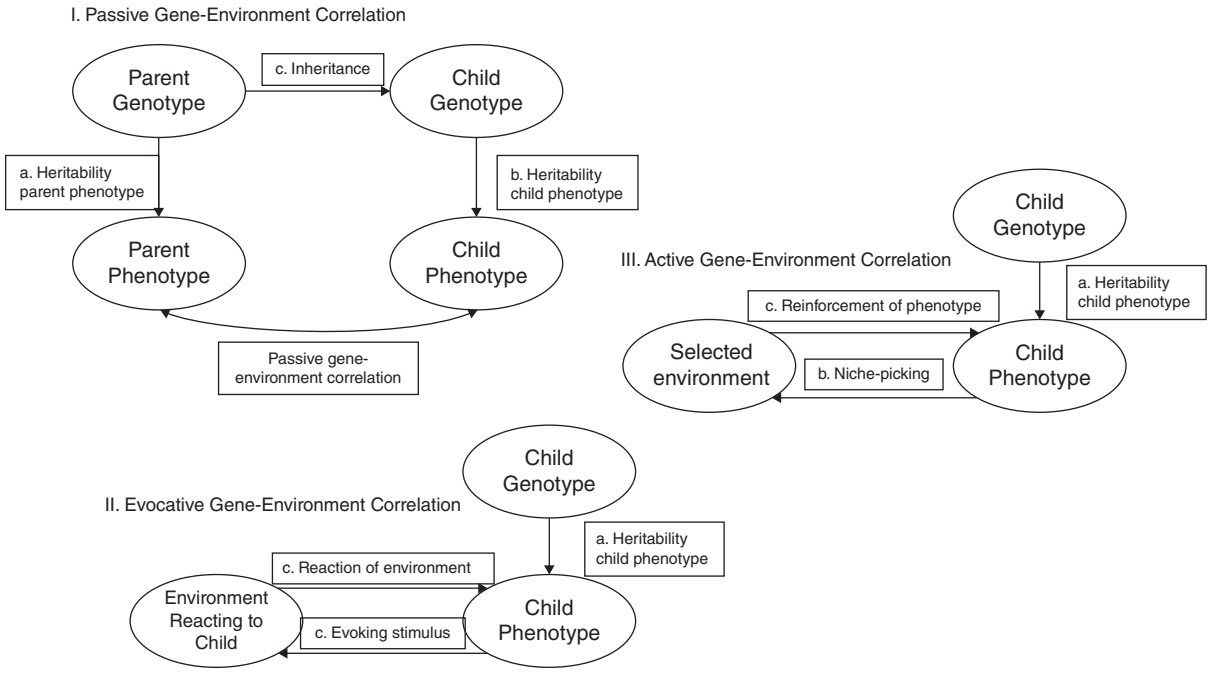

Figure 7.1 Passive, evocative, and active genotype–environment correlations.

correlations are evidence of heritable person effects on the environment due to the person's own actions. For example, individuals who have a genetically based proclivity for antisocial behavior may be especially likely to seek out a delinquent peer group (Kendler, Jacobson, Myers, & Eaves, 2008).

Genotype–environment correlations are often posed as alternatives to causal accounts of the relationships between exposures and outcomes. Indeed, the literature on genotype–environment correlations has led some researchers to conclude that children mainly turn out the way they do because of the genes they have inherited and not because of how they have been socialized by parents or teachers (Harris, 1995). On the one hand, most behavioral geneticists would agree that the existence of genotype–environment correlations undermines a large literature that made causal claims about the importance of parental socialization based largely on correlations between parenting behavior and child behavior (Turkheimer, 2000). On the other hand, most behavioral geneticists also recognize that development is an inherently transactional process between individuals and their environments. That is, even if a parent's use of harsh and coercive discipline is initially a response to a temperamentally difficult child, there is every reason to believe (based on longitudinal data, quasi-experimental data, and data from randomized control trials) that harsh and coercive discipline will amplify preexisting tendencies to engage in antisocial behavior (Jaffee, Strait, & Odgers, 2012; Patterson, DeBaryshe, & Ramsey, 1989).

These forms of genotype–environment correlation differ from gene–environment interaction (GxE), which refers to genetic differences in sensitivity to particular environmental effects (Kendler & Eaves, 1986). Genotype–environment correlations explain why individuals who have a genetic propensity to engage in sensation-seeking behaviors affiliate with drug-abusing peers (Yanovitzky, 2006). GxE explains why heavy drug use is most likely to lead to psychosis only among individuals with a particular genotype (Caspi et al., 2005).

It bears noting that passive, evocative, and active genotype–environment correlations are special cases of more general phenomena in developmental psychology and psychopathology. For example, passive genotype–environment correlations are a specific case of unobserved heterogeneity, in which genes common to parents and children potentially generate spurious associations between exposures and child outcomes. Evocative genotype–environment correlations imply that an individual's behavior actively shapes his or her environment—a process that was described by Bell (1968) in the context of socialization research and was a key tenet of Piagetian theories of cognitive development (Flavell, 1996). The behavioral genetics perspective simply emphasizes

that the behaviors that may evoke specific reactions from the environment have a genetic basis. Finally, active genotype–environment correlations imply that individuals consciously or unconsciously seek specific experiences that are congruent with their genetically based proclivities. Again, this echoes processes of selection and niche picking articulated by life span developmental theories (Elder, 1998), but highlights the genetic basis of the traits driving the selection process.

Evidence for G-E correlations from adoption and twin studies is described in the following two sections. This chapter also describes the strengths and limitations of these designs for (1) detecting G-E correlations and (2) determining the extent to which G-E correlations may account for observed associations between experiences or exposures and measures of emotional or behavioral health. Then it also describes the implications of G-E correlation for understanding developmental process, and evidence for correlations between measured genotypes and measured environments. Finally, it describes efforts to leverage G-E correlations to make stronger causal inferences, concluding with a summary of findings.

GENOTYPE–ENVIRONMENT CORRELATIONS: EVIDENCE FROM ADOPTION STUDIES

Adoption studies are directly informative about the existence of passive genotype–environment correlations. This is because adoptive parents create the environment in which their adopted child is raised, but they are genetically unrelated to their child. In contrast, when parents and their children are biologically related, parents not only create their child's rearing environment, but they also provide their child's genotype. If, for example, an authoritative parenting style is correlated with a child's prosocial behavior, this could reflect at least one of three things. First, it could reflect an effect of the parent on the child, which is how the correlation is often interpreted—parents who are warm, who set consistent, fair, and age-appropriate limits on children's behavior, and who give children age-appropriate levels of autonomy promote (in a causal fashion) the development of prosocial behavior. Second, it could reflect an effect of the child on the parent. Children who are cooperative, empathic, and compliant are more likely to be granted autonomy and to be treated with warmth than are children who are uncooperative, unempathetic, and noncompliant. Third, it could reflect a genetic effect, wherein authoritative parenting style is a marker for a genetic propensity to engage in prosocial behavior that parents transmit to children—that is, a passive genotype–environment correlation. In families where parents and children are *not* biologically related (e.g., adoptive families), any observed association between authoritative parenting and children's prosocial behavior could reflect a parent effect or a child effect, but it could not reflect a passive genotype–environment correlation. If passive G-E correlations (or any other form of G-E correlation) are present, we refer to the association between the exposure and the outcome as genetically mediated in the sense that genes shared by the parent and child account for the observed association. If passive G-E correlations are not present, we refer to the association between the exposure and outcome as "environmentally mediated," recognizing that this does not necessarily mean the exposure has direct effects on the outcome.

When some information is known about an adopted child's biological parents, the adoption design can also be used to identify evocative genotype–environment correlations. In this case, information about the biological parent's mental health or behavior is used as a proxy measure of genetic risk that the adopted child has inherited. To the extent that the child's genetic risk is correlated with how she or he is parented, this is indicative of an evocative genotype–environment correlation. For example, the most parsimonious explanation for why adoptive parents would more frequently use coercive discipline with one child whose biological mother was in prison for assault than with another child whose mother lacked a criminal background is that the first child inherited a genetic predisposition to engage in noncompliant or aggressive behavior and the adoptive parents are responding to this antisocial behavior. Of course it is equally possible that differences in the prenatal environment provided by mothers with versus without a criminal history could account for differences in their children's behavior.

Adoption Studies of Passive rGE

The adoption design has been used to test whether passive genotype–environment correlation accounts for associations between children's behavior and a range of parenting behaviors and family characteristics, including parental divorce or marital conflict, parental psychopathology, and mothers' behavior during pregnancy.

Does Passive rGE Account for Effects of Parental Divorce or Interparental Conflict on Offspring Outcomes?

There is a large literature showing that the children of divorced parents have elevated rates of antisocial behavior

(Emery, 1999), although effect sizes are modest in magnitude (Amato, 2001). Parents who divorce are more likely to have engaged in antisocial behavior in their youth and to engage in antisocial behavior in adulthood compared with parents who do not divorce (Emery, Waldron, Kitzmann, & Aaron, 1999; Fomby & Cherlin, 2007; Lahey et al., 1988) and antisocial behavior is moderately heritable (Rhee & Waldman, 2002). Thus, although the association between divorce and children's antisocial behavior could be causal, divorce could also be a marker for genetic risk for antisocial behavior that parents transmit to children.

Burt et al. (2008) tested whether passive genotype–environment correlations could account for the association between parental divorce and children's behavior using data from a sample of adoptive and nonadoptive families. Consistent with a causal effect of divorce, they found that regardless of whether parents and children were biologically related, children whose parents were divorced engaged in higher levels of antisocial behavior than children whose parents were not divorced. Moreover, children had to have experienced the divorce in order for it to have the predicted effect. Children being raised by two parents, one or both of whom had previously been divorced, had no more behavior problems than children whose parents had never been divorced. Although another study only identified the expected behavioral differences between children from divorced versus intact families if parents and children were biologically related (i.e., consistent with passive G-E correlation), this study included relatively few children who were adopted and whose adoptive parents subsequently divorced (O'Connor, Caspi, DeFries, & Plomin, 2000).

Some adoption studies have shown that interparental conflict is associated with (adoptive) offspring behavior problems and have attempted to identify factors within the family that mediate the association. For example, toddlers engage in relatively high levels of aggressive behavior (Stover et al., 2012) and have more sleep problems (Rhoades et al., 2012) if their adoptive parents' relationship with each other is characterized by relatively high levels of physically and verbally hostile behavior. One reason for this is that parents who are physically and verbally hostile toward each other tend also to be physically and verbally hostile toward their children (Harold, Leve, Elam, et al., 2013; Rhoades et al., 2012; Stover et al., 2012). This pathway from marital hostility to hostile parenting to offspring antisocial behavior problems has also been observed in studies where the inclusion of mothers and fathers who used *in vitro* fertilization technologies (e.g., egg or sperm donation) means that some parents may not be genetically related to the child they are raising (Harold, Elam, Lewis, Rice, & Thapar, 2012).

Does Passive rGE Account for Effects of Parent–Child Conflict on Offspring Outcomes?

Parent–child conflict is characterized by parental criticism of children and frequent arguments between parents and children. Although children and adolescents who have conflictual relationships with parents are at elevated risk for antisocial behavior problems, parent–child conflict, like interparental conflict, could be a marker for genetic risk for antisocial behavior that parents transmit to children. Adoption studies rule out this alternative explanation, however. The association between conflictual parent–child relationships and offspring antisocial behavior is observed both cross sectionally in samples of adoptees and their parents (Klahr, Rueter, McGue, Iacono, & Burt, 2011) and longitudinally (Harold, Leve, Elam, et al., 2013). The association has been observed into young adulthood, where relatively higher levels of conflict between youth and their adoptive parents in early adolescence were predictive of relatively higher levels of conduct problems approximately 4 years later, but early adolescent conduct problems were not predictive of later parent–child conflict (Burt, Klahr, Rueter, McGue, & Iacono, 2011; Klahr, McGue, Iacono, & Burt, 2011). Not only do these results indicate that the relationship between parent–child conflict and child conduct problems is not accounted for by passive G-E correlations, but—given the lack of evidence for child effects on parent–child conflict—they also indicate that the relationship is unlikely to be accounted for by evocative G-E correlations.

Does Passive rGE Account for the Effect of Cumulative Adversity on Child Functioning?

Although most researchers test for passive G-E correlation one risk exposure at a time, psychosocial and physical risk exposures tend to be correlated (Evans, 2004). In developmental psychology and developmental psychopathology research more broadly, it is common for researchers to generate cumulative risk indices instead of focusing on specific risk exposures (Evans, Li, & Whipple, 2013). The concern remains, however, that measures of cumulative risk are markers for genetic risk for psychopathology or other undesirable outcomes that parents transmit to children. These undesirable outcomes may include dysregulation of the stress response system, including the limbic-hypothalamic-pituitary-adrenal axis and its end product cortisol. Individual differences in basal cortisol levels and cortisol reactivity have been associated with

both internalizing and externalizing problems (Gunnar & Vazquez, 2006).

At least one adoption study has shown that cumulative adversity at age 6 years (as indicated by parents' symptoms of depression and anxiety, marital instability, financial need, parents' lack of social support, parents' experience of negative life events, and chaotic family environment) was associated with lower evening cortisol values and less stability in evening cortisol values from age 4.5 to 6 years (Laurent et al., 2014). Thus, although it may be that the association between cumulative risk and cortisol values is accounted for by some unobserved variable, we can rule out the possibility that genetic factors common to parents and children explain the association.

Does Passive rGE Account for the Effect of Parent Psychopathology on Offspring Psychopathology?

There is substantial intergenerational continuity in psychopathology and adoption studies can be informative about the extent to which this reflects environmentally versus genetically mediated pathways. On the one hand, several studies from one sample of adoptive families have shown that even controlling for the biological mothers' symptomatology, adoptive mothers' ADHD symptomatology predicted their children's ADHD symptoms at 6 years of age (Harold, Leve, Barrett, et al., 2013), adoptive mothers' symptoms of anxiety predicted their toddlers' internalizing problems at 18 and 27 months (Brooker et al., 2014), and adoptive mothers' symptoms of depression and antisocial behavior predicted children's internalizing and externalizing symptoms at 18 months, but not change in problem behaviors from 18 to 54 months (Kerr et al., 2013). Studies of adoptees have also shown that the rearing mothers' depressive symptoms are associated with adoptive offspring externalizing problems in toddlerhood (Pemberton et al., 2010) and in adolescence (Tully, Iacono, & McGue, 2008). Maternal depression was also associated with offspring depressive symptoms in adoptive and nonadoptive families (Tully et al., 2008). In contrast, one other study of 402 adoptive and 204 biological families, showed that maternal and paternal antisocial behavior were associated with adolescent offspring externalizing problems only in biological families but not in adoptive families (Bornovalova et al., 2014).

These findings regarding environmental transmission of risk for psychopathology tend to replicate in samples in which parents and children are genetically unrelated because mothers were recipients of donor eggs or sperm or children were born to surrogates (Harold et al., 2011; Harold, Leve, Barrett, et al., 2013; Lewis, Rice, Harold, Collishaw, & Thapar, 2011; Rice, Lewis, Harold, & Thapar, 2013). Findings are less robust for transmission of rearing fathers' psychopathology to his genetically unrelated offspring, however (Harold et al., 2011).

In some cases, the pathways by which parental psychopathology lead to offspring psychopathology are the same, regardless of the biological relatedness of parents and offspring. For example parental hostility has been shown to account for the association between parent and offspring antisocial behavior in both genetically related and genetically unrelated dyads (Harold et al., 2011). In other cases, the pathways differ. For example, high levels of maternal hostility and low levels of maternal positivity account for the association between mothers' and children's depression in genetically related pairs, but these maternal behaviors do not account for links in genetically unrelated pairs (Harold et al., 2011; Rice et al., 2013), though this may have reflected relatively reduced power to detect effects of maternal positivity (if not maternal hostility) in the genetically unrelated pairs.

Does Passive rGE Account for the Effect of Maternal Behaviors While Pregnant on Offspring Outcomes?

In a study of 779 children born through in vitro fertilization whose prenatal environment was either provided by a biologically related mother or a biologically unrelated mother (e.g., a surrogate or the recipient of a donor egg), infants whose mothers smoked during pregnancy had significantly lower birth weights than infants whose mothers did not smoke during pregnancy, regardless of whether the mother and fetus were biologically related (Rice et al., 2009). In contrast, children whose mothers smoked during pregnancy had significantly higher levels of antisocial behavior and hyperactivity than children whose mothers did not smoke only when the mother–offspring pair was biologically related (Rice et al., 2009; Thapar et al., 2009). Thus, smoking during pregnancy is likely to be one cause of low birth weight, but not offspring antisocial behavior or hyperactivity. Interestingly, however, genetically mediated effects of mothers' smoking during pregnancy on offspring conduct problems are observed even when offspring are adopted at birth (Gaysina et al., 2013), suggesting that smoking during pregnancy may be a marker for genetic risk for externalizing problems that mothers transmit to children and that evokes negative interactions with caregivers in the postnatal environment.

Adoption Studies of Evocative rGE

The adoption design can also be used to test for evocative genotype–environment correlations. In this case,

information about the adoptees' biological parents must be available to derive an estimate of the adoptee's genetic risk for some outcome. For example, Ge et al. (1996) used information about antisocial personality disorder and alcohol and drug abuse/dependence among biological parents to identify adoptees at high versus low genetic risk for psychopathology. High-risk adoptees experienced significantly higher levels of harsh, inconsistent discipline and lower levels of warmth and nurturance from their adoptive parents than low-risk adoptees and the relationship between adoptee risk status and adoptive parent behavior was mediated by adoptee antisocial behavior. Thus, a genetic propensity to engage in antisocial behavior made adolescents difficult to manage, resulting in less warmth and more negativity in the parent-adolescent relationship—evidence of evocative genotype–environment correlation.

This finding was replicated in two separate samples. O'Connor et al. (O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998) showed that adoptive parents of children at high genetic risk for externalizing problems (on the basis of the biological mother's antisocial behavior) consistently used more negative control strategies over a 5-year period from late childhood to early adolescence than did adoptive parents of children at low genetic risk. Follow-up mediation analyses indicated that children who were at high genetic risk also had higher levels of externalizing problems, which explained why their parents were more likely to use negative control strategies. Similarly, Riggins-Caspers, Cadoret, Knutson, and Langbehn (2003) found that adopted adolescents who were at high biological risk (on the basis of the biological parents' psychiatric status) were characterized by relatively high levels of conduct problems, which, in turn, were associated with the receipt of harsh discipline. Interestingly, this evocative G-E correlation was only observed under conditions of moderately high environmental risk (e.g., substance use or other psychological problems in the adoptive family, divorce), suggesting that the broader context modified the degree to which parents reacted with harsh and coercive discipline to their child's externalizing behavior.

Even in the absence of data on biological parents' characteristics, evocative genotype–environment correlations can be ruled out as an explanation for observed associations between children's experiences and their behavior if longitudinal data are available from adoptive families. For example, Klahr et al. (2011) estimated a cross-lagged model of the relationship between parent–child conflict and adolescent conduct problems at two time points, separated by approximately 4 years. They found that parent–child conflict was a much stronger predictor of later conduct problems than the reverse, suggesting that the child's behavior (which had been shown to be moderately heritable in biometric models) was not evoking or escalating conflict with parents.

In summary, results from adoption studies are consistent with the hypothesis that many family-based risk factors, including divorce and interparental conflict, parent-offspring conflict, and parental psychopathology have environmentally mediated effects that are not solely accounted for by genes shared by parents and children. Nevertheless, genetically based child characteristics may play a part in evoking risk exposures such as parent–child conflict (Ge et al., 1996; O'Connor et al., 1998). Finally, the evidence suggests that the association between a mother's smoking during pregnancy and offspring externalizing problems is accounted for by passive G-E correlation, although the process by which a genetic predisposition to engage in externalizing behaviors becomes manifest may involve evocative G-E correlations in the postnatal period (Gaysina et al., 2013).

Limitations of the Adoption Design

Although the adoption design automatically eliminates passive G-E correlations as a source of confounding, it is characterized by various limitations. First, because adoptive parents are closely screened by child welfare services, they tend to be less disadvantaged and less likely to be characterized by psychopathology compared with nonadoptive families (McGue et al., 2007; Stoolmiller, 1999). Thus, the adoption design can be relatively uninformative about the effects of extreme adversity and the restricted range of environments in adoptive families can bias estimates of genetic and environmental influences (Stoolmiller, 1999), although it has been demonstrated that range restriction does not affect the magnitude of adoptive sibling correlations for disinhibitory behaviors and IQ (McGue et al., 2007). Second, the adoption design presumes that adoptive children do not maintain contact with their biological parents. Historically, this assumption has probably been valid, as many samples of adoptees were recruited at a time when both closed and international adoptions were common. However, as open adoptions have become increasingly common, researchers must monitor and quantify the amount of contact between adoptees and biological parents in order to determine whether and how much contact biases heritability estimates (Leve et al., 2007). Moreover, adoptive parents' knowledge of the biological parents' mental or physical health history may color their perceptions of their adopted child's behavior. For example, in comparing the offspring of biological parents

who did versus did not have a history of mental or physical health problems, the former were only shown to have more disruptive behavior problems than the latter (as reported by their adoptive parents) if their adoptive parents knew about the biological parents' history (Riggins-Caspers et al., 1999). In the absence of such knowledge, adoptees' disruptive behavior problems were reported to be low regardless of the biological parents' actual psychiatric or physical health history (Riggins-Caspers et al., 1999).

Research designs that utilize samples of women undergoing assisted reproductive technologies (ARTs) are characterized by similar limitations. Women who use ARTs tend to be older and better educated than women in the population overall (Källén, Finnström, Nygren, & Olausson, 2005; Schieve et al., 2007) and this might not only influence their behavior while pregnant, but also the relationship between their behavior while pregnant and offspring behavior. In addition, although data are limited, women who have taken on the physical, financial, and emotional challenges of ARTs and become pregnant are less likely than other women to engage in behaviors that would put the fetus at risk (Källén et al., 2005). Thus, rates of risky behaviors like smoking or drinking alcohol during pregnancy are likely to be very low in these samples, compromising statistical power, and women who do engage in health-risk behaviors while pregnant are likely to be heavily dependent on substances (Thapar et al., 2009).

GENOTYPE–ENVIRONMENT CORRELATIONS: EVIDENCE FROM TWIN STUDIES

Twin studies have provided much of the evidence for genotype–environment correlations by demonstrating that putative environmental measures are heritable (Plomin & Bergeman, 1991). Twin studies capitalize on the fact that environments vary in the population just like any other phenotype. Some children experience more harsh discipline than others. Some adolescents have more deviant peers than other adolescents. Some adults have happier marriages than other adults. Individual differences in experiences can be decomposed into genetic and environmental components just like variation in any other characteristic. Thus, to the extent that MZ twins have more similar experiences (e.g., with parents or peers) than DZ twins, this is taken as evidence that genetic factors make them more similar. To the extent that MZ twins do not have identical experiences (e.g., one twin is frequently bullied and the other is not), this is taken as evidence that some nongenetic factor is making them different (e.g., they may be in different classes at school). Finally, to the extent that MZ twins are less than twice as similar to one another as DZ twins, this is taken as evidence that shared (or common) environmental factors account for individual differences in experiences. This is because the twin design assumes that their genotype is the only thing that makes MZ twins more similar to one another than DZ twins and, on average, MZ twins are twice as genetically similar to one another as DZ twins. Thus, if genes were the only thing that caused twins to have similar experiences to one another, then MZ twins should be twice as similar to one another as DZ twins. If something other than genes is causing twins to have similar experiences to one another (e.g., a mother's depression is making her prone to use harsh discipline with all her children), then DZ twins will be more than half as similar to one another as MZ twins (Plomin, DeFries, McClearn, & McGuffin, 2008).

Two recent meta-analyses have shown that many of the experiences or exposures that have been investigated in developmental psychology and psychopathology are heritable, including marital quality, social support, parental discipline and warmth, global family environment, and peer relationships (Kendler & Baker, 2007). These also include desirable and undesirable life events, including divorce and exposure to trauma. The weighted heritability of these environments ranges from 6% to 39%, with most ranging from 15% to 35% (Kendler & Baker, 2007). In a meta-analysis focused specifically on parenting, genetic factors accounted for 23% of the variation in measures of maternal and paternal positivity and negativity across 32 studies, with heritability increasing significantly in older versus younger children (Avinun & Knafo, 2014). Finally, other experiences that are thought to be important for children's development including the number of years a person participates in organized sports or music lessons and how frequently children are read to by their parents are also moderately heritable (Vinkhuyzen, van der Sluis, de Geus, Boomsma, & Posthuma, 2010).

Two sets of findings support the hypothesis that genetic influences on putative environments reflect evocative G-E correlations. The first is that genetic influences on experiences that are potentially within an individual's control (e.g., a relationship break-up) are stronger than genetic influences on experiences that are not within an individual's control (e.g., losing one's home in a hurricane) (Kendler, Karkowski, & Prescott, 1999). Relatedly, personal life events (i.e., events that occur directly to an individual) are more highly heritable than network life events (i.e., events that occur to someone within an individual's

social network, thus affecting the individual indirectly) (Bolinskey, Neale, Jacobson, Prescott, & Kendler, 2004; Kendler, Neale, Kessler, Heath, & Eaves, 1993). Together, these findings suggest that something about the individual is evoking or eliciting the event.

The second piece of evidence to suggest that genetic influences on putative environments reflect evocative G-E correlations is that genetic influences on observational measures of parent–child interactions tend to be weaker than genetic influences on parent or child reports of parenting (Avinun & Knafo, 2014; Kendler & Baker, 2007). The presence of an observer and the structure of a parent–child observation session may mean that the parent is reacting more to the situation than to the child's behavior (Avinun & Knafo, 2014).

Behavioral geneticists have never claimed that there are genes for harsh parenting or unhappy marriages per se, so how does one interpret the heritability estimates reported in these meta-analyses? How one interprets the heritability of putative environments depends on who is reporting on the twins' experiences. When twins describe their own experiences (e.g., of receiving parental discipline), then heritability estimates can reflect either of two things: (1) genetic influences on twins' perceptions of their experiences; or (2) genetic influences on twins' behaviors that elicit those experiences. For example, Hanscombe et al. (2010) showed that genetic factors accounted for approximately 20% of the variation in twin children's reports of noise, lack of routine, and chaos in their homes. A subsequent analysis suggested that this heritability estimate was more likely to reflect genetic influences on the twins' perceptions of their environment rather than genetic influences on disruptive behavior problems that could have created a noisy and chaotic environment (Jaffee, Hanscombe, Haworth, Davis, & Plomin, 2012).

When parents report on each of their twin children's experiences, then heritability estimates can only reflect genetic influences on the twins' behavior that elicit those experiences (Ge et al., 1996; Jaffee et al., 2004; O'Connor et al., 1998). For example, Jaffee et al. (2004) found that a common genetic factor accounted for most of the observed relationship between children's antisocial behavior and their experiences of corporal punishment. This suggests that genetic factors are correlated with spanking and smacking because they give rise to oppositional and antisocial behaviors that evoke those behaviors in parents. It bears noting that genetic influences on maternal and paternal positivity are identified not only when parenting is described by each twin in a pair but also when parents report how they treat each of their twins (Avinun & Knafo, 2014).

When *adult* twins report on their (nontwin) children's experiences, the interpretation of the heritability estimate changes. For example, when adult twins describe the disciplinary practices they use with their own children, greater MZ relative to DZ correlations for parental discipline reflect the extent to which the adult's genetic propensities modify or create that experience (Wade & Kendler, 2000).

Using the Multivariate Twin Model to Test for G-E Correlation

The hypothesis that genetic influences on putative environments reflect evocative G-E correlations has been tested most extensively using multivariate twin models. The idea is to identify some behavior or ability that could plausibly evoke the environment and estimate how much of the covariation between the behavior and the environment can be accounted for by genetic influences common to both phenotypes. A range of bivariate (or multivariate) models can be estimated, including Cholesky decomposition models, common factor models, and correlated factor models (Loehlin, 1996).

The Cholesky decomposition model is presented in Figure 7.2 which represents a bivariate model in which Trait 1, might represent some measure of behavior (e.g., aggressive behavior) and Trait 2 might represent

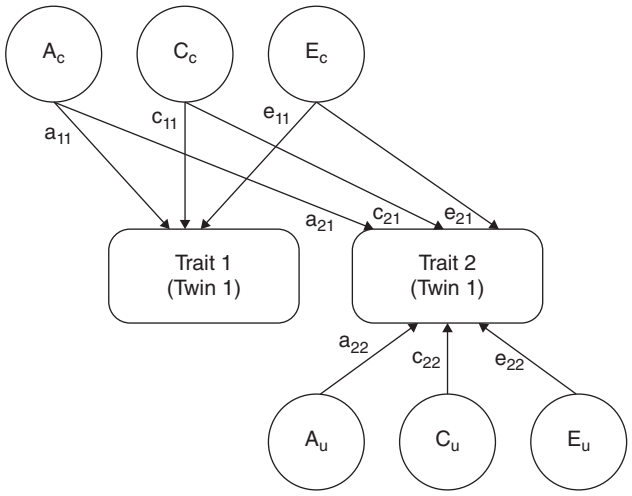

Figure 7.2 Bivariate Cholesky decomposition model. *Note:* A_c refers to genetic factors that account for variation in both phenotypes, C_c refers to common environmental factors that account for variation in both phenotypes, and E_c refers to unique environmental factors (or error) that account for variation in both phenotypes. A_u, C_u, and E_u refer to genetic, common environmental, and unique environmental factors, respectively, that account for variation in only Phenotype 2. The model is presented for twin 1 only. The full Cholesky model (including both twins) would include a correlation equal to 1.0 between the latent C factors (C_c and C_u) for twins 1 and 2 and correlations equal to 1.0 for MZ twins and .50 for DZ twins between the latent A terms (A_c and A_u).

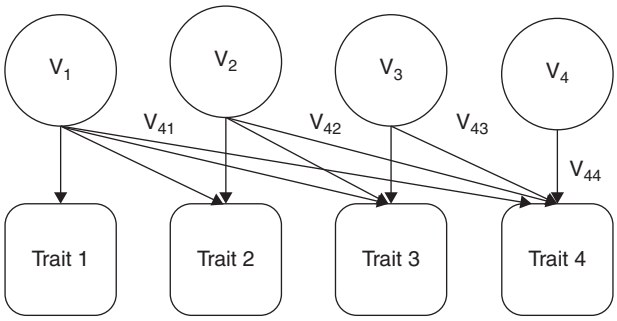

Figure 7.3 Multivariate Cholesky decomposition model. *Note:* Schematic illustrating Cholesky decomposition. Measured traits (Traits 1–4) are regressed on corresponding latent variables (V_1–V_4). V_1 is the total variation in Trait 1 and takes precedence in explaining variance in Traits 2, 3, and 4. V_2 is the residual variance in Trait 2 and has next priority in explaining variance in Traits 3 and 4. V_3 is the residual variance in Trait 3 and has next priority to explain variance in Trait 4. V_4 explains residual variance in Trait 4. Each measured trait is regressed on all preceding latent variables, and all latent variables are uncorrelated. The total variation in Trait 4 is estimated by squaring and summing the paths from V_1 through V_4 to Trait 4 ($v41$ through $v44$, respectively). V_1 through V_4 can be decomposed into additive genetic (A), shared environmental (C), and nonshared environmental (E) components. For example, the total additive genetic variance in Trait 4 would be explained by the squared and summed paths $a41$ through $a44$ from latent variables A_1 through A_4.

some measure of the environment (e.g., delinquent peers). In a Cholesky decomposition, each subsequent observed variable is regressed on the latent A, C, and E variance components of all the previous observed variables. In Figure 7.2, $A_c + C_c + E_c$ explain the total variance in Trait 1. Trait 2 is regressed on the latent variables A_c, C_c, and E_c; in other words, these variance components takes precedence in explaining variance in Trait 2. A_u, C_u, and E_u then explain the residual variance in Trait 2, that is, variance not correlated with A_c, C_c, and E_c. The total genetic variation in Trait 2 is estimated by squaring and summing the genetic paths ($a21$–$a22$). Similarly, shared and unique environmental variation in Trait 2 is estimated by squaring and summing the paths from all C and E components, respectively.

The Cholesky model can be expanded to include additional traits (Figure 7.3). For example, Traits 1 and 2 might represent peer delinquency and aggressive behavior, respectively, measured prior to adolescence. Traits 3 and 4 might represent aggressive behavior and peer delinquency, respectively, measured in adolescence. In this case, V_1 (representing $A_1 + C_1 + E_1$) will have priority in explaining variance in Traits 2, 3 and 4. V_2 will have next priority in explaining variance in Traits 2, 3 and 4. V_3 and V_4 will explain residual variance in Traits 3 and 4, respectively, and are uncorrelated with each other or with V_2 and V_1. Such an analytic approach would allow researchers to temporally order variables and address issues of reciprocal causation.

As an example of this multivariate approach, Jaffee et al. (2012) hypothesized that if the association between chaotic environments and children's disruptive behavior problems reflected a (genetically based) child effect on the environment, then genetic influences on children's disruptive behavior problems at one point in time should account for some of the heritable variation in chaotic environments at a later point in time. Testing this hypothesis involved estimating how much of the variation in the chaotic environment at age 12 was accounted for by genetic factors and then calculating how much of that genetic variation reflected genetic factors that also influenced children's disruptive behavior problems. Although phenotypic cross-lagged regression models had shown that children's disruptive behavior problems predicted increases over time in the level of environmental chaos, the Cholesky decomposition models showed that this child effect on the environment was not genetically based (Figure 7.4). That is, although the chaotic environment was heritable and

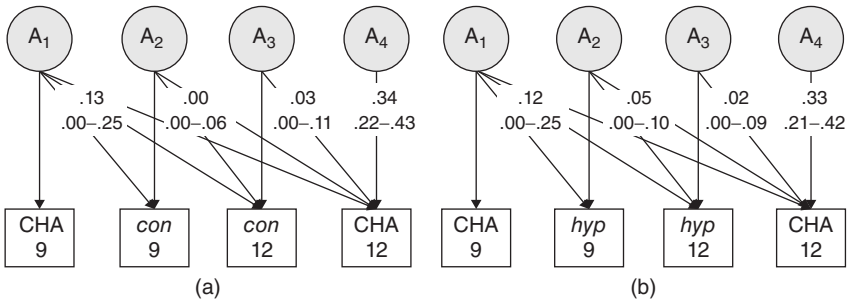

Figure 7.4 Cholesky decomposition showing genetic effects (A) of disruptive behavior on Confusion, Hubbub, and Order Scale (CHAOS) scores at age 12. *Note:* Separate models are shown for the effects of (a) conduct (con) and (b) hyperactivity–inattention (hyp), with both analyses controlling for the genetic effects of CHAOS scores at age 9. A_1 captures the total genetic variation in CHAOS (CHA) scores at age 9; A_2, A_3, and A_4 are the residual genetic variances in disruptive behavior at age 9, disruptive behavior at age 12, and CHAOS scores at age 12, respectively. Standardized (unsquared) path coefficients and 95% confidence intervals are shown.

children's disruptive behavior problems were highly heritable, genetic influences on children's disruptive behavior problems accounted for virtually none of the heritability of the chaotic environment (i.e., the confidence intervals around the A^2 and A^3 paths included zero).

Finally, the basic Cholesky model can be reparameterized to estimate correlated and common factors models which can be useful when there is no logical or theoretical basis for the ordering of variables in the Cholesky decomposition (Loehlin, 1996). Correlated factors models estimate genetic and environmental influences on each trait in a multivariate model and then estimate the correlation between the latent genetic and environmental factors. In the common factors model, genetic and environmental latent factors are decomposed into those that influence all traits in the model and those that are specific to each trait.

In the following section we describe how multivariate twin models have been used to identify behaviors or personality traits that explain genetic influences on putative environments. These efforts generally involve showing that the individual characteristic and the experience or exposure are (1) correlated at the phenotypic level, ideally in fully cross-lagged autoregressive models and (2) heritable in univariate quantitative behavioral genetic analyses. Finally, the multivariate model should show that some significant portion of the genetic variation in the experience or exposure can be accounted for by genetic factors that also influence the behavior or personality trait or that the bivariate heritability is high, indicating that the genes influencing the individual characteristic and the genes influencing the exposure or experience are highly correlated. We focus on five experiences and exposures that have been studied extensively in the literature: parenting, peer relationships, marital status and quality, global family functioning, and classroom characteristics.

Do Genetic Influences on Children's Behavior Account for the Heritability of Parenting Measures?

In child-based twin designs, genetic influences on various measures of parenting have been shown to be at least moderately heritable, including measures of parental hostility (Button, Lau, Maughan, & Eley, 2008; Forget-Dubois et al., 2007; Jaffee et al., 2004; Knafo & Plomin, 2006; Neiderhiser, Reiss, Hetherington, & Plomin, 1999; Shelton et al., 2008; Forget-Dubois et al., 2007; Jaffee et al., 2004); parental warmth (Knafo & Plomin, 2006; Neiderhiser et al., 2004; Neiderhiser, Reiss, Lichtenstein, Spotts, & Ganiban, 2007); and positive parental control strategies (e.g., reasoning or being firm and calm with a child; Knafo & Plomin, 2006).

Parental Hostility. Researchers have hypothesized that children's disruptive, aggressive, and hard-to-manage behaviors evoke harsh or hostile parenting, resulting in G-E correlation. Consistent with this hypothesis, the covariation between parents' use of harsh discipline or hostile parenting and children's antisocial behavior is largely accounted for by a genetic factor common to both phenotypes (Button et al., 2008; Jaffee et al., 2004; Neiderhiser et al., 1999; Shelton et al., 2008).

Genetically based differences in temperament may explain some of these genetic correlations. For example, in a study of approximately 1,300 Swedish twin pairs, genetic influences on aggressive behavior in early adolescence accounted for approximately half of the genetic covariation between parental criticism of adolescent behavior and delinquency in later adolescence, suggesting that genetically based individual differences in the tendency to aggress against others not only elicited criticism from parents, but also promoted delinquent behavior (Narusyte, Andershed, Neiderhiser, & Lichtenstein, 2007).

Longitudinal data potentially shed light on the direction of effects between measures of youth behavior and measures of parenting and can identify the extent to which any cross-lagged associations are accounted for by genetic versus environmental factors. Using data from a longitudinal study of 395 sets of twin and nontwin adolescent siblings, Neiderhiser et al. (1999) estimated cross-lagged associations between measures of adolescent maladjustment (antisocial behavior and depressive symptoms) and measures of maternal and paternal conflict and negativity (e.g., use of coercive and harsh discipline, parent–child conflict, hostility toward child). Parents' reports of conflict negativity at time 1 predicted adolescents' antisocial behavior and depressive symptoms 3 years later, even controlling for stability in adolescent adjustment over time. The reverse was also true: adolescent antisocial behavior and depression predicted change in parental conflict negativity. These cross-lagged phenotypic associations were largely accounted for by genetic factors (Neiderhiser et al., 1999), suggesting that some genetically based temperamental characteristic not only elicited parental conflict negativity but also predisposed adolescents to depression and antisocial behavior.

Parental Control. Although positive parental control strategies (e.g., reasoning, use of firm and calm discipline) are moderately heritable, a study of 9,319 twin pairs assessed at 3, 4, and 7 years of age found that genetic factors

only accounted for a third of the phenotypic correlation, on average, between positive parental control strategies and children's prosocial behavior (Knafo & Plomin, 2006). In contrast, genetic influences on parental negativity (e.g., shouting, smacking) were substantially larger in this study and the correlation between parental negativity and (low) prosocial behavior was largely accounted for by genetic factors (Knafo & Plomin, 2006). Thus, genetic influences on prosocial behavior account for substantially more of the heritability in parental negativity than in parents' positive control strategies.

Overprotective or overcontrolling parenting is another form of parental control that has been shown to be heritable (Eley, Napolitano, Lau, & Gregory, 2010). In a study of 300 8-year-old twin pairs, those who experienced high levels of maternal control during a cooperative Etch-a-Sketch task in which mothers were explicitly instructed to not touch their child's dial (highly controlling mothers disobeyed these instructions) had significantly more symptoms of anxiety compared with children who experienced lower levels of maternal control (Eley et al., 2010). Although genetic influences on child anxiety were correlated with genetic influences on observed maternal control, the absence of longitudinal data makes it difficult to determine whether anxious children were eliciting maternal control or whether overcontrolling mothers were increasing their child's anxiety (Eley et al., 2010).

Do Genetic Influences on Children's Behavior Account for the Heritability of Peer Relationships?

Peer Rejection and Victimization

Peer rejection and peer victimization have been shown to be heritable, with heritability estimates ranging from 16% (Boivin, Brendgen, Vitaro, Dionne, et al., 2013) to 73% (Ball et al., 2008) depending on the child's age, the informant, and the type of peer difficulty (victimization or rejection). Genetic factors account for the stability of victimization experiences from primary to secondary school (Bowes et al., 2013) and the stability of peer difficulties (including rejection and victimization) across middle childhood (Boivin, Brendgen, Vitaro, Dionne, et al., 2013). In a series of studies, Brengden and colleagues (2009, 2011, 2014) have attempted to identify the source of genetic influences on children's peer victimization and rejection. The hypothesis underlying this research is that children are disliked (or actively victimized) partly because their behavior makes them unpopular with other children. For example, children who are aggressive experience more victimization by peers than children who are less aggressive (Brendgen et al., 2011). Similarly children who are depressed are less well liked than their peers who have fewer symptoms of depression (Brendgen et al., 2009). At the phenotypic level, these associations have been shown to reflect both social selection and social causation. For example, although kindergarteners who experienced higher levels of peer difficulties (rejection and victimization) had more disruptive behavior problems in first grade than kindergarteners who experienced lower levels of peer difficulties, the reverse was also true; the more disruptive children were in kindergarten, the more peer difficulties they experienced in first grade (Boivin, Brendgen, Vitaro, Forget-Dubois, et al., 2013).

These relationships between peer difficulties and children's emotional and behavioral problems were shown to be at least partly genetically mediated. For example, genetic factors accounted for approximately a quarter of the variation in peers' reports of how often children in their first grade classrooms were victimized by other children (e.g., hit, pushed, called names; Brendgen et al., 2011) Genetic influences on peer victimization were due entirely to genetic factors that also influenced children's aggressive behavior (Brendgen et al., 2011). In a longitudinal investigation stemming from kindergarten to first grade, 48% of the variation in first graders' peer difficulties was accounted for by genetic factors, with 14% of the heritability attributable to genetic factors that also influenced their disruptive behavior a year earlier in kindergarten (Boivin, Brendgen, Vitaro, Forget-Dubois, et al., 2013). The findings suggested that genetically influenced traits like aggression and disruptive behaviors elicit a negative response from peers.

Similar to the findings for aggression, genetic factors accounted for approximately 30% of the variation in how well-liked children were at the age of 6 years (Brendgen et al., 2009). Approximately half of the genetic variance in 6-year-old children's teacher-reported depressive symptoms was accounted for by genetic factors that also influenced individual differences in how much children were liked or not liked by their peers, suggesting that a genetic predisposition for depression may increase children's exposure to peer rejection (Brendgen et al., 2009).

In contrast to the findings related to aggression and depression, children who were physically unhealthy in the preschool period were not victimized more often in middle childhood (as reported by teachers from age 6 to 12 years) than physically healthier children (Brendgen et al., 2014). Rather, peer victimization in middle childhood predicted physical health problems in adolescence, with genetic influences on peer victimization accounting

for some of the genetic variation in adolescent physical health (Brendgen et al., 2014). Thus, although this study failed to identify the source of genetic variation in peer victimization, it did establish that the association between peer victimization and later physical health was partly genetically mediated.

Prosocial and Deviant Peers

Peer deviance has been shown to be heritable (Harakeh et al., 2008; Hicks et al., 2012; Iervolino et al., 2002; Kendler et al., 2008; Rose, 2002; Samek, Keyes, Iacono, & McGue, 2013), although some studies of early adolescence have identified very small genetic influences on peer deviance (Bullock, Deater-Deckard, & Leve, 2006; Walden, McGue, Iacono, Burt, & Elkins, 2004) and others have identified larger genetic influences in some samples than others (Iervolino et al., 2002). The heritability of affiliation with deviant peers increases from early adolescence to young adulthood, reaching approximately 50% (Kendler et al., 2007; Tarantino et al., 2014). Although many youth who affiliate with deviant peers in mid-adolescence continue to affiliate with deviant peers in young adulthood ($r = .37$)(Tarantino et al., 2014), different factors account for the stability of deviant peer affiliation at different points in time. For example, Tarantino et al. (2014) showed that the phenotypic correlation between deviant peer affiliation at 15 and 18 years was $r = .58$, and that shared environmental factors largely accounted for this stability. In contrast, deviant peer affiliation was equally stable from age 18 to 21 years ($r = .59$), yet genetic factors accounted for stability in the transition from late adolescence to early adulthood (Tarantino et al., 2014).

Researchers have hypothesized that the heritability of deviant peer affiliation reflects genetic influences on aggressive, antisocial, and risk-taking behaviors that cause adolescents to choose delinquent peer groups in which these genetic predispositions can be expressed. If supported, this hypothesis counters social causation theories that propose that affiliating with deviant peers causes youth to initiate antisocial behavior or to increase their antisocial or risk-taking behavior.

There is evidence for genetically mediated selection effects into deviant peer groups. For example, in a sample of nearly 1,800 twins who reported retrospectively on their cannabis use and peer deviance when they were 15 to 17 years old, 18 to 21 years old, and 22 to 25 years old, the best-fitting model was one in which genetic, shared environmental, and nonshared environmental influences on cannabis use and peer deviance were freely estimated and in which a phenotypic regression path ran from cannabis use to peer deviance, accounting for 45% of the variation in the peer deviance (Gillespie, Neale, Jacobson, & Kendler, 2009). Cannabis use accounted for 50% (at ages 15 to 21) to 78% (at ages 22 to 25) of the total genetic variance in peer deviance. This model provided the best fit to the data at all three time points assessed, suggesting that individuals who use cannabis actively select similarly deviant peers.

Similar to the findings for cannabis use, the relationship between conduct problems and peer deviance also appears to be genetically mediated. Using retrospective data on conduct problems and peer deviance at ages 8 to 11 years, 12 to 14 years, and 15 to 17 years, Kendler, Jacobson, Myers, and Eaves (2008) showed that both conduct disorder and peer deviance were heritable, with genetic influences increasing over time. The best-fitting model showed that genetic factors accounted for variation in conduct problems, with aggressive, rule-breaking youth actively choosing to affiliate with deviant peers. At the same time, shared environmental factors accounted for variation in peer deviance, with deviant peer groups promoting conduct problems among twins in the study. Although the genetically mediated pathway by which conduct problems led youth to select deviant peers was constant across adolescence, the pathway by which the effect of the shared environment on conduct problems was mediated by peer deviance was only apparent in early adolescence (Kendler et al., 2008).

In contrast to findings regarding cannabis use and conduct problems, the evidence on alcohol use in adolescence is more consistent with an environmentally-versus-genetically mediated pathway. For example, in a sample of adoptees, the covariation between peer deviance and alcohol use was largely accounted for by shared environmental factors (Samek et al., 2013), suggesting that some third environmental variable explains why youth who affiliate with deviant peers are more likely to use alcohol in adolescence than youth who do not affiliate with deviant peers. Similarly, in a study of 14-year-old twins, Walden et al. (2004) showed that the covariation between measures of peer deviance, parent–child relationship quality, and lifetime substance use (a count of substances ever used) was accounted for entirely by a shared environmental factor. Although Harden et al. (2008) found that genetic variation in best friends' substance use was partly explained by the same genetic factors that accounted for adolescents' substance use (consistent with the possibility that some genetic predisposition causes adolescents to selectively affiliate with substance-using peers), having best friends who frequently smoked cigarettes and drank alcohol was associated with more frequent drinking and smoking among target adolescents, even adjusting for genetic influences on best friends' substance use.

In summary, although there is evidence from twin studies that genetic predispositions—perhaps reflecting aggression or sensation-seeking—cause adolescents to selectively affiliate with deviant peers, the evidence is mixed as to whether peer deviance has causal effects on adolescent behavior, with studies of adolescent cannabis use suggesting not, but studies of adolescent delinquency, alcohol, and cigarette use providing evidence consistent with causal effects, at least in early adolescence.

Finally, variation in the tendency to affiliate with prosocial peers is also heritable (Hicks et al., 2012). Researchers have hypothesized that the heritability of prosocial peer affiliation reflects genetic influences on antisocial behavior (wherein youth who are low in antisocial behavior selectively affiliate with prosocial peers) and this hypothesis is moderately well supported; for example, the correlation between genetic factors influencing adolescent antisocial behavior and youth prosocial peer affiliation was $r_g = -.32$ for boys and $r_g = -.51$ for girls (Hicks et al., 2012). It is possible that genetic influences on adolescent prosocial behavior account for a larger part of the heritability of prosocial peer affiliation.

Shy Peers

Although the majority of research on peer characteristics has focused on peer deviance, Guimond et al. (2014) tested whether socially reticent youth selectively affiliate with socially reticent peers. Having been observed interacting with their peers in an experimental task, kindergarten-aged twins were categorized as being at higher versus lower genetic risk for social reticence (measured by the percent of time they spent in solitary onlooking behavior during the task) on the basis of information about the pair's zygosity and the cotwin's social reticence (Jaffee et al., 2005; Kendler & Kessler, 1995; Ottman, 1994). For example, youth at highest genetic risk for social reticence were MZ twins whose co-twin scored above the 75th percentile on the social reticence measure and youth at lowest genetic risk were MZ twins whose cotwin scored below the 75th percentile on the measure of social reticence (Guimond et al., 2014). Youth who were at higher genetic risk for social reticence were more socially reticent themselves and had more socially reticent friends than youth who were at lower genetic risk for social reticence, indicating an active G-E correlation (Guimond et al., 2014).

Do Genetic Influences on Personality Traits Account for the Heritability of Marital Phenotypes?

Researchers have shown that being married (Jerskey et al., 2010; Johnson, McGue, Krueger, & Bouchard, 2004; Trumbetta, Markowitz, & Gottesman, 2007) and being divorced (Jerskey et al., 2010; Jockin & McGue, 1996; McGue & Lykken, 1992) are accounted for by genetic and nonshared environmental factors, although these tend to be nonoverlapping (Jerskey et al., 2010) and the magnitude of heritability estimates for marriage changes over time, increasing as individuals transition from their twenties to their thirties, but decreasing to near zero as individuals reach their fifties (Trumbetta et al., 2007). Moreover, marriage quality is heritable, with 34% of the variation in marital satisfaction accounted for by genetic factors and the remainder accounted for by nonshared environmental factors (Spotts, Neiderheiser, Towers, et al., 2004).

Researchers have hypothesized that genetic influences on marital status and marital quality can be accounted for by genetic factors that also account for variation in husbands' and wives' personality characteristics. At the phenotypic level, ever-divorced individuals score lower on measures of constraint, but higher on measures of both positive emotionality (the facet of social potency in particular) and negative emotionality compared with never-divorced individuals (Jockin & McGue, 1996). In a study of over 3,000 twins, genetic factors accounted for 55% to 59% of the variation in divorce, with genetic influences on a composite personality score accounting for approximately a third of the genetic variation in divorce (Jockin & McGue, 1996).

Phenotypically, ever-married and never-married individuals also differ in terms of personality, with ever-married men and women scoring higher on measures of positive emotionality and constraint and lower on measures on negative emotionality than never-married men and women (Johnson et al., 2004). Using the same sample of over 3,000 twins that was included in the study by Jockin and McGue (1996), genetic factors accounted for 68% to 72% of the variation in marital status (Johnson et al., 2004). The bivariate heritability was .68 for males and .83 for females, indicating that genetic factors accounted for most of the covariation between the personality composite and marital status (Johnson et al., 2004).

Finally, personality characteristics are correlated phenotypically with marital satisfaction: individuals who are relatively more aggressive, anxious, and relatively less sociable or optimistic tend to report lower levels of marital satisfaction and warmth (Ganiban et al., 2009; Spotts, Lichtenstein, et al., 2005). Moreover, genetic influences on these personality traits account for 50% of the genetic effect on marital quality (Spotts, Lichtenstein, et al., 2005). In an extension of this work, Ganiban et al. (2009) showed that parents who reported lower quality marriages tended to engage in more negative parenting practices as well, with parent personality characteristics accounting for 42% of

this phenotypic association. Moreover, the genetic factors that influenced parents' aggressive, anxious, and sociable personality traits accounted for 57% of the total genetic covariation between marital quality and parenting.

In summary, marital status and marital quality are moderately to highly heritable. Anywhere from a third to half of this genetic variation can be accounted for by genetic factors that also influence personality characteristics.

Do Genetic Influences on Personality Traits Account for the Heritability of Global Family and Interparental Conflict?

Global family conflict refers to the degree of openly expressed anger, aggression, and hostility in a household. Individual differences in global family conflict are moderately heritable (22%) with the remainder of the variance accounted for by nonshared environmental factors (Horwitz et al., 2011). In a study of adult twins, Horwitz et al. (2011) showed that 55% of the genetic variation in global family conflict was accounted for by genetic influences on parents' aggressive personality. Thus, the data are consistent with the hypothesis that parents who have a genetic predisposition to behave aggressively generate and evoke conflict within the family environment.

Whereas parent personality characteristics may evoke conflict within a family, children's personality characteristics filter their perceptions of family conflict. For example, in a study of 600 6- to 11-year-old twin pairs, Nikolas, Klump, and Burt (2013) showed that genetic factors accounted for 2% to 31% of the variation in different aspects of children's perceptions of interparental conflict. Although genetic factors accounted for a small and nonsignificant 2% of the variation in children's perceptions of how frequently and intensely parents argued, they accounted for a significant 31% of the variation in how much children blamed themselves for their parents' arguments. Thus, the data are consistent with the possibility that personality characteristics or social-cognitive biases may influence children's attributions for interparental conflict, but not their perceptions of relatively more objective features of interparental conflict, such as its frequency or severity.

Do Genetic Influences on Children's Behavior Account for the Heritability of Classroom Characteristics?

Multivariate twin models have been used to identify not only G-E correlations within families or peer groups but also how heritable child characteristics evoke reactions within the classroom. For example, 5-year-olds who were rated by parents, teachers, and observers as relatively hostile, oppositional, impulsive, and inattentive required more attention and effort by teachers when they reached early adolescence (Houts, Caspi, Pianta, Arseneault, & Moffitt, 2010). Underlying this relationship was a G-E correlation, whereby genetic factors accounted for approximately 51% of the variation in teacher effort and approximately a third of those genetic factors also influenced children's challenging behavior (Houts et al., 2010).

Adolescents' perceptions of the quality of their learning environment have also been shown to have a genetic basis. Fourteen-year-old twins in the Twins Early Development Study were asked to rate the science learning environment in their classrooms and among their peers with questions such as, "My teacher asks questions that have more than one answer," "I use information to support my answers," "My friends talk about Science outside of class," and "My friends are interested in Science" (Haworth et al., 2013). Genetic factors accounted for 37% of the variation in classroom environment and 39% of the variation in the peer environment with these estimates nearly as large in magnitude as the heritability of a science test taken by participants ($h^2 = 50\%$). Indeed, the phenotypic correlation between science achievement and the science learning environment ($r = .22$) was largely accounted for by genetic factors, suggesting that youth who are genetically inclined to be good at science may perceive the science learning environment differently than youth who are less well inclined (Haworth et al., 2013).

Using the Twin Design to Rule Out Genetic Confounding by Evocative or Active G-E Correlation

The possibility that genetically based individual differences in behavior, temperament, and personality underlie the heritability of parent–child, peer, marital, or classroom relationships, calls into question theoretical models which posit that these relationships or experiences have causal effects on a person's health, behavior, or psychological well-being. The alternative explanation is that individuals evoke or actively select environments or experiences on the basis of the same genetic predispositions that give rise to the phenotype in question (e.g., health, behavior, or psychological well-being). For example, having a warm and trusting relationship with a spouse may decrease a person's risk for depression in a causal fashion. However, the fact that both marital quality and risk for depression are influenced by the same genetically based personality features suggests that individuals who are prone to depression on the basis of their personality

makeup may evoke conflict and lack of trust in their relationships or choose spouses with whom they are unlikely to develop warm and trusting relationships. Such a process would be reflective of evocative or active G-E correlation.

A series of studies have been designed to test whether individual differences in mental, behavioral, or physical health are caused by marital status or marital quality or—alternatively—whether observed associations can be accounted for by genetic selection factors (i.e., the genetic factors that predispose individuals to marry or that influence marriage quality are also involved in health outcomes). In general, these studies show that although there is some selection into marriage (and into highly supportive or highly conflictual marriages), marital status, and marriage quality have causal effects on physical and mental health outcomes. For example, in a sample of 1,566 pairs of same-sex, married twins from Australia, Beam et al. (2011) showed that genetic factors partly accounted for the association between marital support and depressive symptoms in women, but that women (and men) who perceived themselves as having more support from their spouse reported fewer symptoms of depression.

In the Twins and Offspring Study of adult female twins in Sweden, high marital quality (as reported by wives) and social support were both associated with women's well-being and self-worth (Spotts, Pedersen, et al., 2005) as well as women's depressive symptoms (Spotts, Neiderhiser, Ganiban, et al., 2004). Genetic factors accounted for the covariation of marital quality, social support, and women's well-being, self-worth, and depressive symptoms (Spotts, Neiderhiser, Ganiban, et al., 2004; Spotts, Pedersen, et al., 2005). Nonshared environmental factors accounted for the covariation of marital quality specifically and women's well-being, self-worth, and depressive symptoms, indicating that experiences that differed for twins in a family explained why women who were in higher-quality marriages had higher psychological well-being, a higher sense of self-worth, and fewer symptoms of depression than women in lower quality marriages. The data suggested that husbands might have been the source of this nonshared experience, given that nonshared environmental factors accounted for the covariation of husbands' reports of marital quality and their wives' reports of social support and well-being (Spotts, Pedersen, et al., 2005). That is some quality of the husbands themselves that would cause twins in a pair to differ in their psychological well-being and their perceptions of social support might also have explained why some husbands reported higher levels of marital satisfaction than others.

Bivariate twin studies have also been used to test the hypothesis that marital status is related to physical, mental, and behavioral health and that observed associations are not explained by the tendency for healthier and more prosocial adults to marry. Two studies have used data from the National Longitudinal Survey of Adolescent Health (Add Health) to test whether marital status is related in a causal fashion to antisocial behavior, mental health, substance use, or physical health. Both found that married adults were less likely to engage in antisocial behavior than unmarried adults (Barnes & Beaver, 2012), with the benefits of being in a relationship extending to cohabiting couples as well (Horn, Xu, Beam, Turkheimer, & Emery, 2013). Moreover, married and cohabiting adults reported fewer symptoms of depression, less cigarette smoking or alcohol use and less suicidal ideation than young adults who were single (Horn et al., 2013). By estimating genetic and environmental influences on marital status (married or cohabiting versus single) and by controlling for those genetic and family background factors that select individuals into relationships, Horn et al. (2013) showed that the association between marital status and depressive symptoms, suicidal ideation, and alcohol remained significant. In contrast, the association between marital status and cigarette smoking was accounted for entirely by genetic and shared environmental factors that select adults into married or cohabiting relationships. The studies differed with respect to findings on marital status and antisocial behavior, with one showing that being married continued to have a significant (though greatly diminished) effect on reducing antisocial behavior after controlling for genetic factors (Barnes & Beaver, 2012) and the other finding that genetic and shared environmental factors entirely explained why married and cohabiting adults had a lower risk of antisocial behavior than single adults (Horn et al., 2013). Married adults, however, engaged in less antisocial behavior than cohabiting adults and this association was not accounted for by genetic or shared environmental selection factors (Horn et al., 2013).

Finally, the twin design has been used to test whether evocative or active G-E correlations account for the association between various sources of stress (e.g., chronic health problems, employment problems) and symptoms of depression (Schnittker, 2010). Heritability estimates for stressors ranged from $h^2 = .00$ for network life events involving spouses or children to $h^2 = .37$ for perceptions of chronic discrimination. Comparing the fit of models in which the effect of a stressor on depression was estimated (1) in the absence of a genetic correlation and (2) in the presence of a genetic correlation between the two

phenotypes, model fit tended to improve when the genetic correlation was estimated, with the result being that the effect of the stressor on depressive symptoms and on diagnoses of depression tended to be reduced substantially. For example, the correlation between genetic influences on perceived financial strain and depressive symptoms was $r = .38$ and the coefficient for the effect of financial strain on depressive symptoms was reduced from .15 to .08 in the presence of the genetic correlation, both $p < .05$. Thus, the findings suggest that G-E correlations explain some, but not all, of the association between negative life events and depression.

Twin Studies of Passive rGE

Two extensions of the classical twin design are informative about passive genotype–environment correlations: the children of twins (CoT) design and the longitudinal twins and parents design (LTaP).

The CoT design involves parents who are twins and their offspring. The design is premised on the observation that in MZ pairs, the magnitude of the genetic relationship between aunts or uncles and nieces or nephews is the same as that between parents and offspring. For example, a female MZ twin shares 50% of her segregating genes with her own children and with her sister's children. In contrast, in DZ pairs, aunts or uncles are more closely related to their own children than to their nieces and nephews. The design also capitalizes on the fact that twin pairs may be discordant for the circumstances in which they raise their children if, for example, one twin is divorced and the other is not. If the children who are growing up in an intact household have fewer problem behaviors than their cousins whose parents have divorced, then there is a strong basis for presuming that divorce causes offspring maladjustment, because the design automatically controls for genetic differences in pairs discordant for divorce (completely, in the case of MZ pairs wherein the nieces and nephews of the non-divorced twin will have inherited the same genetic liability as the sons and daughters of the divorced twin) and for environmental confounds shared by twins (e.g., ethnicity, socioeconomic background). Figure 7.5a illustrates the pattern of group differences indicative of an environmentally mediated effect of divorce. Comparing the white and black bars, we see that cousins who are discordant for the experience of divorce and whose mothers are MZ twin sisters, differ significantly in their level of behavior problems. The same pattern of effects is observed for the offspring of DZ twins. In contrast, a genetically mediated effect is indicated if differences among cousins whose mothers are discordant for divorce are more pronounced if the mothers are DZ versus MZ twins (Figure 7.5b). This is because genetic sources of confounding are controlled more completely in MZ versus DZ twin families. More formally, a range of analytic approaches is used to model CoT data, including hierarchical linear modeling (Raudenbush & Bryk, 2002), logistic regression models (e.g., Knopik, Jacob, Haber, Swenson, & Howell, 2009), and structural equation models (e.g., Schermerhorn et al., 2011).

Children of Twins and Family Structure and Function

Children of twins studies have tested whether various aspects of family functioning (e.g., marital status, marital quality, family conflict, harsh discipline) are likely to

Figure 7.5 Interpreting patterns of findings in children of twins studies. *Note:* As shown in Figure 7.5a, an environmentally mediated effect of divorce on offspring behavior problems is indicated if children whose mother is divorced have more behavior problems than their cousins whose mother is married and this difference is similar in magnitude regardless of whether cousins come from MZ versus DZ twin families. As shown in Figure 7.5b, a genetically mediated effect of divorce on offspring behavior problems is indicated if differences among cousins whose mothers are discordant for divorce is more pronounced if the mothers are DZ versus MZ twins.

have causal effects on offspring outcomes, even accounting for the possibility of passive G-E correlation. For example, in a series of papers and two different samples, D'Onofrio and colleagues (D'onofrio, Turkheimer, Emery, Harden, Turkheimer, et al., 2007; D'Onofrio, Turkheimer, Emery, Maes, et al., 2007c; D'Onofrio et al., 2005, 2006) compared the offspring of twins discordant for *divorce*. The results were consistent with a causal effect of divorce—particularly before the age of 16—on young adult psychopathology, early sexual intercourse, and educational problems. However, the effects of divorce on early cohabitation and earlier initiation of drug use were genetically mediated (D'Onofrio et al., 2006) and some evidence for genetic mediation was found in the case of offspring tendency to divorce (D'Onofrio, Turkheimer, Emery, Harden, et al., 2007).

In contrast to the causal effect of divorce on offspring psychopathology and some forms of health risk behaviors, the effect of growing up with a stepfather in the household on early age-at-menarche is largely genetically mediated (Mendle et al., 2006, 2009). In a sample of female twins and their daughters, cousins who were discordant for the presence of a stepfather in the household did not differ significantly with respect to age-at-menarche, suggesting that some uncontrolled familial liability accounted for the association between stepfather presence and early age at menarche in the sample overall (Mendle et al., 2006). The sample, however, was underpowered to determine whether the source of the familial liability was genetic or environmental; cousins who differed with respect to the presence of a stepfather may have been similar with respect to age-at-menarche because they were genetically similar or because some other feature of their mothers' backgrounds made them similar to one another.

These findings on stepfather presence and age-at-menarche were replicated in a Children of Siblings sample (Mendle et al., 2009). The Children of Siblings design is a variation of the CoT design that uses information from nontwin sibling dyads who vary in their genetic relatedness (e.g., full siblings vs. half siblings) to estimate the magnitude of genetic and environmental confounds on observed associations between exposures and offspring outcomes. Again, a familial liability explained the association between father absence and age-at-menarche (Mendle et al., 2009). The fact that the difference in age-at-menarche between cousins who were discordant for father absence was greater among the offspring of nontwin siblings than among the offspring of twin siblings suggests that the familial liability was genetic in origin (Mendle et al., 2009).

Two CoT studies have shown that the association between *marital conflict* and offspring externalizing problems is largely accounted for by genetic factors common to both (Harden, Turkheimer, et al., 2007; Schermerhorn et al., 2011), although the model fit was poor and the path estimating common genetic influences on marital conflict and offspring externalizing problems was only marginally significant in one of the studies (Schermerhorn et al., 2011). Schermerhorn et al. (2011) also measured how much parents agreed on how to raise their children and found that youth whose parents shared more similar views had fewer externalizing problems than youth whose parents' views were less similar, but this relationship was partly genetically mediated. In contrast, the greater the level of marital conflict and the greater the level of disagreement about children, the more symptoms of internalizing problems offspring had, even accounting for genetic factors common to marital conflict and internalizing problems and controlling for socioeconomic status (Schermerhorn et al., 2011).

Finally, Lynch, Turkheimer, D'Onofrio, Mendle, & Emery (2006) showed that, within a nuclear family, children who experienced more *harsh physical discipline* than their siblings, had more externalizing problems than their siblings. In addition, children who experienced more harsh physical discipline than their cousins had more externalizing problems than their cousins and the magnitude of this effect was no larger in DZ twin families (where genetic confounds are uncontrolled) than in MZ twin families (where genetic confounds are automatically controlled). Thus, findings were consistent with a causal effect of harsh physical discipline on antisocial behavior.

In summary, the preponderance of evidence from CoT studies supports the hypothesis that divorce, family conflict, and harsh discipline have causal effects on offspring psychopathology, even controlling for genetic factors that could account for observed associations. In contrast, girls who have lived with a stepfather tend to have an earlier age-at-menarche than girls who have not lived with a stepfather and youth whose parents' marriages are conflictual and unsupportive tend to have more externalizing problems than youth whose parents are more happily married because of the presence of passive G-E correlations. Given the high co-occurrence of marital conflict, divorce, and family conflict, it is not clear why only the effects of marital conflict appear to be genetically mediated. More research is needed to determine whether this finding is a function of the samples used to study marital conflict which, to date, have been restricted to intact families (Harden, Turkheimer, et al., 2007; Schermerhorn et al.,

2011). Given that these families may be intact because the parents experience relatively low levels of marital conflict, it would be important to replicate findings in samples that are at higher risk for marital conflict.

Children of Twin Studies of Teen Motherhood

The two CoT studies of adolescent motherhood have shown that the relationship between adolescent motherhood and offspring conduct problems is environmentally mediated and not accounted for by passive G-E correlation. Using data from a sample of Australian twins and their children (Harden, Lynch, et al., 2007) showed that the adolescent and adult offspring of teen mothers reported having had more behavior problems (i.e., conduct, oppositional, attention, and hyperactivity problems), substance use problems, and symptoms of depression compared with their cousins whose mothers delayed childbearing beyond adolescence. However, statistical power was too low to determine whether the magnitude of this effect differed in MZ versus DZ twin families, which would have provided additional information about potential genetic mediation of the observed effect.

Using data from a large Swedish registry sample, Coyne et al. (2013) compared criminal convictions among adult offspring born to twins versus nontwin siblings who were discordant for teen motherhood. Criminal conviction rates varied among cousins as a function of their mother's age at first birth, regardless of whether mothers were full siblings, dizygotic twin, or monozygotic twin siblings. For example, in families where mothers were MZ twins, offspring born to the teen mother were 1.4 times more likely to be convicted of a crime compared to the offspring of her sister who had delayed childbearing beyond adolescence (Coyne, Langstrom, Rickert, Lichtenstein, & D'Onofrio, 2013).

Children of Twin Studies of Parental Alcoholism

Three studies have used the CoT design to test whether the relationship between parent and offspring alcohol use problems is environmentally mediated or can be accounted for by familial factors, including passive G-E correlation. One study produced evidence of an environmentally mediated effect: the offspring of MZ male twins who were alcohol dependent had significantly greater risk for alcohol use disorder than their cousins whose father was not alcohol dependent (Jacob et al., 2003). In contrast, another study found that the offspring of MZ twins who were discordant for alcohol use disorders had equally high levels of alcohol use disorder symptoms regardless of whether their own parent was affected by alcohol use disorder (Slutske et al., 2008). Power was too low to determine whether genetic or environmental factors shared within twin families primarily accounted for the intergenerational transmission of risk for alcohol use disorders (Slutske et al., 2008). Differences between the two studies were potentially accounted for by the use of different statistical approaches. Slutske et al. (2008) explicitly estimated the effect of 0, 1, or both twins in the family having alcohol use disorder whereas Jacob et al. (2003) did not. This between-twin-families effect was a stronger predictor of offspring alcohol use problems than the within-twin-family effect (Slutske et al., 2008), suggesting that the differences observed by Jacob et al. (2003) among offspring of discordant twin pairs may have been reduced with controls for twin-family-wide alcohol use density. Moreover, a follow-up study of the sample included in Jacob et al. (2003) failed to detect evidence of an environmentally mediated effect of childhood exposure to paternal alcohol dependence (i.e., before age 12 years) and offspring risk for alcohol use disorder (Duncan et al., 2006).

Several other studies have tested whether the relationship between parental alcoholism and offspring conduct problems or ADHD is environmentally mediated or can be accounted for by familial factors. Two studies, both using data from an Australian twin sample, have shown that the relationship between maternal alcohol use disorder and symptoms of ADHD (Knopik et al., 2006) and parental alcohol use disorder and symptoms of externalizing problems (Waldron, Martin, & Heath, 2009) is likely to be genetically mediated. Similarly, data from a study of male MZ twins, discordant for alcohol dependence or abuse found that offspring of the unaffected twin had equally high levels of conduct disorder symptoms compared with their cousins whose father was alcohol dependent (Haber, Jacob, & Heath, 2005). Paternal alcoholism, in contrast, was only weakly related to offspring ADHD and this effect was completely reduced in a model that controlled for maternal characteristics (Knopik et al., 2009). Across studies, the weight of evidence supports the hypothesis that the association between parental alcohol use and offspring psychopathology is genetically rather than environmentally mediated.

Children of Twins and Parental Depression

Parents' symptoms of depression and offspring perceived self-competence were measured in a sample in which the mothers and fathers were members of 909 same-sex adult twin pairs (Class et al., 2012). In the sample overall, adolescent and young adult offspring tended to have lower perceived self-competence the more symptoms of depression their mothers or fathers had. Compared with

their cousins, however, with whom they shared a familial liability for depression and associated phenotypes, the offspring of the sister who was relatively more affected by depression had poorer perceived self-competence if the sisters were dizygotic rather than monozygotic twins. In contrast, the offspring of the brother who was relatively more affected by depression did have poorer perceived self-competence than the offspring of the relatively less affected brother, regardless of the pair's zygosity (Class et al., 2012). Thus, the environment created by fathers who suffer from depression is likely to have adverse effects on their children's perceived self-competence, although the mechanism is unclear. In contrast, the observed association between mothers' depression and offspring perceived competence is likely to result from an underlying genetic liability rather than anything about the environment in which depressed mothers raise their children.

The relationship between parent and offspring depression was shown to be environmentally mediated in a sample of nearly 1,300 adult twins from Australia and their spouses and offspring (Singh et al., 2011). Even controlling for the spouse's history of depression, the offspring of the depressed twin in a pair had higher rates of depression than the offspring of the nondepressed twin, regardless of the pairs' zygosity (Singh et al., 2011). In contrast, the association between parental depression and offspring conduct problems was genetically mediated, whereby the offspring of the depressed twin only had higher rates of conduct disorder than the offspring of the nondepressed twin if the pair were DZ, but not if they were MZ (Singh et al., 2011).

Strengths and Limitations of the CoT Design

Strengths of the CoT design include strenuous controls for genetic and environmental factors correlated with the candidate environment, automatically ruling out most unmeasured confounders. However, the design is also characterized by a number of limitations. First, it does not automatically control for unmeasured environments that are correlated with the candidate environment and that are *not* common to both twins. These nonshared factors must be measured explicitly and included as covariates in the design. Second, when the candidate environment is likely to be influenced by both parents (i.e., the twin and his or her spouse), the design may not reliably distinguish between direct and genetically mediated effects of the candidate environment on the offspring phenotype (Eaves, Silberg, & Maes, 2005). This problem might be mitigated by including measured characteristics of spouses as covariates (D'Onofrio et al., 2005; Rutter, Pickles, Murray, & Eaves, 2001). Third, the design does not control for reciprocal effects of the child's behavior on the family environment, although the direction of effects can be addressed in the extended children-of-twins design (see below).

Fourth, the design—like all twin designs—assumes the absence of assortative mating, even though assortative mating is moderately high for most psychiatric disorders and antisocial behavior (Galbaud du Fort, Bland, Newman, & Boothroyd, 1998; Krueger, Moffitt, Caspi, Bleske, & Silva, 1998; Maes et al., 1998). Assortative mating could confound correlations between the twin parent and his or her offspring if the spouse's behavior is strongly associated with the twin parent's behavior. Assortative mating in the grandparental and twin parental generations could also lead to violations of the assumption that DZ twins share half of their segregating genes, on average, and that the offspring of DZ twins will share an eighth of their segregating genes, on average. With assortative mating, DZ twins and or cousins who are offspring of DZ twins will have a greater coefficient of genetic relatedness with corresponding implications for estimates of genetic and environmental influences on phenotypic variance.

Fifth, the design assumes an intergenerational version of the equal environments assumption—namely that adult MZ twins do not spend more time together (and with their nieces and nephews) than adult DZ twins and, as a result, the offspring of MZ twins are not exposed more than the offspring of DZ twins to the environments in which their cousins reside. An explicit test of this assumption found that adult MZ twins did have more contact with each other than adult DZ twins, but that level of contact did not interact with zygosity to predict offspring externalizing problems (Koenig, Jacob, Haber, & Xian, 2010).

Sixth, in the absence of extremely large samples and large parent-offspring correlations, the CoT design cannot reliably estimate which confound—genetic or environmental—accounts for the largest portion of the association between the environment and offspring behavior (Slutske et al., 2008).

Extended Children of Twins Design

Comparing genetic and environmental influences on exposures or experiences in child- versus adult-twin–based designs can be informative about the extent to which passive versus evocative G-E correlations account for associations between putative measures of the environment and outcomes (Neiderhiser et al., 2004). For example, evidence for passive G-E correlation would be obtained if genetic factors accounted for variation in a measure of how frequently adult twins monitor their children and if shared environment factors accounted for variation

in parents' reports of how frequently they monitor each of their twin children (Neiderhiser et al., 2004). Using this logic, Neiderhiser et al. (2004) reported that mothers' positivity and monitoring reflected passive G-E correlation whereas mothers' negativity and control mainly reflected evocative G-E correlations, although patterns of genetic and environmental effects changed somewhat depending on whether mothers, children, or observers were the informants. A somewhat different pattern was found for fathers' behavior; fathers' negativity and monitoring reflected both passive and evocative G-E correlation whereas fathers' positivity and control mainly reflected evocative G-E correlation (Neiderhiser et al., 2007).

The extended children-of-twins design combines data from samples of adult twins and their offspring and child twins and their parents (Narusyte et al., 2008). The design estimates direct effects of parenting (or other exposures in the family) on children, direct effects of child characteristics on parenting (or other exposures in the family), and passive and evocative genotype–environment correlation. The ability to distinguish passive from evocative genotype–environment correlations is a unique characteristic of the model. A simulation study established that the extended CoT model was stable and recovered the true parameter values with high precision under the assumption that individual differences in parenting were entirely accounted for by additive genetic and nonshared environmental factors (Narusyte et al., 2008). The model was able to detect relatively small genotype–environment correlations. Applying the model to data, the relationship between maternal over-involvement and offspring internalizing problems was shown to be accounted for by evocative G-E correlations (Narusyte et al., 2008), as was the relationship between maternal criticism of offspring behavior and offspring externalizing problems (Narusyte et al., 2011). Data from the same sample showed that the association between parental negativity more broadly (including conflict with the adolescence, parental coercion, and parental punitiveness) and adolescent externalizing problems was accounted for by evocative G-E correlations (Marceau et al., 2013).

Finally, an ECoT study involving (1) adult twins and their offspring and (2) child twins who were approximately age-matched to the offspring of the adult twins identified a significant environmental pathway from parent antisocial behavior to youth conduct problems, even accounting for the fact that some of the genetic factors that influenced youth conduct problems were shared with genetic influences on adult antisocial behavior (Silberg, Maes, & Eaves, 2012). A small passive G-E correlation was identified accounting for just over 3% of the variation in youth conduct problems (Silberg et al., 2012).

As reviewed by Narusyte et al. (2008), the requirement that the combined samples be comparable in terms of size, participant characteristics, and measured constructs is a major limitation of the extended CoT design. Samples of twin children and their parents on the one hand and twin parents and their children (who are cousins) on the other hand may produce correlations among youth behavior or parenting constructs that differ in magnitude simply because cousins are likely to be less similar to each other than siblings and because cousins will vary in age while twin siblings will not. Such differences could result in larger residual error terms and poorer model fit. Many researchers will not have access to data that meet these requirements for comparability. The design also assumes that the genes that influence the parent phenotype are the same as those that influence the child phenotype. This assumption is likely to be violated when the parent and offspring phenotypes reflect behavior at different points in development. For instance, it has been shown that gene variants associated with alcohol dependence in adulthood are associated with symptoms of conduct disorder rather than alcohol dependence in adolescence (Dick et al., 2006) and longitudinal data from Eaves et al. (2010) showed that genetic influences on juvenile antisocial behavior were largely different from genetic influences on adult antisocial behavior in the same individual. To the extent that different genes influence the parental versus the child phenotype, passive genotype–environment correlation may be underestimated.

Twins and Parents Design

This design estimates the magnitude of genetic and nongenetic pathways by which a parental phenotype (e.g., parental antisocial behavior) is associated with the corresponding phenotype among offspring. Measured environments (e.g., maltreatment) can be included in the model and their direct effects on the child phenotype can be estimated. The design also estimates the degree of assortative mating between parents. As with the ECoT design, the TaP design assumes that the (genetic and environmental) sources of variation in the parent phenotype are the same as in the offspring phenotype and that the magnitude of the variation in the phenotype is the same in both generations (Fulker, 1982).

Eaves et al. (2010) used the LTaP design to test whether the association between childhood adversity (indexed by retrospectively reported parental neglect, exposure to interparental violence, and inconsistent parental discipline) and

offspring antisocial behavior (as measured by adolescent conduct problems and adult antisocial behavior) was genetically or environmentally mediated.

The use of longitudinal data in this model circumvents some of the more problematic assumptions of the standard TaP model. First, the LTaP design includes measures of the candidate environment (i.e., childhood adversity) and both parents' antisocial behavior, thus providing information about assortative mating and the size of the association between parent antisocial behavior and childhood adversity. Second, the LTaP design includes information about twins' antisocial behavior in adolescence and adulthood, thus providing information about the magnitude of genetic and environmental influences on these behaviors at two different points in development. Third, a model incorporating information on parent antisocial behavior and *adult* offspring antisocial behavior provides information on the extent to which genetic differences in parental behavior account for the relationship between childhood adversity and adult offspring antisocial behavior. Because antisocial behavior is measured at the same point in development for parents and offspring, this model is unlikely to violate the assumption that the same genes influence parent and offspring phenotypes (assuming there are not sizable cohort effects). This model can then be used to identify a model that measures the influence of parental genotype and childhood adversity on juvenile antisocial behavior, including the measure of passive genotype–environment correlation.

Using the LTaP design, Eaves et al. (2010) found that nongenetic effects of parent antisocial behavior on the shared environment were largely mediated by parental treatment of children and that childhood adversity directly accounted for shared environmental effects on offspring antisocial behavior, providing evidence for an environmentally mediated effect of parental treatment. Moreover, effects of the shared environment (including parental treatment) on offspring antisocial behavior persisted from adolescence into adulthood. Very small passive G-E correlations were detected.

Discordant MZ Twins Design

The discordant MZ twin design is not used to estimate G-E correlations directly, but rather to rule them out as a potential confounder of observed associations between experiences and behavior. To the extent that within-pair differences in experience are correlated with within-pair differences in behavior, one can be confident that the effect of the experience is environmentally rather than genetically mediated (i.e., does not arise from evocative, active, or passive genotype–environment correlation). This is because MZ twins are genetically identical, so differences in their experiences cannot logically arise from genetically based differences in their behavior.

The discordant MZ pairs approach has been used to examine 4 categories of exposures: (1) parenting (or parent–child relations); (2) peer relationships; (3) health risk behaviors; (4) and stressful life events and life course transitions. We discuss each of these in turn.

MZ Pairs Discordant for Parenting

In a study of 5-year-old twins, Caspi et al. (2004) showed that the twin about whom the mother expressed more negative feelings was also the twin with more externalizing problems at age 5 and 7 years. Other studies have shown that within-pair discordance for parental negative feelings and parental criticism is associated with within-pair differences in conduct problems in middle childhood (Larsson, Viding, Rijsdijk, & Plomin, 2008; Mullineaux, Deater-Deckard, Petrill, & Thompson, 2009), in a sample of 8- to 16-year-olds (Carbonneau, Eaves, Silberg, Simonoff, & Rutter, 2002), and in a sample of adolescents, even controlling for within-pair differences in conduct problems measured 8 years earlier (Shelton et al., 2008). Studies focused on harsh discipline show a similar pattern wherein the twin who has experienced more harsh discipline also has more conduct problems and lower levels of prosocial behavior (Asbury, Dunn, Pike, & Plomin, 2003; Asbury, Dunn, & Plomin, 2006; Deater-Deckard et al., 2001; Pike, McGuire, Reiss, Hetherington, & Plomin, 1996). In contrast, within-pair differences in mothers' use of criticism or praise in a parent–child interaction task were shown to be unrelated to within-pair differences in 3-year-olds' conduct or emotional problems, although the twin who received more criticism was also the twin who was reported to have lower levels of prosocial behavior (Deater-Deckard et al., 2001). Finally, in a study in which parents of preschoolers were asked to report on their over-protective and hostile parenting, within-pair differences in over-protective parenting were associated with within-pair differences in boys' socially reticent behavior in kindergarten whereas within-pair differences in fathers' hostile parenting were associated with within-pair differences in girls' social reticence, particularly when their fathers also reported high levels of depressive symptoms (Guimond et al., 2012).

When combined with longitudinal data involving repeated measures of experiences and youth behavior, the discordant MZ pairs approach offers a strong test of the

direction of effects. For example, Burt et al. (2006) measured parent-adolescent conflict and adolescent antisocial behavior in a study involving 486 MZ twin pairs assessed at ages 11, 14, and 17 years. They found that among twins highly discordant for the experience of parent–child conflict (as well as for twins highly discordant for antisocial behavior), the twin who experienced higher levels of conflict at age 11 had significantly higher levels of antisocial behavior at age 14 than his co-twin, controlling for both the stability of within-pair differences in antisocial behavior from early to middle adolescence as well as the stability of within-pair differences in parent–adolescent conflict. The results were consistent with the interpretation that parent–adolescent conflict was causally associated with youth antisocial behavior in middle adolescence, although the effect was only present for highly discordant pairs. In a similar analysis, Cecil, Barker, Jaffee, and Viding (2012) identified bidirectional effects across four time points from early childhood into early adolescence between harsh discipline and children's self-control. The twins who experienced higher levels of harsh discipline in early childhood had lower levels of self-control at subsequent waves. Conversely, the twins with lower levels of self-control subsequently experienced more harsh discipline. MZ pairs also differed in the degree to which their mothers expressed negative feelings about them and these within-pair differences were predictive of within-pair differences in self-control, although the reverse was not true.

MZ Twins Discordant for Peer Relationships

In a study of school-age children from Canada, MZ twin differences in peer rejection in kindergarten and the quality of their relationship with their kindergarten teacher predicted within-pair differences in academic achievement in first grade, with the rejected twin (or the twin who had a poorer relationship with his or her kindergarten teacher) showing lower academic achievement than the better-liked twin (or the twin who had a better teacher relationship) (Vitaro, Boivin, Brendgen, Girard, & Dionne, 2012). Moreover, the twin who had relatively more aggressive friends in kindergarten was relatively more aggressive in first grade, partly as a result of peer victimization, presumably at the hands of those very friends (Vitaro et al., 2011).

In a sample of twins from the UK, MZ twins who were bullied had significantly more internalizing problems at age 10 years than their nonbullied cotwin, even controlling for preexisting internalizing problems at age 7 years (Arseneault et al., 2008). Data from the same sample showed that the pathway by which bullying victimization gets under the skin is also environmentally mediated, with the bullied twin in a pair showing blunted cortisol reactivity to a public speaking task relative to the nonbullied twin (Ouellet-Morin, Danese, et al., 2011). Among youth who were bullied or maltreated, blunted cortisol reactivity was shown to be associated with elevated social and behavioral problems (Ouellet-Morin, Odgers, et al., 2011).

Burt, McGue, and Iacono (2009) estimated fully cross-lagged models of the relationship between externalizing problems and peer delinquency at ages 14 and 17. The sample included MZ twins and results showed that controlling for the stability of externalizing problems and peer deviance, the twin who had more externalizing problems at 14 years of age was also the twin with more deviant peers at 17 years of age, regardless of whether twins did or did not share most of their friends. In contrast, within-pair differences in deviant peers at 14 years of age was unrelated to within-pair differences in externalizing problems at 17 years of age. Thus, regardless of any shared genetic liability for externalizing problems, adolescents were actively selecting themselves into particular peer groups on the basis of their actual attitudes, beliefs, or behaviors, although exposure to deviant peers was not increasing their externalizing problems. In contrast to these findings, Loehlin (2010) reported that MZ and DZ adolescent twins who shared fewer friends were also less similar in their drinking, suggesting that something about the composition of the peer group was causing within-pair differences in alcohol use even though there was also some indication that the association sharing friends and alcohol use partly reflected active G-E correlation in female (but not male) pairs.

MZ Twins Discordant for Health Risk Behaviors

The discordant MZ twin approach can also be used to test whether differences in twins' behavior lead to differences in their development. For example, Lynskey et al. (2003) reported that MZ twins who used cannabis by age 17 years had elevated rates of drug use, alcohol dependence, and other drug abuse/dependence in young adulthood relative to their cotwin who did not use cannabis by age 17 years. These associations were not accounted for by other known risk factors for young adult substance use or abuse and the findings imply that the effect of early cannabis use on later substance use is not accounted for by a common genetic or environment liability to use substances.

In a study of 189 young adult MZ twin pairs, male twins who had better sleep quality than their cotwins also had better self-reported health and female twins who had better sleep quality than their co-twins also reported higher

levels of relationship satisfaction (Barclay, Eley, Buysse, Maughan, & Gregory, 2012). Within-pair differences in sleep quality were unrelated to other experiences that were nonshared by twins in a pair (Barclay et al., 2012).

MZ Twins Discordant for Stressful Life Events and Life Course Transitions

The experience of stressful life events is a robust risk factor for depression, but observational studies are typically unable to determine whether some individuals have certain characteristics (e.g., high levels of neuroticism) that (1) make them more likely than others to experience stressful life events and (2) increase their risk for depressive disorder. This hypothesis was ruled out in a study of MZ twins who were discordant for their recent experience of stressful life events. Consistent with a causal effect of stressful life events on increasing risk for depression, the twin who had experienced more recent stressful life events had a greater risk of developing major depressive disorder than the twin who had experienced fewer recent stressful life events (Kendler & Gardner, 2010).

Burt et al. (2010) used longitudinal data from a study of 289 29-year-old monozygotic (MZ) and dizygotic (DZ) twin pairs to test whether active genotype–environment correlations (or other environmental factors) accounted for the association between marital status and men's antisocial behavior. They found that in both MZ and DZ pairs, the married twin in a pair had significantly lower levels of antisocial behavior compared with his unmarried cotwin. Similarly, in a study of middle-aged and older MZ twins from the Midlife in the United States Study, the twin who reported more social support from friends and family also reported higher levels of happiness than the twin who reported less social support from friends and family (Schnittker, 2008). However, within-pair differences in many other characteristics including marital status, social support from spouses, schooling, employment, income, and personal wealth were unrelated to within-pair differences in happiness although the measures were associated with happiness in the overall sample of unrelated individuals (Schnittker, 2008). Thus, to the extent that—in the population—high socioeconomic position, being married, and perceiving one's spouse to be supportive are associated with an individual's happiness, these associations are likely to be accounted for by genetic and family background factors.

Finally, in a sample of Danish adult male twins, the twin who was widowed or divorced reported lower cognitive abilities and more symptoms of depression than the married twin (Osler, McGue, Lund, & Christensen, 2008). Among female twins, the twin who was divorced or widowed also reported more symptoms of depression (Osler et al., 2008). Although within-pair differences in marital status were associated with within-pair differences in men's cognitive abilities and women's depression symptoms in DZ, but not MZ pairs, the confidence intervals around estimates of the marital status effect were largely overlapping in DZ and MZ groups (Osler et al., 2008). Thus, it is not clear whether the smaller effects of marital status observed in MZ pairs reflect a lack of statistical power to detect within-pair differences or whether they show that controlling completely for genetic differences within pairs eliminates associations between marital status and certain outcomes.

Criticisms of the Discordant MZ Twins Design

As discussed by Vitaro, Brengden, and Arseneault (2009), the discordant MZ twins design—especially when it is embedded within a longitudinal design—can allow researchers to make powerful causal inferences about the relationship between experiences and behavior. This is because it eliminates genetic differences within pairs as well as other potential family-wide confounds that might otherwise explain the relationship. A limitation of the design is that it requires there to be sufficient within-pair variability in experiences or outcome and that this reflect true variability rather than measurement error. This requirement is especially challenging for research on adolescents because adolescents have greater autonomy than younger children to select and create their own experiences. To the extent that such selection is driven by genetically influenced characteristics of the adolescent, MZ twins will become increasingly similar for their experiences as they transition from childhood to adolescence. In addition, because the design eliminates so many potential confounds, the variance in outcome accounted for by within-pair differences in experience is often modest (less than 5%).

Finally, the design estimates within-pair differences in exposure (e.g., to cannabis or parental criticism) which it presumes to be the cause of within-pair differences in outcome (e.g., later drug use, delinquency), but the design cannot rule out the possibility that some other event not shared by twins is the real culprit. For example, twins may differ with respect to their peer relationships, with one twin associating with peers who promote both cannabis and later drug use and the other twin associating with a more salubrious social group. Thus, although the design rules out the possibility that genetic differences within pairs account for the relationship between within-pair exposures and within-pair outcomes, it cannot definitively identify

the exposure as the causal agent of within-pair differences in outcome.

GENOTYPE–ENVIRONMENT CORRELATIONS AND DEVELOPMENT

Developmental psychopathologists have long been interested in correlations between persons and environments because of their potential to amplify individual differences as, for example, personality traits evoke reactions from family members, peers, and teachers, cause individuals to actively select certain kinds of experiences, make individuals selectively attentive to information about themselves and others, and influence the ways in which individuals seek to manipulate their environments (Caspi & Moffitt, 1995).

Like person–environment correlations, G-E correlations are also hypothesized to underlie developmental processes. In a simulation study, Beam and Turkheimer (2013) showed that the apparent increase in the heritability of many human traits (e.g., intelligence, personality traits) can be explained by G-E correlations that lead to increasing differentiation of DZ twins relative to MZ twins. Thus, small genetically based individual differences in behavior and abilities become amplified over time as individuals expose themselves to experiences for which they have some affinity and those experiences in turn reinforce and widen preexisting individual differences. Failing to model G-E correlations leads to an apparent increase over time in the heritability of a phenotype when, in fact, genetic influences on the phenotype remain stable over time.

Hicks et al. (2013) provided an empirical example of how G-E correlations underlie the process by which personality can be amplified into psychopathology. In their sample of 11-year-old twins, Hicks et al. (2013) measured the tendency to follow rules and endorse conventional norms—a construct they named *socialization* that shares many features with the Big 5 factor of conscientiousness (Costa & McCrae, 1992). Youth with lower scores on the measure of socialization subsequently experienced higher levels of contextual risk in mid-adolescence, such as a deviant peer group or a conflictual relationship with parents. The relationship between socialization and contextual risk was largely accounted for by genetic and shared environmental factors common to both constructs, indicative of an active G-E correlation. Moreover, youth with lower scores on the socialization measure in early adolescence tended to engage in higher levels of substance use in late adolescence, an association that was mediated by their exposure to contextual risk factors. Thus, genetically based individual differences in personality increased the likelihood that some youth would be exposed to higher levels of contextual risk than others, with implications for the emergence of substance use problems in late adolescence.

Another such example was provided by Klahr et al. (2013), who observed 546 mothers interacting with each of their 6- to 10-year-old twin children during a structured cooperative task. Interactions were coded in real time for maternal and child warmth and control using a joystick method. From minute to minute, children's efforts to exert control in the interaction were countered by mothers' efforts to retain their own control or relax the child's control, with the same genetic factors accounting for these correlations. The reverse was also true, highlighting the reciprocal nature of parent–child interactions over even a brief structured interaction. Thus, mothers and children were responding to genetically influenced tendencies towards submission or dominance. Although maternal and child warmth were also stable across the course of the interaction, nonshared environmental factors accounted for their covariance on a minute-to-minute basis and from one minute to the next (Klahr, Thomas, Hopwood, Klump, & Burt, 2013). Thus, whatever was causing some children or mothers to engage in higher levels of warmth than other children or mothers was specific to the situation and nonshared by twins in a pair.

Finally, studies of G-E correlation reflect and potentially shed further light on processes of developmental change. For example, it is understood that the behaviors that elicit parental irritability or hostility change as children develop. Parents may become frustrated with an infant who is difficult to soothe, a toddler who is prone to temper tantrums, a school-aged child who is oppositional, and an adolescent who breaks rules. Theories of heterotypic continuity assume that these diverse behaviors reflect some underlying construct that is likely to have some common origin. At least one twin study forces us to reexamine this assumption, however—at least in very early childhood. When hostile-reactive parenting behaviors were measured repeatedly over the first 2.5 years of life in a sample of Quebecois twins, genetic influences on these behaviors were only weakly correlated (Forget-Dubois et al., 2007). Thus, on one hand, the data were consistent with the hypothesis that hostile-reactive parenting would be evoked by different behaviors at different ages; on the other hand, the data ran contrary to expectations in showing that there was little common genetic basis to whatever behaviors were eliciting hostile-reactive parenting over time.

GENOTYPE–ENVIRONMENT CORRELATION: EVIDENCE FROM THE MOLECULAR GENETIC LITERATURE

In contrast to quantitative genetic studies, which infer genetic influences from familial correlations, molecular genetic studies measure genotype directly. Although the majority of studies that measure genotypes and putative environments fail to detect significant genotype–environment correlations (and there may be reasonable explanations for this pattern of null findings; Jaffee & Price, 2007), there is a small but growing set of positive findings that highlight issues worthy of further consideration.

Much of the recent work to demonstrate associations between measured genotypes and environments has involved relationships between maternal and child genotype and either reported or observed parenting behaviors. A growing number of studies have focused on interpersonal relationships more broadly, including partner relationships. Researchers interested in genetic influences on parenting have focused primarily on dopamine genes because of the role dopamine has been shown to play in facilitating affiliative behaviors in humans (Barrett & Fleming, 2011; Depue & Morrone-Strupinsky, 2005) and animals (Numan, 2007; Spielewoy et al., 2000) and because dopamine genotypes have been associated with externalizing child behaviors (Gizer, Ficks, & Waldman, 2009; Schmidt, Fox, Rubin, Hu, & Hamer, 2002) that may evoke sub-optimal parenting practices. Researchers have also focused on oxytocin genes because of the demonstrated role of oxytocin in pair bonding, including bonds between parents and children as well as between partners (Numan, 2006; Saltzman & Maestripieri, 2011).

Maternal Dopamine Genotype and Parental Behavior

Lee and colleagues (2010) identified a nonadditive association between maternal dopamine transporter 1 (DAT1) genotype and observed negative parenting behavior in a sample of 207 mother–son pairs, ranging in age from 3 to 7 years. DAT1 is a 40 base pair (bp) variable number tandem repeat located in the 3' untranslated region in exon 15 of the dopamine transporter gene (SLC6A3). The 40-bp sequence is typically repeated 9 or 10 times and the majority of individuals are either homozygous for the 9- or 10-repeat variants (i.e., 9/9 or 10/10) or heterozygous for the 9- and 10-repeat variants (9/10).

In analyses that controlled for parental psychopathology and child disruptive behavior during the parent–child observation, results showed that mothers with the 9/10 genotype engaged in more negative parenting (e.g., using critical and negative statements, using negative physical contact) compared with either homozygous group (9/9 or 10/10), with effect sizes that were small to moderate in magnitude ($d = .35$ for 9/9 vs. 9/10 and $d = .19$ for 10/10 vs. 9/10). Mothers with the 9/9 genotype issued fewer commands to the child compared with mothers who carried the 10-repeat allele ($d = .33$). Maternal genotype was not correlated with positive parenting (e.g., praising child, positive affect, positive physical contact). Moreover, the relationship between maternal genotype, negative parenting, and maternal commands was strongest when children engaged in high levels of disruptive behavior during the parent–child interaction task. When children engaged in lower levels of disruptive behavior (e.g., at the median or lower), levels of negative parenting and the number of commands issued were uniformly low for all maternal genotype groups.

Although main effects of maternal genotype on maternal behavior have been detected infrequently, the finding that the relationship between maternal genotype and maternal behavior is conditional on individual or contextual features is one that has been replicated by other researchers. For example, three studies have shown that the relationship between maternal dopamine receptor D4 (DRD4) genotype and observed maternal sensitivity depends on characteristics of the infant or other features of the mother's environment. One found that mothers who carried the 7-repeat DRD4 allele behaved more sensitively with fussy infants than with nonfussy infants. In contrast, mothers who did not carry any 7-repeat alleles were equally sensitive to their infants, regardless of infant temperament, with this interaction accounting for nearly 3% of the variation in maternal sensitivity (Kaitz et al., 2010). The second study found that mothers who carried the 7-repeat allele were more sensitive with their 3.5-year-olds if, as newborns, their children had lower versus higher levels of birth risk (as indexed by gestational age, birth weight, and admission to the neonatal intensive care unit). Again, mothers who did not carry any 7-repeat allele were equally sensitive to their children regardless of infant birth risk, with this interaction accounting for 5% of the variation in maternal sensitivity (Fortuna et al., 2011). The third study found that the combined effects of DRD4 and catechol-O-transferase (COMT) genotype on how sensitively mothers engaged with their toddler-age children depended on the level of daily hassles mothers reported experiencing. Mothers who had a combination of COMT and DRD4 genotypes associated with the least efficient dopamine transmission engaged in the least sensitive

parenting in the context of high levels of daily hassles, but the most sensitive parenting in the context of low levels of daily hassles, with this interaction accounting for approximately 2% of the variation in maternal sensitivity (van IJzendoorn, Bakermans-Kranenburg, & Mesman, 2008). Taken together, these studies suggest that the behavior of mothers who do not carry the 7-repeat *DRD4* allele is relatively consistent, regardless of child characteristics or other features of the environment. In contrast, the behavior of mothers who do carry the 7-repeat allele (perhaps in combination with specific *COMT* genotypes) is highly responsive to context, with two of the three studies showing that under optimal conditions (e.g., low levels of daily hassles, low levels of infant birth risk) these mothers are more sensitive with their children than 7-repeat-absent mothers, but less sensitive than 7-repeat-absent mothers under less optimal conditions.

Child Dopamine Genotype and Parental Behavior

At least three studies have estimated the relationship between the dopamine receptor D2 (DRD2) allele in the child and parenting behavior. DRD2 has a restriction length fragment polymorphism called TAQ1A (rs1800497) located on chromosome 11q. Taq1A has two alleles, known as A1 and A2 (Eisenberg et al., 2007). Postmortem studies and studies using positron emission topography have shown that individuals who carry the A1 allele (A1 +) have fewer D2 dopamine receptors than individuals who are homozygous for the A2 allele (A1-) (Jonsson et al., 1999; Noble, Blum, Ritchie, Montgomery, & Sheridan, 1991; Pohjalainen et al., 1998; Thompson et al., 1997). In addition, children who carry the A1 allele have been shown to be more anxious and to have higher levels of negative emotionality compared with children who are homozygous for the A2 allele (Hayden et al., 2010; Marino et al., 2004; Mills-Koonce et al., 2007). Thus, Taq1A has been the focus of research on the genetic basis for child effects on parent behavior.

Two studies have shown that A1 + children receive less sensitive and supportive parenting compared with A1– children, as observed during parent–child interaction tasks (Hayden et al., 2010; Mills-Koonce et al., 2007). Effect sizes were small to moderate in magnitude ($d = .25$ for Hayden et al., 2010; $d = .40$ for Mills-Koonce et al., 2007). In addition, in their sample of 473 3- to 4-year-old children, Hayden et al. (2010) showed that the relationship between *DRD2* genotype and supportive parenting was partially mediated by child negative emotionality. Although Mills-Koonce et al. (2007) found a main effect of child (but not maternal) *DRD2* genotype on maternal sensitivity in their sample of 172 mother-infant pairs participating in the Durham Child Health and Development Study, this effect was not moderated by other child, maternal, or family characteristics nor was it mediated by child negativity.

Other dopamine gene variants have been implicated in the genetic basis of child effects on maternal behavior. A separate analysis of children in the Durham Child Health and Development Study showed that DRD4 genotype was also associated with maternal sensitivity; children with the long DRD4 allele (6–8 repeats or 7-repeats) experienced lower levels of warm-responsive parenting than children with the short form of the allele ($d = .34$) (Propper, Willoughby, Halpern, Carbone, & Cox, 2007). When followed up at school-age, DRD4 genotype was also associated with girls' academic outcomes, with mediational analyses showing that low levels of sensitive parenting in the preschool years explained why girls who carried the long form of the DRD4 allele scored lower on a standardized achievement test and were judged by teachers to perform more poorly in the classroom compared with girls who carried the short form of the allele (Propper, Shanahan, Russo, & Mills-Koonce, 2012). For boys, DRD2 genotype was associated with parental sensitivity and school performance (Propper et al., 2012). Finally, in an age-6-year follow-up of children who participated in the study reported by Hayden et al. (2010), those who carried the DAT1 9-repeat allele experienced more hostility ($d = .22$) and received less guidance ($d = .28$) from their caregivers during a structured task compared with 10/10 homozygotes and this association was partly explained by elevated levels of negative emotionality directed at the caregiver by children who carried the 9-repeat allele (Hayden et al., 2013).

Oppenheimer et al. (2013) estimated the association between child COMT genotype and parental sensitivity in a sample of 263 third, sixth, and ninth graders. Although no main effects of youth genotype on parental sensitivity were identified, there was a significant interaction between youth genotype and parental personality characteristics. If parents were high in extraversion or low in neuroticism, the more copies of the Val allele youth carried, the more sensitive parenting they received. In contrast, if parents were low in extraversion or high in neuroticism, youth genotype was unassociated with parental responsivity. These interactions accounted for 1% to 2% of the variation in parenting. Thus, the extent to which genetically influenced characteristics of youth evoke sensitive or insensitive parenting may depend on characteristics of the parents.

Child Dopamine Genotype and Peer Relations

Homophily refers to the tendency to bond with similar others. Heterophily, in contrast, reflects the tendency to gather in diverse groups. These processes have been shown to have a genetic basis, such that adolescents' genotype for the Taq1A polymorphism in the DRD2 gene was positively predictive of their friends DRD2 genotype (i.e., genetic homophily) and adolescents' cytochrome P450 2A6 (CYP2A6) was negatively predictive of their friends' CYP2A6 genotype (i.e., genetic heterophily; Fowler, Settle, & Christakis, 2011). To the extent that these genotypes are associated with personality and social behavior, they may explain why genetically similar (or dissimilar) others are drawn to each other (Fowler et al., 2011).

In an extension of these results, Boardman, Domingue, and Fletcher (2012) demonstrated that genetic homophily for the Taq1A polymorphism in DRD2 was strongest in schools characterized by the highest levels of socioeconomic inequality, suggesting that friends' genetic similarity may not reflect the active selection by one adolescent of a genetically similar friend but rather structural factors (e.g., tracking within school curricula) that sort genetically similar individuals into similar environments. Thus, genetically-based homophily under these circumstances may reflect evocative G-E correlations (e.g., teachers responding to a youth's innate ability by tracking them along a more or less advanced curriculum) as opposed to active G-E correlations (Boardman, Domingue, & Fletcher, 2012).

Finally, measured genotype has been associated with peer delinquency. Two studies, both using data from the National Longitudinal Study of Adolescent Health reported that the 10-repeat variant of DAT1 was associated with adolescent reports of peer delinquency (Beaver, Wright, & DeLisi, 2008) as well as reported delinquency from the adolescent's peer network members (Yun, Cheong, & Walsh, 2011). However, these associations were only detected for White males from high-risk family backgrounds in stratified analyses, calling into question the robustness of the effect.

Serotonin Genotype, Parenting, and Peer Relations

Because of the role that serotonin plays in the regulation of anxious, depressed, and impulsive behavior, researchers have hypothesized that variants in serotonin system genes may be related to parenting behavior, although the only genome-wide association study of children's anxiety did not identify variants in the serotonin system (or anywhere else in the genome) that met genome-wide levels of significance (Trzaskowski et al., 2013) and serotonin system gene variants have inconsistently been associated with children's depressed or anxious behaviors in candidate gene studies. Nevertheless, in a study of 376 3.5-year-old children, Pener-Tessler et al. (2013) reported that boys who carried at least one copy of the short allele of the serotonin transporter gene-linked polymorphic region (5-HTTLPR) were observed to experience less positive parenting from their mothers and this was because 5-HTTLPR genotype was associated with lower levels of boys' self-control.

Maternal Oxytocin Genotype and Maternal Behavior

Oxytocin is a hormone that plays an important role in facilitating affiliative maternal behavior in animals (Numan, 2006; Saltzman & Maestripieri, 2011) and is a focus of investigation in a growing number of studies of human maternal behavior (Galbally, Lewis, van IJzendoorn, & Permezel, 2011; Gordon, Zagoory-Sharon, Leckman, & Feldman, 2010; Naber, van IJzendoorn, Deschamps, van Engeland, & Bakermans-Kranenburg, 2010). For these reasons, researchers have investigated whether common polymorphisms in oxytocin genes are related to maternal sensitivity. In a sample of 176 mothers, the oxytocin receptor gene *(OXTR;* rs53576*)* was associated with maternal sensitivity, accounting for 3% of the variation; mothers with the GG genotype behaved more sensitively in observed parent–child interactions with their toddlers than mothers with the AG or AA genotypes (Bakermans-Kranenburg & van IJzendoorn, 2008). In an effort to identify physiological mediators of genetic effects, Riem and colleagues (2011) exposed 40 women without children to recordings of infant crying bouts and recorded their heart rate. Women with the GG genotype had greater heart rate reactivity to infant cries, but only if they did not have high levels of depressive symptoms, with this interaction accounting for 20–25% of the variation in autonomic arousal. The authors hypothesized that, for nondepressed women at least, high levels of autonomic arousal underlie quick responding to infants' needs.

Oxtyocin and Pair-Bonding Behavior

Variation within the OXTR gene has also been associated with other forms of pair-bonding. For example, in a study comprising three independent samples of Swedish adult and child twins, one of 12 SNPs genotyped across the *OXTR* gene (rs7632287) was associated with a measure of marital quality, support-seeking behavior, and marital instability in the sample of older adult twins (Walum et al., 2012). The association between rs7632287 and affectionate

relationship quality was also observed in the 323 young women (but not the 142 young men) who were in romantic relationships in the younger adult twin sample. In both samples, women who carried one or two copies of the A allele had poorer relationship quality scores than women who carried two copies of the G allele. Moreover, in the older adult twin sample, women who carried one or two copies of the A allele were approximately 50% more likely to have reported a marital crisis or threat of divorce in the past year than women who carried two copies of the G allele. Finally, the *husbands* of women who carried one or two copies of the A allele reported significantly lower marital satisfaction than the husbands of women who carried two copies of the G allele.

In the younger adult sample, women in romantic relationships who carried one or two copies of the A allele scored significantly higher on the CBCL Social Problems Scale when they were 8 to 9 years old compared with women in romantic relationships who carried two copies of the G allele, with Social Problems, in turn, predicting poor relationship quality in young adulthood (Walum et al., 2012). Thus, a variant in the OXTR gene was associated not only with pair-bonding behavior in adulthood but also with developmental precursors of pair-bonding behavior.

Using data from a sample of 909 adult twins, Walum et al. (2008) reported that a polymorphism (RS3) in the arginine vasopressin receptor subtype 1a (AVPR1a) gene was associated with pair-bonding behavior in men, such that men who were homozygous for the RS3 334 allele reported less marital satisfaction, support seeking, and poorer relationship quality than men who carried 1 or 0 copies of RS3 334. Moreover, carrying two copies of the 334 allele was associated with double the risk of having experienced a marital crisis in the past year compared with carrying 0 copies of the 334 allele.

Genome-Wide Association Studies

Although genome-wide association studies of complex physical and mental disorders have become common, genome-wide association studies of putative environments are still rare. Butcher and Plomin (2008) conducted a two-stage analysis that first involved pooling DNA from 4-year-old twins whose families were selected for inclusion because they scored at the high versus low extremes on a measure of chaotic family environment. A comparison of allele frequencies in the high versus low chaos groups was then used to inform the selection of SNPs ($n = 48$) for individual genotyping at the second stage of analysis, which involved one twin from each of the remaining pairs in the sample ($n = 3,529$). However, none of these 48 SNPs was associated with chaotic family environment (Butcher & Plomin, 2008).

Recently, researchers in the social sciences have adopted the practice of consolidating data from multiple data sets that include genetic as well as social science data (Rietveld et al., 2013; van der Loos et al., 2013). By conducting GWAS meta-analysis, SNPs have been identified that are associated with educational attainment, though any given SNP accounted for less than 1% of the variance in educational attainment and even a linear combination of all measured SNPs explained only about 2% of the variance (Rietveld et al., 2013). Another GWAS meta-analysis failed to identify individual SNPs that exceeded genome-wide levels of significance and that were associated with the tendency to be self-employed (van der Loos et al., 2013). The data were consistent with the possibility that multiple genes of small effect additively account for variation in this phenotype (van der Loos et al., 2013).

Summary of Findings from Molecular Genetic Studies and Future Directions for Research

Although the field remains small, a growing number of studies have identified correlations between maternal or child genotype and maternal behavior or between individual genotype and pair-bonding behavior more generally. These associations are typically modest in magnitude, accounting for as little variation in outcome as any single construct typically does in studies of developmental psychopathology. Often these associations are conditional on other features of the interaction, including characteristics of the child, the mother, or the broader context. In some cases, the data are consistent with the notion that some individuals are more susceptible than others to their environments in a for-better-and-worse fashion (Fortuna et al., 2011; Kaitz et al., 2010; Oppenheimer, Hankin, Jenness, Young, & Smolen, 2013).

The field of molecular genetic research into genotype–environment correlation faces three major challenges. The first is to produce a body of replicated findings. This goal is undercut by the fact that a great number of researchers who publish papers on measured genes and measured environments still fail to report genotype–environment correlations, possibly because the research is usually focused on identifying gene × environment interactions. As just one example, in the 10 nonexperimental studies of differential susceptibility to environment reviewed by Bakermans-Kranenburg and Van IJzedoorn (2011), only

five reported whether child (or maternal) genotype was correlated with the environmental measure. Thus, in many cases it is not clear whether a finding has been replicated because the test of genotype–environment correlation has not been reported.

Moreover, as has been observed in the literature on genotype × environment interaction, efforts to replicate findings have been challenged by the use of heterogeneous measures of the environment (Uher & McGuffin, 2010), making it unclear whether a specific genotype × environment interaction has not been replicated because the original finding was a false positive or because the replication sample involved a measure of the environment that was substantially different from the measure used in the original sample. In the first instance, replication attempts should involve measures of the environment that are operationalized as closely as possible to the original measure. Once it has been established that the original finding is replicable under these narrow conditions, the field can proceed to test the sensitivity of the genotype–environment correlation to alternative specifications of the environment.

The second major challenge to the molecular genetic study of associations between genotype and environment is for this enterprise to articulate its raison d'être. This research demonstrates an important proof of principle—that genes and environments do not just act additively and interactively to influence behavior, cognition, or psychopathology, but that (in the words of Richard Dawkins; Dawkins, 1982) genes get "outside the skin" to affect the environment itself (Kendler, 2011). A critic might take the position that beyond such generalizations this research does not tell us anything we did not know already. That is, the idea that *person–environment* correlations are important in shaping development has long been recognized in life span developmental psychology and developmental psychopathology (Elder, 1998; Rutter & Pickles, 1991). The primary focus of attention should remain the specific behaviors that serve to influence environments, not the genotypes that cause those behaviors (Moffitt, Caspi, & Rutter, 2005).

However, if molecular genetic studies of genotype–environment correlation do not have immediate translational implications, they may still merit study. There is often a long span of time before the translational benefits of epidemiological and basic research are realized (Rutter & Plomin, 2009) and the more immediate pay-off may be in a better understanding of the biological basis of behaviors that shape environments crucial for our survival and healthy development. For example, how do we optimize the chances that children will be sensitively nurtured by their caregivers? Many clinicians already screen for difficulties that caregivers might face in providing sensitive care, including a lack of social support, substance use problems, postpartum depression, and domestic violence, although beyond making caregivers aware of relevant services, there is generally little follow-through to ensure that caregivers are actually coping. A current lack of joined-up services aside, imagine that as our understanding of the biological basis of children's difficult temperament advances, researchers can identify a panel of biomarkers which exceeds some threshold of sensitivity and specificity for identifying children who fail to establish regular sleeping or feeding routines, react strongly and negatively to novelty, frequently fuss and cry, and are difficult to soothe. Combining this information about children's biological risk with information about their social circumstances may help clinicians and social service workers identify particularly vulnerable infant-caregiver dyads and provide caregivers with adequate support and training to cope with challenging infants. This combination of screening and parent training could potentially circumvent evocative genotype–environment correlations in which difficult children elicit harsh and insensitive care from adults and it could potentially do so before clinically significant child behavior problems emerge.

A third challenge in this research is methodological. To date, research on measured genes and measured environments has generally proceeded on a gene variant by gene variant basis. In some cases, researchers have combined information from two genes (Oppenheimer et al., 2013; van IJzendoorn et al., 2008). However, the prior probability of an association between a genetic polymorphism and an environment is exceedingly low (Davey Smith et al., 2007). Genome-wide association studies (GWAS), with their measures of hundreds of thousands of single nucleotide polymorphisms (SNPs) provide the means to test hypotheses about genetic influences over the environment on a scale that is appropriate to our lack of knowledge about how genes act (Butcher & Plomin, 2008). These vast yet affordable studies also provide opportunities to conduct pathway analyses and to group genes in functionally similar sets (Sun et al., 2010) or to aggregate multiple genes of small effect (Purcell et al., 2009).

The problem with these approaches is that GWA studies often require tens of thousands of participants to generate sufficient statistical power to detect genetic main effects and, consequently, there are practical limitations as to the kinds of environmental measures that can be collected. For example, observational assessments of parents and children would not be feasible in a sample of

20,000 participants. One possible solution is to use the information generated from GWAS of personality traits and behaviors that are hypothesized to mediate relationships between genes and environments. For example, the Five Factor Model of Personality can be evaluated with a relatively brief paper-and-pencil instrument that could be administered to large numbers of individuals. These individuals could be genotyped and statistical approaches could be used to generate polygenic scores (i.e., SNP sets) that predicted substantial amounts of variance in personality factors. If one hypothesized that individuals who were high in negative emotionality and low in agreeableness were especially likely to elicit hostile reactions from their romantic partners, then one could genotype those SNP sets in a smaller sample that allowed for intensive observations of interactions between couples and test for associations between the polygenic score and couples' behavior with each other.

Several caveats bear noting with the proposed approach. The first is that once researchers move from candidate gene approaches to polygenic scores, the possibility of testing mechanistic hypotheses is eliminated. Because they aggregate information across thousands of SNPs, polygenic scores are no more informative about the mechanisms by which genes influence brain and behavior than black box genetic risk estimates derived from family data (e.g., knowledge of a relative's diagnostic status). Moreover, they are usually far less predictive of outcome—although, unlike family history, polygenic scores are able to predict disease risk within as well as between families (Ruderfer et al., 2011). The second caveat is that although GWAS of personality traits are underway, results have been mixed and variants that reach genome-wide statistical significance generally account for less than 1% of the variation in personality traits (Shifman et al., 2008; Terracciano et al., 2010; van den Oord et al., 2008; Verweij et al., 2010).

Finally, some of the findings described in this section underscore the complexity of G-E interplay—specifically, the coexistence of genotype–environment correlations and genotype–environment interactions. For example, in the study conducted by van IJzendoorn et al. (2008), mothers with Val/Met or Val/Val COMT genotypes reported experiencing more daily hassles than mothers who were homozygous for the Met genotype—a genotype–environment correlation. Moreover, when compared with mothers who were homozygous for the Met allele, their parenting was also more adversely affected by these daily hassles, particularly if they also carried the DRD4 7-repeat allele—a genotype × environment interaction. As another example, although mothers who were homozygous for the 9-repeat allele of DAT1 engaged in lower levels of negative parenting than mothers who carried the 10-repeat allele (Lee et al., 2010), child DAT1 genotype was unassociated with negative parenting in the same sample (Lahey et al., 2011). However, the adverse effect of negative parenting on boys' conduct problems was strongest when the sons were homozygous for the 9-repeat allele (Lahey et al., 2011). Here, then, the same genotype that was associated with lower levels of negative parenting was associated with higher levels of child conduct problems but only when boys were exposed to high levels of negative parenting.

USING GENOTYPE–ENVIRONMENT CORRELATIONS TO UNDERSTAND CAUSAL MECHANISMS

As reviewed so far, genotype–environment correlations have been a focus of study by quantitative and molecular genetic researchers who want to demonstrate that putative environments are under genetic influence. In quasi-experimental studies, genotype–environment correlations are treated as potential confounds that must be rejected as alternative explanations for observed associations between exposures and outcomes. A third reason investigators are interested in genotype–environment correlations is because they can be used to determine whether specific exposures (e.g., diet, health-related behaviors, toxins) have causal effects on disease. Genetic associations can be interpreted as causal. The processes that determine one's genotype—meiosis and possibly mutation in the parental germ-line cells, followed by fertilization—are causally prior to outcomes. This excludes the possibilities of reverse causality and transactional relationships between genotypes and outcomes like psychopathology. For example, an episode of depression cannot cause changes in the structure of DNA (although it could lead to epigenetic changes). Since the process by which the maternal and paternal chromosomes in each cell are reshuffled during meiosis to produce gametes is random, most kinds of confounding are also excluded. The major confound is population ancestry, the effects of which can be controlled for statistically if genotype data is collected on a sufficient scale (Devlin, Bacanu, & Roeder, 2004; Price et al., 2006).

Risk genotypes do not necessarily have direct effects on outcomes, however, and often their effects will be mediated by measurable environments. This phenomenon can sometimes be exploited to show causal environmental effects. Let us imagine that there exists a genetic variant whose biological function mimics that of the environment,

or indeed directly influences the degree of exposure. Under certain circumstances, the genotype can act as a proxy variable or *instrument* for the environmental exposure, but one that is untroubled by confounding and reverse causality. As a consequence, association between the genetic proxy and an outcome can be interpreted as evidence for a causal effect of the environment. (It bears noting that the term *environmental exposure* in this context can mean nutritional or toxin exposures or sometimes health behaviors that are more typically studied as outcome variables in psychology and psychiatry.)

Although the concept of instrumental variables and the related statistical methodology originates in the field of econometrics, its application to genetic epidemiology has been dubbed "Mendelian randomization" (MR) (Davey Smith & Ebrahim, 2003). The technique is premised on Gregor Mendel's second law—the law of random assortment—which states that traits are inherited independently of each other. A genotype that influences exposure, but has an independent effect on the outcome—or is linked to another genotype that does—would confound their association, rather than measure it. Mendel's second law does not operate in the presence of pleiotropy or linkage, and neither does MR. (In technical terms, these are violations of the requirement that an instrumental variable be *exogenous*—that is, its value is determined by factors that are external to the causal system under study). These conditions are difficult to guarantee because we do not usually know the full range of effects of any particular genotype, not to mention the many nearby genotypes that may have correlated effects due to linkage disequilibrium. In addition, the range of exposures that could be considered for a MR experiment is restricted to those with documented genetic proxies that have reasonably strong effects—and this is currently a very short list.

The aldehyde dehydrogenase 2 (ALDH2) gene has been used as a genetic proxy for alcohol exposure in many studies because it fulfills these assumptions. ALDH2 metabolizes an ethanol byproduct, acetaldehyde, into acetate. Homozygotes for the mutant ALDH2*2 allele have negligible ALDH2 activity and, after drinking alcohol, they experience an unpleasant flushing reaction with associated nausea, drowsiness, and headache as a result of acetaldehyde accumulation. Heterozygotes have reduced ALDH2 activity and experience less severe flushing. The ALDH2*2 allele is common in East Asian populations and there is clear evidence of a correlation between ALDH2 genotype and alcohol exposure, with alcohol intake increasing as a function of the number of ALDH2*1 alleles (Lewis & Smith, 2005).

Although ALDH2 has primarily been used as a genetic proxy for alcohol exposure in studies of cancer, Irons, McGue, Iacono, and Oetting (2007) used MR to test the gateway hypothesis that alcohol use in adolescence leads directly to other forms of drug abuse and disinhibited behavior. Critics of the gateway hypothesis argue that alcohol use (or marijuana use) is correlated with the use of harder drugs because of a general propensity to try drugs and that the reason adolescents tend to try alcohol and marijuana before trying harder drugs is because opportunities to try the former tend to present themselves before opportunities to try the latter (Morral, McCaffrey, & Paddock, 2002). MR provides a test of the gateway hypothesis because ALDH2 will be associated with alcohol use, but the law of random assortment means that it is unlikely to be associated with other individual factors (e.g., delinquency, sensation-seeking, socioeconomic status) that are also correlated with alcohol use and could explain observed associations between alcohol use and later drug use.

Using data from a sample of 180 East Asian adolescents, they found that ALDH2 deficient adolescents (i.e., those who were homozygous or heterozygous for the ALDH2*2 allele) used alcohol less often than ALDH2 nondeficient adolescents, thus establishing that ALDH2 genotype was associated with alcohol exposure. However, youth who carried the ALDH2*2 allele (i.e., the proxy for low alcohol exposure) did not engage in significantly less lifetime or past-year use of other drugs (including tobacco, marijuana, or other illicit substances) or less disinhibited behavior compared with youth who were homozygous for the ALDH2*1 allele. The findings suggest that alcohol use per se is not a gateway to the use of other drugs or to disinhibited behavior.

MR may have applications in other areas of developmental psychopathology where researchers are interested in the role of dietary factors and toxin exposures in disorders like attention deficit/hyperactivity disorder (ADHD) and in neurodevelopmental disorders (Froehlich et al., 2011; Nigg, 2010). For example, Mendelian randomization could be used to test whether folate supplementation in early pregnancy causes reductions in neurodevelopmental and behavioral problems in early childhood, potentially via epigenetic changes in gene expression involving methylation (Glymour, Veling, & Susser, 2011). Folate triggers a metabolic process by which homocysteine is converted to methionine, which plays a role in DNA methylation (Lucock, 2000). MR studies of the association between folate intake and neurodevelopmental outcomes would require the identification of a functional gene variant that mimics the effects of folate intake. With some caveats,

the gene methylenetetrahydrofolate reductase (MTHFR) meets this condition. MTHFR has a common variant (MTHFR C677T) that influences the speed at which homocysteine is converted into methionine. The *677TT* allele encodes an enzyme that is associated with a slower conversion of 5, 10 MTHF to 5 MTHF. Consequently, the conversion of homocysteine into methionine is also slowed, a process that mimics the effects of folate restriction. Thus, MTHFRC677T status can potentially be used as a proxy for folate status, although the validity of this approach has been questioned based on the observation that very high folate concentrations effectively silence the effects of MTHRF677TT (Schatzkin et al., 2009).

As a final example, there is some evidence that iron deficiency (and a range of other micronutrient and toxin exposures) is associated with ADHD (Froehlich et al., 2011). The biological plausibility of this association is bolstered by the observation that iron status affects myelination, dopamine neurotransmission, and cortical fiber conduction (Froehlich et al., 2011). Gene variants that influence serum iron concentrations, such as the hemochromatosis allele (HFE C282Y) could serve as genetic proxies for serum iron status (Schatzkin et al., 2009). Associations between these gene variants and ADHD would be strongly suggestive of a causal role for iron status in ADHD.

Mendelian randomization makes a number of assumptions, some of which may be more defensible than others. Thus, Mendelian randomization, like other quasi-experimental methods, cannot be considered a gold standard, but the findings from studies using MR must be viewed in the context of findings from other research designs that make different assumptions and have different strengths and weaknesses.

As genome-wide association studies identify more and more of the genetic determinants of a range of biomarkers, the potential for using MR in the context of developmental psychopathology is likely to expand. However, MR will only be a promising methodological prospect to the extent that researchers understand the biological mechanisms by which specific exposures "get under the skin" to influence behavior. Clearly, the potential for using MR is limited by the nature of the exposure, such that those involving physical effects on the organism are likely to be more empirically tractable than those involving psychological (as well as) physical effects. For example, researchers hoping to use MR to test hypotheses about the relationship between abusive parenting or social deprivation and psychopathology are unlikely to identify plausible genetic proxies. Although there have been relatively few efforts to date to identify genes associated with social environments (Benjamin et al., 2012; Butcher & Plomin, 2008; Rietveld et al., 2013; van der Loos et al., 2013), this may be changing as social scientists join consortia devoted to consolidating data sets that include information on genotype and social science traits (e.g., education, income, attitudes).

TRANSLATIONAL IMPLICATIONS

Research designs that can measure and potentially rule out G-E correlations as potential sources of confounding are valuable from an intervention standpoint because they provide data on which exposures or experiences are likely to have causal effects on development. Such designs can be important complements to randomized control trials, which are characterized by their own strengths and limitations. Because they control for observed and unobserved heterogeneity, genetically sensitive designs (more so than observational studies) can identify upper and lower limits on the size of the effects that are likely to be observed in randomized control trials and they can potentially be informative about the breadth of effects that are likely to be observed. For example, interventions to reduce parental substance use may be effective in achieving that aim, but reductions in offspring externalizing problems are unlikely to be a serendipitous by-product of such interventions because the association between parent substance use and offspring externalizing problems appears to be genetically rather than environmentally mediated (Table 7.1).

CONCLUSIONS

The recognition that genes get outside the skin to shape the environment has important implications for research in developmental psychology and psychopathology. Namely, genotype–environment correlations over-turn conventional models of the determinants of individual differences in health, behavior, and cognitions. Genes and environments do not always act independently (additively or interactively) to influence phenotypes. Rather, our genes shape our behaviors and cognitions and these, in turn, shape our environments. Thus, social causation theories must explicitly rule out the alternative hypothesis that genotype confounds the relationship between exposures and outcomes. Otherwise, researchers run the risk of misidentifying the true causal agent in the relationship between a given exposure and a given outcome.

As summarized in Table 7.1, the data are largely consistent across research designs in the conclusions they draw

TABLE 7.1 Summary of Findings from Across Twin and Adoption Studies Testing Genetic Versus Environmental Mediation

	Adoption	Bivariate twin	Children of Twin	Twins & Parents	MZ Difference
Harsh parenting	ENV (Harold et al., 2012; Harold, Leve, Elam, et al., 2013; Rhoades et al., 2012; Stover et al., 2012)		ENV (Lynch, Turkheimer, D'Onofrio, Mendle, & Emery, 2006)	ENV (Eaves et al., 2010)	ENV (Asbury et al., 2006; Asbury et al., 2003; Cecil, Barker, Jaffee, & Viding, 2012; Deater-Deckard et al., 2001; Pike et al., 1996)
Parental criticism and parent–child conflict	ENV (Burt et al., 2011; Harold, Leve, Elam, et al., 2013; Klahr et al., 2011)		GEN (Marceau et al., 2013; Narusyte et al., 2011)		ENV (Burt, McGue, Iacono, & Krueger, 2006; Carbonneau et al., 2002; Caspi et al., 2004; Cecil et al., 2012; Larsson et al., 2008; Mullineaux et al., 2009; Shelton et al., 2008)
Interparental conflict	ENV (Harold et al., 2012; Harold, Leve, Elam, et al., 2013; Rhoades et al., 2012; Stover et al., 2012)		GEN (Harden, Turkheimer, et al., 2007; Schermerhorn et al., 2011)		
Divorce					
On externalizing and internalizing	ENV (Burt, Barnes, McGue, & Iacono, 2008) GEN (O'Connor, Caspi, DeFries, & Plomin, 2000)		ENV (D'Onofrio et al., 2005; D'Onofrio et al., 2006)		
On internalizing			ENV (D'Onofrio et al., 2005; D'Onofrio et al., 2006) GEN (D'Onofrio, Turkheimer, Emery, Maes, et al., 2007)		
On substance use			GEN (D'Onofrio et al., 2006) ENV (D'Onofrio et al., 2005; D'Onofrio, Turkheimer, Emery, Maes, et al., 2007)		
On cohabitation and transmission of divorce			GEN (D'Onofrio et al., 2006; D'Onofrio, Turkheimer, Emery, Harden, et al., 2007)		
Intergenerational transmission depression/anxiety	ENV (Brooker et al., 2014; Kerr et al., 2013; Tully et al., 2008)		ENV (Singh et al., 2011)		
Maternal depression to offspring conduct problems	ENV (Kerr et al., 2013; Pemberton et al., 2010; Tully et al., 2008)				

(*continued*)

TABLE 7.1 (*Continued*)

	Adoption	Bivariate twin	Children of Twin	Twins & Parents	MZ Difference
Intergenerational transmission antisocial behavior	ENV (Kerr et al., 2013) GEN (Bornovalova et al., 2014)		ENV (Silberg et al., 2012) ENV (for boys) (D'Onofrio, Slutske, et al., 2007) GEN (for girls) (D'Onofrio, Slutske, et al., 2007)		
Intergenerational transmission substance use			ENV (Jacob et al., 2003) GEN(Duncan et al., 2006; Slutske et al., 2008)		
Parental substance use to offspring ADHD and conduct problems			GEN (Haber et al., 2005; Knopik et al., 2006; Waldron et al., 2009)		
Peer victimization and rejection					ENV (Arseneault et al., 2008) (Ouellet-Morin et al., 2011a) (Vitaro et al., 2011) (Vitaro et al., 2012)
Peer deviance					
On cannabis use		GEN (Gillespie et al., 2009)			
On antisocial behavior		GEN (Kendler et al., 2008)			Nongenetically- mediated child effect (Burt, McGue, & Iacono, 2009)
On nicotine or alcohol use		ENV (Harden et al., 2008; Samek et al., 2013; Walden et al., 2004)			(Loehlin, 2010)
Marital status					
On antisocial behavior		ENV (Barnes & Beaver, 2012) GEN (Horn et al., 2013)[1]			ENV (Burt et al., 2010)
On depression		ENV (Horn et al., 2013)			ENV (Osler et al., 2008)
On happiness					GEN (Schnittker, 2008)
Marital quality		ENV (Beam et al., 2011; Spotts, Pedersen, et al., 2005)			GEN (Schnittker, 2008)
Smoking in pregnancy on externalizing problems	GEN (Gaysina et al., 2013; Rice et al., 2009; Thapar et al., 2009)				

Note: ENV = environmentally mediated effect; GEN = genetically mediated effect (via passive, evocative or active G-E correlation).
[1]The genetically mediated effect was specific to the comparison of married and cohabiting versus single respondents; reduced antisocial behavior in married versus cohabiting individuals was not confounded by genetic or shared environmental selection factors (Horn et al., 2013).

about whether observed associations between exposures (or experiences) and outcomes are environmentally or genetically mediated. Such consistency is crucial, given that each method of identifying and accounting for G-E correlations has its own weaknesses. For example, there is no question that genetic factors partially explain why some parents more frequently use harsh discipline or express hostility toward their children than other parents; such evidence of genetic effects is obtained when adult twins report on how they parent their own children and when (nontwin) adults report on how they parent their twin children. The existence of these G-E correlations implies that observed associations between parents' use of harsh discipline and offspring conduct problems are inflated in magnitude when estimates are based on samples of genetically related parents and offspring. Despite the existence of G-E correlations, however, significant associations between harsh parenting and offspring conduct problems are observed in children of twins designs (which control for passive G-E correlation), twins and parents designs (which also control for passive G-E correlations), MZ difference designs (which control for all forms of G-E correlation), and adoption designs (which control for passive G-E correlation). Consistent evidence of environmentally mediated effects implies that researchers can usefully focus research on efforts to identify mechanisms by which harsh parenting increases risk for offspring conduct problems as well as conditions under which this mechanism would not be observed.

The old nature–nurture dichotomy—while alive and well in newspaper headlines—fails to capture the complexity by which genes and environments act together to influence normal and abnormal behavior. Genetic risk factors modify sensitivity to environmental risk factors (GxE) and—as described extensively in this chapter—they influence a person's exposure to environmental risk factors (rGE). Although not covered in this chapter, the environment also has the potential to regulate gene expression (Cole, 2011) and the epigenome (Mill, 2011). Advances in genetic epidemiology are therefore conditional on advances in environmental epidemiology (Moffitt et al., 2005). We have noted an important corollary: advances in genetic epidemiology can also *prompt* advances in environmental epidemiology.

A number of research designs are also available that are capable of ruling out genotype–environment correlations as alternative explanations for associations between risk exposures and outcomes. Although many of these designs require genetically sensitive data (e.g., measured genotypes or data from individuals who vary in their genetic relatedness), not all do. For example, studies of within-individual change merely require longitudinal data to test the hypothesis that a given event can change a person from one point in time to the next. More analytically sophisticated versions of these models allow researchers to account for simultaneous change in other aspects of the person's environment that may—alongside the focal exposure—change the individual's behavior (Sampson, Laub, & Wimer, 2006). In addition, genotype–environment correlations can be—under some conditions—leveraged to identify genetic proxies for environments and used to make causal inferences about environmental exposures. In summary, although genotype–environment correlations have received relatively less attention than G-E interactions, they are likely to play a key role in development. Taking account of genotype–environment correlations in research on putative environments is likely to enhance our understanding of environmentally mediated causes of individual differences in normal and abnormal development.

INTRODUCTION

From the beginning of the quest to comprehend the forces of human development (i.e., their typology and etiology), there was a notion that these forces had different sources: there is something that a child gives to this world (i.e., through abilities to be developed into competencies and expertise), and there is something that the world gives to the child (i.e., proximal adults, various experiences, or chance). Justifiably or not, these sources have been viewed as distinct entities and labeled as nature and nurture, respectively. Throughout the history of the developmental sciences, whether embedded in other sciences or forming sciences themselves, nature and nurture and their relationship have been defined across a continuum, from being independent to interdependent, with all possible variations in between.

Fast-forward to today, where the prevailing view in the developmental sciences is that nature and nurture are intertwined. This means that, although separable via extreme main effects, nature and nurture shape developmental trajectories together through co-action, whether at the level of a cohort or an individual. The separation of nature and nurture arises only in relatively rare situations, in fact, in which nature overrides nurture—e.g., severe genomic lesions resulting in high mortality regardless of environmental circumstances, or in which nurture overrides nature (e.g., severe nutrient deficiency resulting in high mortality regardless of the exposed genotype). In other words, it is now commonly recognized that the structural variation in

As none of the authors consider themselves GxE researchers, working on this manuscript was very educational for us all. We hope that reading the chapter will also be educational for the readership of the Handbook. We are grateful to Dr. Cicchetti for inviting this contribution. We are thankful to our funders, whose patronage supported this work (the Spencer Foundation—PI Grigorenko; funds from the "International Expert Meeting on Gene–Environment Interactions" at the University of Utrecht and from "Nature and Nurture: Genetic and Environmental Influences on Children's Response to Adversity," a workshop on GxE held at a meeting of the NICHD, where earlier versions of this chapter were presented; Autism Speaks postdoctoral fellowship #7614—PI Campbell; T32MH18268—PI Leckman, T32 fellows Campbell and Bick). We are also highly appreciative of the help of our first reader and editor, Ms. Mei Tan, and of the comments of the "International Expert Meeting on Gene–Environment Interactions" organizers, Geertjan Overbeek and Joyce Weeland.

the genome alone cannot explain most cases of inherited diseases/disorders. Similarly, it is widely accepted that environments, however defined, cannot explain most cases of acquired diseases/disorders. It is far more probable that environments as well as self-determined behavior (e.g., lifestyle), interacting with the structure of the genome, result in the manifestation and dynamics of these diseases and disorders as well as normative development.

This nature–nurture co-action is exemplified plentifully in numerous phenomena in the developmental sciences, including, but not limited to, the manifestation of differential responses to environments that are demonstrated by humans throughout the life span. Illustrations of such differential responses are abundant and are exemplified, primarily, in the literature on responses to different early rearing conditions in general (e. g., Cicchetti, Rogosch, Gunnar, & Toth, 2010; Lawler, Hostinar, Mliner, & Gunnar, 2014) and variation in caregiving quality in particular (Kochanska, Askan, & Joy, 2007; Suomi, 1997); moreover, these responses are traceable, although manifested in different forms, throughout the life span (Aron & Aron, 1997; Evans & Rothbart, 2007; Posner & Rothbart, 2007). Differential responses are acknowledged when the removal of either nature or nurture susceptibility factors negates the outcome (Caspi & Moffitt, 2006; Rutter, 2006).

These differential responses, whether with regard to typical or atypical development, have been theorized about in a number of models, most notably, the transactional/dual-risk model (Sameroff, 1983) and the diathesis–stress model (Meehl, 1962; Monroe & Simons, 1991; Zubin & Spring, 1977; Zuckerman, 1999). The main theme of these models is that, even upon their initial arrival to this world, children already differ in vulnerability, and those who are deemed vulnerable are likely to be adversely affected, disproportionally or even selectively, by environmental stressors (e.g., child maltreatment, inadequate parenting or schooling, negative life events). Thus, atypical development (or psychopathology) is a systemic outcome of co-effects or synergisms of inherent vulnerabilities (diatheses) and negative environments (stressors). This theme has been further developed in what is known as the differential susceptibility (Belsky, 1997, 2014; Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Belsky & Pluess, 2009; Pluess & Belsky, 2013) and biological sensitivity to context (Boyce & Ellis, 2005; Boyce, Sokolowski, & Robinson, 2012; Ellis, Essex, & Boyce, 2005; Ellis, Jackson, & Boyce, 2006) hypotheses, stipulating that the very same individuals who are deemed vulnerable and suffer the most from adversity, are also the ones who will profit the most from the amelioration of adversity and enrichment of their environment. These hypotheses, although similar in their position on the importance of the co-action of nature and nurture and their inclusion of the notion of developmental plasticity (Belsky & Pluess, 2009), differ in their accents. Thus, in the nature–nurture co-dynamics of the development and emergence of individual differences, the former hypothesis accentuates the part of nature, whereas the latter accentuates the part of nurture. Both hypotheses are grounded in the theory of evolution, emphasizing the rationale for differential responsiveness in a continually volatile environment (Wolf & Krause, 2014; Wolf, van Doorn, & Weissing, 2008) and, correspondingly, for maximizing fitness through diversity (Belsky, 1997) by programming, prenatally and postnatally, hyperreactivity and hypersensitivity to stress to adaptively match those unpredictable environments (Boyce & Ellis, 2005).

Empirically, these hypotheses are rooted in the large literature known as the gene–environment interaction literature (e.g., Bakermans-Kranenburg & van IJzendoorn, 2006, 2011), which captures an ongoing quest of ever-gaining momentum (Hunter, 2005) for the understanding of the empirical and mechanistic texture of nature–nurture co-action. In this chapter, we intend to introduce this literature and highlight its particularly distinct facets. As an introduction, by definition, is not a comprehensive overview of the field, this chapter is segmented into three parts: the first presents the concept of gene–environment interaction; the second discusses various aspects of the operationalization of the concept; and the third exemplifies issues arising in the actual implementation of the operationalization and application of GxE in empirical research. Thus, the chapter introduces the trilogy of gene–environment interaction (i.e., the presentation and discussion of the phenomenon's conceptualization, operationalization, and implementation).

THE CONCEPT

The most intuitively appealing conceptualization of gene–environment interaction (GxE) is the dependence between two factors—the genetic (G) and environmental (E) in their effects on a trait. The presence of GxE is posited when the effect of the genome depends on the immediate environment in which it exists or when, vice versa, the effect of the environment depends on the genome (Duncan & Keller, 2011). In other words, biologically, GxE interactions signify all of the different ways that

a genetic structural variant may give rise to a particular phenotype within a particular environment, or vice versa (Manolio, Bailey-Wilson, & Collins, 2006). Statistically, GxE indicates differential associations between the genotype and the phenotype in the presence, absence, or dosage of a particular environmental exposure.

From a public health perspective, GxE interactions are highly important (Thomas, 2010a). Broadly speaking, their importance is two-fold, as they have negative and positive facets. The negative facet of GxE is that it can mask a main effect (either G or E), so that the research generates false negatives or inconsistent results (Bos et al., 2005; Ko, Hsu, Hsu, Ko, & Lee, 2004; Ordovas et al., 2002; St-Pierre et al., 2003; Tai et al., 2003). The positive facets of GxE are thought to be numerous (Le Marchand, 2005; Le Marchand & Wilkens, 2008); these aspects reflect both future promises and current shortcomings of this concept. Specifically, first, understanding the mechanics of GxE may produce insights into the biological pathways of typical and atypical development (Thomas, 2010a). Thus, it is possible that many genetic risk factors act synergistically, but do not demonstrate marginal effects (i.e., do not appear to have an impact when examined individually). If so, understanding related interactions would be pursued not for the sake of the discovery of the interaction per se (Kraft, Yen, Stram, Morrison, & Gauderman, 2007), but for the sake of identifying the genetic risk factors. The same logic applies to understanding environmental hazards and their deleterious effects (Hunter, 2005). Second, in situations when both the susceptibility genetic factor and environmental exposure should be present for a disorder to manifest, GxE interactions are viewed as instrumental in altering or diverting the effects of harmful genes by avoiding exposure to harmful environments (Manolio et al., 2006). Third, understanding GxE might aid in both qualifying and quantifying the degree of etiological heterogeneity, whether genetic or environmental (Greene, Penrod, Williams, & Moore, 2009; Ioannidis, 2007). Fourth, ideally, if GxE interactions are of substantial magnitude, they could be incorporated into risk prediction models with consequences for practice in both the domains of public health and personalized medicine (Thomas, 2010b).

Although relatively young, the field of studies of GxE has had an impressive trajectory (Thomas, 2010a). It was formulated prior to the discovery of the structure of DNA, that is, when G was not measurable, and prospered through quantitative genetic (e.g., twin) studies. The field has since learned how to measure G in stages, initially through the utilization of single polymorphisms[2] and now through high-throughput technologies capturing the variation in the whole genome. With the subsequent development of relevant measurement tools (e.g., genotyping and sequencing), the field has flourished. Initially, the GxE field was dominated by candidate–gene (or, more precisely, candidate-polymorphism) studies. The premise for this hypothesis-driven or inferential approach in general, as well as for the selection of gene candidates, was the existence of a known connection between a given environmental factor and the genetic pathway that carried that factor on (e.g., metabolized it, such as the metabolic pathway of alcohol or tobacco).[3] Then, a particular gene within a specific pathway or a particular polymorphism within a specific gene could be singled out and nominated as a candidate gene or a candidate polymorphism, deemed to serve as a proxy or a marker for a specific biological process. As the field's sophistication has grown, the focus of GxE studies has moved from single polymorphisms and single genes to entire pathways, along with the genes, exposures, and various cofactors deemed relevant to these pathways. The same technological and theoretical advancements that increased the complexity of the hypothesis-driven approach to GxE have triggered a hypothesis-free or agnostic approach to studies of GxE. This approach is rooted in the availability of large amounts of genetic data generated, initially, by genome-wide association studies (GWAS, which allow testing for associations between common genetic variants and phenotypic traits) and now by genome-wide sequencing studies (GWSS, which allow the discovery of new rare variants accounting for phenotypic variation). Although the initial investigations of these data intended and attempted to investigate main effects, there is now an increasing interest in investigating interactive effects (Cordell, 2009). Although not all, many GWASes and GWSSes, either by design or by the nature of samples (e.g., in cohort studies), include relevant indicators of environment and, thus, the data they produce might be utilized in GxE studies. These studies might be of two

[2]In whatever type these polymorphisms (i.e., genetic variants at a particular position of the DNA sequences) were available, namely, restriction fragment length polymorphisms—RFLPs, variable number tandem repeat—VNTRs, or single nucleotide polymorphisms—SNPs.

[3]Of note is that there is a certain field specificity in how this approach is manifested in medical (e.g., psychiatry) and behavioral (e.g., developmental psychopathology) candidate–gene GxE studies. The former, in fact, are much more hypothesis oriented than the latter.

kinds: the first aimed at exploring signals that do not reach genome-wide significance in the context of main-effect analyses, but might in the context of interaction-effect analyses (Holmans et al., 2009); and the second aimed at mining patterns of interaction effects to identify novel biological pathways (Sebastiani, Ramoni, Nolan, Baldwin, & Steinberg, 2005).

As the number of GxE studies, conducted either in old (i.e., candidate gene or polymorphism) or new (i.e., whole genome) style, has been increasing exponentially, there has been a push to establish and propagate a set of systematic requirements to guide GxE discovery and replication. Although this chapter is not the forum for setting such requirements, our intention is to highlight and discuss issues that have been flagged as important and problematic in GxE research, and that require understanding and reflection by any individual who aims to be an informed reader and/or a qualified contributor to the GxE literature.

Both historically and currently, the literature contains many different notions of the term *interaction*; the multiple meanings of the term have been and are likely to remain a source of confusion (Clayton & McKeigue, 2001). Due to such ambiguity, it is customary to see disclaimers in the literature that differentiate a *statistical* form of an interaction (i.e., statistical interaction—a quantitative description of the joint effects of multiple factors) from a *biological* form of an interaction (i.e., biological interaction—the causal and biological mechanisms; Cox, 1984; Rutter, Moffitt, & Caspi, 2006; Thompson, 1991). There are historical and conceptual reasons for differentiating these concepts.

Tabery (2007) distinguished so-called biometric and developmental concepts of GxE. He attributed the former to R. A. Fisher and put forth an interpretation of the concept of GxE (GxE_B) within Fisher's general biometric paradigm aimed at partitioning total phenotypic variance into its components, including genetic and environmental ones. As his paradigm was defined by a particular set of assumptions, the concept of GxE was neither native to it nor readily assimilated by it, being viewed as a potential source of bias[4] for other components of the decomposition of phenotypic variance equation. Being aware and concerned about biases, Fisher investigated the concept of GxE quite closely, but in a single empirical investigation, and arrived at the conclusion that, in fact, the magnitude of effects associated with this concept were not impressive and, therefore, not substantial; in fact, it could be eliminated with a transformation of scale.

Tabery (2007) contrasted Fisher's biometric concept of GxE with the *developmental* concept of GxE (GxE_D) conceived by L. Hogben. For Hogben, GxE was a facet of the natural course of events that is as embedded in nature as development itself. In other words, GxE is omnipresent and the question is whether our statistical apparatus can detect it and appraise its magnitude. According to Tabery, the tension between these two interpretations of GxE has shaped the relevant literature in the last century and remains highly present today.

It so happened, as is often the case in science, that these two different interpretations arose from the fact that the two scientists followed rather different scientific and personal pathways to the derivation of GxE interaction, both conceptually and statistically. Fisher, working on the foundations of what is now known as quantitative genetics and behavior genetics, first viewed the environmental variable as randomly distributed (Fisher, 1918). Yet, his later experiences at the Rothamsted Agricultural Research Station, where, reportedly, his charge was to evaluate environmental variation, challenged his view on this randomness and triggered his thinking on the possible "interaction of causes" (Fisher, 1925). To follow up on his thinking experimentally, Fisher examined different combinations of various sorts of potatoes with various types of manure. He stated, as a result of his single experiment, that the deviations from additivity observed in his potato-compost system were not significant; that is, the potato varieties did not exhibit differences in their reaction to different types of manure (Fisher & Mackenzie, 1923), and, therefore, there was no reason to believe that the "interaction of causes" should create important complications to his approach to the decomposition of phenotypic variance. Thus, for Fisher, genetic and environmental forces, especially the former, remained the major causes; any co-action between them, however defined, constituted mere nonstatistically significant deviations from additivity, (i.e., possible qualitatively, but not essential to account for quantitatively)—of "possible, but unproved, importance" (Tabery, 2007, p. 967).

Hogben's (1932) conceptualization of GxE interaction was very different. In part, it was inspired by his own scientific journey while teaching at the London School of Economics (Tabery, 2007). Although unequivocally recognizing the usefulness of differentiating genetic and environmental factors in understanding causality of development, he was highly critical of their separation, even if only for the sake of deriving testable statistical models.

[4]Where bias is defined as "any process at any stage of inference which tends to produce results or conclusions that differ systematically from the truth" (Sackett, 1979, p. 60).

In fact, Hogben underscored the critical nature of a third type of variance, which manifests itself when a particular combination of genetic factors interacts with a particular combination of environmental factors. In doing so, he postulated both the ubiquitous character of GxE in development and the flaw in statistical representations of G and E when their interaction term is omitted.

The ubiquity of GxE comes from the very fact that the genome does not exist without an environment; thus, the developmental version of the GxE concept, or, specifically, GxE_D (Tabery, 2007), is as important a player in human development as G or E individually. The GxE_D interaction could be studied experimentally (Krafka, 1920), although the options for such studies are limited with regard to research on humans. Although not directly referenced by Hogben, similar ideas were developed by Richard Woltereck in Germany in the early twentieth century with regard to his concept of *Reacktionsnorm*, or norm of reaction—a complete set of developmental outcomes that could emerge when the same genotype is immersed in different environments (Sarkar, 1999 & Peirson, 2012).

To summarize, for Fisher, the phenomenon of GxE (GxE_B, today referred to mostly as statistical GxE) did not exist unless it was explicitly detectable (i.e., representable by a statistical term in his variance decomposition equation) and statistically significant. Moreover, even if there were evidence for the significance of the term, the interaction might be removable by transformation of variables and the corresponding portion of the variance manifested on the side of G.

For Hogben (1932), the GxE phenomenon ($Gx E_D$, today referred to mostly as biological GxE) existed a priori, and, if statistical rather than experimental approaches mattered at all, they needed to be perfect to capture it. Thus, Fisher (1925) argued that his biometric machinery could detect the interaction if it was there, while Hogben argued that, in most cases, it was there, even if it was not detectable statistically. After an exchange of letters and a number of cross-referencing debates in the literature, neither conceded. Fisher's position was that the burden of proof was on the opposition; one needed to show that something exists before the discussion of how to assess or measure it could meaningfully take place.

This debate has not been resolved, and, moreover, its essence has framed much of the relevant research today. The relevant discussions have gone through a variety of different stages, engrossing many scientists, and generating many new concepts. Highly engaging, both theoretically and historically, this debate will be represented in this chapter only by a limited number of highlights. Fisher's view of GxE as a mere phantom whose existence needs to be proved has been adopted by many scientists in a number of different contexts (Jensen, 1969, 1973; Lush, 1937). Whatever the phenotypic trait at the focus of discussion, the meagerness of the GxE interaction term, as estimated in a Fisher-style decomposition of variance approach, was compared to the substantial main effects of G and E (and the error term) and, therefore, dismissed. In turn, Hogben's ideas both inspired and framed the thinking of C. H. Waddington, who, pursuing the premise of the developmental preeminence of GxE, introduced the concepts of epigenetics and an epigenetic landscape (i.e., a physical and temporal map of the genetic regulation of development; Waddington, 1957, 1975). The indisputable reality of GxE has also been endorsed by R. Lewontin (1974), who, in his discussion of the biometric approach to phenotypes, asked a very important question about the limitations of this approach for making inferences about the magnitude of genetic effect on a trait (i.e., heritability estimates, or the proportion of phenotypic variance accounted for by genetic variance) in environments that have not yet been encountered (Feldman & Lewontin, 1975).

The debate crystallized in the distinction of two extreme positions, often referred to as *interaction versus interactionism*, where the former represented Fisher's views and the latter—Hogben's. A new interpretation of this debate has surfaced more recently in the work of M. Rutter and colleagues, who discussed the narrow sense (i.e., statistical concept) and broader sense (i.e., biological concept) of the GxE phenomena (Rutter, 2006; Rutter & Pickles, 1991). Regardless of the terms used, the crystallization of this debate recognizes the importance of both conceptualizations of GxE and argues that they often, yet do not always, function sequentially. The ongoing nature of this debate also illuminates the different stages of the field's understanding of how genomes and environments co-act (i.e., in that they are inseparable within an individual, but can be statistically isolated when considered at the population level). In other words, a registration of statistically significant GxE at the population level can be followed up with an investigation of the underlying biological mechanism, either at the individual or group/population level, just as the registration of a biological phenomenon in a particular individual/group can be later investigated at the population level, so that its role as a risk factor in the larger population can be appraised. A recognition that both types of GxE are important may help to reconcile the two extreme views; such an appeasement would be supported by many scientists (e.g., Vreeke, 2000).

THE OPERATIONALIZATION

From Concept to Term

Conceptually, interaction refers to the co-participation of two factors in a causal mechanism (Rothman, 1986). A GxE interaction transpires when subsets of a population (or a specific sample, if not representative of the population), distinguished by a specific genotype (e.g., a polymorphism, a risk-associated haplotype, several causal variants within a gene, or even some complex index of genetic risk, constructed from several causal variants, Thomas, 2010a), differentially respond to varying environmental conditions (Rowe, 2003). This observation is translated into statistical terms, according to which GxE interaction is present when the impact of a specific genotype on one's susceptibility to a disease or disorder depends on exposure to a specific environmental factor; the reverse (from environment to genotype) is also true (Clayton & McKeigue, 2001). Specifically, G and E demonstrate dependence such that genetic influences on the phenotype are conditioned on the environmental context, whereas an organism's phenotypic response to the environment is conditioned on the genotype. Rephrased, GxE interaction can be defined as *differences in the effect* of an environment on disease/disorder risk in carriers of different genotypes or, equivalently, *differences in the effect* of a genotype on disease/disorder risk in persons with different environmental exposures (Ottman, 1996).

In general terms, an interaction is qualitatively indicated when an effect is explained, not merely by independent and relative contribution of one or more variant(s) within a gene (or many variants within many genes) and one or more environmental exposures, but by the joint contribution of these two (G and E) factors. Correspondingly, tests for interaction (GxE) address the fit between a chosen model and the data. A test for the main effect (or the average effect) of exposure assumes the null hypothesis of no difference between risk in exposed and unexposed subgroups, and for genotype assumes the null hypothesis of no difference between risk associated with genetic variability. A test for interaction assumes the null hypothesis of the co-action of these two factors, as described by a specific statistical model. Conventionally, when testing for GxE, a multiplicative model is used, which assumes that the product of functions of the genetic and environmental risk factors explain the relative risk of manifesting a disease/disorder. A joint effect that differs from the predicted value of the specified model is deemed a form of interaction. Or, in other words, the presence of interaction is marked by lack of fit to the statistical model (Clayton & McKeigue, 2001; Thomas, 2010a).

A common measure of effect is the ratio of the incidence of a disease or disorder in exposed to unexposed subgroups, which can be captured (in a case–control study, for example) by an odds ratio. In this context, a multiplicative model for the joint effects of risk factors (e.g., G and E) assumes that the risk ratio between exposed and unexposed subgroups (i.e., subgroups of E) does not vary over subgroups defined by the genetic factor (i.e., subgroups of G). As the presence of interaction entails differences in the risk ratio across different subgroups, statistically, it will mean a lack of fit to the multiplicative model. Of note, the detection of statistical interaction might or might not aid in understanding the underlying biological mechanics associated with GxE. In order to contribute to this understanding, the null hypothesis needs to have a clear biological interpretation. Moreover, the same statistical model for the risk ratio could be associated with many different biological models or mechanisms. In fact, the registration, by statistical means, of the presence of interaction does not imply the strengthening of any corresponding theory of pathogenesis (Eaves, 2006; Rothman & Greenland, 2005; Rothman, Greenland, & Walker, 1980; Thompson, 1991).

The central issue here is that of biological validity, as biologically essential interactions can typically be detected without statistical techniques. An oft-cited example of a biologically valid interaction is that of phenylketonuria (PKU)—a disorder resulting from an interaction of homozygous loss-of-function mutations in the gene encoding the phenylalanine hydroxylase enzyme, and dietary exposure to phenylalanine. As phenylalanine is abundant in the human diet, under typical conditions (i.e., when a baby is exposed to typical early care) the interaction is not statistically detectable because the exposure variable is fixed (i.e., every human baby is exposed to phenylalanine). Yet the knowledge of this interaction is critical as it determines both prevention and intervention.

As evident from the previous historical notes, the field of GxE started with the statistical estimation of the corresponding term, defined within Fisher's model of phenotypic variance decomposition (i.e., the so-called quantitative-genetic model), in which case many components of the equation were unmeasured. Specialized statistical models (Andrieu & Goldstein, 1998; Eaves & Erkanli, 2003; Purcell, 2002) to test for the variance components of GxE have been developed over time. These black box statistical approaches have undoubtedly made a substantial contribution to the fields of quantitative and behavior genetics. However, these advances in statistical modeling have had much less relevance for researchers wanting to utilize the results of the GxE studies to make specific practice-related recommendations. Gradually, different

versions of the general variance-decomposition model have been developed, so that unmeasured terms have been replaced with measured terms (in different combinations).

In this part of the chapter, we will comment on the issues that arise when both of these approaches (i.e., one with unmeasured and the other with measured terms are exercised). The discussion will primarily focus on the concept of statistical interaction, as this is what is utilized in the majority of studies in the developmental sciences in general, and developmental psychopathology in particular.

When Terms Are Unmeasured

In quantitative-genetic (also often referred to as behavior-genetic) studies, GxE interactions are reported primarily in attempts to understand how genetic influences are moderated by different aspects of the environment. In other words, these studies allow researchers to appreciate the magnitude by which the impact of a specific genotype is either augmented or limited by exposure to a specific environmental factor. Yet, depending on what particular model of moderation is assumed, rather distinct types of results and interpretations are expected. Carlson, Mendle, and Harden (2014) exemplified these expectations as follows. One model of moderation is the diathesis-stress model (see above). According to this model, individuals differ in the degree to which they can be negatively affected by adverse environments, and this differential risk can be attributed to individual variations in genetic vulnerability (Monroe & Simons, 1991). In other words, such environments may moderate the role of the genetic factors associated with disease/disorder risk by magnifying the likelihood that genetically vulnerable individuals will develop negative outcomes. This translates into an assumption that genetic variance will be higher in low-quality, adverse environments, and lower in high-quality environments.

Conversely, some models focus on the relationship between specific genetic predispositions and their capacity to benefit from advantageous environments (Bronfenbrenner & Ceci, 1994; Pluess & Belsky, 2013). This translates into the assumption that genetic variance will be higher in high-quality environments and lower in lower quality environments.

Finally, the differential susceptibility model (Belsky et al., 2007; Ellis et al., 2005) assumes the existence of genetic predispositions that are marked by greater plasticity overall, so that both adverse and advantageous environments differentiate these genotypes and magnify the resulting outcomes as more negative or positive than those for carriers of less-sensitive genotypes in negative and positive environments, respectively. This translates into an expectation that genetic variance will be maximized at opposing extremes of the moderating environmental factor (Ellis, Schlomer, Tilley, & Butler, 2012), but will be negligible in average environments (South & Krueger, 2013).

The literature provides a number of illustrations of quantitative-genetic studies of GxE (Jaffee, Price, & Reyes, 2013). For example, it has been demonstrated that in environments that facilitate substance use—that is, those that impose lower taxes on substances (Boardman, 2009), have greater alcohol availability (Boardman, 2009; Kendler, Gardner, & Dick, 2011) or are characterized by greater existence or dominance of social norms encouraging drinking (Boardman, Saint Onge, Haberstick, Timberlake, & Hewitt, 2008; Timberlake et al., 2007), increased affiliation with deviant peer groups in adolescence (Kendler et al., 2011), urban (vs. rural) environment (Dick, Rose, Viken, Kaprio, & Koskenvuo, 2001), avoidance of organized religion (Timberlake et al., 2006), and lower levels of parental monitoring (Dick et al., 2007)—genetic variance in alcohol and tobacco use is higher.

A similar pattern of greater amount of genetic variance has been observed for youth externalizing problems when adolescents are exposed to a broad range of adversities in their environment (Hicks, South, DiRago, Iacono, & McGue, 2009). Otherwise, adverse childhood environments appear to suppress genetic influences, compared to more advantaged environments (Carlson et al., 2014), predisposing youth, over and above their genetic differences, to earlier initiation of sexual activity (Belsky, Steinberg, Houts, Halpern-Felsher, & the NICHD Early Child Care Research Network, 2010; Coley & Chase-Lansdale, 1998).

Conversely, a suppression of genetic variance in substance abuse has been demonstrated in environments imposing high social control (Kendler et al., 2012), high parental monitoring (Dick et al., 2007), religious upbringing (Koopmans, Slutske, van Baal, & Boomsma, 1999), and positive marital relationships (Dick et al., 2006). Recently, such a list of positive environments has been extended to include that of competitive, achievement-oriented, high-quality schooling (Benner, Kretsch, Harden, & Crosnoe, 2014), shedding light on the nature of previously reported overlapping genetic influences between, for example, nicotine use and educational attainment (McCaffery et al., 2008), academic mastery and alcohol dependence (Bryant, Schulenberg, Bachman, O'Malley, & Johnston, 2000; Crosnoe, 2006; Kiecolt, Aggen, & Kendler, 2013), and verbal ability and alcohol dependence (Latvala et al., 2009).

Of note, aligned with both the expectation regarding the diversity of possible GxE patterns and the theoretical assumptions outlined above, there are traits and genotypes that benefit from relative social advantage. Thus,

it has been shown that genetic influences on age at the initiation of sexual activity are greater in contexts of relative social advantage and suppressed in more adverse conditions (Carlson et al., 2014; Waldron et al., 2008). Similarly, greater genetic variance has been registered in more advantageous environments for traits of intelligence (i.e., higher levels of SES; Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003) and early reading (i.e., higher teacher quality; Taylor, Roehrig, Soden Hensler, Connor, & Schatschneider, 2010).

When Terms Are Measured

The term that researchers started to measure first in GxE studies was that of environment. One (although not the only) reason is that by the beginning of the 21st century, the field of epidemiology had accumulated enough data (Hemminki, Lorenzo Bermejo, & Forsti, 2006) to demonstrate that environmental factors have amplified the background incidence of so-called common complex diseases and disorders in high-income countries to over 10 times the level observed in low-income countries (Buchanan, Weiss, & Fullerton, 2006; Colditz, Sellers, & Trapido, 2006; Willett, 2002). This observation corresponds to the growing recognition that combinations of these environmental factors, characteristic of high- compared to low-income countries, with specific genetic predispositions, are responsible for the most recent epidemics of chronic disease. The challenge of epidemiological research today is to identify these combinations (Weaver, Buckley, & Groopman, 1998) so that the course of the epidemic can be reversed (Chakravarti & Little, 2003). One example of such a combination is the interaction between today's environment of overabundance of calories with presumed famine-protective genetic predispositions, which is argued to have contributed to the current obesity epidemic in the United States (F. S. Collins, 2004).

Although quite often in GxE research genetics (G) and environmental (E) have been conceived, rather simplistically, as dichotomous variables, both G and E factors, in reality, are complex and multidimensional (Thomas, 2010a). Consider, for example, air composition, which can be specified as polluted/unpolluted dichotomous E, but whose indicators, in reality, represent a multifarious brew of gases and particles with different properties (Ghio, Carraway, & Madden, 2011; Nieuwenhuijsen, Gómez-Perales, & Colvile, 2007), so that types of polluted air may vary dramatically with regard to the level of danger associated with exposure. In addition, G and E might have other sources of variability, such as time and intensity. With regard to the former, many environmental risk factors can be modified by such time-based factors such as age at or duration of exposure (Thomas, 1988). With regard to the latter, the intensity and number of exposures could be a much more important source of information than whether or not an exposure has occurred (Miller, Schlosser, & Janszen, 2000).

The technological developments in the measurement of both the genome and the environome (i.e., the combination of aspects of the environment that can be systematically extrapolated such as nutritional intake, amount of physical exercise, amount of sleep, level of stress and so forth) coupled with the development of computational capacities, has resulted in a dramatic shift away from GxE studies in which none of the terms are measured toward those in which all of the terms are measured. In addition, the development of robust analytical methods for assessing both main effects and interactions has permitted the interrogation of these complex effects on a population scale (van den Oord, 1999). Yet, this change has also brought up a number of new concerns not previously voiced in the GxE literature. These concerns are many and they will be discussed primarily in the next section of this chapter. Here we mention only those that are relevant to the measurement of genes and environments in the context of GxE studies.

First, as the broader field of genetics (both quantitative and molecular) transitioned from unmeasured to measured G and E, the problem of missing heritability of common traits (Maher, 2008; McCarthy & Hirschhorn, 2008) arose. The field anticipated a translation of the high heritability estimates obtained from quantitative-genetic studies into similarly high heritability estimates obtained from molecular-genetic studies. However, this did not happen. In fact, the latter were estimated to be nowhere near as high as the former. The major effort to qualify and quantify genetic variation triggered, in part, by the Human Genome Project, had produced an ocean of genome-wide association studies (hereafter, GWAS will refer to the method and GWASes will refer to studies carried out using the GWAS method). These studies led to the identification of >1,200 loci whose genetic variants were shown to be associated with >165 common human diseases/disorders and complex traits; collectively, these variants implicated many previously unknown or unconsidered roles for numerous biological pathways (Hirschhorn, 2009; Lander, 2011; Manolio, Brooks, & Collins, 2008). It was expected that these very first GWASes (measuring the genome in this case with single nucleotide polymorphisms, SNPs) would result in the translation of previously obtained

heritability estimates into effect sizes for measured G (i.e., specific genetic variants). The GWAS-based estimate of heritability is the ratio of the heritability due to the variants used in the GWAS (specified as the numerator), estimated directly from their observed effects, to the total heritability (specified as the denominator), obtained either from previous studies or from the same study (if the sample is comprised of related individuals), or inferred indirectly from population data (Zuk, Hechter, Sunyaev, & Lander, 2012). However, these first GWASes and all subsequent ones (until recently, when the data-analytic approach changed and genomewide complex-trait analysis, GCTA, was introduced, e.g., Plomin et al., 2013), reportedly accounted for only a small proportion of the previously published heritability estimates of diseases/disorders and complex traits. This discrepancy between what was expected based on results from quantitative-genetic studies and what was observed based on the results from molecular-genetic studies was labeled as the "missing heritability" problem. As GWASes have become bigger (i.e., larger samples) and better (i.e., denser coverage of the genome), results have improved, with the referenced amount of variance reaching 20–30% or even 50% in isolated cases. However, the puzzle remains, as only a smaller portion of the previously obtained heritability estimates have been mapped onto specific genetic variants measured by GWASes (Lander, 2011).

As the problem of missing heritability became apparent, the dominant explanation was that it arose from incomplete coverage of the genome, i.e., the assumption that there were still some (or many) undiscovered variants not included in the numerator, leading to estimates biased on the lower side. Yet another possibility pertains to the overestimation of the denominator: the phenomenon referred to as *phantom heritability* (Zuk et al., 2012). Such an overestimation can arise, for example, if models do not take into account epistatic genetic interactions within loci (in that effects of each loci may not merely be additive but interact with each other to predict disease/disorder risk) (Zuk et al., 2012). To illustrate their point, Zuk and colleagues (2012) referenced Crohn's disease—an inflammatory bowel disease that impacts various components of the digestive tract. For this disease, in a traditional GWAS paradigm, 71 risk-associated loci have been identified (Franke et al., 2010). If an additive model is assumed, then these loci account for only 21.5% of the heritability, which was previously estimated at 50% (Halme, Paavola-Sakki, Turunen, Färkkilä, & Kontula, 2006), yet, if an epistatic model is assumed, then these loci explain 80% of the adjusted heritability (the phantom heritability was estimated at 62.8%). Unfortunately, it is estimated that very large sample sizes (~500,000) are required to detect genetic interactions even for such a relatively heritable disease as Crohn's. The authors (Zuk et al., 2012) concluded that current estimates (and, therefore, the whole discussion) of missing heritability might not be meaningful, as these estimates were obtained without taking into account genetic interactions. This observation is quite congruent with the worry that most previously reported heritability estimates are, indeed, artificially elevated. In fact, most of these estimates come from twin studies, which tend to provide an upper limit to the genetic component of the variance of a disease/disorder or a trait, and thereby may lead to invalid conclusions (Wallace, 2006).

The second concern relevant to the measurement of G and E, as mentioned above, is with the selection of the candidate genes and candidate environments used in GXE studies. For most, if not all, common complex diseases and disorders, even main effects of G and E are still rather mysterious (see the discussion for psychiatric disorders in Flint & Munafò, 2008). In fact, almost two decades of candidate gene association studies have produced, arguably, little or no unequivocally accepted findings regarding genetic effects (Burmeister, McInnis, & Zöllner, 2008). This observation is especially worrisome given that most (if not all) hypotheses about specific candidate genes emerged from strong neuroscience research that uncovered the putative properties and functions of these genes (Hebebrand, Scherag, Schimmelmann, & Hinney, 2010); these candidate genes, most of which are protein-coding, were selected because they were found to have functional variants that somehow changed the properties of synthesized proteins, which were implicated in complex diseases and disorders. Given the lack of prior success in uncovering main effects of G for a given complex disease or disorder, there is understandable skepticism regarding the possibility that more complex associations, such as between a specific variant in a specific candidate gene (or any other type of genotype) and a specific facet or a general characteristic of a particular environment (Duncan & Keller, 2011; Ioannidis, 2005), will also be uncovered.[5]

The GWAS approach is fundamentally different and hypothesis-free. Correspondingly, it is not surprising that

[5]A prior probability distribution (the prior) of an uncertain quantity *p*, in Bayesian statistics, is a distribution capturing expectations about *p* prior to the accumulation of the relevant evidence.

thus far, results of GWAS do not align with hypotheses generated by candidate–gene research. In fact, out of 531 SNPs labeled as the most robustly associated (SNPs) to various medical and psychiatric phenotypes in GWAS studies, 45% are intronic, 43% are intergenic, and only 11% are exonic (Hindorff et al., 2009). Moreover, when specific polymorphisms in specific candidate genes are investigated (i.e., those that have been featured in numerous candidate gene studies, such as the serotonin transporter gene promoter polymorphism) in GWAS designs, they reportedly do not demonstrate performance above the level of chance (Bosker et al., 2011; Lasky-Su et al., 2008; Need et al., 2009; Sullivan et al., 2008). To summarize, GWASes do not appear to be converging on the expected candidate genes, and the SNPs that GWASes are illuminating are mostly not exonic. This state of affairs has been referred to as a failure of both candidate gene studies (Little et al., 2009) and GWASes (McClellan & King, 2010), as their respective findings do not converge.

Yet several considerations are important to mention here. Many fashionable polymorphisms that are used in GxE candidate gene studies are not present (and cannot be present due to their biological makeup) in GWASes; thus, they need to be imputed. For example, the polymorphism in the promoter region of the serotonin transporter gene may be imputed in Caucasian samples with high (~93–95%) accuracy using multiple SNPs present in some GWAS arrays (Knodt, 2012; Lu et al., 2012). Conducting such imputations for groups other than Caucasians is much more difficult. Importantly, GWASes are designed primarily to investigate main effects of G (or its specific variants). However, the polymorphism in the promoter region of the serotonin transporter gene has not been registered to exert substantial main effects on various aspects of psychopathology and is known primarily through publications on GxE. As GWASes routinely do not test for interactions, perhaps it is not surprising that this polymorphism (or its imputed proxy) is not associated with phenotypic variation in these studies. Finally, often phenotypes used in GWASes and phenotypes used in GxE studies are quite different, even if they might be stated to tap into the same disease/disorder (e.g., depression). GWASes' phenotypes tend to be substantially less detailed and elaborate than the phenotypes showcased in GxE studies. Correspondingly, criticisms that GWASes have not implicated specific candidate genes that have been featured in GxE studies have to be examined carefully with specific caveats (e.g., what polymorphisms and what phenotypes) in mind.

The third concern is self-evident: the nonconvergence of findings from different methodologies is not encouraging and seems to indicate lack of insight into the genetic mechanisms underlying complex human diseases/disorders, at least at the level of formulating specific and verifiable hypotheses pertaining to candidate genetic polymorphisms and candidate genes (Hebebrand et al., 2010). It has been stated (Colhoun, McKeigue, & Davey Smith, 2003) that the overwhelming majority (up to 95%!) of main effect findings obtained in genetic association studies appear to be false positives. This estimate, under the assumption of statistical power between 10% and 90%, in turn, is translated to a prior probability of a true association being 0.3–3.0%. Furthermore, this estimate might well be inflated, as testing main effects demands less statistical power than testing GxE interaction effects, meaning the prior for the latter might be even lower than 0.3–3.0%. In light of these considerations, Duncan and Keller (2011) concluded that under the relatively expectant assumptions of a prior of 5% and power of 55% (which seem rather unrealistic, as small sample sizes are the norm rather than the exception among GxE studies), approximately 63% of positive findings are likely to represent Type I error. These researchers argued that if these assumptions are altered to be more realistic—i.e., a prior of 1% and statistical power of 10%—the false discovery rate is likely to be at 98%. This problem of dealing with false positive findings is quite familiar to epidemiologists, who for a long time and with little satisfaction have been engaged in detecting subtle effects, whether for environments (Taubes, 1995) or genes (Crow, 2011).

Commenting on this situation, Clayton and McKeigue (2001, pp. 1357–1358) noted the following:

> If we could specify in advance that the effect of the environmental factor on disease risk would be restricted to a subgroup of individuals with a particular genotype, there would, of course, be a gain in power from testing only this subgroup for the effect of the environmental factor. In practice, such an extreme situation is unlikely to be frequently encountered in the study of complex diseases, and entails a level of knowledge of underlying biology that would probably render epidemiological studies redundant. In less extreme situations, and where previous knowledge is more limited, a combined test would need to be done for the main effect of environmental exposure and its interaction with genotype. Since such tests have multiple degrees of freedom, the gain in power is much reduced; indeed, power might even be lost.

Fourth, there is both conceptual and statistical uncertainty as to whether the terms, as defined, are really G, E, or GxE, particularly given the findings from earlier quantitative genetic studies (Burton, Tobin, & Hopper,

2005). For example, it has been shown that if the environment, E, is separated into shared (common, C) and nonshared (unique, E) components, then the term GxC will inflate the estimate of G, whereas the term GxE will inflate the estimate of E (Molenaar, Boomsma, & Dolan, 1997). These uncertainties were brought to the forefront in GxE discussions: "Importantly, however, we must acknowledge an almost complete ignorance of the relevant gene–environment interactions—as data accumulate, causes that now seem to be environmental could turn out to be gene–environment interactions" (Hemminki et al., 2006, p. 961). Such interactions could erroneously inflate heritability estimates (Hemminki et al., 2006).

A final concern is that both the genotypic frequency (i.e., the observed frequency of particular genotypes, including those associated with risk) and frequency of exposure (i.e., the observed frequency of encountering the risk environmental factor) are crucial for discovery as well as replication (Caspi, Hariri, Holmes, Uher, & Moffitt, 2010), as the same GxE phenomenon might (1) not manifest when the prevalence of exposure is very low; (2) manifest via statistical interaction when the prevalence is moderate; and (3) manifest via main effect when the prevalence is very high. To maximize statistical power, it is recommended that the distribution of genotypes and exposure within a given sample follow a so-called balanced design, when rates of both derived (i.e., minor) allele frequencies and exposure are at ~50%. However, such a balance is often unrealistic, especially when utilizing a case–control design or considering more than one polymorphism. Moreover, the number and nature of subgroups resulting from the joint distribution of genotypes and environment is often unknown. Facing such a situation, researchers may be tempted (Flint & Munafò, 2008) to search for the best outcome, exhausting all analytic possibilities in a drive to register nominal statistical significance, in response to publication bias toward positive results (Ioannidis & Trikalinos, 2007). As the number of subgroups and sub-subgroups is large, so is the number of comparisons (Ioannidis, 2006; Patsopoulos, Tatsioni, & Ioannidis, 2007). Such comparisons have been used, for example, in situations when the original effect of GxE failed to be replicated in the whole sample, but was registered to operate in particular subgroups (Eley et al., 2004). Yet, extensive subgrouping is highly susceptible to false positive findings (Brookes et al., 2001).

For the brave who are willing and able to take on GxE studies in spite of the above caveats, specific recommendations have been offered (Moffitt, 2005). These recommendations include seven distinct steps.

The first step assumes a survey of the existing quantitative-genetic literature. It is always helpful if there are studies in which the specific GxE interaction in question has been evaluated already and deemed to be substantive and important, particularly if there is an explicit biological mechanism that has been coupled with this statistically significant interaction. If the relevant publications have not explicitly tested for GxE, particular attention should be given to the estimates of G (in particular, the additive genetic component, A) and E (in particular, the nonshared component of E). As discussed earlier (Molenaar et al., 1997), if GxE is not explicitly modeled, GxC can look like G (A) and GxE can look like E (E). Therefore, moderate-to-large estimates of A and E can signify the presence of potentially large GxE interaction effects (Purcell, 2002).

The second step is to identify a candidate environmental factor, the exposure to which is known to have a (preferably strong) main effect on the phenotype (trait, behavior, disease, or disorder) in question. To illustrate such a factor, Moffitt (2005) referenced early maltreatment for antisocial behavior, arguing that the former is particularly relevant through its association with biological correlates of the latter (DeBellis, 2001), although the behavior itself has been associated with multiple environmental risks (Loeber & Farrington, 1998). As a substep, Moffitt urged researchers to ensure the environmental mediation of the selected risk factor (for an illustation, see Fujisawa, Yamagata, Ozaki, & Ando, 2012). Otherwise, the selection of the environmental risk factor may be misguided, as it might capture the interaction between different genotypes rather than between genotype and environment (which could, in fact, be an issue with the maltreatment—antisocial behavior connection, Schulz-Heik et al., 2007).

The third step provides recommendations for the selection of specific measurements to be used to capture the exposure. Indeed, minimizing measurement error is associated with enhanced power (Luan, Wong, Day, & Wareham, 2001; Wong, Day, Luan, & Wareham, 2004). However, Moffitt's reference to the possibility of related reduction of sample size in situations when near flawless assessments of exposure are used is misguided.

At the fourth step, attention is switched from environments to genes. The main recommendation here is to stay in touch with the literature, as the knowledge of various gene–behavior associations advances rapidly, through the addition of new candidates and the elimination of old candidates (via nonreplication) from the list (Insel & Collins, 2003). Other recommendations are aligned with those that are present in many writings on GxE, and are discussed in

this chapter. Specifically, the genotypes of interest should be relatively prevalent in the general population. Both high and low prevalence of genotypes of interest, although they may be reflective of particular evolutionary dynamics (Hill, 1999; Searle & Blackwell, 1999), can generate various statistical biases (Lachance & Tishkoff, 2013; Vinkhuyzen, Wray, Yang, Goddard, & Visscher, 2013). Similar to the expectations for exposure, it is desirable that the candidate genetic factor be previously implicated as exerting a main effect on the phenotype of interest, although this expectation may not be realistic, given the general landscape of nonreplicability of such main effects. Finally, it is always recommended to look for a candidate that permits the formulation of a biologically plausible hypothesis as a counterpart to the statistical hypotheses. In illustrating these points, Moffitt references the polymorphism in the promoter region of the serotonin transporter (see Illustrations), arguing that the plausibility of the selection of this candidate polymorphism was substantiated by evidence from studies in psychopathology (Caspi et al., 2003), animal models (Bennett et al., 2002; Murphy et al., 2001), and human brain imaging research (Hariri et al., 2002). She also references both experimental research (e.g., Sayette, Griffin, & Sayers, 2010) and large-scale efforts documenting the range of responses of different genotypes to various environmental risks (Kaiser, 2003) as particularly important sources of nomination of candidates for GxE studies.

The fifth step is the statistical test itself. Although a reference is made, in passing, to a variety of designs used in the field (Moffitt, Caspi, & Rutter, 2005; Ottman, 1990; van Os & Sham, 2003; Yang & Khoury, 1997), the representative population-based cohort is endorsed as the most informative. It is argued that this type of design allows not only an appraisal of the presence or absence of the interaction (by the statistical test of GxE), but also an evaluation of the magnitude of this interaction. Of note is that such population-based cohorts require large sample sizes in order to capture a full distribution of E and provide enough power for various statistical tests.

The sixth step is to ensure the specificity and robustness of the registered effect by exploring the model via substitution of different candidates, both genetic and environmental. It is argued that, although it is vital to be hypothesis-driven in setting up the evaluation of GxE, having registered it, it is important to evaluate the original hypothesis among other plausible hypotheses (Licinio, 2003).

The seventh and final step calls for replication, although it is not specified whether this request pertains to replication within the same research effort (i.e., with a different sample by the same investigator), by different investigators on the same data, or some other form of replication. This recommendation acknowledges the tentative nature of an isolated GxE discovery but argues that its presentation (whether the interaction is ultimately true or not) should trigger both attempts at replication and collateral research.

So far, we have presented the literature on GxE focusing on the emergence and history of the concept and its operationalization. In the next part of this chapter, we will summarize the literature through the lens of the current state of affairs in the field of GxE.

THE ANALYSES

Almost 15 years of intensive research into GxE have generated many published reports, which, in turn, have provided the foundation for meta-analyses, systematic reviews, targeted literature reviews, and opinion pieces (e.g., Calati, Gressier, Balestri, & Serretti, 2013; Decoster, van Os, Myin-Germeys, De Hert, & van Winkel, 2012; Duncan & Keller, 2011; Eaves, 2006; Flint & Munafò, 2008; Gressier et al., 2013; Karg, Burmeister, Shedden, & Sen, 2011; Keller, 2014; Modinos et al., 2013; Munafò, Durrant, Lewis, & Flint, 2009; Munafò & Flint, 2009; Risch et al., 2009; Uher & McGuffin, 2008). In general, the field is in a curious state. On one hand, the number of empirical reports on GxE, whether positive or negative, has been growing both overall and annually, as exemplified by studies of the specific polymorphism in the promoter region of the serotonin transporter gene. Figure 8.1 captures the studies discussed in the following illustrations and listed in the Appendix; the x axis shows the number of publications, and the y axis shows the year of publication. In other words, this research is still widely funded, which motivates researchers to engage with it and

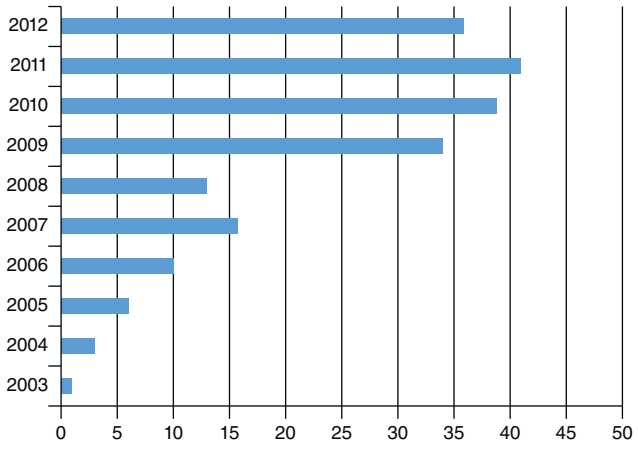

Figure 8.1 Number of publications GxE, by publication year. See footnote 1.

publish extensively on it. On the other hand, meta-analyses and literature reviews on GxE have generated results and comments that are unabashedly skeptical. It seems that the larger the literature grows, the more incredulity it generates; yet, it still keeps growing! This incredulity stems from concerns pertaining both to the content (definitional) and the formal (analytical) aspects of this literature. As the former has been discussed already, this section of the chapter will focus on the latter.

As for analytical concerns, observations have been made with regard to the following. First, en masse, the literature on GxE is characterized by a low replication rate (Kaufman, Gelernter, Kaffman, Caspi, & Moffitt, 2010; Munafò, Durrant, Lewis, & Flint, 2010). Second, although low even in the published literature, the replication rate is, probably, even lower among all attempts to replicate due to publication bias toward positive findings but not null findings. That is, it is impossible to know how many attempts at replication have failed and therefore have not been published (i.e., the file drawer problem), and the specific magnitude of this capitalization is difficult to appraise (Munafò & Flint, 2009). In fact, it has been argued that the false discovery rate in the GxE literature is substantially higher than the Type I error rate of .05 (Duncan & Keller, 2011; Flint & Munafò, 2008) commonly utilized in inferential statistics. Third, as a whole, studies conducted on small samples are common in this literature, thereby adding additional complications associated with insufficient statistical power to detect effects, especially statistical interactions. This can, somewhat counterintuitively, serve to inflate the rate of false-positive results reported in the literature, as null findings are less likely to be published in small-sample underpowered studies relative to the likelihood that positive findings are reported in such samples, whereas the likelihood of reporting both null and positive findings is more equal in sufficiently powered, large sample studies (Burmeister et al., 2008).

In essence, there is an expectation that the fate of GxE findings will be similar to that of GWAS findings (Murcray, Lewinger, & Gauderman, 2009) when the GWAS field leapt from small- to large-sample studies and was not able to replicate the majority of its previously celebrated findings (Bosker et al., 2011; Collins, Kim, Sklar, O'Donovan, & Sullivan, 2012; Need et al., 2009; Sanders et al., 2008; Sullivan et al., 2008). Although such a situation is anticipated, we certainly hope that it will not transpire. Yet if it does, it is important to understand why it has transpired and, moreover, be as accurate and comprehensive as possible in appraising the findings that are in the literature on GxE. In the next part of the chapter, we consider a number of characteristics of GxE studies that may explain why successful replications have proven difficult to realize.

Measurement Error

As discussed already, GxE studies are highly susceptible to measurement error in the assessment of genetic (Wong et al., 2004) and environmental exposure (Caspi et al., 2010; Luan et al., 2001) indicators. The former is viewed as less threatening, as quality control for genetic data is typically set at a threshold of 1% or less, and error per se can be quantified exactly by genotyping the same individuals on the same markers twice. The latter is thought to be much more concerning, as the magnitude of measurement error in exposure can be large, especially if captured by retrospective self-reports. Moreover, if measurement error around the exposure variable is high, even relatively small genotyping errors can result in a discernible impact on interaction estimates. In turn, poor measurement leads to a substantial loss of information. For example, it has been demonstrated that the mode of measurement of exposure (e.g., stressful life events) can have an overpowering effect on indicators of both frequency of occurrence and predictive power of this exposure (Monroe & Reid, 2008), which can bias the results of the interaction regression. Thus, care must be exercised in determining how indicators of exposure are ascertained. There is a direct connection between reducing measurement error and improving the statistical power of a study, which suggests that minimizing measurement error may be a more cost effective alternative in conducting GxE analyses than increasing the sample size. In quantifying environment or exposure, it is suggested that precise objective measures be used, such as environmental sampling or observational measures and experimental techniques capturing biological indicators of stress, rather than subjective reports.

It has been argued that smaller GxE studies tend to use these higher precision prospective measures, whereas larger ones tend to use lower precision retrospective reports (Caspi et al., 2010; Lotrich & Lenze, 2009). While this may be true, sufficient sample size for a study depends on a number of indicators, measurement error being only one of them. Even with the use of these more precise measurement tools, small studies can still be underpowered, and therefore more susceptible to either inflated false positive rates or publication biases, than larger ones, and it is generally difficult to justify a certain sample size without the use of comprehensive statistical power calculations. It is important to note that the presence of measurement error does not signify only one type of bias. The problem

is that if either factor (G or E) has been measured with error, the relation between them will be altered and biased toward a multiplicative model (Clayton & McKeigue, 2001). Specifically, Clayton and McKeigue illustrated that if the presence of interaction is established through lack of fit to a multiplicative model, the test for interaction will be conservative if there is measurement error, such that if the null hypothesis is correct, the test will not yield significant results more often than expected by chance. If any other definition of interaction is used, the bias of the test (conservative or liberal) in the presence of measurement error is difficult to predict.

There are ways to correct for measurement error in environmental variables (Thomas, Stram, & Dwyer, 1993), but these corrections typically require clear ideas of what the errors are, how they arise, and what their time-based properties are. Of note, in large-scale studies, exposures might not even be measured at the individual level, but rather, may be assigned based on some other information indicating ecologic-level exposures (e.g., exposure to natural disaster as a mere fact of having a registered address in the area where the disaster occurred, even though a given person might or might have not been in the area at the moment of the disaster), or obtained from another prediction model. Such uncertainties can lead to the manifestation of unpredictable biases, which may be especially detrimental to the model's accuracy if these biases are differential with respect to the phenotype. As a result, spurious interactions can be introduced (Holmans et al., 2009).

It is worth noting that even though there are methods of correction for measurement errors in indicators of G and E that are well established in studies testing for main effects, they have rarely been used in studying GxE (Lobach, Carroll, Spinka, Gail, & Chatterjee, 2008; Wong, Day, Luan, & Wareham, 2004). Nevertheless, interactions are less likely to be biased than main effects, except when the measurement errors are differentially associated with both exposure and genotype and, as a result, the measurement error is not equal for G and E factors (Thomas, 2010a).

Confounders

Yet another relevant issue that has been comprehensively addressed in the recent literature (Keller, 2014) pertains to controlling for potential confounders. The general point that an interaction term of interest should be adjusted for the effects of confounding variables has been put to force in other behavioral sciences (Hull, Tedlie, & Lehn, 1992; Yzerbyt, Muller, & Judd, 2004), but has not penetrated the field of GxE research. In its typical form, the analytical facet of GxE studies includes three variables—the genetic polymorphism (typically dummy-coded), the environmental factor (typically either continuous or somehow categorized), and the interaction effect (typically captured by the product of the two main effect variables). These variables are then placed in a linear or logistic regression with a predicted variable of conceptual interest (e.g., delinquent behavior, academic achievement, mental health indicator). Keller (2014) and others (Hebebrand et al., 2010) rightfully noticed, however, that there are additional variables—race/ethnicity, gender, age, socioeconomic status, education, IQ, among many—known to be predictive of outcomes of interest, as main effects or members of other interaction terms, that are often treated by GxE researchers as noise to be controlled for. To that end, these potentially important variables are either residualized out prior to fitting the regression, or else they are included as covariates. Keller, however, argued that the proper account for the confounding effects of these additional variables can be achieved only if the full factorial model is tested, specifically, if all of the covariate × environment and covariate × gene interaction terms are tested for in the same model where the GxE interaction is featured. For example, to adjust the GxE term for gender and general cognitive ability, the regression should include the following terms in addition to the two main effects (of G and E), and their interaction (GxE): the main effects of the covariates—gender, general cognitive ability, and the interaction of the covariates with both G and E—gender × G, gender × E, general cognitive ability × G, and general cognitive ability × E.

Keller (2014) attributed his view on how best to adjust for confounding variables to Yzerbyt and colleagues (2004) but provided an application of this general solution to GxE models specifically. He also elaborated on the nature of related biases, and illustrated the profound gap between his expectations for adjustments to avoid confounding and the selected GxE literature he reviewed—in fact, not a single study that was featured as novel by Duncan and Keller (2011) met Keller's expectation. Although such a lack of proper statistical treatment, on its own, might not mean that the previously published GxE findings were not real, it does generate uncertainty about them (Keller, 2014). In all fairness, Keller (2014) acknowledged that the recommended treatment could be objected to, specifically, via references to model overfitting and multicollinearity. The pros and cons related to either approach are discussed in the broader epidemiological and other related literature (e.g., Chen et al., 2008; Kalil, Mattei, Florescu, Sun, & Kalil, 2010; Kim, Watkinson, & Anastassiou, 2011; Mizushima,

Tsuchida, & Yamori, 1999; Singh, Repsilber, Liebscher, Taher, & Fuellen, 2013), with no unequivocal outcome.

Scaling

There is a debate in the literature on how GxE interaction effects should be scaled. In psychology, the presence of interaction is typically detected via adding an interaction (product) term to a regression model and establishing the statistical significance of this term. In linear regression analyses, the product term's coefficient captures the degree of deviation from the additivity of main effects on the outcome (Kendler & Gardner, 2010). In logistic regression analyses, the product term's coefficient captures the degree of departure from multiplicativity in the risk of the outcome (Knol, van der Tweel, Grobbee, Numans, & Geerlings, 2007). Although it has been argued (Darroch, 1997) that the additive model of interaction is preferable, in fact, the literature is replete with examples of both types of regression analyses.

Because the field of GxE interaction, particularly as delineated in this chapter, is defined first and foremost by the statistical conceptualization of the interaction, making inferences regarding the mechanistic or biological relationships between the predictors and outcomes requires adherence to a set of conditions and assumptions (VanderWeele, Hernández-Díaz, & Hernán, 2010). One of the issues relates to the scaling of the interaction effects (Kendler & Gardner, 2010). Thus, simple scale transformations, e.g., logarithmic transformations that are commonly used for normalization purposes, can yield a statistically significant although spurious interaction, whereas *bona fide* interactions can disappear (Eaves, 2006; Kendler & Gardner, 2010; Thompson, 1991). The issue of scaling in the GxE field has been (Rothman et al., 1980) and remains (Eaves, 2006; Rothman & Greenland, 2005) disputed without an adequate resolution.

To gain a more concrete appreciation for how the concept of scaling removes interactions in a GxE study, we performed two simple simulation studies.

Simulation 1

We started by generating genotypes and environmental exposures for 500 participants. Genotypes, using the variable name geno, were sampled randomly from the set {0,1}, with 75% probability of a 1 and 25% probability of a 0. This represented a very simple case of a single gene under a dominant heritability model, in which the gene is captured by two alleles, B and b, with B being dominant over b. The genotypes BB and Bb were assigned the value 1, and the genotype bb was assigned the value 0.

TABLE 8.1 Contingency table of genotype (geno) and environmental exposure (env) in simulated dataset.

	env	
geno	0	1
0	69	60
1	172	199

We then generated an environment, with the variable name env, as a simple yes-no exposure to an environmental factor, with a 0 (no exposure) 50% of the time, and a 1 (exposure) 50% of the time.

We assumed environmental exposure to be independent of genotype as both variables were generated independently. Table 8.1 is the contingency table showing the randomly generated data.

This indicates that of the sample of 500 participants, there were 371 participants with either BB or Bb genotypes and 129 participants with the bb genotype; there were 241 unexposed and 259 exposed individuals. Of the BB and Bb participants, 172 were unexposed and 199 were exposed to the environmental factor; of the bb carriers, 69 were unexposed and 172 were exposed to the factor.

Next, we created a continuous (noncategorical) phenotype from the genotype and environmental exposure of each participant. We defined the genotype effect, g, and the environment effect, e, as the contribution of each feature to the phenotype, and assigned them values of 2 and 1, respectively. We then defined phenotype as an additive function of genotype and environment with the expected value of phenotype for each subject, given the genotype and environment, is g*geno + e*env. Table 8.2, the contingency table of means was thus.

Here we created an additive model. To do so, we added the same fixed value (in this case 2) to every column, going from the first row to the second row; and, we added the same fixed value (1) to each row, going from the first column to the second column.

The actual phenotype of each participant was the expected mean for that participant, plus some randomly generated (Gaussian) noise. As we started with a standard deviation for a noise level of 0.05, the following

TABLE 8.2 Table of expected means of the phenotype for each genotype/environment combination.

	env	
geno	0	1
0	0	1
1	2	3

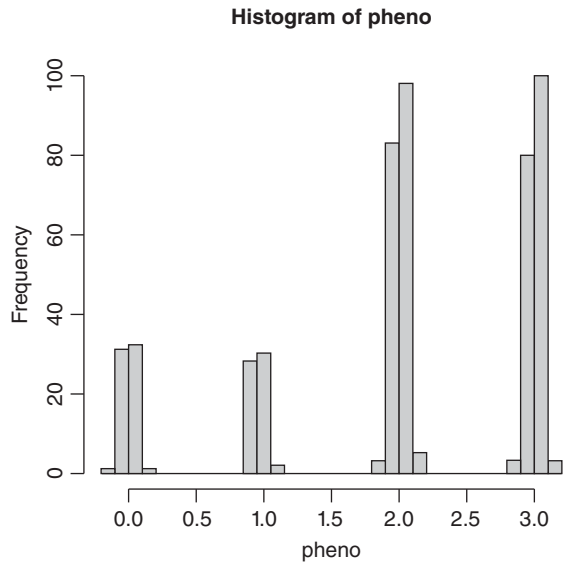

Figure 8.2 Histogram of simulated phenotypes using a standard deviation of 0.05.

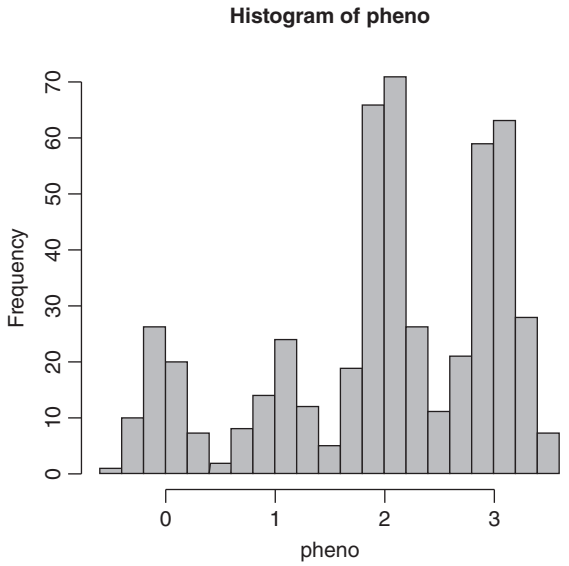

Figure 8.4 Histogram of phenotypes using a standard deviation of 0.2.

distribution of phenotype values was produced, as indicated in Figure 8.2.

In this case, with a small level of noise in relation to the magnitudes of the G and E effects (indicated here by g and e, respectively), the values of genotype and phenotype were quite obvious for each participant. In the second step of our simulation, we increased the standard deviation of the noise to 1 so that the statistical problem was not so trivial. This increase in noise changed the distribution of phenotypes, as indicated in Figure 8.3.

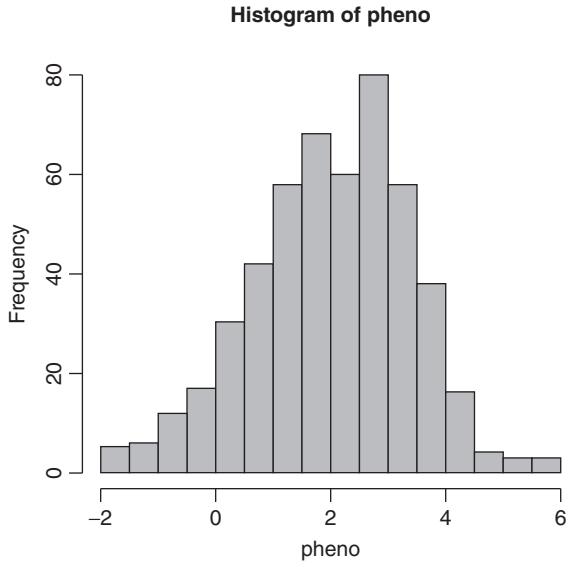

Figure 8.3 Histogram of simulated phenotypes using a standard deviation of 1.

This increase in noise relative to the effect sizes (G and E) caused the distribution of phenotype values to resemble a continuous spectrum. In contrast to the previous example, the genotype and phenotype values were no longer clear.

As a third simulation (Figure 8.4), we established a noise level somewhere in the middle, e.g., 0.2. In this scenario, the distribution of phenotypes was different enough to estimate the specific genotype and environment effects, as shown below. However, the issues related to noise were not trivial, even in this circumstance.

Consider the average value of the phenotype for each genotype–environment value (Table 8.3).

These data are consistent with the parameters used to construct the model. This model is an additive model with no interactions between gene and environment, because it was constructed that way.

However, in practice, one never knows what the true underlying model is: one might have a good idea of what it should be, based on prior evidence, but all a researcher really has is the phenotype, genotype, and environment values and a guess for the model. We then guessed that we had an additive model with a GxE interaction, and used

---
Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05
                                    '.' 0.1 ' ' 1
Call : lm(pheno ~ geno + env + geno:env)
Coefficients:
            Estimate Std. Error t value Pr(>|t|)
(Intercept) -0.01970    0.02487  -0.792    0.429
geno         2.03303    0.02883  70.519   <2e-16 ***
env          1.05346    0.03589  29.349   <2e-16 ***
geno:env    -0.06086    0.04144  -1.469    0.143
---
Signif. codes:  0 '***' 0.001 '**' 0.01 '*' 0.05
                                    '.' 0.1 ' ' 1
Call : lm(pheno ~ geno + env + geno:env)
Coefficients:
            Estimate Std. Error t value Pr(>|t|)
```

There are two things to notice here. First, our estimates for geno and env (in other words, g and e) were highly significant, and very close to the true values of 2 and 1, respectively. Second, the GxE variable was not significant—there was no statistical evidence for a GxE interaction. This was no surprise to us, but it might have been if this were real data instead of simulated data.

Next, to show what would happen if we scaled the data in a different way, we took the pheno values calculated above and replaced them with 10^{pheno} (that is, the inverse of taking the logarithm, base 10) (Table 8.4). We called this new phenotype variable pheno2.

In Figure 8.5 are the histogram of pheno2 and a table of means for each GxE combination.

We transformed our additive model into a multiplicative model: the second column became 10 times the first column, and the second row 100 times the first row. (These

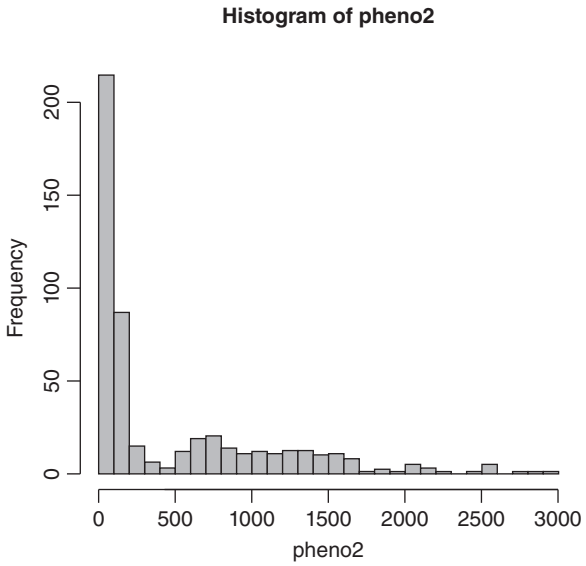

Figure 8.5 Histogram of phenotypes using a standard deviation of 0.2, after scaling the phenotypes by an exponential transformation.

multiplicative factors are not an accident—they are equal to 10^1 and 10^2, where 1 and 2 were our values of e and g.)

We then ran the same regression model—an additive equation with interaction—on these rescaled data:

```
Call: lm(pheno2 ~ geno + env + geno:env)
Coefficients:
            Estimate Std. Error t value Pr(>|t|)
(Intercept)    1.043     42.229   0.025   0.9803
geno         112.925     48.955   2.307   0.0215 *
env           10.779     60.952   0.177   0.8597
geno:env    1015.325     70.368  14.429   <2e-16 ***
Call: lm(pheno2 ~ geno + env + geno:env)
Coefficients:
            Estimate Std. Error t value Pr(>|t|)
(Intercept)    1.043     42.229   0.025   0.9803
geno         112.925     48.955   2.307   0.0215 *
env           10.779     60.952   0.177   0.8597
geno:env    1015.325     70.368  14.429   <2e-16 ***
Call: lm(pheno2 ~ geno + env + geno:env)
Coefficients:

geno:env    1015.325     70.368  14.429   <2e-16 ***
```

This analysis showed an extremely highly significant interaction effect. Also, among the main effects, only genotype was significant, and to a much lesser extent than in the previous model.

What can we learn from this? Suppose the data came from a biological process that was truly multiplicative; that is, that the multiplicative model was a true reflection

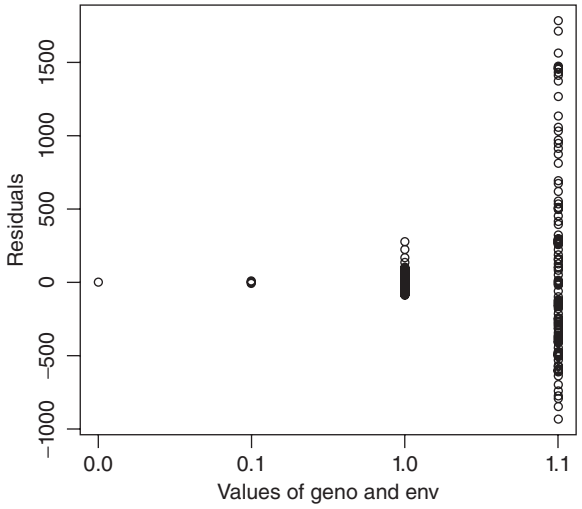

Figure 8.6 Model residuals using exponentially-transformed phenotypes, as a function of genotype and environmental exposure. Note the large difference in variance of the residuals among different combinations of genotype and environmental exposure.

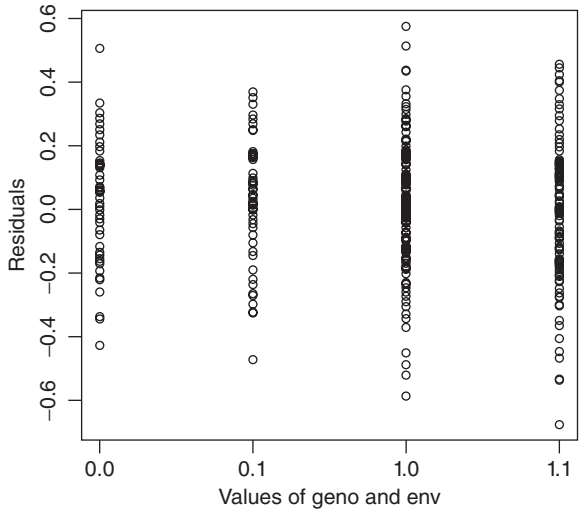

Figure 8.7 Model residuals using unscaled phenotypes, as a function of genotype and environmental exposure. Variance of residuals is approximately the same across all genotype/environment pairs.

of reality and the interaction term above always appeared using this type of additive model. We could then propose taking the logarithm of the phenotype variable—and if we do that, then we would get the first regression model with no significant interaction term (note that if we took the log with respect to a base other than 10, the estimated coefficients would change but the nonsignificance of the interaction term would not). In other words, if we have a significant interaction term in one model, it can be wiped out in another model by transforming one of the variables.

Another lesson to be learned is that the two regression models here were not equally valid. One of the assumptions of a regression model is that the variance of the error term should not depend on the explanatory variables. For our second model, when the additive model applied to pheno2, this was not the case: Figure 8.6 of the residuals against the combinations of genes and environments shows that that the residuals exhibited a huge variance for the 1–1 case, but a variance near zero for the 0–0 case.

This type of structural dependence of residuals on variables used in the model is a hint that the model is inappropriate for the data, and that transformations of the data *should* have been applied. For comparison, we looked at this plot of residuals for our first model (Figure 8.7), when pheno was on its original scale (or equivalently, after taking logs of pheno2).

This is preferred—the residuals now appear to be independent of both genotype and environment.

Simulation 2

In Figure 8.8 we give an account of an interesting example from L. Eaves (2006) of a scenario in which a standard analysis of affectedness by logistic regression is likely to show a significant GxE interaction, whereas a good case can be made that there is no such interaction in the disease etiology. The disease model assumes additive effects of a candidate gene and measured environment on a latent liability to the disease, and a person is affected if that person's liability is greater than a threshold that is constant over the population.

Before describing our second simulation, we consider the example illustrated by Figure 8.8. For simplicity we consider two possible genotypes G = 1 and G = 2; this could be a SNP locus with a dominant allele, for example. There are four possible values for the environmental variable E = 1, 2, 3, or 4. For each genotype G = 1 and G = 2, there is a baseline distribution of liability when E = 1, and each additional unit of E adds a constant increment to the liability—it is important to emphasize that these increments take a constant value (0.35 in this example) not depending on the value of G. In this sense, there is no interaction between G and E in the etiology of the disease. The two baseline liability distributions (one for G = 1 and one for G = 2) are shown as the two probability density functions in the first row (corresponding to E = 1) of the figure above. Both of these baseline liability distributions happen to be bimodal mixtures of two normal distributions. This may look a bit exotic but helps make

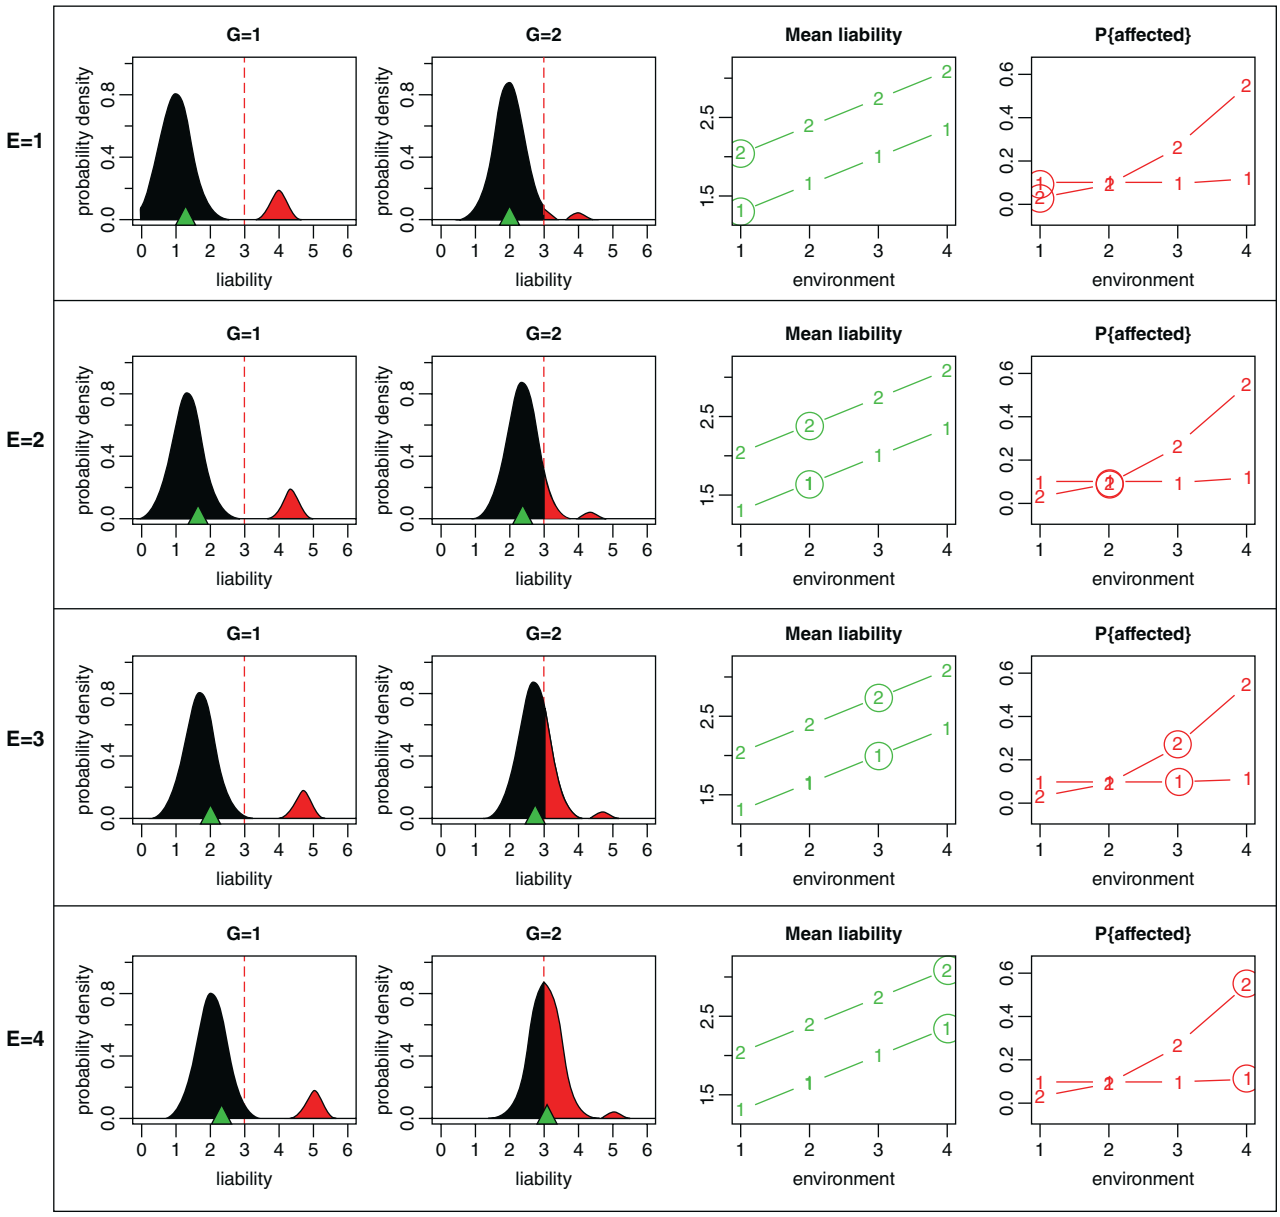

Figure 8.8 Illustrating an example of Eaves (2006) having GxE interaction in a model of affectedness but no GxE interaction in the corresponding model of liability. See footnote 1.

the phenomenon easy to generate and visualize, and, as we intend to show elsewhere, similar phenomena can also be manifested with simpler normal distributions.

Scanning down the first column of Figure 8.8 we see that when G = 1, the effect of each unit of E is to shift the liability distribution to the right by a constant amount, here 0.35. Similarly, scanning down the second column, when G = 2, the effect of each unit of E is precisely the same, adding 0.35 to the liability. The green triangles in the first two columns show the mean liabilities in the various (G,E) combinations. Notice how moving from one plot to the next in a column simply shifts the liability distributions and their means to the right by 0.35. These mean liabilities are illustrated in the green plots in the third column of Figure 8.8. In both the third and fourth columns of the figure above, the 1's and 2's in the plot indicate which genotype is being plotted, and the points corresponding to the value of E in a row are circled. So in the third column, the circled green values mark the two mean liabilities for G = 1 and G = 2 for the value of E shown in that row. Since the effect of environment on liability is the same for all genotypes, there is clearly no interaction between

genotype and environment in determining liability. This is reflected in the third column of figure above, which shows the classic configuration of parallel lines, signifying no interaction.

However the situation is very different if we look at the probability of being affected. We assume each person is affected if his or her liability is greater than 3.0. In the liability densities shown in the first two columns of Figure 8.8, the threshold at 3 is shown as a red dotted line, and the red areas under the liability density curves to the right of the threshold represent the probability of being affected in each (G, E) combination. These probabilities are plotted in the fourth column of Figure 8.8. For example, when E = 1, looking at the two liability density plots in the first row, we see the red area is larger when G = 1 than when G = 2; in the P{affected} plot in the E = 1 row, this corresponds to the circled red 1 being above the circled red 2. In contrast, when E = 4 in the bottom row, we see that the red area for G = 2 is much larger than that for G = 1; this corresponds to the circled 2 in the P{affected} plot in the fourth row being well above the circled 1. The nonparallel (indeed, crossing) nature of the curves showing the dependence of P{affected}on E for the two values of G suggests an interaction.

To investigate the kind of behavior we can expect when standard data analysis methods are applied to a scenario like this, we simulated 1000 data sets, each of which consisted of 1000 people having genotypes, environments, liabilities, and affectedness generated according to specifications following Eaves (1996). Analyzing the liabilities by ordinary least squares regression showed no evidence of GxE interaction: the P values for the interaction term were uniformly distributed between 0 and 1, with 46 of the 1000 P values (4.6%) falling below 5%, as expected when there is no interaction. On the other hand, using logistic regression to analyze the affectedness typically showed a very highly significant GxE interaction; in fact, the median P value for the interaction was only 0.0000032, and fully 99.6% of the P values for GxE fell below 0.05. Taking a look at how these two analyses came out for a very typical data set came out as follows, with the ordinary regression for liability gave output

```
Call: lm(formula = liab ~ g + e + g:e)

Coefficients:
            Estimate Std. Error t value Pr(>|t|)
(Intercept)  0.27959    0.13410   2.085   0.0373 *
g            0.59320    0.07854   7.553 9.62e-14 ***
e            0.41732    0.07696   5.423 7.37e-08 ***
g:e         -0.01054    0.04402  -0.239   0.8108
```

whereas the logistic regression for affectedness gave output that included an impressively significant interaction

```
Call: glm(formula = dx ~ g + e + g:e, family
                  = binomial)

Coefficients:
            Estimate Std. Error z value Pr(>|z|)
(Intercept)  -1.1273     0.6101  -1.848 0.064651 .
g            -1.4386     0.3931  -3.659 0.000253 ***
e            -0.5886     0.2946  -1.997 0.045772 *
g:e           0.7752     0.1704   4.549 5.38e-06 ***
```

So was there an interaction in these examples, or not? As we have seen, a case could conceivably be made for both answers in both examples. However, if an explanation involving interaction relies on a particular scaling of the variables, and another reasonable scaling exists in which the interaction disappears and a simple additive model fits well, one might well prefer the simple additive model. In the first simulation, a very simple, ubiquitous transformation—taking logarithms—was sufficient to transform a multiplicative process that appeared to have a strong interaction to an additive process with no interaction. In the second example, a simple binary transformation generated an appearance of GxE, even though the main effects of G and E on an underlying quantitative trait (the liability) were purely additive. So the liability provided a simple additive description of the disease process with no GxE interaction, but as the liability is a latent variable it may require more ingenuity or sophisticated methods to uncover this simple description.

These simulations raise a more general concern pertaining to the definition of GxE interaction (Flint & Munafò, 2008). Indeed, given that statistical interactions are susceptible to scaling effects, the issue is how useful this term actually is, especially if the null hypothesis, however formulated, has no discernible biological meaning.

Types of Interactions

It is assumed that only 1–2% of cancer syndromes can be explained by inherited cancer syndromes of high penetrance (Ponder, 2001). In fact, the population-attributable fractions of known environmental factors are considered to be up to 90% for cancer syndromes (Doll & Peto, 1981; Higginson, 1968). Similarly, the population-attributable fractions of known environmental factors are considered to be up to 70% for coronary heart disease, stroke, and type 2 diabetes (Willett, 2002). However, recent understanding of the related causation reflects a number of complexities. Specifically, it appears that some environmental factors

(e.g., tobacco smoking and asbestos exposure for lung cancer) interact and increase risk multiplicatively, not additively (IARC, 1990, 2004). Moreover, there appears to be a tremendous amount of individual variation in how environmental exposures are converted into cellular mechanisms and the role of genetic factors (e.g., carcinogen metabolism, DNA repair, cell-cycle control and apoptosis) in this conversion (Vogelstein & Kinzler, 2002). Thus, what were previously considered straight environmental factors might, in fact, reflect the co-action of G and E, which leads to the etiological conclusion that most diseases/disorders are interactions of G and E or multiple Gs and multiple Es (Guttmacher, Collins, & Carmona, 2004). Multiple dimensions have been discussed in the literature that allows the classification of GxE interactions. Here we exemplify some of these dimensions.

First, Ottman (1990, 1996) discussed a number of biologically plausible types of relationships between G and E with regard to their differential effects on disease risk. In the first model, exemplified by PKU, the effect of G is to generate or magnify the role of a risk factor, which can also be generated by E. In the second model, G exacerbates the effect of the risk factor but has no effect if the person is not exposed to this factor (E). This model is exemplified by the relationship between an autosomal recessive disorder, Xeroderma Pigmentosum, and ultraviolet (UV) radiation with regard to skin cancer. Although, in the general population, excessive exposure to UV radiation increases risk for skin cancer, this exposure is substantially riskier (and, thus, results in an elevated odds ratio) for individuals with this disorder, as they are deficient in an enzyme required for the repair of DNA damage induced by UV radiation. Per the third model, E exacerbates the effect of G, but not in individuals with the low-risk genotype. For example, individuals with the autosomal dominant disorder, Porphyria Variegata, develop skin problems of different severity (i.e., excessive blistering, scarring, changes in pigmentation under exposure to sunlight). Although an exposure to barbiturates is inoffensive in the general population, such individuals respond to the same exposure with acute attacks that might result in paralysis or even death. In the fourth model, both G and E risk factors are required to increase risk. To illustrate, most individuals with an X-linked recessive disorder glucose-6-phosphate dehydrogenase (G6PD) deficiency are asymptomatic; yet the consumption of fava beans (an ingredient widely used by the general population) by these individuals might result in the development of severe hemolytic anemia. Finally, in the fifth model, both G and E risk factors have some unique impact on the disease/disorder risk so that their co-occurrence either elevates or decreases the risk compared to their occurrence in isolation. An illustration of this model comes from the development of chronic obstructive pulmonary disease (COPD) in the context of a-1-antitrypsin deficiency (i.e., an inherited disorder causing dysfunction of the lungs and liver) and smoking; in fact, risk of COPD is elevated both in nonsmokers with a-1-antitrypsin deficiency and in smokers without a-1-antitrypsin deficiency, but is particularly increased in smokers with a-1-antitrypsin deficiency.

Second, as in epidemiology (Gail & Simon, 1985), two types of interactions are differentiated in GxE research. Crossover (qualitative) interactions are stated to transpire when a particular level of a factor (either G or E) is superior for some subset (or subsets) of the sample, whereas a different level of a factor is superior for other subsets. Noncrossover (quantitative) interactions are said to manifest when there is variation in the magnitude, but not the direction of the effect. The theoretical and practical values of these interactions are different, with the former being associated with higher significance and the latter with lower significance. The interactions also differ with regard to associated methodological vulnerabilities, such as sample size and power as well as high rate of false-positive effects (Bogdan, Agrawal, Gaffrey, Tillman, & Luby, 2014).

Third, another important typology pertains to the differentiation of essential and removable interactions (Wu et al., 2009). This differentiation occurred in the accrual of data from GWAS. While working with SNP × SNP interactions of different orders, these two types of interactions were defined such that an interaction is essential when the direction (and, possibly, but not critically, the magnitude) of the effect for at least one of the SNPs is changed in the presence of the other SNP (or SNPs). The interaction is removable when only the magnitude (but not the direction) of the effect of at least one SNP is changed in the presence of the other SNP (SNPs). This differentiation and systematic screening of all possible interactions is a chance to detect more interesting and stronger effects (Chen, Liu, Zhang, & Zhang, 2007; Marchini, Donnelly, & Cardon, 2005). The corresponding number of interactions, however, even limiting the scope of consideration to two-way interactions, is staggering, with a count of a million and more.

The importance of such constellations of interactions is obvious as most candidate gene studies are embedded in conceptual models featuring a specific biochemical pathway (or often multiple pathways), including more than one

gene and more than one polymorphism. To illustrate, the Southern California Children's Health Study, investigating the impact of air pollution on children's health in general and the manifestation of asthma in particular, is based on a theory engaging such etiological factors as inflammation, oxidative stress, and anti-oxidant intake (Gilliland, McConnell, Peters, & Gong, 1999). Similar reasoning is applicable to environmental or to a mixture of environmental and genetic factors; although the original study of GxE in cannabis usage (Caspi et al., 2005) tested for a direct interaction, subsequent studies tested for three-way (Henquet et al., 2009; Henquet et al., 2006) and four-way (Peerbooms et al., 2012) interactions.

The translation of this theoretical model into specific hypotheses assumed the simultaneous investigation of multiple genes representing such pathways. Indeed, polymorphisms in these genes, genes themselves, and pathways can interact; these interactions should be properly modelled and analyzed. Furthermore, these genetic interactions can be layered with interactions with specific environmental factors. There are various methods that are suitable for multivariate analysis of high-dimensional data. These methods include standard multiple regression techniques, various machine learning, and pattern recognition methods (Cordell, 2009; Hoh, Wille, & Ott, 2001; McKinney, Reif, Ritchie, & Moore, 2006; Moore & Williams, 2009; Ritchie & Motsinger, 2005).

GxE Study Designs

To explore main and interaction effects of genes and environments, studies of GxE utilize conventional epidemiological designs such as cohort, case–control, or a hybrid of the two (e.g., case–cohort; Andrieu & Goldstein, 1998; Manolio et al., 2006; Yang & Khoury, 1997). Just as in epidemiological research, the selection among designs is driven by weighing their strengths and weaknesses vis-à-vis factors such as biases and confounding variables, temporal sequences of exposure and disease, data accessibility and quality, and capacity to investigate common and rare diseases, disorders, and risk factors (Thomas, 2010a).

In addition, the literature contains a specific line of discourse pertaining to the utilization of traditional epidemiological designs specifically for the purposes of GxE studies (e.g., Collins, 2004; Manolio et al., 2006). As of today, the most present design in the GxE literature is that of case–control. In this design, a sample of carefully chosen people with (cases) and without (controls) the disease/disorder should be ascertained for a specific primary outcome so that similarities and differences between the two groups can be investigated with regard to the distributions of genetic (e.g., frequencies of specific polymorphisms) and environmental (e.g., frequencies of specific exposures) factors (Gordis, 2000). In other words, these studies aim at investigating all individuals who are cases of disease/disorder, or are a representative sample of cases compared with a representative sample of all individuals who are free of disease/disorder. The literature acknowledges many advantages of case–control studies, specifically their relative ease of administration and low costs, their suitability for studies of rare diseases/disorders, and their capacity to sample multiple exposures retrospectively, maximizing the success of identifying true risk factors.

The majority of case–control studies are retrospective; thus, although they ascertain cases after the onset of the disease/disorder, they collect information about genetic and environmental risk factors that predates the onset of the disorder and, in so doing, make a priori assumptions about causality (Doll, 2002). It follows that they are exposed to multiple sources of bias. Indeed, as the corresponding literature has accumulated, the shortcomings of case–control studies have become a limiting factor in the utilization of this design. Among many such shortcomings, the most relevant to this discussion are the following:

1. The tendency for individuals with positive family history to participate at higher odds (Bhatti et al., 2005; Wang, Fridinger, Sheedy, & Khoury, 2001), which biases sample structure in a particular way
2. The tendency for clinically diagnosed cases to represent the most severe tail of the distribution (Guo, 1998), which biases the prevalence-incidence estimates (Neyman, 1955) and overlooks specific cases such as short-episode or fatal cases (Taube, 1968)
3. The difficulty for undiagnosed controls to constitute a bias-free group (Schlesselman, 1982; Wacholder, Silverman, McLaughlin, & Mandel, 1992) and the degree of comparability (by geographic and ethnical ancestry and by predominant environmental exposures) of cases and controls (Helgason, Yngvadottir, Hrafnkelsson, Gulcher, & Stefansson, 2005; Rosenberg, Li, Ward, & Pritchard, 2003)
4. The difficulty of accurately documenting exposure, as most of these studies rely on recalled rather than evidenced exposures to environmental (Feinstein, 1985) or genetic (Silberberg, Wlodarczyk, Fryer, Ray, & Hensley) risk factors.

In realizing the magnitude of these biases and the difficulties associated with the qualification and quantification of risk at the population level (Austin, Hill, Flanders, &

Greenberg, 1994; Hill, 1965) even when specific adjustments for these biases can be applied (e.g., Ben-Shlomo, Smith, Shipley, & Marmot, 1993), it has been argued that the estimates of risk at the population level is best obtained through prospective, population-based cohort studies (Gordis, 2000).

A number of arguments are put forth when the advantages of cohort studies are discussed (e.g., Manolio et al., 2006). First, in contrast to case–control studies, prospective cohort studies utilize representative samples of the population before disease/disorder onset. The underlying idea here is to follow a representative sample from before, throughout, and after specified time points (Manolio, 2003). These time points can be defined in a number of ways, e.g., as bracketing the age at onset of a particular disease/disorder (e.g., type 1 diabetes) or as developmental stages (e.g., infancy, childhood, adolescence, adulthood). The main aim of this design is to ascertain, in the population as a whole rather than among already affected individuals, risk factors for the manifestation of the disease/disorder or biomarkers for the disease/disorder's development. Thus, reduction of many related types of bias is the chief consideration for choosing prospective cohort design over case–control design. Second, cohort studies are particularly important for understanding the etiology and course of diseases/disorders with regard to investigating risk factors that are subject to recall biases (Langholz, Rothman, Wacholder, & Thomas, 1999). Third, prospective cohort design allows a comprehensive and standardized collection of various indicators of premorbid exposure in accord with the main objectives of the study. The problem of recall bias is not relevant, as exposure information is collected prior to the onset of the disease/disorder (Colman & Jones, 2004). Fourth, all members of the cohort are recruited and followed in a systematic way, so that the resulting sample is truly representative and all types of cases of disease/disorder are marked by equal probability of detection. Thereby, the case identification bias that is so problematic in case–control studies is minimized (Manolio et al., 2006). Fifth, unlike the case with case–control studies, multiple diseases/disorders can be studied simultaneously and the time window for disease/disorder onset can be established more precisely (Manolio et al., 2006).

Prospective cohort studies impose a number of requirements (Manolio et al., 2006). First, it is assumed that individuals ascertained into the cohort are characterized by similar genetic (e.g., ancestry) and environmental (e.g., dietary preferences) factors that are distinct from those who are not included in the cohort. Second, it is assumed that participants who are excluded due to attrition are similar to the remaining participants with regard to disease/disorder risks, both genetic as well as environmental. Third, inclusion/exclusion criteria, recruitment, and definition of outcomes should be unified for all members of the cohort. In other words, to avoid biases and ensure the similarity of data collection between cohort members who are and are not exposed to risk factors, whether genetic or environmental, it is assumed that the probability of disease/disorder diagnosis is independent of the exposure to the environmental risk factors, as well as of potentially confounding factors such as age, access to care, and other critical exposures. It is particularly important to document and track changes in exposure history; thus, exposure information should be collected repeatedly (Zeger, Liang, & Albert, 1998). Fourth, it is assumed that all members of the cohort are systematically evaluated for the occurrence of diseases/disorders. The critical feature of prospective cohort studies is that all cohort members have equal probability for the detection and diagnoses of diseases/disorders, regardless of their access to medical care. Therefore, cohort studies cannot rely on the identification of outcomes in the course of everyday clinical care and must embed regular evaluations of the cohort participants into the study procedures. Such evaluations, given their time-consuming and resource-heavy implementation, are the target of criticism of cohort studies. Fifth, and most importantly, it is assumed that prospective cohort studies adequately capture both incidence and accumulation of diseases/disorders and, thus, are characterized by large sample sizes. Sixth, it is assumed that these studies provide an opportunity to comprehensively sample risk factors of interest prior to the onset of cases.

To summarize, it has been argued that prospective cohort studies (Manolio et al., 2006) are particularly suited to (1) studying the full range of disease/disorder manifestations (e.g., diseases/disorders with high mortality at onset like pancreatic cancer or with a long preclinical phase such as type 2 diabetes; Collins, 2004); (2) the identification of predictive biomarkers manifesting prior to the clinical presentation of the disease/disorder (Langholz & Goldstein, 1996); (3) the identification of risk factors that transform after the onset of disease/disorder due to treatment, change in lifestyle, or imperfect or biased recall (Colman & Jones, 2004); (4) the investigation of common complex diseases/disorders of a polygenetic nature (Foster & Sharp, 2005); (5) the simultaneous investigation of multiple outcomes (ARIC Investigators, 1989; Colditz, Manson, & Hankinson, 1997; Kolonel et al., 2000; Leibowitz et al., 1980; Lloyd-Jones, Larson, Beiser, & Levy, 1999; Newman

et al., 2006; Troyer, Mubiru, Leach, & Naylor, 2004; Tsai et al., 2002; Women's Health Initiative Study Group, 1998); (6) confirmation and extension of findings obtained by other means—i.e., via other designs, such as case–control studies (Aleksic et al., 2002; Ellenberg & Nelson, 1980; Kannel, 1995) and dispelling misconceptions (Kannel, 1995; Stamler, 1991); and (7) providing, with adequate protection, wide access to data and samples for analysis and reanalysis (Marshall, 1997).

There are multiple examples of large-scale cohort studies that contribute to the world's general understanding of the epidemiology of health and disease/disorders, including studies in the United Kingdom (Foster & Sharp, 2005; Harvey, Matthews, Collins, Cooper, & U.K. Biobank Musculoskeletal Advisory Group, 2013; Pramanik et al., 2012; Swanson, 2012; Ul-Haq et al., 2014), Iceland (Winickoff, 2001), Germany (Aleksic, Jahn, Heckenkamp, Wielckens, & Brunkwall, 2005; Wichmann, 2005; Wichmann & Gieger, 2007), Sweden (Abbott, 1999), Canada (Gibson et al., 2008; Godard, Ozdemir, Fortin, & Egalite, 2010; Kosseim et al., 2013; Webster, 2008), France (Goldberg & Zins, 2014; Spira, 2014), and Japan (Yuasa & Kishi, 2009). These samples are of considerable size. For example, the UK BioBank, with a case population of 10,000, is considered to be adequately powered to detect risks of <1.15 for G and 1.50-2.00 for GxE (G. D. Smith et al., 2005). However, the public-health significance of genetic risk below 1.50 is not apparent, although it is of etiological and general scientific interest (Terwilliger & Weiss, 2003). Moreover, there are ethical, legal, and social issues related to establishing, maintaining, and using biobanks (Gottweis, Chen, & Starkbaum, 2011; Haga & Beskow, 2008; Kaiser, 2002; Weisbrot, 2012).

Notwithstanding such concerns, it has been argued that there is no comparable study in the United States and there is a need for (at least) one (F. S. Collins, 2004). The justification for this need is that, although there are many prospective cohort studies (Kannel, 2000; Riboli & Kaaks, 1997; The Women's Health Initiative Study Group, 1998), not a single one is substantially large or comprehensive enough to address the modern dominant causes of morbidity and mortality that may occur during the life span or to cover the diverse characteristics of the general U.S. population (Manolio et al., 2006). To illustrate the magnitude of effort that is envisioned in this context, consider the following excerpt from a power calculation, conducted to set up a framework for research using prospective cohorts (Manolio et al., 2006).

> According to our estimates, a prospective cohort study of 1,000,000 subjects would have sufficient power to detect an environmental exposure odds ratio of ≥1.5 for diseases of ≥0.05% incidence per year, such as colorectal cancer, whereas a study of 200,000 people could only detect an environmental odds ratio of ≥2.3 for diseases with this incidence. The minimum detectable odds ratios for genetic factors were slightly lower (indicating the power of the study was higher), mainly because a single individual has two "chances" of carrying a dominant risk allele. For interactions, however, the minimum detectable odds ratios were much higher (that is, the power was lower), as would be expected from the much smaller number of participants exposed to both genetic and environmental risk factors. Whereas a prospective cohort study of 1,000,000 had sufficient power to detect a GxE interaction odds ratio of ≥1.4 for diseases of ≥0.5% incidence a year, a study of 200,000 could only detect this GxE interaction odds ratio for diseases of ≥3% incidence. For a disease of 0.05% incidence, the minimum detectable odds ratio was about 2.4 in the 1,000,000-person study, and as much as 7.0 in the 200,000-person study. Minimum detectable gene–gene odds ratios were slightly lower than GxE odds ratios. Genetic and environmental marginal odds ratios and interaction odds ratios of at least 1.5 are likely to be important to detect, as this is the magnitude of risk associated with genetic variants that is known to be important in complex diseases such as diabetes (Altshuler et al., 2000; Grant et al., 2006). A cohort of 200,000 will provide adequate power within 5 years for only the most common diseases, such as cataracts and hypertension, and will miss these effects for important diseases such as myocardial infarction, diabetes and all cancers. By contrast, a cohort size of 500,000—the number recommended by the NHGRI Expert Panel for a US cohort—will capture many more of these effects. For rarer diseases such as Parkinson disease or schizophrenia, GxE interactions would probably not be detectable within 5 years, even with 1,000,000 participants, but might be approached by continued follow-up and accrual of additional cases (or pooling with other cohort studies) over time. Conversely, GxE interactions for more common diseases, such as hypertension, could be examined early in follow-up and could be assessed for consistency in key subgroups. Of course, consideration of higher order interactions (gene-by-gene-by-gene, or multiple interacting genetic and environmental factors) will require larger sample sizes and might not be approachable within a single study, even for the most common outcomes. (Manolio et al., 2006, PP. 817–818)

Although the envisioned efforts are breathtaking and impressive, the value of cohort studies is not universally accepted (Barbour, 2003; Khoury, 2004). The main points of criticism are the necessity for large sample sizes and long durations, both of which are associated with high costs (Clayton & McKeigue, 2001). Other criticisms of prospective cohort studies point to their lack of flexibility and innovation, as they are locked into particular constraints by design and original hypotheses (Jamrozik, Weller, &

Heller, 2005; Kannel, 2000; Taubes, 1995). Moreover, there are concerns about a multiple testing issue (Terwilliger & Weiss, 2003), as there are a large, and perhaps infinite number of models that could fit the generated data. Arguing against forming new prospective cohorts (the anticipated cost of which is estimated at $3 billion), some (Willett et al., 2007) have suggested assembling cohorts using a combination of samples from existing studies. Although appealing from a cost-reducing standpoint, such a strategy has a number of drawbacks, specifically, lack of standardization of measures across samples, inability to take advantage of new developments in measurement (e.g., dietary intake) and exposure assessments, lack of representation of all strata of the society, uneven age bands (most if not all of existing cohorts include individuals younger than 50, yet it is important to cover a whole spectrum of life span, from birth to death), and constraints pertaining to free and open access to the data by qualified investigators (Collins & Manolio, 2007). These concerns are part of an ongoing discourse, where both sides are trying to negotiate the best possible solution that utilizes both approaches, to whatever degree possible.

In sum, given that both of the major designs used for studying GxE (i.e., case–control and cohort designs) are less than ideal and come with their own array of pros and cons, the field has been challenged with the development of methodological innovations that might overcome the limitations of both or either approaches.

One such innovation is the nested case–control design (i.e., subsamples of both controls and incidence cases from the cohort), which represents an attempt to capitalize on the strengths of both designs while compensating for their weaknesses. The case–control within a cohort or nested case–control design (Mantel, 1973; Prentice, 1986) assumes the utilization of an informative subgroup of cohort members. Although a subtype of the classic case–control design, this design is more resistant to various biases because it permits selection of incident cases and a sample of disease-free controls from an already-established prospective cohort. In other words, as various environmental indicators are collected for the cohort in an outgoing fashion, critical exposures are assumed to be measured before the onset of diseases/disorders of interest. Moreover, biological samples in cohort studies are typically collected if, at the study entry, they can provide unique preexposure information. This design allows the construction of subsamples of cohort members as grouping meets specific objectives of an investigation (e.g., examining the impact of exposure to a particular environmental toxin at a particular geographic location). The use of biobanks, then, overcomes the concern of reverse causation by relying on stored specimens and the information on exposure, both of which were obtained at enrollment.

Yet another innovative design is referred to as Mendelian randomization—a technique that permits an investigation of the causal effect of modifiable exposure to a disease/disorder while capitalizing on the availability of the measured variation in genes of known function (Gray & Wheatley, 1991; Greenland, 2000; McGrath, Mortensen, Visscher, & Wray, 2013; Relton & Smith, 2012). The logic behind this design is as follows: in an ideal genetic association study, Mendelian laws are assumed to guarantee the comparative evaluations of groups of individuals, so that groups established based on specific genotypes (e.g., AA, aa, and Aa) will be comparable to a randomized comparison. This is reasonable given that these genotype-based groups should not differ systematically, except for the effect of linkage disequilibrium (i.e., the dependency between genetic sites that extend over the locus under study due to the phenomenon of linkage disequilibrium). This design is thought to be less susceptible to reverse causation and confounding (Clayton & McKeigue, 2001; Didelez & Sheehan, 2007; Julier et al., 1991; Smith & Ebrahim, 2003) and has been used in GxE studies (Lewis et al., 2011).

In addition, there are numerous nonconventional epidemiological designs applicable to the analyses of GxE interactions. One such design is a cluster of family-based association tests (FBATs), which can be exemplified through case–parent trios (Schaid, 1999), case–sibling pairs (Gauderman, Witter, & Thomas, 1999), extended pedigrees (Laird & Lange, 2006), and other combinations of relatives (Cui et al., 2003; Guttmacher et al., 2004). The FBATs are designed to avoid bias from population stratification. In general, population stratification is of concern for studies of GxE only if there are differential relationships between gene and environmental factors in the population of the substructures (e.g., dissimilar genetic ancestries in exposed and unexposed individuals). One of the most frequently utilized designs is that of the case-parent trio design (Shin, Infante-Rivard, Graham, & McNeney, 2012). In this design, the exposure information is collected only on the cases, and the comparison carried out is that of the relative genetic risks between exposed and unexposed cases. Notably, this design assumes that the parents are also genotyped; this information is especially important for studies of early-onset diseases. Yet another oft-used design is that of discordant sibships (Dabelea et al., 2000; Hoffmann et al., 2011). In this design, the exposure information is collected on all cases and controls and the interaction is tested by means of standard

conditional logistic regression. In addition, the literature contains examples of the utilization of twin studies (Boomsma, Busjahn, & Peltonen, 2002), family segregation (Andrieu & Demenais, 1997), and linkage analyses (Gauderman & Faucett, 1997; Gauderman & Siegmund, 2001; Schaid, Olson, Gauderman, & Elston, 2003) for testing the existence of GxE with unknown genes or specific genetic regions (Yang & Khoury, 1997). Yet, although FBATs are quite powerful for testing GxE interactions, assuming that relatives' exposures are not highly correlated (Gauderman et al., 1999), these designs lack power for testing main effects. In fact, their power for testing main effects is substantially less than that of conventional case–control studies that utilize unrelated controls.

Another design that could be used only to test interactions, not main effects, is the case-case or case-only design (Piegorsch, Weinberg, & Taylor, 1994). This design was developed to overcome the poor power for the detection of multiplicative interactions attributed to small numbers of cases or controls in cells at the cross-overs of risk factors for G and E (i.e., where the risk is present for both G and E) in the standard case–control design (i.e., the counts in the cells where both G and E risk factors are manifested can be low). The key feature of this design is the assumption of GxE independence in the general (source) population; specifically, this assumption allows one to avoid estimating this association among control individuals, which, in turn, increases power for the test of interaction. If this assumption is not violated (e.g., as it is in the case of air pollution), then the case-only design will generate reasonable estimates of odds ratios for GxE. However, if this assumption is violated, the design will generate a biased estimate of the interaction and an elevated Type I error rate (Albert, Ratnasinghe, Tangrea, & Wacholder, 2001). In reasoning through the bias vs. efficiency predicament, a two-part process might be helpful, wherein first, a formal test for the adequacy of the GxE independence assumption is carried out, and, second, the results of this test are used to determine whether the more robust case–control or the more powerful case-only design should be utilized. Yet this process has its own caveats (Mukherjee et al., 2008). First, the majority of GxE studies are still carried out on samples of modest size and would therefore be underpowered to test for the independence of G and E, likely resulting in a biased process. Second, the corresponding calculations for the variance components in the underlying model can be challenging given the model's uncertainty. The field has offered ways to overcome some of these caveats. For example, a method called empirical-Bayes (EB)-type shrinkage estimator has been developed (Mukherjee & Chatterjee, 2007) to achieve a balance between bias and efficiency. In other words, this estimator can maintain optimal or close to optimal mean squared errors among all of the different estimators of interactions irrespective of the true state of the GxE relationship. Empirical interrogations of this estimator suggest that it is unbiased asymptotically. Furthermore, most violations of the assumption of G and E independence are not egregious (Liu, Fallin, & Kao, 2004). The usage of the estimator, then, in conjunction with the increase in the sample size, is thought to result in an eventual decrease in Type I errors (Mukherjee et al., 2008). This estimator appears to present an approach to detecting and estimating GxE interactions from case–control studies by maintaining a desired level of Type I error. Moreover, it does this in the context of realistic assumptions of G and E dependence while improving power compared with the traditional case–control studies that assume G and E independence.

Yet another type of nonconventional design is that of a two-phase case–control design (White, 1982). This design leverages readily available surrogate indicators of exposure (e.g., self-reported retrospective accounts of exposure, phase one) to choose individuals for more detailed assessment of exposure or genotyping (e.g., indicators of exposure based on particular biomarkers, phase two). Phase one typically capitalizes on the existence of both disease/disorder status and the surrogate indicator of exposure present in an ongoing case–control or cohort study, so that a sample for phase two can be built using independent sampling. Thus, although phase one might be relatively inexpensive, phase two can be quite expensive because information on exact doses, confounders, or modifiers requires additional data collection (Breslow & Chatterjee, 1999). Optimally, in phase two, more rare cells (typically, the exposed cases) are overrepresented. In the analyses, the information from both phases is combined so that corrections for biased sampling in phase two can be introduced. An illustration of the utilization of the two-phase case–control design comes from the Atherosclerosis Risk in Communities (ARIC) study, where the interaction between polymorphisms in *GSTM1*/*GSTT1* genes and cigarette smoking on the risk of coronary heart disease was investigated (Breslow, Lumley, Ballantyne, Chambless, & Kulich, 2009; Li et al., 2000). The literature has examples of direct (Caporaso et al., 2009; Thorgeirsson et al., 2008) and indirect associations (Thomas, 2000). A two-phase design was used in a randomized trial of estrogen plus progestin to evaluate interactions of treatment with thrombosis biomarkers (Dai, LeBlanc, & Kooperberg, 2009). According to the results of this study, estimates of the

interaction effect were much more accurate than the estimates obtained from either the case–control study or the two-phase study (and corresponding estimators) in which G and E independence was not assumed.

The two-phase design has a number of derivatives, one of which is countermatching. In this design, each case is matched to one or more controls on the basis of exposure; each matched set should contain the same number of exposed individuals. An illustration of countermatching comes from studies of breast cancer (Langholz & Goldstein, 1996). Notably, the usage of this design has been stated to increase power both for main effects and for interactions (Andrieu, Goldstein, Thomas, & Langholz, 2001).

Finally, it is important to note alterations in established designs such as those of GWAS using either microarray (Engelman et al., 2009) or sequencing (Bickeböller, Houwing-Duistermaat, Wang, & Yan, 2011) data. Now GWAS is used to carry out whole-genome analyses for environmentally responsive variants, known as Genome–Environment-Wide Interaction Study (GEWIS; Khoury & Wacholder, 2009). The expected advantages include both improvement in the targeting of interventions and treatment and the provision of more data for understanding mechanisms of complex human diseases and disorders (Caspi & Moffitt, 2006). However, as GEWIS is new, it has a number of challenges, chiefly those dealing with multiple testing (Caspi & Moffitt, 2006), handling effects of nested environments (Rodgers, Ezzati, Vander Hoorn, Lopez, & Lin, 2004), utilizing existing specimens and medical and other records (Modinos et al., 2013), and interpreting GxE findings (Zammit, Lewis, Dalman, & Allebeck, 2010). To date, there are only limited examples of GEWIS. For example, GEWIS has been utilized to examine the role of genetic moderators in the effect of coffee drinking on Parkinson's disease (Hamza et al., 2011).

As Clayton and McKeigue (2001) pointed out, "The prospects for epidemiology in the post-genome era depend on understanding how to use genetic associations to test hypotheses about causal pathways, rather than on modelling the joint effects of genotype and environment" (p. 1359).

Power

As it gains experience and wisdom, the field is able to look back and reflect on its own accomplishments and failures. Thus, it is a well-recognized problem that the majority of early candidate–gene studies recruited samples that were substantially too small (Wacholder, Chanock, Garcia-Closas, El Ghormli, & Rothman, 2004). As sample size is directly related to effect size, there is always a question of what magnitude is considered to be of enough importance and interest to justify a research effort. The current trend in the literature is to view odds ratios of 1.4 as important, interesting, and potentially significant for public health (Hemminki et al., 2006). Detecting effect sizes of this magnitude calls for large sample sizes. Furthermore, the requirements for sample size increase exponentially when whole-genome rather than candidate gene studies are considered (Wang, Barratt, Clayton, & Todd, 2005). Perhaps unsurprisingly, the cost–benefit ratio of an association study that requires a sample of 10,000 cases and 10,000 controls to identify a gene whose variant is associated with an odds ratio of 1.4 has been questioned (Wang et al., 2005).

It is a well-established observation—empirically and theoretically, in both data-based and simulation-based studies—that statistical power is lower for interactions compared to main effects. It is also widely understood that the consequences of lower power are twofold: when underpowered, true effects are more likely to be missed; while conversely, the proportion of false discoveries among all discoveries is more likely to be high. In general, the power needed to establish and evaluate the impact of any predictor is positively related to the variance of that predictor; lower power to detect interactions is chiefly due to the fact that the dispersion of the product term in nonexperimental settings tends to be low (McClelland & Judd, 1993). On the other hand, power is maximized when the sample is drawn from the extremes of the distributions of main effects. While capitalizing on extremes is possible and suitable in experimental studies, it may be impossible and even inappropriate for human research, especially in the realm of public health.

Many researchers (e.g., Boks et al., 2007; Garcia-Closas & Lubin, 1999; Hwang, Beaty, Liang, Coresh, & Khoury, 1994; Smith & Day, 1984) have specifically investigated the statistical power of GxE studies and have similarly concluded that the power to detect GxE interactions is substantially lower than the power to detect either G or E main effects. Sampling alterations (e.g., the utilization of the extremes design) are possible with environmental/exposure extremes (i.e., sampling from high and low environments at equal numbers), but are near impossible with genotypic extremes (i.e., ascertaining the two types of homozygous carriers at the same frequency). Correspondingly, the way to maximize the variance in the product term is to maximize the variance in first-order (i.e., main effects or G and E) terms (Boks et al., 2007). For example, for a single-polymorphism/single-exposure study, it would mean looking for a polymorphism in which the frequency of the

derived (i.e., minor) allele in the population of interest is as close to 50% as possible; an exposure factor observed at its extremes at approximately the same numbers (e.g., 50% are highly or severely exposed to the factor of interest and 50%—never or only slightly exposed) would also be needed. Moreover, as described already, other considerations, such as sampling strategy (Cologne et al., 2004), study design (Kraft & Hunter, 2005), measurement error in the terms (Burton et al., 2009), correlations between variables capturing G and E (McClelland & Judd, 1993), and types and distributions of outcome and exposure variables (Luan et al., 2001) also impact statistical power to qualify and quantify the GxE interaction.

When these general considerations are applied to the literature on GxE, the overwhelming conclusion is that, so far, GxE studies have been underpowered (Burton et al., 2009; Duncan & Keller, 2011; Luan et al., 2001). This consistent conclusion has been reached in a number of studies (Mukherjee, Ahn, Gruber, Ghosh, & Chatterjee, 2010) for a variety of designs and circumstances: case–control studies (Foppa & Spiegelman, 1997; Garcia-Closas & Lubin, 1999; Hwang et al., 1994; Luan et al., 2001), case-only designs (Yang, Khoury, & Flanders, 1997), and association studies for detecting genetic main effects, where the use of GxE interaction is indirect (Hein, Beckmann, & Chang-Claude, 2008; Kraft et al., 2007). It is noteworthy that the largest studies of putative GxE effects to date have largely produced null results (Surtees et al., 2006), again, raising the suspicion that findings in smaller studies may, in fact, embody false positives.

Notwithstanding the study design, there are other factors that are important to consider in the determination of sample size. These factors are allele frequency, mode of inheritance, the prevalence of exposure (or its distribution if continuous), odds ratio for the main effects of G and E and the interaction effect of GxE, significance level, and desired power (Thomas, 2010a). Moreover, power appears to be sensitive to the nature of the estimators used to qualify and quantify GxE (Mukherjee et al., 2008). There are multiple pieces of software for the relevant power calculations, most notably, QUANTO (http://hydra.usc.edu/gxe, Gauderman, 2002) and POWER (Garcia-Closas & Lubin, 1999).

It appears that the current state of affairs in the field of GxE studies is characterized by the winner's curse phenomenon (Capen, Clapp, & Campbell, 1971): when the power is low, discovery studies presenting positive findings are more likely to report substantial effect sizes (Flint & Munafò, 2008). Such an ascertainment bias leading to an overestimation of genetic effects has been discussed (Goring, Terwilliger, & Blangero, 2001), as well as illustrated in the field of genetic association studies (Lohmueller, Pearce, Pike, Lander, & Hirschhorn, 2003). Thus, in a meta-analysis of 301 association studies, out of 25 loci detected as significantly associated, for 24, the odds ratios reported in replication studies were substantially lower compared with the initial report (Lohmueller et al., 2003). It is assumed that the pattern of results for GxE studies is similar (Flint & Munafò, 2008). The genetic association studies whose results have been replicated, as well as the replication studies, have utilized samples that included thousands (Zeggini et al., 2007) and tens of thousands (Cox et al., 2007) of individuals. GxE studies, compared with these genetic association studies, use sample sizes that are smaller, despite the fact that power calculation procedures prescribe the opposite. Although there are some large samples (>4,000, Surtees et al., 2006), they represent exceptions to the rule, and the average size of GxE samples is much smaller. For example, for the 18 studies of the serotonin transporter, the average sample size was 600 (Uher & McGuffin, 2008). The general rule is that if the interaction is of the same magnitude as the main effect and the power is maintained at the same level, the sample size for a study of GxE must be increased fourfold (Brookes et al., 2001; Smith & Day, 1984). This ratio, however, changes dramatically (to 100 or greater) if subtler (<20% of the main effect) effect sizes for interactions are considered (Brookes et al., 2001). Improved (i.e., with denser marker coverage) and enhanced (i.e., with larger sample size) GWASes should also include detailed indicators of environment, so that not only G, but also E is measured (Vineis, 2004; Willett, 2002). As discussed already, in many situations, interaction terms (either GxE or GxG) can bias and overestimate heritability estimates if they are not measured and modeled properly.

Replication

In general, it has been observed that the degree of replicability in the field of GxE is low. There are many different sources of heterogeneity in GxE studies, both for G (e.g., the ancestral population allele frequency) and for E (e.g., different sizes or chemical constituents of particulate air pollution across regions), as well as for confounders (e.g., co-pollutants, ethnic distributions with differing genetic background risk) that are inevitable and par for the course (Thomas, 2010a). If explained, understood, and accounted for, these sources of heterogeneity can provide insights into the etiology of the disease/disorder (Greene et al., 2009). Yet if sources of heterogeneity are attributable to spurious

inconsistency resulting from methodological limitations, data differences, and random differences between various studies, they turn into sources of noise (Thomas, 2010a).

Moreover, even if the field has conscientiously invested in attempting to replicate a finding, there is still ambiguity with regard to understanding and interpreting the results generated by such attempts. For example, the influential study by Caspi and colleagues on the connections among variation in the promoter of the serotonin transporter gene, stress, and depression (Caspi et al., 2003) has generated numerous replication attempts that have yielded contradictory results. Meta-analytic approaches have also generated conflicting conclusions: for one meta-study that exercised an inclusive approach, the phenomenon is replicable (Karg et al., 2011), whereas for another exercising a less inclusive approach, the phenomenon is, in fact, an epiphenomenon propagated by publication bias (Duncan & Keller, 2011). It is important to mention that results of meta-analyses themselves might be biased, depending on how the specific studies to be included are selected (Egger, Smith, & Phillips, 1997).

It has been suggested that the poor track record of replicating previously reported findings of GxE interactions is partially attributable to lack of power in both the discovery and replication samples (Burton et al., 2009; Ioannidis, Trikalinos, & Khoury, 2006; Matullo, Berwick, & Vineis, 2005). It is clear that better powered studies are needed for both discovery and replication attempts. Yet, this realization triggers another concern: as discussed above, it is not clear whether the results of large-scale studies aimed at dissecting a small effect of GxE are worth the effort, as their public health significance is questionable. It has been argued that specific genes involved in interactions are more likely to be affected through marginal rather than interactive effects (Clayton & McKeigue, 2001). The counterargument is that even when marginal effects are not detectable, there could be statistically significant interaction effects, which will be missed if the focus is exclusively on marginal effects. Indeed, it has been stated that the presence of interactions in the absence of main effects is a ubiquitous phenomenon in nature (Moore, 2003; Moore & Williams, 2009). Yet most examples of such universality come from studies at the molecular and cellular rather than the epidemiological level, although there are some examples of specific G factors that appear to group only with specific E factors, and that very combination generates excessive risk (Guttmacher et al., 2004).

In summary, there is much concern about the low rates of replication in the field of GxE. Yet these concerns are not limited to this field; in fact, the field of GxE is only one of many in which concerns about replicability and effectiveness of research are profound (Macleod et al., 2014).

Publication Biases

Both scientists and scientific journals are leery of publishing so-called null results (i.e., results that do not generate new findings). Among the many reasons for this phenomenon, the main one is that null results (or nonreplications, if a study was an attempt to replicate a previous finding) cannot be viewed as definitive: the inability to reject the null hypothesis does not mean that the null hypothesis is proven. Simply put, both attention and rewards in science are given mostly for the discovery of something new rather than the negation of something old. This publication bias, although logically understood, is assumed to be quite harmful to scientific literature in general and to the GxE literature in particular (Duncan & Keller, 2011), due both to its ubiquity (Thornton & Lee, 2000) and its distortion of the true significance of discovery findings (Ioannidis, 2005). The impact of this harm is difficult to quantify precisely, although some relevant estimates suggest that it is qualitatively large (Duncan & Keller, 2011), as per the hypothesis that many negative results go unpublished, amounting to an increased field-wide Type I error rate.

Another type of bias is nested within the bias against the publication of null results. This bias is captured by the disproportional publication of attempts at replication depending on (1) the nature of the finding (positive or negative), (2) the sample size used, and (3) whether an attempt at replication was coupled with a novel finding or presented by itself. It appears that the threshold for a publication of a nonreplication is substantially higher (i.e., a much larger sample size, sixfold compared with positive studies) if required, and a broader scope of work (i.e., a positive result on an additional GxE) is anticipated (Duncan & Keller, 2011).

It is important to note that the GxE literature is not unique in terms of producing a publication pattern characterized by a small number of high-profile findings, followed by a mixture of replications and nonreplications (Flint & Munafò, 2008). Such a pattern has been seen before in the literatures on GWAS (Munafò et al., 2003; Munafò, Matheson, & Flint, 2007) and endophenotypes (Flint & Munafò, 2007; Munafò, Brown, & Hariri, 2008).

Illustrations

So far, we have reviewed the general set of considerations for conducting GxE studies and have exemplified issues and

observations that have been accumulated by the field. In this section of the chapter, we will illustrate these generalities with two scenarios: one statistical (using a variety of diverse phenotypes and exposures and a single variant of G) and the other biological (using a cluster of related phenotypes, a single type of E, and a type of G).

Understanding the Variation in the Promoter of the Serotonin Transporter Gene

In mammals, serotonin (5-HT) is a major neurotransmitter, involved in numerous highly important biological processes like food intake, sleep, reproduction, circadian rhythm, thermo-regulation, pain, learning and memory, perception, social behavior, and mood regulation (Kriegebaum, Gutknecht, Schmitt, Lesch, & Reif, 2010). Its function in the brain is to substantiate a major type of brain signaling. Multiple proteins regulate the synthesis, degradation, transport, and reception of serotonin, and the production of these proteins involves multiple genes (Duman & Canli, 2010). Specifically, the synthesis of serotonin starts from the amino acid tryptophan and is two staged: the first rate-limiting step is catalyzed by tryptophan hydroxylase (TPH, the production of whose isoforms is controlled by two genes: TPH1, expressed primarily in the periphery; and TPH2, expressed primarily in the CNS). The degradation of serotonin engages enzymes monoamine oxidase A and B, encoded by the X-linked MAOA (central to the degradation of serotonin following its reuptake from the synaptic cleft by the serotonin transporter) and MAOB (central to the degradation of dopamine) genes, respectively. Serotonin is transported into the vesicles near the presynaptic membrane of neurons by the vesicular monoamine transporter (Vmat). The reuptake of extracellular serotonin is necessary for regulating serotonergic transmission and tone. This process is accomplished by the serotonin transporter, a protein encoded by the serotonin transporter gene (referred to as 5-HTT, SERT, or SLC6A4 and located at 17q11.1-q12) that enables the reuptake of excess serotonin from the synaptic cleft. Postsynaptically, serotonin binds to multiple serotonin receptor subtypes, which are encoded by 16 different genes.

In humans (but not exclusively), the SLC6A4 gene is highly polymorphic. One of the most studied polymorphisms in this gene is a common VNTR polymorphism in the promoter region (known as 5-HTTLPR polymorphism). This polymorphism exists in the form of two alleles: a short (*s*, composed of 14 copies of 20–23 base-pair repeated units); and a long (*l*, composed of 16 copies of the repeat unit) variants. The allele *l* has an embedded SNP (rs25531), which involves an A to G substitution. The presence of the G allele is associated with an expression rate similar to the *s*-allele (Hu et al., 2006). Although the allele frequencies for both polymorphisms (VNTR and SNP) vary in different populations, neither is rare, generating a robust source of individual differences in the functional properties of the synthesized protein. Individuals homozygous for the short variant (*s*-carriers) are thought to be characterized as demonstrating lower mRNA transcription (Lesch et al., 1996), increased extracellular 5-HT levels (Mathews et al., 2004; Montañez, Owens, Gould, Murphy, & Daws, 2003), and altered 5-HT receptor densities/function (D.-K. Kim et al., 2005), although recent work has suggested a more complex mechanism, such as regional up- and down-regulation of specific 5-HT receptors (Hariri & Holmes, 2006). The VNTR polymorphism is one of the most studied for associations between structural variability in the genome (i.e., variation at this site) and a plethora of behavioral traits (emotional regulation, Hariri & Holmes, 2006; coping with stress, Homberg, 2012; social conformity, Homberg & Lesch, 2011; social behavior, Kiser, Steemers, Branchi, & Homberg, 2012; emotionality, Murrough & Charney, 2011). As investigations of this polymorphism account for a substantial portion of the behavioral GxE literature, we have undertaken a descriptive characterization of this work.

To accomplish this task, we identified, using the PubMed, PMC, and Medline databases, a set of empirical articles published between January 2000 and December 2012 (including those published electronically, even if the journal publication date was in 2013); no unpublished work (i.e., dissertations) was included. Two literature searches were performed, using selection algorithms (1) ((“alleles” OR “genotypes” OR “genes” OR “polymorphisms”) AND (“GxE” OR “G by E” OR “gene × environment” OR “gene by environment”)) AND (Humans) and (2) ((“alleles” OR “genotypes” OR “genes” OR “polymorphisms” OR “GxE” OR “G by E” OR “gene × environment” OR “gene by environment”)) AND (“serotonin transporter” OR “HTTLPR”) AND (“humans”). The resulting pool of articles ($n > 1{,}000$) was examined with the following inclusion-exclusion criteria. The publications were included if the study examined an interaction between the serotonin transporter gene promoter polymorphism and an environmental exposure indicator deemed relevant to developmental psychopathology as a predictor of a psychological/psychiatric outcome (some of these studies also examined additional variants in other genes). The articles were excluded if (1) exposure indicators were obstetric complications, environmental toxins, diet, physical exercise, medical conditions, or hormonal intervention; (2) no

exposure indicator was identified and the interaction term included G and such factors as indicators of temperament, personality factors, or other psychiatric disorders (e.g., depression, anxiety, addiction); (3) outcome variables were other (nonpsychiatric) medical diseases or disorders (e.g., Crohn's disease, obesity); (4) the sample included related individuals of any kind (twins, other sibling pairs, or any other family members); and (5) more than one variant in the *SLC6A4* gene was investigated (e.g., haplotypes were analyzed). The application of inclusion–exclusion criteria resulted in the selection of 192 articles (see Appendix).

These articles were reviewed to extrapolate answers to a number of specific questions systematically. In general, the intent of the analyses presented here was to see whether this literature contains indications of the utilization of the best practices in the field (i.e., regarding observations and recommendations discussed in this chapter) in the selected publications. Thus, both the extrapolations and interpretations are based on the descriptive analyses of these studies as a group.

The first set of questions dealt with the sample size and the design of the analyzed studies. The sample size ranged from $n = 24$ to $n = 4{,}334$. Importantly, indicators of central tendency were quite variable: mean = 594.5, median = 301, mode = 118 (sd = 769.8). Taken together, this set of studies was still quite far from what is recommended as the standard in the field in terms of sample size. The majority of the samples were characterized cross sectionally ($n = 123$, 64.1%), but a substantial number of samples ($n = 69$, 35.9%) contained longitudinal data. All studies utilized a version of the traditional case–control design, even if there were previously collected longitudinal data.

Second, the studies were diverse in terms of utilizing samples including only women ($n = 27$, 14.1%), only men ($n = 9$, 4.7%), or both genders ($n = 156$, 81.3%). The studies were also diverse in terms of including different races and ethnicities.

The third block of questions pertained to issues of measurement error, both in G and E variables, however defined. In general, details of measurement were not well explicated in this set of studies, although many contained conventional psychometric indicators of the assessments that were utilized either to measure the outcomes or the exposure (E). The presentation of the measurement approach toward G was predominantly characterized by missing information with regard to the error rate for genotyping: only 34 studies (17.7%) reported error rates. Furthermore, only a handful of studies reflected on whether these rates met the expectations established in the field and discussed possible related biases. Notably, very few publications contained information pertaining to the presence of missing data and the process by which this missing data was accounted for (n = 28, 14.6%).

Fourth, only a very small proportion of outcome variables (6.8%) were transformed.

The fifth set of questions had to do with the range of outcomes, exposures, and polymorphisms (see exclusion and inclusion criteria above) utilized in the articles. All three were observed to present considerable ranges: 1–59 for outcomes (mean = 2.7, median = 2, mode = 1, sd = 4.7), 1–35 for exposures (mean = 2.2, median = 1, mode = 1, sd = 2.9), and 1–14 for polymorphisms (mean = 1.8, median = 1, mode = 1, sd = 2.0). Importantly, only 23 studies (12%) exercised any type of correction for multiple comparisons. The most frequently used was the Bonferroni, with other methods such as false discovery rate (FDR) applied only rarely.

Sixth, among the statistical techniques utilized for testing interaction effects, preferences were given to ANOVA/ANCOVA or MANOVA/MANCOVA (~20%) or different types of regression approaches (linear or logistic, ~60%). Typically, the statistical software used was not specified. When specified, the software was not tailored for GxE analyses in the majority of cases, and, therefore, was not necessarily the best vehicle to analyze the data.

Seventh, relatively few studies ($n = 45$, 23.4%) reported the obtained effect sizes and discussed their practical meaning.

Curiously, there were journals that were particularly receptive to the GxE studies involving the serotonin transporter gene during the period of time between 2000 and 2012. Thus, *Biological Psychiatry* published 15 and *Journal of Affective Disorders* published 12 of the 192 articles commented on here.

In this section, we summarized studies utilizing the statistical concept of GxE. Clearly, this interpretation of GxE attracts a lot of attention in the field and appears to generate studies, with the rate of published studies increasing over time. Interestingly, there appears to be a delayed reaction of the field to the criticisms that have been explicated in multiple reviews and meta-analyses. As this summary of the 192 articles demonstrates, the majority of the studies are still underpowered, have not paid enough attention to the issue of multiple comparisons, may not be sensitive enough to issues of measurement error, variable transformations and tracking confounders, and, most importantly, do not discuss the robustness, meaningfulness, or practical significance of the established interactions.

Understanding the Reaction Range in the Acquisition of Academic Skills

It is impossible, in modern society, to overestimate the impact of key academic skills such as reading, mathematics, and science reasoning on subsequent life success and life outcomes. This impact is omnipresent worldwide, and the effectiveness of country-specific primary and secondary educational systems is judged, in part, by how well students score on international competitions, such as the OECD Programme for International Student Assessment (PISA). In the twenty-first century, PISA has become "the world's premier yardstick for evaluating the quality, equity and efficiency of school systems in providing young people with these skills" (http://www.oecd.org/pisa/keyfindings/pisa-2012-results-overview.pdf, p. 2). While the importance of these skills is not disputed, there are two additional considerations that are also rather axiomatic at this stage. First, it is accepted, with the exception of a few rare developmental trajectories (i.e., extreme giftedness or circumscribed skills manifested in certain types of atypical development like autism), that all academic skills are constructed by a child as he or she experiences schooling. In other words, a child acquiring these skills builds a number of new cognitive (i.e., brain-based) representations that will guide the processing of relevant information. The formation of these representations requires a functional reorganization of the brain. Second, it is also known that, within any educational system (whether it is high-scoring such as Chinese, Taiwanese, or Finnish; mid-range-scoring such as German, Spanish, Russian, or American; or low-scoring such as Mexican or Indian, as per a number of PISA cycles), a tremendous amount of individual difference scatters student performance across the continuum. The presence of individual differences has been of interest to researchers around the world. As schooling was put in place only in the first half of the last century, the research into the student-based variation in learning that occurs even when teaching is homogenized has a history of only about 50 years. Yet these 50 years of research have unequivocally established that the efficiency of mastering the key academic skills of reading, mathematics, and scientific reasoning is tightly connected to variation in both the brain (in terms of its processing of the relevant information) and the genome (both structurally and functionally). Thus, the understanding of both the acquisition of, and individual variation in, core academic skills requires the investigation of how structurally diverse genomes assume the task of reorganizing the neural connections of the brain through schooling to acquire the academic skills of reading, mathematics, and scientific reasoning under the pressure of particular educational systems. In other words, this understanding requires a differentiation of the mechanism (or mechanisms) that delivers the environment (teaching or schooling) under the skin, so that a biological machinery (i.e., within a child) that ensures both the initial acquisition of skills and their further automatization and that explains individual differences in both the acquisition and utilization of these skills may unfold. It is argued here that one such mechanism is that of epigenetic regulation in general and DNA methylation in particular.

Five bodies of literature substantiate this argument.

First, the literature substantiates a high degree of genetic control in both the acquisition and maintenance of these three academic skills (reading, mathematics, and scientific reasoning), with some variation across skills. The literature also offers evidence that, while the degree of genetic control seems to be stronger in individuals who exhibit low performance on the academic tasks that utilize these skills, there is no reason to believe that the mechanisms of genetic control for poorer performers are different from the mechanisms of genetic control for stronger performers. In fact, it appears that whatever these mechanisms are, they operate across the range of academic performance (Elliott & Grigorenko, 2014).

Second, similar to other complex phenotypes, academic skills such as reading and reading-related components are highly heritable. However the currently considered candidate genes and corresponding polymorphisms do not account for meaningful portions of the previously estimated heritability. This phenomenon, which applies to these specific phenotypes among many others, has been referred to as the missing heritability problem. Concordantly, although limited, there is growing literature on the importance of GxE for the acquisition of academic skills (Pennington et al., 2009; Rosenberg, Pennington, Willcutt, & Olson, 2012; Taylor et al., 2010).

Third, there are large literatures (Fields, 2011), although uneven for the three skills, substantiating the presence of distinct distributed brain signatures that differentiate individuals who (1) are engaged in particular tasks requiring skills of reading, mathematics, and scientific reasoning as compared to individuals who are engaged in other types of tasks (or when the same individual is engaged in different types of tasks); (2) have acquired the skills versus those who have not (i.e., either when comparing young children who have not yet begun their formal education to older children who have completed

of primary education, or adults who have corresponding functional skills against those who do not have them, for example, literate and illiterate adults, or adults who can and cannot perform operations involving quantitative or scientific reasoning); and (3) perform within the normal range (i.e., within a particular quantification, whether 1, 1.5, or 2—whatever the criterion dictates—standard deviations around the population mean) compared with those who perform outside the normal range (i.e., outside of the established criterion, as defined already).

Fourth, there is a growing body of research indicating the role of epigenetic mechanisms in general and DNA methylation mechanisms in particular in all types of learning (Levenson & Sweatt, 2005). This research, however, has been conducted predominantly on animal models. The human epigenetic literature, however, has assessed the role of this mechanism only in social learning, and there is not a single study that investigates the role of this mechanism in cognitive/academic-related learning to date.

Fifth, there is now a strengthening line of reasoning which connects the literatures on the missing heritability problem, GxE studies, and epigenetics (Slatkin, 2009).

Thus, we argue that the acquisition of academic skills, all of which are both heritable and sensitive to environmental exposure (i.e., pedagogy), exemplifies the biological concept of GxE. As was the case 100 years ago, there is substantially less research on this biological interpretation of GxE compared to its statistical interpretation, but the reasoning presented in this chapter can and certainly should be translated into testable hypotheses.

FUTURE DIRECTIONS

Three observations appear to be instrumental in summarizing the material presented in this chapter in light of future developments. First, there is a critical mass of literature, spread across multiple fields of inquiry (epidemiology, genetics, psychology, and other fields) that indicates that designing, implementing, and interpreting GxE studies require conscientious consideration of a number of methodological caveats. Future studies of GxE should be judged being both aware and proactive about these caveats. The field is too advanced now to forgive any naïveté in those who wish to practice in it. Second, methodological rigor should be expected not only of publications, but also of proposals for GxE studies. In other words, funders should be educated along with researchers on the pros and cons of GxE studies. Finally, the whole field should carefully consider the practical implementations of GxE research. Even when carried out as rigorously as possible, what can the field learn from this research and at what cost? Answers to these questions should surely frame the future of GxE research.

CONCLUSIONS

There is no question that GxE studies have made an impact on the fields of developmental psychopathology, neuropsychiatric genetics, and genetic epidemiology, among others. As is obvious from the discourse above, this impact is complex and has instigated numerous kinds of actions and reactions.

First, there are hopes. The appeal of studying GxE is in the possible applications of the most reliable findings (yet to be secured!). Given the state of the field, it is difficult to predict what findings will be deemed reliable and what applications might be derived from these findings. Specifically, such findings can form a foundation—or at least lead to a set of guidelines—for targeting interventions for individuals at high risk (Khoury & Wagener, 1995). Three types of such guidelines have been discussed. The first type of recommendation (following the established the presence of the statistical GxE interaction) involves avoiding specific exposure. For example, researchers (Vandenbroucke et al., 1994) investigated whether the occurrence of venous thrombosis in young women who use oral contraceptives might be explained by the factor V Leiden mutation (this mutation results in resistance to activated protein C and, therefore, increases susceptibility to thrombosis). The reported differential increases in risk (Vandenbroucke et al., 1994) were four-fold among users of oral contraceptives, eight-fold among carriers of the mutation,, and 30-fold among carriers who used contraceptives. Clearly, carriers should consider alternative methods of contraception. The second type of recommendation involves forming relevant public-health policies. For example, in a study in Rwanda (Kolassa et al., 2010), individuals with extremely high levels of trauma exposure were stratified based on their genotypes at the serotonin transporter gene promoter site. It was reported that the individuals with the ss genotype were marked by a higher chance of manifesting lifetime PTSD regardless of the number of traumatic experiences, whereas the individuals with the l allele (i.e., ll or sl) had an elevated chance of developing lifetime PTSD only when the number of traumatic experiences was elevated. In the Florida Hurricane Study, individuals with the s allele were characterized by (1) the elevated

risk of PTSD only when their exposure to hurricane was higher and their social support was lower, compared to the rest of the sample (Kilpatrick et al., 2007); and (2) the decreased risk of PTSD in low-risk environments, but with an increased risk in high-risk environments (Koenen et al., 2009). Assuming that the multiple inconsistencies of GxE studies may be resolved and the robust findings replicated, relevant policies can be established to diversify services for individuals in disaster zones. The third type of recommendation involves seeking and receiving particular interventions in accordance with a particular genotype. In general, it has been stated (Baird, 2001; Rose, 1992) that in the realm of public health, the predicted health gains are superior in situations when the whole population, not just the high-risk group is targeted. This superiority is justified (Wallace, 2006), in particular, by the relative unimportance of genetic mechanisms in the risk of common complex disorders/diseases (e.g., lung cancer); the complexity of various types of interactions, GxG and GxE (e.g., schizophrenia); and the simplicity of the representation of environmental exposure, as typically captured by a single environmental factor. At the present time, there is no convincing support for the idea that delivering interventions based on individual genotypes improves the desired outcome. Yet, there are hopes that such examples will appear (Benner et al., 2014; Tucker-Drob & Harden, 2012), as, at least in developmental psychopathology, it has been suggested that "differential susceptibility may ideally lead to differential intervention and thus more effective treatment" (van IJzendoorn et al., 2011, p. 50). There is also hope that the biological interpretation of GxE will help the field connect currently unconnected dots (e.g., to understand in detail the acquisition of highly heritable skills, for example, academic skills, which require a specific type of environmental exposure for each individual).

Second, there are precautions. In particular, two scientific journals, *Behavior Genetics* (Hewitt, 2012) and the *Journal of Abnormal Child Psychology* (Johnston, Lahey, & Matthys, 2013), have established requirements to be met before manuscripts presenting candidate–gene main or interaction effects can be considered for review. These requirements reflect many of the caveats of the field that we have discussed in this chapter. Thus, 15 years of GxE studies have taught the field to be particularly sensitive to the methodological aspects of research in general and the reproducibility of the results in particular.

Third, there are commentaries. This chapter was conceived as a constellation of observations from the literature on GxE, which is large and continues to grow, regardless of precautions. Although hopes for GxE remain high, so far, their realization has, in general, not risen to the level of our expectations. If anything, this discrepancy, as well as the numerous issues discussed in this chapter, "provides significant reason to pause for reflection" (Eaves, 2006, p. 1).

SUMMARY 369
REFERENCES 370

This chapter focuses on the rapprochement between genetics and the social sciences in the study of the family. This rapprochement began nearly a century ago and has accelerated in the last decade. This rapprochement has revised our concepts of family development, of how its subsystems influence one another and how the family shapes development of its child and adult members. This rapprochement extends into family-level interventions designed to treat individual and relational disorders or for preventing them. However, despite nearly a century of intellectual transaction between social and genetic approaches to the family system there remains troublesome disarticulation between the two perspectives. Moreover, there is notable disarticulation within the domain of genetic analyses between quantitative (twin and adoption methods) and molecular approaches.

GENETICS AND THE SOCIAL SCIENCES: A HISTORICAL SKETCH

The rapprochement achieved so far emerges from a long, and sometimes troubled, history of the connection between genetics and social science. It is now possible to recognize significant turning points in a century-long history of combat, truce, and alliance between these two essential approaches to the study of human development. The purpose of this review is to outline how this emerging rapprochement of social and genetic analysis has reshaped our understanding of the family and to suggest the practical significance of this revised view. We also suggest that rapprochement has helped reshape our view of genetics and, while not a primary focus of this chapter, some of these changes will be noted in order to gain a better understanding that—in the rapprochement of two lines of work—both the science of genetics and of family systems has been irreversibly altered.

As we note later, the systematic application of genetic principles to understand emotions and behavior extends back millennia. However, we lack a published history of behavioral genetics, as this field of inquiry is now termed, although there have been preliminary efforts (Gottesman, 2008; McGue, 2010). Moreover, there is no systematic effort to review the history of the transactions between

behavioral genetics and social science. In this vacuum several assumptions have arisen; among the most important of them is a view that social science is the older, softer, and less coherent discipline and that its inferences about families and human development must be significantly revised in the light of the much newer discipline of genetics. In this chapter, we will review areas where genetic studies require major revisions in thinking about the family. However, a systematic history of the interplay of genetics and social science might offer a different perspective: both the formal study of behavioral genetics and of social science have their roots in the late nineteenth century and each prodded the other to change during the ensuing decades.

The ancients had a firm practical grasp of both genetics and family systems. Darwin in *Variations in Plants and animals under domestication* (Darwin, 1920 (1868) documented the acumen of the ancients in cross breeding. He cited the thirtieth chapter of Genesis, where Jacob exacts revenge on his father-in-law by the selective breeding of Lavan's sheep (and became wealthy by keeping the best). Further, after Darwin praises the keen observations of and implicit knowledge of heredity by British animal and plant breeders, he cites Plato, Alexander the Great and Virgil for equal acumen. The Book of Genesis also provides evidence of the keenest observations of the interplay between family process and social convention. It would be hard to find in current accounts a shrewder appreciation of family social systems than the story of Tamara's successful seduction of her father-in-law, an account interleaved between two halves of the sage account of the interplay between parent–child and sibling relationships in the story of Jacob, Joseph, and his brothers.

At what point does keen observation and intuitive understanding of lawfulness of biological and social processes shade into science? While this question may give way to endless, and some might argue fruitless, philosophical debate there seems little doubt that the exacting experiments with peas by Gregor Mendel marks a starting point for scientific genetics. Mendel presented his results to the Natural History Society of Brunn in 1865. The society published his paper the following year (Mendel, 1948 (1866)) in their journal to which a large number of European scholarly libraries subscribed. Further, Mendel was said to have distributed many reprints of his paper and drew attention to it in scientific correspondence (Hunter, 2000). However, it was not until 1900 that Mendel's work was recognized and highlighted by the German botanist, Carl Correns (Correns, 1950). By this time a searching and rigorous social science was well underway as exemplified by the remarkable study of the social factors in suicide by Emil Durkheim (Durkheim, 1951 (1897)). With the same rigor that Mendel sought to illustrate the independent assortment of heritable traits of the pea plant so did Durkheim painstakingly attempt an isolation of factors of social cohesion—in religion, family life, and political stability—that prevented suicide. As we now understand the analysis of covariance, confounding, and counterfactuals, Durkheim understood that testing his thesis required accounting for the potentially confounding role of mental illness, alcoholism, heredity, season, and geographical location. Well before these historically decisive publications by Corrans and Durkheim, Francis Galton, with his strong interest in both heredity and life circumstance, published the first paper on the use of presumptively identical twins to identify sibling specific experiences in life that led to differences in their competence in adult life (Galton, 1876), a phenomenon that now goes by the awkward name *nonshared environment* and is investigated using the same strategy.

THE TWIN METHOD AND THE EQUAL ENVIRONMENTS ASSUMPTION

The current age of behavioral genetics, however, had a very clear starting point: the discovery of the twin method. As Rende, Plomin, and Vandenburg (1990) pointed out, the first use of the twin method—as we know it today—was by the Stanford graduate student Curtis Merriman. His was the first of many major advances in behavioral genetics to be developed by a graduate student. Merriman published his thesis in 1924 to argue first, that there were two types of twins: fraternal and duplicative. Then he demonstrated that the correlation on intelligence tests between twins was higher for the latter. Since there were no agreed on criteria for identifying duplicative twins he knowingly used a short cut that blunted his analysis. Opposite-sex twins must be fraternal and among same-sex twins roughly half are duplicative. Hence, a comparison of same-sex versus opposite-sex twins should provide a lower bound for estimating genetic influence on intelligence. Rende and his colleagues also underscored an even more direct use of the twin method by the German dermatologist Herman Siemens who, in 1924, directly compared concordance rates and correlations between identical (one egg as he termed them) and fraternal (two-egg) twins. Siemens understandably focused on skin conditions but also reported on children's mental capacities and school performance. His 1927 paper anticipates modern-day diagnosis of twinships

specifying physical characteristics that are likely to be identical in one-egg twins (Siemens, 1927).

In the two decades following Merriman's (1924) and Siemens' (1927) path breaking advances the twin method was applied to a broad range of human variability. Perhaps none were as controversial as those of Franz Kallman, who estimated high heritability of schizophrenia from comparing concordance rates of monozygotic (MZ) and dizygotic (DZ) twins (Kallmann, 1946). Conflict between the study of families as social systems and the study of genetics reached a fever point in the ensuing years because family systems researchers proposed an entirely alternate theory of the origins of schizophrenia as a disorder shaped by abnormal interactions in the family.

The most influential and enduring social formulation was that of Margaret Singer and Lyman Wynne, who developed a family process concept of *transactional thought disorder*. Parents' communication style, particularly their vague, amorphous, and shifting descriptions of ambiguous stimuli, could induce thought disorder and ultimately schizophrenia in their children. These parental patterns could be readily observed in the parents' responses to Rorschach blots. Singer and Wynne could, using blind coding of parental communication deviance and child's thought disturbance, successfully identify parents with a schizophrenic offspring (e.g., Singer & Wynne, 1965). Their argument for the social transmission of schizophrenia was indirectly buttressed by a stream of attacks on the twin method, mainly by family clinicians and researchers (Jackson, 1960), criticism that continues (Joseph, 1998, 2001). Critics compiled evidence that identical twins were treated much more similarly by their parents than were fraternal twins and hence differences of between-twin correlations between the two groups of twins reflected environmental rather than genetic influences. As strident as this debate became, it also set the stage for an extended process of scientific conflict resolution since both sides, the geneticists and the environmentalists, could agree that the validity of key assumptions of the twin method were not only critical but also testable. The fundamental assumption of the twin method was that the environments (social and physical) of DZ twins were as correlated as those of MZ twins: *the equal environments assumption*.

Thus, an early order of business was the resolution of debate about the equal environments assumption of the twin method, an endeavor that reflects equally the work of social scientists and geneticists. The first step towards exploring the equal environments assumption was a more precise definition of this assumption. Clearly, family researchers were correct about the special treatment of MZ twins: they were more frequently dressed alike, had names that went together such as Jane and June and were more likely to be confused by family members and strangers alike. But if estimates were of, say, the heritability of schizophrenia, could it be argued that clothes, first names, or even being confused with one's sib are plausible etiologies of schizophrenia? Moreover, MZ twins might have more correlated environments because they are genetically similar (Eaves, Foley, & Silberg, 2003). For example, babies with irritable temperaments evoke annoyance or withdrawal of their parents. If this temperament is heritable then evoked reactions of parents will be more similar for MZ than DZ twins because the former are identical. Thus, the definition of the equal environments assumption focused on the equality of correlated environments plausibly linked to the behavior under investigation that do not arise as a consequence of the twins' genotype. Stated thusly, the equal environments assumption is not easy to test by straightforward computations in traditional twins studies. Two strategies, however, have demonstrated its validity.

The first has been analysis of twin samples where twins or their parents or both have misperceived their zygosity. Usually, it is MZ twins that are misperceived as DZ though the reverse sometimes happens. Early studies made efforts to correctly diagnose zygosity through fingerprinting (Goodman & Stevenson, 1989) or blood typing (Scarr, Scarf, & Weinberg, 1980) and recent studies have added more elaborate genetic testing (Conley, Rauscher, Dawes, Magnusson, & Siegal, 2013). All studies published thus far, using this approach, have shown that twin misperception does not materially affect heritability estimates: MZ-DZ differences are the same or greater in genetically diagnosed twins as they when the distinction is made only by the parents' or the twins' perceptions.

A second strategy provides even more persuasive evidence: the analysis of twins reared apart. In two separate samples (Bouchard, Lykken, McGue, Segal, & Tellegen, 1990; Pedersen, Plomin, McClearn, & Friberg, 1988; Plomin, Pedersen, McClearn, Nesselroade, & Bergeman, 1988) correlations between MZ twins reared apart were equal to, or nearly so, for many but not all measures of temperament, personality, cognitive measures, and a range of physical measures such as height and blood pressure.

These important confirmations of the equal environments assumption should have allayed the major concerns of social scientists studying the families although it needs testing continuously as the twin method is used in new domains of study where the equal environments assumption might not hold. Moreover, other assumptions lie beneath the standard computations of the twin method

that need constant examination including the assumed absence of notable interaction of the environment with a subjects entire genotype and no genetically-based mate selection in the parents of the twins.

THE ADOPTION METHOD AND SELECTIVE PLACEMENT

There are two different designs that capitalize on the natural experiment of adoption. Both involve comparing a characteristic of the parent, or the environment shaped by the parent, with characteristics of the child. In one design, adoptive parents and their children are compared and this comparison is contrasted with identical comparisons between a second group: parents rearing their biological children. A second, more difficult design, recruits birth parents who have placed their child for adoption at birth or very soon thereafter. Comparisons between the birth parents and the child are contrasted with those between the adoptive parent and their child. While the child may be placed at birth, the biological mother cares for her child for 9 months of pregnancy so that potential effects of prenatal rearing must—where possible—be ruled out. A recent design, to be discussed later, capitalizes on the new technology of in vitro fertilization. Mother-child comparisons are made between two groups: one where the mother's own egg is fertilized and then implanted in her womb and another where a donor's egg is implanted (Rice et al., 2009).

The first use of the adoption design was published only three years after Merriman and Siemens published the first use of twin studies. In 1927, Barbara Stoddard Burks, a psychologist and student of Lewis Terman, published an elegant paper comparing adoptive parents' intelligence scores with their adopted children and contrasted that with a closely matched group of biological parents raising their own children (Burks, 1927). This remarkable report recognized that biological parents provided both environmental and genetic influences whereas adoptive parents only environmental. Where parent–child correlations for the biological group exceeded those of the adoptive group, she reasoned, the difference represented the role of genes in parent–child transmission. Moreover, she recognized that parental intelligence was a limited measure of environmental influence on children and thus included a culture index of the home that included parental education, interests, and the size of their library—a measure that anticipated current and widely used measures of the home environment (Caldwell & Bradley, 1978). Finally, Burks recognized that valid inferences drawn from the adoption design assume that the adoption process does not selectively place children in order to match characteristics of the birth parents—say intelligence, interests, or occupational background—with those of the adopting parents. The *selective placement assumption* is logically equivalent to the equal environments assumption; if it is violated results will seriously overestimate genetic effects. In presenting the results of this prescient paper, Burks exploited a special advantage of the adoption method: the capacity to directly assess the environmental effects of parental characteristics and of the home environment on child development. She found evidence that both genes and environment contributed to variation in child IQ.

Two teams independently carried out the first use of the adoption method for the study of the transmission of psychopathology from parents to children. Leonard Heston, who at the time of his study was a psychiatric resident, reported a comparison of the adopted away offspring of a group of mothers with schizophrenia, hospitalized in Oregon, and a matched control group born to mothers without major mental illness. The children were placed at or near birth in a foundling home or with a family; the latter included some who were relatives of the mother with schizophrenia (a potential confound in an otherwise remarkable effort by an investigator taking his first step in research). Heston reported a preponderance of psychiatric problems in the offspring of schizophrenic mothers (Heston, 1966). At the time Heston was tracking the offspring of psychiatric patients after their Oregon hospitalization, Seymour Kety, Paul Wender, David Rosenthal, and Fini Schulsinger were tracking adopted offspring of schizophrenic female patients in Denmark and also both the biological and adopted relatives of the adopted offspring who became schizophrenic. They reported a preponderance of psychopathology in the offspring of the schizophrenic parents (Rosenthal et al., 1968) as well as in the biological but not in the adoptive relatives of adopted offspring who developed schizophrenia (Kety, Rosenthal, Wender, & Schulsinger, 1968). These data were presented at an epochal meeting in Dorado Beach, Puerto Rico where Heston reported additional data from his study showing no effect of the rearing conditions of his adoptees—institutional care versus family care—on the psychopathology he measured (Heston & Denney, 1968). The cumulated evidence argued for an important role of genetics in the parent-to-child transmission of schizophrenia, entirely circumventing the weaknesses of the twin method. However, these investigators also concluded that that there was little evidence that rearing

played any role in schizophrenia. Heston showed no effect of the extreme variation between foundling-reared and family-reared adoptees, and the Kety group found no excess of schizophrenia and related disorders in the adoptive parents.

The impact of these presentations and their conclusions were particularly dramatic since they directly followed a summary at Dorado Beach by Lyman Wynne of his many studies showing an association of communication deviance in parents with their offspring's schizophrenia (Wynne, 1968). Although Wynne was circumspect about the etiological significance of his work, the overwhelming impact at the time was that genetics were important and the social origins of this disorder were, at the very least, unproven. However there were serious flaws—clear now after more than 40 years—in the arguments of both camps.

The Danish and Oregon teams did not recognize that institutional versus family rearing—the key comparison in the Heston report—might not be the decisive environmental contributor to schizophrenia. (The effects of institutional rearing on child development were clarified in a much later adoption study by Michael Rutter and his colleagues (Rutter & O'Connor, 2004) where the effects were not psychotic disorders but on cognitive development and on promiscuous attachment to strangers.) Similarly, the diagnosis of schizophrenia in a rearing parent—the focus of the Rosenthal group—was not necessarily an index of a home environment specifically pathogenic for schizophrenia. Both teams missed the opportunity to do a simple cross tabulation to detect the possibility that a poor rearing environment might enhance the impact of genetic liability—however crudely measured—although the small samples were vastly underpowered to test for statistical interactions.

For their part the Wynne group underestimated the importance of the genetic relatedness of the parents and children they studied. While they viewed parental Rorschach responses from an interpersonal perspective their measures might reflect only the behavioral expression of the same genes in the parents that, transmitted to their children, enhance their liability for schizophrenia. Now called *passive gene–environment correlation*, this form of parent–child transmission is a major counterfactual to all studies seeking to establish a causal link between family process and child development where parents and children are genetically related. Interestingly, the adoption design provides a uniquely direct method for estimating the importance of passive gene–environment correlation. For example, using the same adoption design as Barbara Stoddard Burks seven decades later, McGue and his colleagues reported an association between parental alcohol dependence and impulsive and delinquent behavior in their offspring. However, this association held only for biological parents rearing their own offspring and not for adoptive parents and their children. The findings suggested parental alcoholism was not an environmental risk factor for offspring behavioral problems but that genetic factors influencing alcoholism in parents were passively transmitted to children where those same genetic factors impaired the offspring's behavioral self-control (King et al., 2009).

There were important epilogues to this dramatic Dorado Beach confrontation, a confrontation that may be among the most pivotal moments in the history of developmental psychopathology. Lyman Wynne partnered with the Finnish psychiatrist Pekka Tienari to replicate and extend the Danish and Oregon studies. Tienari tirelessly tracked children of Finnish schizophrenic mothers placed for adoption at an early age and developed a closely matched control group of adoptees whose biological parents were not psychotic. The ultimate sample was almost five times larger than the Danish and Oregon studies and included measures of communication deviance as well as other direct measures of family process. Assembling the sample took years, and it was not until 30 years after the Dorado Beach conference that the first major results were published. Parental communication deviance did not have a main effect on schizophrenia, but it did have decisive moderating effect on the genetic liability for thought disorder in the adopted offspring. At high levels of communication deviance offspring with genetic liability showed *more* thought disorder than did offspring without genetic liability, but at low levels of communication deviance the offspring with genetic liability showed *less* thought disorder than controls (Wahlberg, Wynne, Oja, Keskitalo, et al., 1997). Wynne and his colleagues recognized this pattern as one formulated by Kendler and Eaves 9 years before; Kendler and Eaves (1986) termed it *genetic control of sensitivity to the environment*. Individuals with this sensitivity genotype would show greater adaptation that those without the genotype under favorable environmental conditions but do worse under unfavorable conditions. This form of gene–environment interaction was reintroduced by Jay Belsky and colleagues with the term *differential susceptibility* (Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2007; Belsky & Pluess, 2009) apparently without recognizing either the original contribution of Kendler and Eaves or the findings of Wynne and Tienari. Perhaps because Belsky and his colleagues were better known in developmental psychology their papers became the basis for a wide range of research on differential susceptibility

gene–environment research in developmental psychology and psychopathology.

The Dorado Beach conference had a second long-term epilogue, one that led to a major disarticulation of genetic and family process studies that rivaled that of the 1960s. The data from the Danish and Oregon studies were, legitimately, very encouraging to research on the genetics of schizophrenia. After all this was an entirely different method than the twin study that was still under a cloud of methodological concern. Although a review of subsequent work on the genetics of schizophrenia is well beyond the scope of this chapter, it is important to recognize that many subsequent twin studies established that the genetic factors contributed well over half the variance for the schizophrenia diagnosis, that the search for specific genes—selected in advance of study as candidates—was unsatisfying and that a current focus is on genome-wide association studies (GWAS) using samples that exceed 30,000 individuals (for a review of the current status of this field along with a commentary on family and other environmental effects see Iyegbe, Campbell, Butler, Ajnakina, & Sham, 2014). Improved methods of genotyping have identified over 100 gene variants that are reliably associated with the schizophrenia phenotype; all these methods assume that important genes in the pathogenesis of schizophrenia enhance *liability to illness* and not, as initially suggested by Kendler and Eaves and demonstrated in the finding of Wynne and colleagues, that important genes might enhance *sensitivity to environment*. Comprehensive reviews of the etiology of schizophrenia acknowledge the large role of a broad range of prenatal and postnatal environmental social factors associated with schizophrenia. Some mention the work of Wynne (Tandon, Keshavan, & Nasrallah, 2008), and some do not (Iyegbe et al., 2014). To encompass the probability that environmental factors might additively or interactively contribute to GWAS analyses in understanding the pathogenesis of schizophrenia, GWAS researchers have proposed polygenic risk scores to summate the genetic component of such multifactorial inquiry. However, these scores reflect only genotypes identified as enhancing disease liability. The fundamental disarticulation here is that family processes researchers—beginning with Wynne and continuing with Belsky and those family researchers influenced by his work—have called attention to a functional significance of genotypic differences that, ironically, was first delineated by two behavioral geneticists, that is, the function of increasing sensitivity to environmental differences. Distressingly, this idea has been pushed to the margins in the current mammoth and hugely expensive search for vulnerability genes.

Leaving aside this very substantial disarticulation, let us summarize what the adoption design has contributed to the emerging articulation of genetic and family systems studies. First, by verifying findings on genetic influence of twin studies it has foundational status in all the more recent work on the genetics of psychopathology. Second, it has permitted more accurate estimates of the role of parenting and the family environment in the development of offspring. The original Burks study illustrates the delineation of family factors that have a substantial effect on child competence controlling for passive gene–environment correlation. The much later adoption work of McGue and colleagues illustrated the equally important weakening of a popular environmental theory positing parental alcoholism as an environmental risk factor for emerging impulsive disorders in offspring (King et al., 2009). Third, the adoption design provided a distinctive, direct way to demonstrate how the family environment moderates genetic risk for psychopathology. And finally, the adoption design provided a particularly graphic illustration of the role of genes in enhancing sensitivity to the environment; in doing so it offered an enticing and provocative challenge to mainline genetic search for liability genes to which the great majority of genetics research on psychopathology has not responded.

QUANTITATIVE GENETICS AND FAMILY THEORY: NONSHARED ENVIRONMENT, GENETIC INFLUENCES ON ENVIRONMENTAL MEASURES, AND REINTERPRETING ENVIRONMENTAL EFFECTS

We have already seen that the assumptions of the twin method were being rigorously explored by 1980, and as early as 1968, the adoption method was buttressing the conclusions of twin studies on the heritability of psychiatry's most severe disorder, schizophrenia. These two techniques, because they estimate the relative weights of all genetic influences and all environmental influences, are referred to as *quantitative genetics,* and in the 1980s the results of their use began to challenge, in some cases severely so, theories about families and their influence on child development. Three notable challenges will be reviewed here: the concepts of nonshared and shared environmental influences, genetic influences on measures of the family environment, and the role of genes in explaining the association of variables measuring the family and those measuring the psychological functioning and development of its members.

The Nonshared and Shared Environment

As early as 1932 a curious pattern of findings began to emerge in twin studies. In a remarkably well-done twin study, Harold Carter, an assistant professor in a quantitatively sophisticated department of education at Berkeley, published a twin study of personality. He found, for example, that correlation for neurotic tendencies was .62 for identical and .36 for fraternal twins after correcting for measurement unreliability (very small in his studies) and range restriction. Ordinarily, we obtain a crude estimate of heritability by subtracting these correlations and then doubling the difference (since the difference between MZ and DZ twins covers only half of the possible range of genetic differences between sibs). Here we get the value of 56% suggesting the variance attributable to not-yet-identified or anonymous genotypic differences in this and comparable samples. That leaves 46% attributable to anonymous environmental differences. Since these values are already corrected for measurement error, 1–.62 is a direct estimate of the environment that makes siblings different, the awkwardly termed *nonshared environment*. In this case the value is 38%. Since the total variance attributable to environmental causes is 42% this means that .38/.42, or 90%, of the environmental effects are those that make siblings within the same family different. Many subsequent studies found similar patterns but John Loehlin and Robert Nichols were the first to emphasize how challenging these findings were to most family theories (Loehlin & Nichols, 1976).

The major paper in the evolution of this line of reasoning was a review by Robert Plomin and Denise Daniels in 1987 (Plomin & Daniels, 1987). They emphasized that, as in the early Carter paper, evidence for the singular importance of the nonshared environment has been lying in plain sight in twin studies of personality, cognitive capabilities, and psychopathology. They also summarized the results of several adoption studies where the sample included families with two children adopted from different biological parents. If family attributes common to children in the same family influence child's temperament, personality or cognitive abilities then genetically unrelated siblings—adopted very early in childhood—should show correlations with each other at well above chance levels and these correlations should increase the longer they are exposed to these conditions. In fact, in these special samples, between-sibling correlations were small, often statistically insignificant and became even smaller the longer adopted siblings were members of the same adopting family. If measurement error is taken into account, differences between MZ twins are arguably the most direct way of assessing nonshared environmental influences. However, by definition, twins are identical in age. Thus, small differences between them—either in non-heritable physical features, temperament or environmental experiences, may be used by them and their parents to differentiate one MZ twin from the other and lead to an uncommonly high influence on their differences in their developmental trajectories. Thus, the MZ twin method may overestimate effects of the nonshared environment. Two studies using ordinary siblings support this idea: sibling correlations on several measures of adjustment tend to decrease as age differences between siblings decrease (Feinberg & Hetherington, 2000; Schachter, Gilutz, Shore, & Adler, 1978). Thus, adoption designs provide an important check here on twin findings as they did in the genetics of schizophrenia. That is, correlations among genetically unrelated siblings provides a direct measure of the shared environment; adding this to estimate of heritability derived from comparisons of MZ and DZ twins provides an alternate approach to estimating the nonshared environment. Years after the influential Plomin and Daniels review, Reiss and colleagues derived estimates of the nonshared environment on height, weight and vocabulary in adolescents using full, half and step siblings and correcting for between-sibling age differences; if anything estimates of the magnitude of nonshared effects were greater than those using just MZ and DZ twins in the same sample providing further support for the estimates by Plomin and Daniels (Reiss, Neiderhiser, Hetherington, & Plomin, 2000).

For studies of family systems there were three important sequelae of the landmark Plomin and Daniels paper. First, twin studies of individual differences in both behavioral and medical measures have been consistent, for the most part, in showing that environments that make siblings different in the same family outweigh, at a single time of observation, the importance of between family differences that would render siblings similar (see a recent summary by Plomin, 2011).

A second sequel to the Plomin review were efforts to identify specific environmental factors that might differ between siblings and be associated with outcomes for children, adolescents or adults. Researchers have frequently used the MZ twin difference measure although limitations in this design, as noted, surround these results with caution. If a difference in the environmental measure is associated with a difference in a measure of adjustment this suggest a nonshared effect. For example, Pike and her colleagues found—in a cross sectional MZ difference study—that differences in parental negativity directed at the adolescent

were associated with differences in both depression and antisocial behavior (Pike, Reiss, Hetherington, & Plomin, 1996). More convincing, of course, are longitudinal studies that ether control for measures of adjustment in the first wave or directly employ cross lag analyses. Controlling for child antisocial behavior at age 5, Caspi and colleagues reported an association between maternal expressed emotion at age 5 and child antisocial behavior at age 7 (Caspi et al., 2004). Likewise, using a longitudinal MZ twins design, with 4,508 twins, Viding and colleagues successfully predicted differences in 12-year-old children's conduct problems but not child callousness from differences in negative parental discipline 5 years previously. The associations were small, accounting for about 1% of the variance. More complex findings using the MZ twin method have been frequent. For example, Guimond and colleagues predicted differences in kindergartners, social reticence from differences in maternal and paternal over protectiveness and hostility at age 30 months (Guimond et al., 2011). The results were complex: main effects were found only for boys, and only girls showed an interaction of parenting differences scores with paternal depression. To add to the complexity, in a multipanel study Charlotte Cecil and her colleagues found reciprocal relationships between harsh parenting and self-control in children followed from age 3 to 12 (Cecil, Barker, Jaffee, & Viding, 2012). Child effects on parenting were at least as prominent as the reverse. Indeed, some studies conclude that nonshared parental environments are a consequence of sibling differences in adjustment (Vitaro et al., 2011). The MZ difference method has been used to study nonshared environments beyond the family of procreation. For example, Lichtenstein studied twins discordant for recent loss of a spouse to show that this later life differential spousal loss was associated with differentia mortality rates (Lichtenstein, Gatz, & Berg, 1998). Vitaro and colleagues showed that differential experience of aggression in friends anticipated differential aggressiveness in the MZ twins (Vitaro et al., 2011).

A second approach to exploring the role of specific nonshared experiences, *multivariate genetic modeling*, begins with an observed association between an environmental variables and a specific outcome (e.g., a contemporaneous association between maternal negative parenting and adolescent depression of .57). Multivariate genetic modeling allows a decomposition of this covariance into a portion that can be attributable to (1) the influence of the children's genotypic differences both on negative behavior of their parents toward them (a topic to which we will return) and on the child's depression; (2) the shared environment common to parent and child measures; and (3) the nonshared environment common to both. Reiss and his colleagues conducted the most comprehensive survey to date, using this method, of the role of specific nonshared factors. They used this technique to study parents, siblings, peers, and other nonfamily influences on both maladjustment and the positive development of adolescents and combined data from observer, child and parent reports (Reiss, Neiderhiser, Hetherington, & Plomin, 2000). Of the 86 contemporaneous associations examined, 29 showed a statistically significant role for the nonshared environment, mostly for maternal and paternal negative parenting and its association with both psychopathology and positive outcomes such sociability, social responsibility and self-worth. In the case of maternal negativity and adolescent depression, 10% of the covariance was attributable to the nonshared environment. Cross-lagged analyses, across three years of adolescence, showed a more diminished role for the nonshared environment almost certainly because this class of influences tends to be unstable across time in children and adolescents (Blonigen, Carlson, Hicks, Krueger, & Iacono, 2008; Ganiban, Saudino, Ulbricht, Neiderhiser, & Reiss, 2008; Larsson, Larsson, & Lichtenstein, 2004; Reiss et al., 2000). Meta-analyses of siblings from longitudinal twin and adoption studies by Tucker-Drob and Briley (Briley & Tucker-Drob; Tucker-Drob & Briley, 2014) suggest that for cognition stable genetic influences may peak or even decline in the transition to adulthood. In contrast, stable nonshared influences continue to rise across development into old age. For personality, stable genetic influences tend to decline as stable nonshared influences rise in the transition to adulthood. In general, as indivduals age stable nonshared influences become at least as important as stable genetic influences.

Subsequent to the study of Reiss and his colleagues a number of investigators used multivariate models to evaluate the role of specific nonshared environments, again with a focus on parenting and child development. Most of these have focused on negative parent–child relationships and the development of poor self-control, impulsiveness, and aggression in children (Burt, McGue, Krueger, & Iacono, 2005; Jaffee et al., 2004; Knafo & Plomin, 2006; Larsson, Viding, Rijsdijk, & Plomin, 2008). The sibling specific experience of peer relationships and its relationship has also been tested in this paradigm (Button et al., 2007). In one case with sibling-specific peer experiences playing the preeminent role (Bullock, Deater-Deckard, & Leve, 2006), general genetic factors played the predominant role in most of the reported associations but, to a lesser degree, so did nonshared environment.

Perhaps the most notable success in exploring the nonshared environment is in adult rather than child development. In 1998, an influential paper by the criminologist John Laub and colleagues reported on a 25-year longitudinal study following boys at high risk for criminal behavior. They found that a broad range of childhood characteristics could not predict continuity of or desistance from adult criminal behavior but that men's attachment to a spouse had a strong protective effect (Laub, Nagin, & Sampson, 1998). This echoed findings from 14 years before when Michael Rutter and colleagues reported the apparent salutary effects of a favorable relationship with a spouse on adult women who had been institutionalized as children (Rutter & Quinton, 1984). Each study examined only one child in a family and used standard procedures to ask whether the effects observed could be attributed to the effect of the marital relationship or whether they reflected hidden strengths of the high-risk individuals that enabled them to form these bonds. Genetically informed designs permit us to revisit this critical issue of selection versus influence from a novel perspective. For example we may follow the marriages of sibling pairs. If one twin has a happy marriage and the other does not, is there an effect of this difference on differences in their adjustment *and is this effect the same for MZ and DZ twins?* If both conditions are met findings favor an effect of marriage over an effect a heritable factor in the twins that favors a happy marriage. Erica Spotts and her colleagues reported the first cross sectional studies linking marital satisfaction to both depression and positive well-being in adult twin women an effect of marriage although, lacking longitudinal data, the effect might have been the other way around (Spotts, Neiderhiser, Ganiban, et al., 2004; Spotts, Pederson, et al., 2005). However, a prospective study reported by Burt and colleagues (2010) strengthened inference of a causal effect of marriage. Later in this chapter we will return to the significance of the nonshared environment for the study of adult development.

A third sequel to Plomin and Daniel's (1987) paper is the increasing number of reports on the importance of the shared environment. These reports have softened the blunt conclusions of the Plomin and Daniels review. These newer studies delineate environments shared by siblings that are associated with their psychological development and adaptation. These include reports on support from relatives in adult subjects (Agrawal, Jacobson, Prescott, & Kendler, 2002), types of peer groups chosen by adolescents (Tarantino et al., 2014), early substance abuse (Walden, McGue, lacono, Burt, & Elkins, 2004), adolescent delinquency (Burt, McGue, Krueger, & Iacono, 2007), conduct disorder, attention-deficit/hyperactivity disorder (ADHD), and oppositional disorder in adolescents as well as their co-occurrence (Burt, McGue, Krueger, & Iacono, 2005), cognitive performance in early childhood (Petrill & Deater-Deckard, 2004), and for measures of autonomy and sociability in adolescence (Reiss et al., 2000). An adoption study, published well after the Plomin and Daniels review, took a second look at the comparison of full biological sibling and genetically unrelated adopted adolescent siblings (Buchanan, McGue, Keyes, & Iacono, 2009). Across six measures shared environment accounted for about 20% of the total variance. In a recent publication, Alexandra Burt has clarified why this approach provides a more direct and unbiased estimate of shared environment (Burt, 2014) Results showed notable correlations for adopted adolescent siblings not only for externalizing problems, consistent with more recent twin studies cited above, but also for IQ. This contrasts with the finding from Scarr and Weinberg (Scarr & Weinberg, 1978) of near zero correlations for the same group of siblings, a finding crucial to the argument of Plomin and Daniels. The Scarr and Weinberg sample were approximately 5 years older, suggesting the possibility that the influence of environments siblings share wanes as offspring age.

Perhaps the most interesting result to date in this quest for shared environmental effects is the unheralded role of sibling relationships. Insofar as sibling relationships are reciprocal, the relationship constitutes a shared environment for each sibling. If one sibling's aggression towards a co-sibling is fully reciprocated then both share an aggressive sibling environment. If between-family differences in this shared environment are associated with measures of adjustment for each sibling, correcting for genetic effects, then we can estimate a shared environmental influence on sibling adjustment, especially with the use of longitudinal data.

Twin data provide creditable evidence for this effect but so do adoption data. For example, McGue and colleagues—in an adoption design—found that parental alcoholism problems were related to adolescent offspring alcohol use only when comparing biological parents and their offspring but was absent for adoptive parents and their adopted children; in sharp contrast sibling effects held in both groups (McGue & Sharma, 1995). Indeed, between-family shared sibling environments have regularly been associated with the development of aggression and of substance use in each sibling, controlling for genetic effects, in many twin studies (Natsuaki, Ge, Reiss, & Neiderhiser, 2009; Slomkowski, Rende, Novak, Lloyd-Richardson, & Niaura, 2005). A particularly striking set of findings comes

from the comprehensive study of adolescent twins by Reiss, Plomin, and Hetherington. To meet concurrent standards of family research they combined reports by both parents and the siblings themselves and observed ratings of videotaped sibling interaction in their own home to assess both warm and supportive relationship patterns as well those of conflict, hostility and physical abuse. They reported a total of 18 associations between these sibling measures and measures of adolescent psychiatric symptoms as well as positive attributes such as sociability, social responsibility and engagement in school and related activities. In 13 of these associations the *predominant* source of covariance was shared environment. This suggested that reciprocal relationships among siblings might constitute a shared environment crucial to the development of both of them. We will return to this finding in the next section as a prime illustration of unanticipated yield for family studies of data from a genetically informed design.

Genetic Influences on Measures of the Family Environment

In 1981 David Rowe was a young psychology assistant professor at Oberlin College. Although trained in behavioral genetics, Robert Plomin supervised his dissertation, and he became fascinated by the reports of family systems research. In particular, he was intrigued by reports that children's perceptions of how they were treated by their parents might be as predictive of their development as are observational measures of their parenting. He saw the twin method as a way of understanding this effect. If twin siblings were highly correlated in their perception of parenting, and there was little difference, between MZ and DZ twins then it might be the case that perceptions did reflect some aspect of parenting behavior as it actually occurred. Indeed, this is what Rowe found for most of his measures of perceived parenting save one: the twin perception of rejection by their fathers. Here, MZ twins perceived their father's rejection or acceptance much more similarly than did DZ twins even when their greater time spent together was accounted for. This suggested that the perception may have arisen more from heritable features of the twins themselves rather than from their parents. Rowe seemed little interested in this apparently aberrant finding (until later in his career) and family researchers even less so.

At the time Rowe published his study most family researchers were using direct observations of family interaction as a gold standard for measuring family process. For example, the meticulous work of Mishler and Waxler (1968) and Gerald Patterson (1982) and his colleagues were major influences on this standard. Thus, a report claiming genetic influence on subjective impressions of children would have carried little weight even if it had been more definitive (and had been read at all by family researchers). Thus a pivotal finding was that of Judy Dunn, the British developmental psychologist, and Robert Plomin; in their study biological parents rearing their own toddlers treated them more similarly than did adoptive parents treat their two children adopted from different birth parents (Dunn & Plomin, 1986). While there are many interpretations possible of this finding, two studies published 10 years later and in the same issue of *Developmental Psychology* and including meticulous observational coding of parent–child interaction, heavily weighted a genetic explanation. Xiaojia Ge and his colleagues (1996), in a small (45) sample of adoptive parents and their children at midadolescence, reported that the harsh parenting of both *adoptive mothers and of fathers* could be predicted by severe, hospitalizable externalizing psychopathology of the *child's birth parents* and this effect was mediated by antisocial behavior of the adolescents.

Alison Pike (1996) and her colleagues, using data from the Nonshared Environment in Adolescent Development study, used a much larger sample of twins, full sibs, half sibs, and unrelated sibs totaling 719 pairs of sibs and their families unselected for psychopathology in parents or children. They reported the same phenomenon: genetic factors that influenced negative parenting also influenced not only antisocial behavior but also depressive symptoms in a group of somewhat younger adolescents. Most importantly, these common genetic factors accounted for *most of the correlation between the measures of parenting and of adolescent adjustment*. Reiss and his colleagues (2000), using data from the same study in the most comprehensive investigation to date of the role of genes in explaining covariance between family variables and offspring development, studied the association of a range of parenting, marital, sibling variables and both psychopathology symptoms as well cognitive achievement, sociability, autonomy and self worth in a sample of 719 pairs of twins, full sibs, half sibs and unrelated sibs. Meticulous coding of observed interaction in the family's homes was combined with their self-report of relationships quality. Genetic factors common to parenting and child development and marital conflict about the child and development accounted for a substantial and often most of the covariance between the family and the offspring variable.

These data might have been regarded as uncovering one of the most astonishing and unacknowledged confounds in the history of developmental psychopathology.

Alternatively, it might simply reflect the relatively noncontroversial heritability not only of psychopathological symptoms but also of personal strengths such as self-esteem and autonomy. Thus, genetic influence on the covariance may reflect simply the reaction of parents to a child that has either developed a full-blown psychiatric syndrome or a very well developed prosocial and self-confident personality. Indeed, Richard Q. Bell (1968), in his highly influential paper on child effects on parenting, used genetic data of this kind as part of his argument. Analyses carried out by Neiderhiser and other colleagues in the Reiss group suggested a different scenario: heritable features of less well developed behaviors—perhaps temperaments—evoke parental reactions which, as a consequence of this evocative gene environment correlation, go on to accelerate the transformation of simple temperaments into syndromes of pathology or psychological health. Were that the usual case it would revive the notion of genetic *expression outside the* skin first formulated by the geneticist Kenneth Kendler (2001). That is, genetic information proceeds through the usual channels (DNA → RNA → protein → neural processes → behavior), but the next step is not simply a prodrome of a syndrome of adaptation or maladaptation. The next step it is a *social evocative behavior* and the development of an adaptive or maladaptive syndrome does not proceed unless evocation actually occurs (see Reiss & Leve, 2007, for a full exploration of this idea).
