Follow-up twin studies partially confirmed the plausibility of this novel idea about genetic expression (see, e.g., Burt et al., 2005; Larsson et al., 2008; Tucker-Drob & Harden, 2012). However it has fallen to a currently ongoing prospective adoption design to delve more precisely into the precise sequencing and developmental timing of this outside-the-skin process. Data are drawn from the Early Growth and Development Study that is following, across infancy and childhood, over 500 adoption units consisting of a birth mother, two adoptive parents and a child placed for adoption at birth; birth fathers were also recruited for many of these families. In this study, for example, Harold and colleagues traced the genetic liability transmitted to four year olds by having birth mothers high on ADHD symptoms. By 4 years of age these children showed increases in impulsive behavior that evoked hostility towards the child from their adoptive mothers that appeared to amplify the impulsive behavioral style into ADHD symptoms age 6 (Harold et al., 2013). A similar sequence has been mapped from birth mother temperamental disengagement to social withdrawal by her placed child at 27 months to hostile responses by the adoptive mother to disrupted peer behavior at age 4 (Elam et al., 2014).

An intriguing conditional sequences was mapped by Fearon (2014) in this same research group: birth parent externalizing pathology to subjective feelings of maternal distress and incompetence by child age 9 months that persisted at least another 18 months at which time the sequence had led to child conduct problems. However this sequence occurred only in the presence of marital distress between the adoptive parents. To put the matter more graphically, marital satisfaction blocked this avenue of outside the skin expression of genetic influence as securely as methylation of a gene promoter site.

As we will see, molecular genetic studies are also beginning to map out similar sequences beginning with a known gene variant and extending through an evoked response from a parent and continuing with the evolution of a pattern of behavioral maladjustment. However, the unparalleled advantage of an adoption design is that these sequences start with behavioral syndromes in the parents of already established adaptive significance. For example, the Fearon report begins the sequence with variation in birth mother's externalizing problems including clinically diagnostic levels of antisocial personality disorders and substance abuse. We can then ask how are the genetic risks for these highly comorbid conditions first manifested in infancy, controlling for the effects of prenatal exposure to drugs, alcohol and smoke and the effects of birth mother's psychopathology on self care and obstetrical complications. The answer is important here: by 9 months these genetic risks are first expressed in dysphoric feelings *in the adoptive mothers* about their functioning as a mother. But these initial effects are already being offset by satisfying marriages. What heritable features in the child evoked this maternal dysphoria? Fearon and colleagues diligently searched among the usual suspects, temperamental features of the child, without success. We will return to this informative failure in a moment.

While these informative sequences of evocative gene–environment correlation are just being mapped out many studies have established the substantial effects of genetic factors on a broad range of environmental measures including peer relationships in childhood and adolescence and social support in adults (see Kendler & Baker, 2007, for a review). Many studies report substantial genetic effects on the probability of becoming married, achieving marital satisfaction, and getting divorced. (Jerskey et al., 2010; Jocklin, McGue, & Lykken, 1996; Johnson, McGue, Krueger, & Bouchard, 2004; Lykken, 2002; McGue & Lykken, 1992; Spotts, Lichtenstein, et al.,

2005; Spotts, Neiderhiser, Towers, et al., 2004; Spotts, Prescott, & Kendler, 2006; Trumbetta, Markowitz, & Gottesman, 2007). These results reflect not only genetic influences of a spouse's own behavior within a marriage but also evocative effects of one spouse's heritable qualities on the marital satisfaction of the co-spouse. In toto, many of the heritable characteristics that have evocative effects on marital and parent–child relationships can be attributed in part to heritable features of temperament and personality but across many reports these are accounting for, at best, a modest proportion of these effects (see the previously cited review, Jaffee & Price, 2007). While beyond the scope of this chapter, these data suggest a need to refine and reformulate our understanding of heritable features of children and adults that evoke responses from others. Beyond patterns of self-regulation, cognitive processing, organization of habits and sociability—encompassed in current schemes of temperament and personality—we will certainly want to consider in children genetically influenced individual differences such as differences in their subtler social cognitions, their physical appearance, their smell and their tactile sensitivity.

Returning specifically to the parent–child relationship, a recent meta-analysis by Ashlea Klahr and S. Alex Burt (2014) reviewing no fewer than 56 twin and adoption studies confirms substantial genetic effects on the parent–child relationship. Not only do they report robust evocative effects of heritable attributes of the child, but also there are notable genetic effects of the parents' genotypes on parenting behavior. David Rowe, (1981) the first to report genetic influences on how adolescents perceived their parents, might be astonished to see this extraordinary confirmation of his first, very tentative observation; regrettably his creative and penetrating work in behavioral genetics was cut short by his very untimely death.

Taken together, these findings of genetic influences on measures of the family environment constitute the starkest challenge to business as usual in both typical family studies and for most genetic studies as well. They make clear that models of family influence on offspring development are seriously misspecified without genetic information. First, despite Bell's (1968) challenge to the field over 45 years ago child effects in parent–child relationships are almost certainly underestimated. Indeed, inferences drawn from classical longitudinal studies and their consequent cross-lagged correlations between child factors such as temperament and parental factors such as hostile parenting are seriously weakened by these data. In this example, we can note that child temperament is only partial heritable; individual differences in temperament also reflect environmental influence including parenting. Child temperament at 3 months, for example, might be a proxy for variation in parenting at 1 month. In contrast, genotypically influenced behavior is tied to the child and evocative genotype environment correlation in this context is much more securely child based; children's genotypes are what they bring to human relationships and although genetic expression—within the cell nucleus and outside the skin—is sensitive to social influence, genotype is completely resistant to it.

Likewise, the effects of a parent's own genotype on his or her parenting, an inference we draw from twins who are parents, poses another challenge to traditional family research. Parents may treat children harshly in part because of their own genotype. When their genotypes are transmitted to their offspring the genotype of the child may be expressed as antisocial behavior. This *passive gene–environment correlation*, a phenomenon we have already noted in describing earlier studies of the transmission of schizophrenia, can masquerade as a direct social effect of parenting. Two genetically informed research designs directly address this possibility. The first are adoption designs that correlate a characteristic of a parent, (one that is thought to have a direct social impact on the child) with a measure of adjustment in the children and then compare these two correlation for birth parents and the children they are raising with adoptive parents and their adopted child. This is precisely the design of the first adoption study by Barbara Stoddard Burks. A second design focuses on children of twins, particularly twins who are discordant for the parental characteristic. For example, parental alcoholism is thought to have disruptive effect on parenting and on household routines and through these social mechanisms to increase the liability of impulsive behavior and alcohol use in offspring. If this were the case then the correlations between parents and children should be the same in biological and adoptive families.

To extend this example to children of twins, let us suppose we have sample of twins who are mothers and where there is a substantial number of these twin mothers who are discordant for alcoholism. In the case of MZ twins the child's aunt (the identical twin sister of the child's mother) is a genetic carbon copy of the child's mother. Thus, if the parental influence is entirely genetic then the child's liability should be the same no matter whether it his mother or his aunt who drinks; the liability for the child—in the case of the genetic transmission—should be less if his mother is a DZ twin. If the liability is social transmitted then the liability should only be among children of the drinking twin. As a recent review of children of twin studies (McAdams

et al., 2014) has shown, the pattern is quite distinct for parental depression and alcohol use. Social mechanisms are involved in the transmission of depression from parents to offspring although the reverse influence, the social effect of child psychopathology on the parent cannot be ruled out. However, the association of parental alcoholism with offspring alcohol use as well as with other forms of impulsive behavior is via genetic mechanisms with little evidence of the role of social processes. This corresponds to findings from adoption studies where parent–child associations of parental depression and offspring depressions (and other problems as well) are found almost equally in biological and adoptive families (Bauer et al., 2007; Marmorstein, Iacono, & McGue, 2012; Tully, Iacono, & McGue, 2008).

The refrain must now be familiar: the verification of an important finding in quantitative genetics by two radically different procedures: twin and adoption. As the McAdams et al. (2014) review illustrates, the children of twin design has been used for more direct measures of family process including marital conflict and parenting styles with evidence for environmental effects and passive gene–environment correlation depending on the family measure and assessment of the offspring. A more recent elaboration of the children of twins design—incorporating a second sample of children who are twins in the same analytic model—can now distinguish between three mechanisms of transmission: social, passive gene–environment correlation and evocative gene–environment correlation. Among other results these studies have confirmed the importance of evocative gene–environment correlation in the association of parental negativity and externalizing in adolescent offspring (Marceau et al., 2013; Narusyte et al., 2011).

A simple solution for controlling for passive gene–environment correlation—for estimates of parental social influence—is to study parents genetically unrelated to their children: adoptees. In this brief history of the interface of social and genetic research we encounter once again the pivotal role of adoption studies. Although excruciatingly difficult to design and execute, in comparison to twins studies, they are the most direct approach to controlling for the effects of passive gene–environment correlation.

We have reviewed an impressive body of data converging on two major ideas. In the shorter term the association between parenting and child development or between the parents' marital satisfaction and child development may be attributable to genetic factors common to both. In the longer term, the transmission of parental characteristics to children—including those that directly shape the child's social environment—may influence child development solely because the genes that influence the parentally-shaped environment also, when transmitted to the child, shape the child's behavior. Need every study of family life now require a twin or adoption design? We think not, but we will return to this topic briefly in the coda to this chapter.

Before concluding this section let us return to siblings for a final time to consider a paradox. By adolescence most genetically informed studies suggest that a great deal, if not most, of the covariance between many measures of parenting and measures of adolescent adjustment can be accounted can be accounted for by genes common to both. The reverse, several studies suggest, is true for sibling relationships. The covariance of measures of sibling adjustment with carefully measured qualities of the environment they provide for each other is attributable, in most cases, to shared environment. To put the matter another way for many family variables studied thus far, parents are important to adolescent development substantially because they amplify, as a consequence of evocative gene–environment correlation, heritable characteristics in their offspring. However, the environments created by siblings for themselves—through sustained patterns of interactional reciprocity—appear to have a main effect on adolescent adjustment independent of their genotype. Are genetic data suggesting that siblings are the tyrants of their families—for better or for worse? Not only are adolescents, by virtue of their genotype shaping their parents' behavior toward them, but also they are providing an influential world for themselves. While many parents of adolescents might agree with such a view a single report by Danielle Bussell and her colleagues on the Nonshared Environment in Adolescent Development project suggest a different scenario. She proposed that multivariate genetic modeling can be applied to covariance between measures of two family subsystems. Thus, the covariance between parent–child subsystems and the sibling subsystem can be decomposed into that attributable to common genes (the same genetic factors in the child that evoke parent–child hostility also evoke sibling hostility), to shared environment (between family differences in parenting style are associated with between family differences in sibling relationships independent of child genotype) or nonshared (the parenting hostility uniquely directed at one sibling is associated with that siblings hostility toward the co-sib independent of genotype of the child and of between-family differences in parenting). In examining both positive and negative interaction of mothers with adolescents and the sibs with each other Bussell found that it was the shared environmental components of the parenting–sibling relationship

association that was, by far, the most important (Bussell et al., 1999). Given the remarkable stability of the quality of parent–child relationships across adolescence (Reiss et al., 2000), it is reasonable to suppose that the quality of mother–child relationship measured at child age 14 reflects not only current status of that relationship but also its recent past. If that assumption is correct it might be said that the sibling relationship bears a memory of between family differences in parenting style and becomes an agency of that difference in emerging adolescence. We linger over these data because this commemorative function of sibling relationships has been little studied in classical family research but is an arresting example of possible new vistas on the family opened up by genetically informed design—new unless you count the Book of Genesis and its clear portrayals of the interleaving of parent–child and sibling relationships in the case of Rebecca, Jacob and Esau or, as noted, repeated in a second generation of the same family between Jacob, Joseph and his brothers.

MOLECULAR GENETICS AND THE FAMILY

How molecular genetics entered the field of family research. Thus far we have reviewed studies where the knowledge of genetics is inferred from correlations between individuals of known genetic relatedness. However, none of those studies identifies which of the 30,000 genes in the genome, or which noncoding regions, play a role in these effects. The lessons to be applied from this line of quantitative genetics to research on the human family are clear, challenging, and—for the most part—unheeded. The tools of quantitative genetics have been developed over decades; its inventors were psychologists, physicians and educators who wanted answers to practical problems. The assumptions behind the methods were vigorously investigated; different methods were used to arrive at comparable estimates and much of the work was conducted well under the radar of the broad reaches of biomedical science or public acclaim.

Just the reverse has been true of molecular genetics. Francis Crick, a physicist by training, and James Watson a biologist with an early interest in molecular genetics, collaborated to identify the structure of DNA in a highly competitive and conspicuous race with Linus Pauling among others seeking the same goal. Their one page publication in Nature (Watson, 1952) attracted worldwide attention as the discovery of the secret of life. Nine years later they became Nobel Laureates. Skipping quickly over the following decades of this history we come, 31 years later, to a raucous meeting of the biotechnology firm Cetus. There, Kary Mullis presented a poster describing his work, in collaboration with other Cetus scientists, on the double-probe technique that was to be the foundation of the polymerase chain reaction (PCR). Mullis, a tempestuous figure throughout his life, had to be separated from a physical brawl at that meeting. In contrast to the unpredictable temper of its prime developer, PCR emerged as a fully reliable tool for genotyping and spread rapidly throughout the biological sciences. Like his molecular genetic forebears a generation earlier, Mullis was awarded the Nobel exactly nine years after his first report of his findings. His trip to Stockholm also included a brush with the Swedish police (Rabinow, 1996) and left a continuing controversy over whether he deserved the award. PCR is fundamental to most of the molecular genetic studies published in the last decade relevant to understanding families. Subsequent phases of the story of molecular genetics hardly needs retelling but once again a monumental and widely publicized competition between the Celera Corporation and the US Federal Government led to the almost simultaneous announcement of the complete sequencing of the human genome, an accomplishment that has rapidly led to huge investments in searching the genome for both common and rare variants of genes that might be related to human disease including psychiatric disorders. These genome wide association studies, requiring mammoth samples, have been applied to social variables broadly considered (see a review and critique, Chabris et al., 2013) and even to a directly measured family variables (Butcher & Plomin, 2008). When a version of this chapter is written a decade hence, this tool may have yielded insight for the study of the family, but not yet.

Not long after it was developed, PCR was applied to the understanding of behavior. A working premise was that a single gene variant might lead to a single, well-specified disorder. Plomin, Owen, and McGuffin (1994) reviewed this work to highlight its utility in a restricted number of syndromes, mainly those of severe intellectual deficiency. They drew attention to an alternate conception of the relationship between genes and disorders, quantitative trait loci, where many genes operating in concert were necessary to influence the emergence of complex behavioral syndromes. They proposed that the severity or distinctiveness of a genetically influenced syndrome might be related to the number of these gene variants possessed by an individual, that some of the genes may not be necessary for development of a syndrome and that somewhat different gene sets may lead to the same disorder.

Several developments led to a major revision of this view. A new idea was that genetic variation might not be a necessary or contributory cause of complex human behavioral syndromes but rather that it rendered individuals

more or less sensitive to environmental variation. Quantitative genetics made the first contributions to this idea. As we have seen, this idea was formalized by Kendler and Eaves in 1986 and was demonstrated clearly in the work of Wahlberg (1997) and his colleagues on schizophrenia. Kendler and colleagues, using a population-based twin sample, showed that identical non-depressed twins of depressed women were more sensitive to stress, and subsequent depression, than were fraternal twin siblings of depressed co-twins (Kendler, Kessler, Walters, MacLean, et al., 1995). Long before, Cadoret observed that genetic liability for antisocial behavior rendered children more sensitive to adverse rearing conditions in their adoptive families (Cadoret, 1982; Cadoret & Cain, 1981; Cadoret, Cain, & Crowe, 1983). At the other end of the spectrum, animal research—often in mice—was able to deploy powerful knockout and transgenic methods to cause or identify specific genetic deficit and reverse these with highly targeted pharmaceuticals (e.g., Cases et al., 1995); these more highly controlled models suggested clearer links between single genes and more complex behavior such as aggression. Finally, variations in single genes seemed to have reproducible effects on the structure and function of the human brain as revealed by constantly improving brain-imaging techniques (Hariri et al., 2002). These lines of evidence prompted Stephen Suomi (working with rhesus macaques) and Avshalom Caspi and his colleagues (working with a large, longitudinal human study) to select particular genes for scrutiny. Suomi was the first to report on the association of a single gene variant with heightened sensitivity of infant macaques to variations in their early rearing environment. They focused on the statistical interaction of two variants of the rhesus version of the serotonin transporter gene with adverse early rearing environments, mother rearing or nursery rearing. Macaques with the inefficient gene variant showed the clearest effects of early rearing experience on early-appearing adaptive behavior, particularly activity patterns (Champoux et al., 2002). A the same time Caspi and colleagues reported children with the less efficient version of an x-linked gene, MAOA (similar to the gene well explored in animal studies), and who were exposed to maltreatment, developed significant aggressive behaviors (Caspi et al., 2002). A year later the Caspi group reported similar findings for the serotonin transporter gene; in this second report, young adults with the inefficient form of the serotonin transporter gene showed the effects of both childhood maltreatment and recent stress on the evolution of depression (Caspi et al., 2003). These findings attracted immediate and broad attention across all of biological science and in the public press as had other reports in the brief history of molecular genetics. They also attracted the attention of many behavioral scientists because these findings were drawn from the meticulous longitudinal Dunedin study, named for its place of origin on the South Island of New Zealand. The study had already yielded major findings in a group of almost 1,000 children followed from early childhood, and as this chapter is written, most of these children have been followed well into adulthood.

All three of these highly influential papers had three major features in common: the main effects of environmental adversity were very substantial; the main effects of the gene variants were tiny or non-existent; and the effects of the interaction were between the two. Strongly influenced by this paradigm, most subsequent work has examined single gene variants, analyzed singly or in very small numbers combined into polygenic risk scores, as *indices of individual differences in response to environmental variation*. That is, almost all subsequent work has focused on genetically influenced *receptive capacities* of individuals in families. In contrast the robust evidence for quantitative genetics of very substantial genetic effects on *effector capacities*, the capacities of individuals to select and influence their own environments, has received much less attention. Moreover, taken together, these papers had a persistent influence on the study of parent child relationships—to focus on individual differences in the sensitivity the *offspring* reactions to parents rather than on differences in the *parents'* sensitivity to children. The Caspi 2003 report focused on stress in adult life although it contained a generous section on child maltreatment that reinforced an underlying theme in the Suomi 2002 and Caspi 2002 papers adding weight, almost certainly inadvertently, a picture of individuals as responders to rather that creators of their own environments. To be clear, molecular gene–environment interaction studies have probed many aspects of healthy and pathological adult development but have rarely focused on adults as parents. Thus the great majority of subsequent reports relevant to this chapter on the family have, collectively, focused on genetic effects on individual differences among children that accounted for their varying response to their rearing conditions in contrast to a parallel focus on genetic differences among parents that account for differences in their response to their children although we will review some studies in this latter category. We will also review the very small number of molecular genetic studies that explored effector capacities in children.

Cautions in Interpreting Molecular Data

Despite these limits on the new paradigm, clearer in retrospect, the interest in these early reports was well founded.

All three were built on prior findings in quantitative genetics but also, and of immediate interest, on well controlled laboratory studies of animal and human neurobiology. Thus, there was a promise of bringing studies of the family into a unifying field of developmental human biology. Indeed, in retrospect, it is now clear that the introduction of molecular genetics into the study of the family has had entirely different dynamic than its older cousin, quantitative genetics. The former emerged slowly across half a century and with great resistance of researchers on social processes; many of its major lessons remain unlearned in family research. Since the Barr et al., 2003 papers, genotyping samples of families has been so rapidly included in the repertoire of family research that those from other disciplines—including geneticists—have called for caution (among many examples see Plomin, 2013). Some of these cautions seem well founded and we begin our review of selected, illustrative reports of this work with three of them in mind.

First, several reviews—using standard approaches to meta-analysis or the analysis of publication bias—have raised concerns about the reproducibility of some of these initial findings, particularly the moderation by the serotonin gene variants on the relationship of stress to depression in adults (Duncan & Keller, 2011; Karg, Burmeister, Shedden, & Sen, 2011; Munafo, Durrant, Lewis, & Flint, 2009; Risch et al., 2009). A particularly striking failure to replicate comes from the improbable circumstance that a second, large 30-year longitudinal study of children—the Christchurch Health and Development Study—is also ongoing on the South Island of New Zealand (Fergusson, Horwood, Miller, & Kennedy, 2011) whose population of just over a million seems to include an inordinate number of developmental researchers. However, using broader criteria for reproducibility several reviews find evidence for replicability of the Caspi report on the serotonin transporter gene (Karg et al., 2011; Mak, Kong, Mak, Sharma, & Ho, 2012; van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012). Caspi's 2002 paper on the interaction of the less efficient MAOA gene variant and child maltreatment on the development of aggression in boys has been confirmed by a very recent meta-analysis of 20 studies; importantly, this analysis found no difference in findings between smaller or larger samples or between earlier or later publications addressing, at least, some concerns about publication bias (Byrd & Manuck, 2014). Equally important, successful replication was limited to child maltreatment and not other childhood adversities. Included among the confirmatory finding is indeed one from the other South Island longitudinal study (Fergusson, Boden, Horwood, Miller, & Kennedy, 2011).

Kary Mullis's PCR gave social scientists a tool they never had before: a reliable, inexpensive ascertainment of differences among individuals, differences that preceded all else in their prenatal and postnatal social and physical world. Moreover, PCR can be used years after a study had concluded (if only a cheek swab or saliva sample can be obtained). This unique ascertainment has enabled an astonishing number of attempted reproductions of the original studies in little more than a decade. However, energized by these recent reports, investigators have examined many other gene variants—some of that work is reviewed here—with a broad variety of environmental variation and developmental outcomes. Many of these reports come from multivariate, multi-panel studies that genotyped subjects for many gene variants thus allowing investigators a wide latitude in associations they choose to study and report. Often these reports contain data only about one of these variants leaving skeptical readers to wonder whether null findings with other variants have gone unreported. Thus, particularly in this case, the empty file drawer procedure—usually regarded as a safeguard in meta-analysis against the findings of unpublished papers—cannot offer protection against unpublished analyses (Duncan & Keller, 2011).

Caspi and colleagues have presented a strong case for an alternate strategy to meta-analysis for reviewing evidence in this field: reviewing studies in animals and humans that are theoretically linked and may help explain, the moderation of environmental effects by specific gene variants (Caspi, Hariri, Holmes, Uher, & Moffitt, 2010). The fundamental idea here is that the foundational papers were exploring a theory of inherited sensitivity to stress rather than a specific hypothesis about the pathogenesis of depression. Thus, for example, a comprehensive review should include—as theirs did—experimental studies of the moderating effect of the gene variant on cortisol responses to standard stress stimuli in a laboratory setting. We cautiously explore this strategy in our current selective review. Our interest is to explore both possible as well as established use of molecular genetic tools to better understand family process.

Finally, we note that questions about the reproducibility of the foundational papers in this field—or of those that follow—is not unique to molecular genetic studies of the family. Nor have many, if any, studies in the recent history of behavioral sciences attracted such persistent efforts at reproducing the original findings. More generally, reproducibility of findings in all branches of science remains

a major concern. A survey by Begley and Ellis (2012) noted serious problems of replication problems in cancer treatment research and a special issue of *Psychological Science* raised concerns about replicability in psychology considered broadly (e.g., Pashler & Wagenmakers, 2012). As an ironic twist, the Begley and Ellis survey is—because of its lack of detail and precision—very likely itself not replicable.

A second problem in evaluating this rapidly emerging field is the high variability with which investigators explore genetic confounds. For example, population stratification is a threat to all gene association studies—for main effects and for interactions. Race is a crude marker of population stratification and there are examples of gene–environment interaction findings that do not generalize across race that serve as a reminder of the potential importance of this source of confounding (Widom & Brzustowicz, 2006). Within a study sample, unidentified subgroups may have different genetic ancestries. As a consequence, they may differ both in the frequency of the gene variants being investigated and in the behavioral measure of interest thus producing a spurious gene–behavior correlation. Likewise, where environmental variation is attributable to a blood relative (such as variation in parenting) passive gene–environment correlation may masquerade as a gene–environment interaction. It is a rare and commendable paper that examines these potential confounds (see, e.g., Sulik et al., 2012) for a test of population stratification and Kim-Cohen and colleagues for ascertainment of passive gene–environment correlation (Kim-Cohen et al., 2006). Further, investigators rarely specify in advance whether they are expecting the genetic effect to be additive (where the effect of the interaction increases from individuals who have neither deficient gene variant to those who have one to those who have two) or nonadditive, and if the latter, whether the effect should be dominant or recessive.

A particularly intractable problem is the possibility that two or more genes are at work completely mimicking gene–environment interaction: the measured gene, thought to be moderating an environmental effect, may be interacting with unmeasured genes that have notable influence on the same environmental variance. In their 2003 paper on the serotonin transporter gene, Caspi and colleagues addressed this problem by varying the timing of variables measured but only animals studies that experimentally vary rearing conditions, as in the Suomi studies, or human studies that experimentally vary the environment through an experiment (e.g. the laboratory induction of stress by Way, Taylor, and their colleagues (Way, & Taylor, 2010; Way & Taylor, 2011) or a randomized trial (e.g., Brody, Beach, Philibert, Chen, & Murry, 2009) fully addressed this issue. Indeed, virtually none of the papers we will review even address this concern, let alone test for it. Reviews of the literature in this area, either meta-analyses or conceptual, that we have already cited fail to examine papers for their adherence to this genetic toilette.

A final problem with evaluating this literature is its heavy dependence on statistical interaction although, unlike the three foundational papers, genetic main effects have been reported and we will survey some of these. Some prospects (Reiss, Leve, & Neiderhiser, 2013) and problems (e.g., Eaves, 2006) of interpreting statistical interactions have been reviewed elsewhere. The first set of problems is inherent in the statistics of interactions and, because of their wide coverage elsewhere, need only be mentioned here; these include statistical power, scaling of variables and testing for regions of significance. Of particular interest here is the problem of controlling for confounds in interaction testing. For example, Keller has suggested that most gene–environment interaction testing has failed to test for confound environment interactions or confounder–gene interactions and hence ruling out confounds has been insecure at best (Keller, 2014). A second problem is deriving mechanistic interpretation from patterns of interaction. For example, Widaman and colleagues presented an ingenious approach to both identifying crossing points in statistical interactions and attaching confidence intervals to these points. This rigorous approach can distinguish ordinal from disordinal interactions, with well-specified assumptions and limits. Widaman and colleagues argued that disordinal interactions, rigorously analyzed, favor a mechanistic theory termed differential susceptibility, a theory noted above in relationship to gene–environment interactions in schizophrenia. Ordinal interactions, according to this view, favor the original Caspi idea of inherited sensitivity. However, as Reiss and colleagues note (Reiss et al., 2013), disordinal interaction can also indicate a quite different mechanism of goodness of fit: some individuals benefit for environment A but do much worse in environment B whereas, in other individuals, the reverse is true.

The Early Growth and Development Study, using an adoption design, nicely illustrated this phenomenon: toddlers at risk for externalizing disorders (birth mothers had externalizing problems) develop favorably when parents structure assigned tasks in contrast to children at low risk for these disorders who do well when task are unstructured but respond poorly to high levels of parental structuring

(Leve et al., 2009). As for ordinal interactions, they may be due to effective social compensation for deficits associated with genotypic differences as well as to those genotypic effect on positive adjustment that are only manifest under favorable social environments (e.g. the heritability of intelligence is most apparent in favorable economic circumstances (Bates, Lewis, & Weiss, 2013; Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003). There is a growing consensus that experimental studies are crucial to advancing causal reasoning beyond statistical interactions however carefully the latter are accomplished.

Thus, in viewing over a decade of work following from the initial Suomi and Caspi papers we exercise both enthusiasm about the enlarging prospects for placing the study of the human family with a broader science of developmental biology but also remain cautious until a literature accumulates where genotyping is planned from the start of the adequately powered study, where well-conceived hypotheses provide substantial prior probabilities, where statistical and genetic artifacts are reasonably ruled out and detailed mechanistic explanations are sought in planned comparisons across studies, methods and species and in valid, experimental models. An exhaustive review of studies published thus far is beyond the scope of this chapter; as noted, we have selected studies more to illustrate the potential of molecular genetics techniques for studying the family, particularly in better specifying theories of individual differences in both responding to and evoking family process.

SPECIFYING THEORIES OF FAMILY PROCESS AND INDIVIDUAL DIFFERENCES

A core objective for systematic observation of families, certainly since the time of the redaction of the Book of Genesis, has been a better understanding of six processes within the family: variations in how children respond to very adverse parenting as well as its more ordinary variation; variations in how children evoke parental responses; factors inherent in parents that shape differences among them in sensitivity and style; variations inherent in adults that shape their marital relationships; difference among families in their response to stress; how family experience in one generation shapes the family lives of offspring when, as adults they constitute their own families years; and differences among families in their response to family-level therapeutic and preventive interventions to improve mental health. As noted, the great majority of molecular genetic studies address the first of these six questions. Some of the remaining questions have been addressed by no more than one or two studies.

Differences Among Children in Their Response to Parenting

Molecular genetic techniques have been applied to understanding individual variation in children in their response to parenting and, in far fewer instances, individual differences in parents in response to children. As noted, Caspi et al. (2002) reported that boys with the less variant of the MAOA, x-linked gene explain variations in response to maltreatment, much of it by their parents, as expressed in their developing their own antisocial behavior. This is the most securely replicated finding in the molecular genetic investigation of family social process.

Cicchetti and colleagues (Cicchetti, Rogosch, & Thibodeau, 2012) explored other moderating genes regulating serotonergic brain systems that might account for individual variation in children's response; they replicated the MAOA finding and found that the inefficient variant of serotonin transporter as well as the inefficient variant of tryptophan hydroxylase gene had a moderating relationship as well. In general, these findings suggested that children with less efficient genotypes inherited a sensitivity to maltreatment. This group also explored genes regulating other systems and with other outcomes. For example, they reported that a gene variant regulating corticotrophin releasing hormone receptors in the HPA system moderated the impact of maltreatment on diurnal cortisol variation with an interaction suggesting inherited sensitivity to stress (Cicchetti, Rogosch, & Oshri, 2011) and a gene variant regulating the oxytocin system moderated the association of maltreatment with diminished perceived social support from friends and family (Hostinar, Cicchetti, & Rogosch, 2014). The GG variant of this gene was associated with children's increased sensitivity to the stress of maltreatment although the literature on this variant is unclear whether it is expected to have protective or sensitizing properties. A recent paper from this group is of special interest; a gene variant regulating receptors of acetylcholine moderated the effects of maltreatment on personality, particularly neuroticism. Unlike, other studies of maltreatment these results suggested the gene variant enhanced neuroticism in maltreated children but diminished it in nonmaltreated controls (Grazioplene, Deyoung, Rogosch, & Cicchetti, 2013), an example that arguably reflects differential susceptibility

Molecular genetic techniques have also been applied to study variation among children in their response to less extreme variation of parenting than the stark distinction

between maltreatment and no maltreatment. A few examples, from a rapidly growing literature, illustrate the possibilities here. Starting during fetal development inefficient gene variants of the serotonin transporter are reported to influence individual differences in fetal response following exposure to maternal anxiety in utero as manifested in postpartum infant negative emotionality (Pluess et al., 2011) and the effects of maternal postnatal anxiety on infant irritability (Ivorra et al., 2010). The former interaction pattern suggested differential sensitivity to stress but the latter, given a main effect of the genotypic difference, suggested that nonanxious mothers could offset the apparent negative effect of the inefficient variant. Pluess and colleagues (2011) reported a similar study with a pattern suggesting inherited sensitivity to stress. Sulik and colleagues (2012) reported on variation in parenting quality and aggression and conduct problems in toddlers; the interaction in this report revolved around the *efficient* form of the serotonin transporter as marked by variation in two locations in the same gene. Surprisingly, children with the efficient form of the gene benefited from favorable parenting but suffered from unfavorable parenting; a pattern suggesting differential susceptibility. Kochanska and colleagues have followed approximately 100 children from toddlerhood to nearly school age; when the children were about 4 the deficient form of the serotonin transporter gene was sensitive to differences in security of attachment between the mother and the child. On a test battery assessing facets of self control (Kochanska, Philibert, & Barry, 2009) secure attachment offset the disadvantage associated with the deficient genotype. A similar pattern emerged a year later in the children's development. This time a responsive maternal style offset deficits in school and social competence (Kochanska, Kim, Barry, & Philibert, 2011). However, for measures of children's moral competence, children with less efficient variant showed performance that was better than those without if they had highly responsive mothers and worse if they did not, an example of differential susceptibility.

Differences Among Children in Evoking Parental Responses

As quantitative genetics has shown, genotypic variation in children not only influences variation in their receptiveness or sensitivity to parenting but also plays a major role in evoking parental response. As noted in the discussion of quantitative genetics, genetic studies add a significant dimension to the study of child effects. For example, family research has accumulated evidence that irritable children who display negative emotions frequently evoke equally negative response from parents (e.g., for infants see van den Boom & Hoeksma, 1994). Molecular genetics has taken an early, hesitant start in identifying specific genotypic difference that might account for these evocative effects.

Mills-Koonce and his colleagues (2007) appear to be the first to explore this area examining the role of an infrequent variant of a gene regulating a dopamine receptor because of its association with child temperament. Following from reports of van den Boom and Hoeksma (1994) and others, we might expect such genetically influenced temperament to be disruptive of mother–infant relationship, a finding confirmed by Mills-Koonce et al. Unfortunately, they tested the effect of this variant after ruling out the effects of child mood and temperament rather than examining their mediating role in the effect of this genotype. However, working among a research group with a primary focus on the family as a social system, Mills-Koonce et al. added an innovation: genotyping the mothers as well as children raising the possibility of studying an interpersonal gene by gene interaction. In this analysis such an interaction was not found, but the less frequent gene variant in the child was associated with less sensitive parenting, an important documentation that the genotype of one member of the family might affect the behavior of another.

Elizabeth Hayden and her colleagues (2010) reproduced this finding in a larger sample of older children. In this study, the child's negative affect was explored as a mediator of the genetic effect; it did made a marginal contribution to mediating the association of gene variant and evoked parenting. The dopamine systems in the brain, presumably those most involved in emotion regulation, were explored using another gene variant—this one regulating dopamine transport from intercellular space to intra-neuronal locations. Again, because of its association with potentially troubling child temperament, Hayden and colleagues (2013) explored its role in evoking negative parenting; they reported its apparent influence on both parental hostility and lack of guidance; in these findings child negative affect played a more distinctive mediating role.

Copeland and colleagues (2011), working in a group focusing on psychiatric epidemiology, studied a gene variant regulating the endogenous opioid system in positive parenting; in animal studies a comparable gene variant is important in influencing attachment behavior. Copeland reported that children with the variant that enhances opioid receptor efficiency elicited more positive parenting for those parents that had a history of psychiatric problems; these findings resonate with an idea about genotypic variation in children that might actively heal potentially problematic parent–child relationships.

Differences Inherent Among Parents That Shape Their Response to Children

Molecular genetics techniques have also been used to explore the role of genetic variation in parents. Much of this work has been stimulated by an extended series of animal studies on the role of the neuropeptides vasopressin and oxytocin (see Donaldson & Young, 2008, for a review). These nearly identical peptides are produced in the hypothalamus, transferred to the pituitary, and then released into the peripheral circulation where they have a number of regulatory roles. They are also transferred to brain regions where their effects on social behavior in animals have been intensely studied. Perhaps the most influential animal models have been contrasts among monogamous voles, as compared to promiscuous voles, where vasopressin plays a distinctive role not only in male pair bonding but also in male parental behavior, whereas oxytocin plays an approximately comparable role in females.

Working in the context of family process, attachment, and early intervention research group, Bakermans-Kranenburg and van IJzendoorn (2008) were the first to report the association of one of several variants of the gene controlling the oxytocin receptor and observed sensitivity of parenting. Four years later Feldman and her group reported a comparable finding but with a different variant of the same gene (Feldman et al., 2012). In another study Mileva-Seitz and colleagues (2013) reported the association of a variant in a gene regulating oxytocin synthesis to maternal vocalizations towards her infant but not in maternal sensitivity. Genes regulating the oxytocin system also are associated with an apparent buffering effect.

Using the same gene variant as in the original Bakermans-Kranenburg and van IJzendoorn study (2008), Sturge-Apple and her colleagues found that it rendered the mother more sensitive to conflict with her husband (Sturge-Apple, Cicchetti, Davies, & Suor, 2012). Those with the sensitive variant were less sensitive and less warm with their toddlers when there was high marital conflict but more so when there was low conflict. Notably in this study, as in the Mileva-Seitz 2011 study, there were no main effects on maternal parenting of this gene variant. As another example, Apter-Levy and colleagues, in the Feldman research group, reported a buffering effect for the same variant on the oxytocin receptor gene that, in their previous study, was associated with sensitive parenting (Apter-Levy, Feldman, Vakart, Ebstein, & Feldman, 2013). In the new study, they focused on the effects of sustained mothers' depression on the development of psychopathology of their school-aged offspring. The variant associated with maternal sensitive parenting in the first study here was associated with a protective effect on offspring development. Genes regulating other neural systems have also been explored both for their direct effects and buffering effects on maternal parenting. These include genes regulating dopamine (Fortuna et al., 2011; Kaitz et al., 2010; Lee et al., 2010), serotonin (Bakermans-Kranenburg & van IJzendoorn, 2008; Mileva-Seitz et al., 2011), and vasopressin (Bisceglia et al., 2012).

Individual Differences and Marital Processes

As noted, quantitative genetics has illuminated both environmental and genetic process related to marriage; for the latter there appear to be notable genetic influences on whether individuals become married and then divorced or stay single. Moreover, genetic influences have been reported for satisfaction in marital relationships with evidence for evocative effects; the genotype of one spouse is associated with the marital satisfaction of the other spouse. There has, however, been scant attention to the molecular bases of these findings. In the very first attempts investigators have used two strategies. The first approach was strongly influenced by findings in the prairie voles on the role of oxytocin and vasopressin in pair bonding. Two reports came from the same Swedish twin study. For men, the presumably more efficient variant of the gene regulating vasopressin receptors in the *husbands* were associated with their *wives*' marital satisfaction. For women, variations in their oxytocin receptor influenced, but to a lesser extent, their husbands' marital satisfaction (Walum et al., 2008, 2012). As expected, these were main effects though small in magnitude. A second strategy follows from many others we have cited: genotypic variation was explored for its association to individual's sensitivity to the marital context. In two studies, the less efficient allele of the serotonin transporter gene was associated with enhanced sensitivity of the spouse to the affect of the other marital partner (Haase et al., 2013; Schoebi, Way, Karney, & Bradbury, 2012). Finally, the mother's marital history has been studied as a varying environment in the development of ADHD in boys across a broad age range. The same gene regulating the D2 dopamine receptor, that played a role in other studies cited here had opposite effects depending on whether mothers had an adverse marital history (divorces, remarriages etc.) or not (Waldman, 2007). It is possible that this maternal history was a proxy for serious personality disturbances and the negative parenting that often accompanies them.

Individual Differences in Family Functioning in Response to External Stress

We can cite but only example here on differences among mothers in their vulnerability to postpartum depression in response to either economic adversity or advantage. Mitchell and colleagues report that two less efficient variants of the serotonin transporter gene are associated with heightened risk for postpartum depression under adverse economic circumstance—indexed by mother's educational attainment—but reduced risk under favorable circumstances (Mitchell et al., 2011).

Differences Among Adults in the Role of Childhood Experiences in Shaping Their Adult Family Roles

At least three studies have examined intergenerational effects in families: do individual offspring differ in the degree to which harsh or favorable parenting influences their behavior, years later, with a spouse or romantic partner? Initial evidence suggests that several gene variants enhance the transmission from positive parenting to subsequent positive partner relationships and also favor the transmission of negative parenting to unfavorable relationship with subsequent partners (Beaver & Belsky, 2012; Masarik et al., 2014; Simons et al., 2013).

Differences Among Families in Response to Family-Level Interventions

Finally, molecular genetic techniques have been applied to understand individual differences in response to family-oriented behavioral interventions. In doing so, these studies follow in the tradition of pharmacogenetic studies that investigate how genetic variation may forecast response to specific pharmacologic agents. In applying these techniques to behavioral intervention it is important to distinguish two questions. First, does a specified genetic variation forecast an individual's responsiveness to a therapeutic agent or, second, does it offset a current or future pathological condition associated with the genetic variation? In both cases, individuals with the predictive genotype will show a greater response to an intervention but for distinct different reasons (see Reiss et al., 2013 for a more complete explanation). This distinction in mechanism has great practical significance. If a genotypic *responsiveness mechanism* is established by repeated, adequately powered randomized trials then genotyping might become a rational basis for recommending particular treatments only to those individuals who have a responsive genotype. In contrast, where a data on a behavioral treatment clearly demonstrates a *compensatory mechanism* then that treatment could be recommended to individuals even though their syndrome has a clear association with (and is probably influenced by) their distinctive genotypic profile.

Investigators experienced in family intervention techniques have reported small-sample studies of brief parent training interventions for externalizing behavior (Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, & Juffer, 2008) and ADHD (van den Hoofdakker et al., 2012). The former showed evidence that a variant of a dopamine receptor gene forecast greater responsiveness of children to the intervention; in the latter graphical presentation of the data (not analyzed statistically) suggested treatment had a compensatory effect for a more severe form of ADHD associated with a dopamine transport gene variant. In both cases genotyping was completed only on a subset of subjects after the trial was completed with a consequent loss of the protection from confounding ordinarily afforded by a randomized trial; thus, both reports serve as informative proof of concept' studies. This reservation does not to apply to data from two large trials of a family-oriented program for the prevention of alcoholism in African American teenagers reported by Gene Brody and his group. The great majority of participants were genotyped and gene variants associated with several neural systems were evaluated for their capacity to predict alcohol use in teens that were not already affected. These sizable genotypic predictive effects appeared only in the control groups but not in the treatment groups providing one of the best sets of evidence we now have that behavioral interventions can offset the behavioral risks associated with genotypic differences (Brody, Chen, & Beach, 2013). Yet to be resolved in these studies are the surprisingly large main effects of single genes given very much smaller single gene effects noted in GWAS studies. Perhaps a combination of poverty and racism that face these families operate as moderator, not measurable in this study, enhancing single gene effects. Or it could be a winner's curse.

Beyond Individual Differences: The Prospects for a Developmental Biology of Families

Within an astonishingly brief period of time, the PCR technique first reported by the flamboyant and controversial Nobelist Kary Mullins has spread rapidly among researchers on family process. The foundational papers by Suomi and colleagues and Caspi and colleagues are rightly credited with making a link between a molecular technique

and the social process of the family. The reports we have reviewed here constitute only an illustrative sample of this notable spread. In introducing this work we have already outlined reasons why it should be read with caution. Nonetheless, the exuberance of this work is based on much more than the new tools it affords for specifying unheralded sources of individual differences in the responses of family members to one another. Beyond individual differences these techniques, linked with other rapidly developing tools of developmental biology, promise a more mechanistic understanding of the development of family relationships and of its constituent members. However, to reach these goals, two major steps are in order now. First is the careful testing of longitudinal process models *of family and individual development*, and second is a more strategic use of *experimental modeling* to test the assumptions and explore mechanisms behind the associations studies that we have reviewed and related reports we did not. A full account of these approaches is beyond the scope of this chapter, yet a failure to mention them unfairly narrows the scope of our appraisal of what molecular genetics may contribute to the study of the family.

Longitudinal Process Models

Process models are distinct form the individual difference models we reviewed in the last section. They are designed to investigate the specific gene–environment interplay, in mechanistic fashion, that unfolds as development proceeds through well-specified periods of time. They begin to address the question not of whether but of how genotypic variation influences family process and individual development.

The best illustrations of this approach come from the application of molecular genetic techniques to understand evocative gene–environment correlations. For example, in the same report, but using two different samples, Walum and colleagues reported that same oxytocin receptor gene variant that influenced the marital satisfaction of spouses of married women at midlife also influenced variation in the quality of the social relationships for girls at ages 8–9, as rated by their parents (Walum et al., 2012). A tempting speculation here is that the oxytocin receptor variant expressed itself earlier in positive social relations that widened and deepened the social skills of the developing woman, affording her a happy marriage years later. In the parlance of genetics relational skills of adolescent girls might be an intermediate phenotype in the causal path from genetically influenced variation in the oxytocin receptor and marital satisfaction. Or as Kendler and Neale (2010) pointed out, the genotypic influence in social relationships of young girls might simply be an early indicator of gene variant that improves the prospect of a happy marriage but has no causal role. Moreover, to sketch a longitudinal process model, we need to make a shaky assumption that the two different samples reported by Walum and his colleagues are equivalent.

In another instance, and again piecing together results from samples, two separate research teams reported the evocative effect of a gene regulating brain opioid receptors. In childhood this variant is associated with positive parent–child relationships—especially where parents have prior behavioral problems (Copeland et al., 2011). Later in development, this same variant protects against the development of substance abuse in the transition from adolescence to young adulthood in males, an effect mediated by the adolescent's participation in alcohol using peer groups (Chassin et al., 2012). Again, it is tempting speculate that the opioid receptor variation, because it evoked positive parent–child relationships under difficult circumstances protects the developing boy so that at adolescence, he avoids alcohol-using peers and thus avoids an alcohol-abusing early adulthood. Such a sequence would be consistent with the quantitative genetic study of Neiderhiser and colleagues that reported a common genetic influence on evoked parenting, delinquency of peers and substance abuse by early adulthood (Neiderhiser, Marceau, & Reiss, 2013).

However, inferences about developmental processes of this kind require longitudinal data within a single sample. An intriguing example is provided by Propper and her colleagues (Propper, Shanahan, Russo, & Mills-Koonce, 2012) who studied a gene variant controlling the D4 dopamine receptor in girls. This variant was associated with several measure of these girls' academic achievement in first grade as mediated by its apparent evocation of engaged parenting when these girls were toddlers. Although statistically challenging, process models can be explored not only for genetic main effects, as in evocative gene–environment correlation, but for gene–environment interactions. For example, Davies and Cicchetti (2014) explored a process model to explain the interaction of maternal unresponsiveness to their 2-year-olds with a variant of the serotonin transporter gene on the development of externalizing two years later. This interaction was mediated by the aggressive responses of the child towards the mother at age 3, suggesting that this reaction to mothers' negative parenting is a developmental way station on the road to maladjustment. However, the child's gene variant here that was sensitive to parental negativity was the so-called long or efficient form of the transporter gene that, in most studies, has been

shown to be the insensitive variant. As at many points in the molecular genetic literature it hard to know if this is a novel finding or a failure to support previous findings on the role of the short variant in stress sensitivity.

Longitudinal process models will be immeasurably aided by a detailed knowledge of the timing in development when gene–environment interplay occurs. For example, Daniel Choe and Daniel Shaw and their colleagues reported the interaction of the inefficient variant of the MAOA gene with harsh parenting on adult antisocial behavior in a longitudinal design that had followed these men from infancy: those with low efficiency variant were particularly vulnerable at observations made between ages 1.5 to 5 (Choe, Shaw, Hyde, & Forbes, 2014).

Experiments

Passive cross sectional and longitudinal studies, that is, those that have no planned and randomized interventions, are insufficient to understand mechanisms underlying observed main effects and interaction of gene variants including those we have already reviewed. All independent variables in these studies are subject to confounding. For example, natural variation in parenting may be a proxy for genetically influenced variation in parental personality; those personality genes when transmitted to a child may influence that child's adjustment—an instance of confounding passive gene–environment correlation. Or the natural variation in parenting may reflect the evocative effect of children's heritable characteristics that are either not measured in the study or are, as yet, unknown. Thus an apparent gene–environment interaction is here confounded by gene–gene interaction. Also, causal pathways may be too complex to unravel in passive longitudinal studies. In the example above, many variables can affect a parent's engaged response above and beyond the influence of the D4 dopamine receptor gene variant. Although never used in genetic studies, the pseudo-family design—where parents and children are randomly matched in a laboratory setting—can help to isolate the effect on a parent of a child's heritable characteristics (Reiss & Oliveri, 1983). Likewise, many processes critical to understanding the genetically influenced biology of family processes, such as functioning of the brain's cortex, cannot be visualized in the settings where most passive longitudinal studies unfold. Thus, the major objectives of experiments are effective control of independent variables free of confounds, simplification of complex causal networks, and visualization of otherwise occult biological process.

Experimental procedures have a long history in the study of family relationships (Howe & Reiss, 1993). The Strange Situation is an experiment holding constant mother–child reunions while focusing on variations in children's reactions. Experiments have sought to experimentally vary parental response through standardized instructions to parents to feign affect (Hornik, Risenhoover, & Gunnar, 1987) or hold infant temperament constant by the use of standardized simulated babies (Rutherford, Goldberg, Luyten, Bridgett, & Mayes, 2013). Where visualization of evoked potential is required to identify cortical response involved in parent–child relationships, computer simulations of reunion experience can be programmed so that the precise moment of simulated reunion can be related to the timing of cortical responses that follow just a few milliseconds afterwards (White, Wu, Borelli, Mayes, & Crowley, 2013). The ecological validity of these experimental settings are always open to questions as are the degree to which variables manipulated in experiments successfully simulate more ordinary occurring experience in families. However, experimental models involving genotyping have one advantage over other models of complex family processes: the genotyped variable is absolutely constant across settings. To a large extent this is true even when animal models are used in experimental probes of mechanisms of gene-family process interplay. While even in close human relatives, such as Rhesus macaques, there are some differences in gene structure and variation the analogies in structure and function provide high levels of security that, in these animal experiments, genetic variation effectively models that in humans.

As an example of an experiment exploring a molecular genetic influence on family process, Peltola and colleagues (2014) provided women with brief exposure to infant and adult faces and measured the evoked cortical potentials immediately following these exposures. Their results suggested that the same gene variant associated with sensitive mothering in a passive design also led to more rapid and intense cortical responses to infant but not adult faces displaying intense emotions. Mothers, in contrast to women without children, showed more rapid and intense reactions to high emotion in the infant pictures but the effect of the gene variant on cortical response held for both mothers and nonmother controls. These results, not yet replicated, suggest that the gene variant is associated with a trait of emotional responsiveness to infants independent of the substantial neuroendocrine and psychological transformations that attend pregnancy, parturition and early child rearing.

There is a broad repertoire of experimental approaches available for linking the available findings on molecular genetics to a to the emergent science of developmental

biology. Experimental studies of humans, such as those of Peltola and colleagues (2014), have been abundant; among many see the work of Baldwin Way, Shelly Taylor, and their colleagues (Moons, Way, & Taylor, 2014; Way & Taylor, 2010, 2011).

Some investigators have argued that randomized, controlled trials might also be considered as experiments (see, e.g., van IJzendoorn & Bakermans-Kranenburg, 2012) since randomized interventions that change family interaction patterns do, as in more traditional experiments, experimentally control family environment assuming the randomly assigned treatment condition is effective. However, treatments that are designed to remediate or prevent serious clinical problems are invariably complex with many components and many undetected effects that may contribute to their efficacy. Howe, Reiss, and Yuh (2002) termed these meditational confounds. While techniques for componential and meditational analyses are well developed in psychotherapy research their combined complexity renders randomized controlled clinical trials a poor way to model naturally occurring, well-specified variation in the environment as occurs in ordinary development.

Experiments designed to unravel mechanisms have a fourth objective, especially in the investigation of gene–environment interaction. As detailed elsewhere (Reiss et al., 2013), experiments seek to *uncover the genetic main effect* accounting for the interaction. Recall that in their foundational 2003 report by Caspi and colleagues found no main effect of the less efficient variant of the serotonin gene on depression but rather an interaction between stress and the variant. Caspi postulated a genetic main effect on stress sensitivity and selected the serotonin transporter gene in part because of an already published brain imaging experiment where, in a small sample, Hariri and colleagues (2002) reported that this variant had a sizable main effect on amygdale function in response to experimental manipulation of stressful images. It is tempting to place these findings into a hypothesized longitudinal process model: children born with one or two copies of the inefficient gene variant have amygdale that are excessively responsive to the stress of early maltreatment and when they become adults, the gene variant sensitizes them to a range of life stressors. This main effect of a genetic variant on amygdale function then interacts with stress during the life course to lead to depression (and perhaps other adverse outcomes). In this scenario, amygdale function would be a genetically influenced intermediate phenotype in a longitudinal process model.

Indeed, Caspi's foundational publication has stimulated well over 30 subsequent experiments where brain imaging studies of individuals with and those without the inefficient gene variant are placed in a magnet for brain imaging in ways roughly comparable to the original Hariri report. We could not identify another experiment that came close to this one for rigorous attempts at replicating a result on a main genetic effect on a process that might mediate a molecular gene–environment interaction. A recent meta-analysis of these publications suggest, however, that this "candidate" intermediate phenotype may not be able to play its proposed role in the interplay among the gene variant, stress, and development (Murphy et al., 2013). The effect size in this analysis, though replicating in direction the original Hariri study, was far smaller than the original with an excess of positive reports over those expected given the statistical power of the publications in the meta analysis (suggesting a reporting bias). Perhaps most pertinent, a major source of heterogeneity among studies was age of subject; contrary to what might be expected for an early-appearing intermediate phenotype effect size increased in direct proportion to the *increases* in subjects' age. However, the few studies of children and adolescents were not included in the review and its overall estimates included unpublished as well as published data.

Just as certain patterns of gene–environment interaction suggest an inherited sensitivity to stress so have some patterns suggested—as we noted—an inherited differential susceptibility to the environment for better or worse. Experiments able to define these mechanisms and test the putative plasticity genes for the main effects on these mechanisms. Van IJzendoorn and Bakermans-Kranenburg (2012) recently reviewed evidence of these experiments, but, small in number, they are all randomized clinical trials that, as noted, have limited probative value.

As noted, animal experiments also play an essential role in delineating developmental mechanisms. However, not to exceed the bounds of this chapter we mention them only briefly. Recall, they helped shape the hypotheses of the foundational Caspi papers. In animal experimental models, subjects can be randomly assigned to adverse environments. For example, infants of mothers likely to be abusive may be cross-fostered to mothers who are highly unlikely to be and vice versa (see Maestripieri, Lindell, & Higley, 2007). Rodent models allow for a range of experiments unthinkable in humans, and in many primates including inbreeding, transgenic, knockout, and knockdown experiments.

Finally, it is now essential to link passive human studies of gene–environment interplay to in vitro experiments of two kinds. The first of these two are continuing in vitro experiments to establish the transcriptional efficiency of

gene variants employed in human studies (Flint & Munafo, 2013). For example, among the studies we have reviewed on gene variants regulating the oxytocin receptor, no fewer than six have been reported across the different studies with investigators each pursing different variants. At the level of biological efficacy are all these gene variants equivalent in effect? Are each a separable indicator of the status of oxytocin receptors, and if so, shouldn't they all be used in future studies to test the role of this receptor in family process? A strategy of this kind may be thought of as the backward utility of in vitro experiments. However, in vitro experiments may have forward utility as well. For example, Steven Cole and his colleagues identified a variant of a gene regulating the proinflammatory interleukin 6 by determining the effects of norepinephrine on the expression of the gene that regulates interleukin 6's circulating level; norepinephrine, a reliable product of stress-induced activation of the sympathetic nervous system, served in an in vitro model of the role of stress on the interleukin gene. Bringing this model forward, Cole and colleagues tested the role of this gene variation on its role in moderating the effect of depression on mortality (Cole et al., 2010). Although this study is not, strictly speaking, relevant to family studies it an important proof of concept for the forward utility of in vitro experiments in identifying gene variants relevant to the stress of family life

HAS GENETICS ALTERED THE WAY WE THINK ABOUT THE FAMILY AS A SOCIAL SYSTEM?

The State of the Evidence

This chapter has attempted to convey both the promise of genetic methods in the study of the family but also methodological challenges and controversies that these methods have raised. There is little question that the use of these methods have changed our thinking about families but before summarizing these changes it is important to inventory the security with which we can draw major inferences from the data we have reviewed.

Quantitative genetics is built on twin and adoption methods that began their development almost 90 years ago. They became highly relevant to the study of the family, particularly on mechanisms by which psychopathology is transmitted from parent to offspring, by the 1960s when the fateful Dorado Beach conference witnessed a confrontation between social and genetic explanations. There has been a vigorous program of investigation of many but not all the assumptions behind these methods, and as our review here indicates, many of the major findings in the application of these methods to the family have been reproduced. However, uneasy lies the head that is complacent about these methods.

Model testing approaches to analyzing twin data still rest on assumptions that are probably untenable unless specifically tested each time they are applied. For example, assortative mating of the twins' parents (the selection of one another on the basis of similar, heritable traits such as alcohol use or intelligence) can underestimate heritability of traits since this pattern of mating will inflate DZ correlations but not MZ correlations. As we noted, Burt (2014) clearly showed that the twin method, particularly the model testing methods used to analyze its data, may underestimate shared environmental effects and thus underestimate the importance of between-family differences. Not to batter the twin method too severely, but we have also noted its potential problems in overestimating the nonshared environment and also have presented data to argue against that concern. The adoption method has often come to the rescue of the twin method either by providing a corrective for estimates derived from the twin method or by circumventing its assumptions. Assortative mating in adoption studies leads to overestimating heritability; moreover, the adoption method better estimates the shared environment—especially in adoption designs where siblings born to different birth parents are adopted into the same family. As we have seen, the adoption method entirely circumvents the equal environments assumption; that is why it not only had a major impact at Dorado Beach but also established beyond doubt the substantial genetic contribution to the pathogenesis of schizophrenia and thus its use by Kety, Rosenthal, Wender, Schulsinger, and Heston emerged as a foundation of biological psychiatry 1968.

However, the adoption method has its own headaches. For example, as noted, the birth mother does rear her offspring for nine months: from conception to birth. While it is relatively easy to rule out the confounding effects of her use of prescription and nonprescription drugs during pregnancy the science of fetal environment is growing rapidly. Birth's mother self care, psychological status and exposure to second had smoke and toxins may confound inferences about the role of genetics in the transmission of maternal characteristics to offspring development and these are much harder to track either prospectively or retrospectively. As noted, a new version of the adoption design includes a group of mothers who adopt a fertilized egg shortly after conception thus permitting a cleaner separation of genetic and fetal environmental influence. However, the adoption-at-conception design cannot

readily distinguish prenatal from postnatal environmental effects and the number of women who, having endured the substantial medical stress of egg implantation procedures, go on to smoke or use drugs during pregnancy is extremely small (Rice et al., 2009) reducing the power of this design to distinguish genetic from exposure effects on fetal development. Recently, the adoption-at-conception and the adoption-at-birth design have been combined (Gaysina et al., 2013) to provide a much clearer delineation of genetic, prenatal, and postnatal influences of smoking on the development of conduct problems. Criticism has also been leveled at the conventional adoption design because adoptive families are typically middle class and hence there is a restricted range of environmental adversity and, critics have argued, a diminished opportunity to estimate the effects of harsh environment on child development (Stoolmiller, 1999). However, a searching empirical test of this possibility did not support this concern (McGue et al., 2007).

Overall, the corpus of work in the field of quantitative genetics is substantial, increasingly well designed, and the major findings have been frequently reproduced. Our historical review has clarified how essential it has been to ferret out all the assumptions behind these methods, to test them rigorously and to have two entirely separate methods, each with its own improvements, to estimate both genetic and environmental influences at work in the human family.

With some notable exceptions, these claims cannot be made for molecular genetic approaches. After all, its history is barely a tenth the age of its senior partner but its use has become much more widespread. We have introduced our selective review with cautious about the findings thus far. Indeed, in some minds, these cautious are sizable leading to recommendations that this line of research is of limited value (Flint & Munafo, 2013; Plomin, 2013); further, some investigators in this domain are encountering considerable difficulty in gaining funding for their work. Work in this field needs challenge and may thrive on it. Funding continuing investigation and encouraging students to enter this field should remain a high priority.

Nonetheless, investigators in this field—and to some extent editors of journals that publish their reports—have often made matters more difficult and opened it to unnecessary criticism. For example, it is rare that papers reporting results of the interplay of specific gene variants and social variables in the family include an independent replication. Given the relative ease of genotyping (in contrast, for example, to developing a twin sample) such a practice would enhance the likelihood of reproducing results in follow on studies—particularly when a new combination of gene variant, moderating environment and outcome are reported from the first time. A recent report provides an example. Petra Zimmermann and her colleagues (2011) at the Max Planck Institute of Munich combined forces with Avshalom Caspi and Terrie Moffitt and their colleagues at Duke. They drew on two longitudinal studies to report independent and confirmatory analyses of the role of variants of a gene regulating the corticoid receptor in the HPA axis feedback system on sensitivity to stress as indexed by the development of first-episode depression.

As we noted, critical assumptions behind the methods of molecular genetics as applied to families have remained largely unexamined. We have already noted many of these and need only re-state three of these assumptions here: (1) no passive gene–environment correlation for those studies of the effects of parenting; (2) no interaction between the measured gene of interest and an unmeasured gene or genes that influence the environmental variable; and (3) no confounding population stratification.

Finally, the path between quantitative and molecular genetics needs smoothing. Quantitative genetics now has excellent tools for identifying family process variables that moderate genetic influences on developmental psychopathology. Using those moderating variables in molecular genetic studies adds explanatory power to the quantitative analyses and is an important source of heightened prior probability (and hence replicability) for molecular analysis. The work of Danielle Dick (2011) illustrates this nicely. Using a twin design, she identified parental monitoring as a moderator of genetic influences on adolescent substance use; high levels of monitoring reduced genetic influence, a finding she extended using specific gene variants (see her account of this strategy). In another domain, molecular genetic analyses seems little concerned with heritable evocative effects that quantitative genetics has illustrated repeatedly not only in children and adolescents but in the marriages of adults. These have become more compelling as recent adoption research has illustrated more clearly their probable role in pathogenesis. Moreover, molecular genetics is not digging into an enormous domain for the study of gene–environment interaction: variations in the *sensitivity of the social environment* that moderate these heritable evocative effects. Finally, it seems odd that molecular genetic tools have not been deployed to investigate the most striking findings of all in the quantitative genetics of the family, the finding that genetic influences on family variables (e.g., parent–child conflict) overlap with those on individual measures of adjustment (e.g., antisocial behavior) and in notable instances account for the majority of the observed covariance between the two. Twelve years

after Suomi and Caspi introduced molecular genetic tools to study the family we have little insight into what genes might be involved in these associations.

Thus, a fair reading of nearly a century of work applying genetic approaches to the study of the family can conclude: quantitative genetics speaks to the study of family process with the voice of authority, whereas molecular genetics speaks, at present, with the softer voice of promise. What are these voices saying?

Family Research Listening to Molecular Genetics

We turn first to molecular genetic analyses. Here we summarize three areas of family research where molecular genetics can be illuminating. These examples are offered with a clear purpose. As already indicated, the attractiveness of this approach to analysis is the promise of placing the study of the human family into a secure location in the rapidly advancing domain of developmental biology. Thus, it is more than high time for molecular genetics to move beyond the almost promiscuous search for more variants connected to more environments connected to more outcomes although continued promiscuity in the search of fresh liaison with the truth is still defensible.

Child Maltreatment

Even our selective review makes it clear that many filaments of molecular genetic analyses of family converge on this major public health problem. Molecular genetics has added a much clearer delineation of individual differences in response to this severe and sustained stress in childhood. Most literature focuses on the genetically moderated impact of maltreatment on behavioral disorders in children, adolescent, and adults. However, from a public health perspective, the long-term impact of child maltreatment on adult medical health may be its most important scourge. Precisely, what is the risk of adult mental and physical illness attributable to child maltreatment? The computation of attributable risk is a secure public health indicator because it allows a calculation of the reduction in disease incidence and prevalence that one might expect if the risk factor were eliminated or fully offset by intervention. Such estimates are just being published. For example, Kessler and colleagues estimate the risk for a broad spectrum of adolescent and adult psychiatric disorders attributable to early adversity, mostly maltreatment, is an astonishing 30% (Kessler et al., 2010). This estimate may be revised downward as future studies correct for passive gene–environment correlation and retrospective bias but estimates might be revised upward in a subset of individuals if their vulnerability genes are included in the epidemiological inquiry. We do not have gene–environment studies for adult medical illness associated with child maltreatment comparable to those for child and adolescent psychopathology. However, we do not lack fastidious longitudinal studies documenting this risk (e.g., Danese et al., 2009; Widom, Czaja, Bentley, & Johnson, 2012; Wilson & Widom, 2011). Nor do we lack studies that explore the mechanisms by which this risk persists into adulthood (e.g., see Miller, Chen, & Parker, 2011) for a review chronic inflammation occasioned by the stress of early maltreatment and (McCrory, De Brito, & Viding, 2012) for persistent effects on brain structure and function). Data thus far on molecular genetic vulnerability to child maltreatment augurs well for this vital extension to adult medical illness and a trickle of data on this domain is beginning to appear (Brummett et al., 2008; Xie et al., 2013; Zhao, Bremner, Goldberg, Quyyumi, & Vaccarino, 2013).

One might think that identifying gene variants that increased children's sensitivity to maltreatment would be the most obvious public health benefit of current research and perhaps it will lead at some point to fitting remediation to specific children by virtue of their genotype. However, it hard to imagine that current efforts to reduce the prevalence of child maltreatment or to reduce the time that children are exposed to it or to remediate its potential impact on the children would become more focused or even efficient with further molecular genetic study. Would anyone now deny a child the benefit of the nurse visitation programs or child–parent psychotherapy programs, programs that seem to have an overall beneficial effect in maltreatment (Cicchetti & Banny, 2014), on the basis of their genotype? Genotyping provides fresh insights into mechanisms that might account for the impact of maltreatment on children but has no obvious impact yet on therapeutic innovation.

The reverse is true for the long-term effects of child maltreatment on adult medical illness that may become manifest decades after the maltreatment. Even if we had a thoroughly enlightened international policy on child maltreatment and its amelioration it is likely that many adults, seriously maltreated in childhood, would reach adulthood with no obvious signs of medical illness apparent but at substantial risk of future malady. It is here where an understanding of genotypes and liability can have huge implications for selective preventive interventions.

Developmental Family Neuroscience

It is fair to say that major advances in social neuroscience rest substantially on laboratory experiments where

complex social stimuli are modeled by a broad array of auditory and visual stimuli, briefly presented to just one member per family and correlated with various cortical recordings, brain imaging and blood sampling techniques. Social neuroscience becomes more social when comparable recordings are made in simulated or actual interactional games (see Todorov, Fiske, & Prentice, 2011, for review of these approaches). Social neuroscience moves into the family when these techniques test the moderation of the presence of family members on neural responses to standard stimuli (e.g., Coan, Schaefer, & Davidson, 2006; Conner et al., 2012) and validated against the quality and durability of important intimate relationships (e.g., Eisenberger et al., 2011).

Many of the molecular genetics papers we have reviewed offer a tantalizing vision of a substantial enlargement of this field to focus on the development of the family as a system deploying the technology of social neuroscience but guided by genotyping. Genotyping can be regarded as a probe of relatively stable individual differences in the operation of neural systems although Plomin et al. (1994) cautioned against the simple notion of one gene being associated specifically with one disease. A comparable caution is warranted here: the neural systems of the brain are complex and interrelated and variations in a single gene may be imprecise indicators of stable individual differences in their function.

Bearing these caution in mind, let us imagine a sequence suggested by these papers. The sequence can start with mating and marriage here. Quantitative genetic data suggest genetic influences on becoming married (Jerskey et al., 2010); it is conceivable that specific genes may be identified that regulate this starting point in the assembly of a family; it is relevant that Walum and colleagues (2008) showed an association of very small effect of a variant of the gene regulating vasopressin receptor in men on whether couples with adolescent children were married or cohabiting. That is, where a man possessed one variant the couple remained together without the commitment of marriage and if he possessed the other variant they were married. It is conceivable that members of a couple pick each other because of similarities in genotypes although such an investigation may confound population stratification effects with choice effects. Nonetheless, once married small effects of gene variants—vasopressin for men and oxytocin receptor for women—have been reported (Walum et al., 2008, 2012). Moreover, parental gene variants may promote the parent–child relationship through its enhancement of sensitive parenting (Bakermans-Kranenburg & van IJzendoorn, 2008; Feldman et al., 2012). Children's genes may also promote this relationship through eliciting or evoking positive parenting and (Hayden et al., 2013; Hayden et al., 2010; Mills-Koonce et al., 2007; Propper et al., 2012). Moreover, there are gene variants in parents and in children that might be said to have a protective effect on parent–child relationships. For example, genotypic variants may protect mothers post partum from depression despite external difficulties (Mitchell et al., 2011); they may protect parental function from marital problems (Sturge-Apple et al., 2012) and protect the parent–child relationship from the mother's own depression (Apter-Levy et al., 2013). We have described one report of a child gene-variant regulating the endogenous opiate system that appears to protect a positive parent–child relationship when parental psychiatric problems might otherwise perturb it (Copeland et al., 2011). Finally, there appear gene variants that protect relationships in a subsequent generation in the family from the transmission of interactional difficulties in the prior generation (Beaver & Belsky, 2012; Masarik et al., 2014; Simons et al., 2013). Even from these initial fragments it is possible to sketch, with the lightest and most tentative hand, a developmental sequence of between-family difference in genetically influenced promoting and protective processes unfolding across two generations in the development of the family.

When a sequel to this chapter is written, perhaps 10 years hence, it seems likely that many of these specific findings will have evaporated as attempted replications may fail or improved genetic and statistical toilette is satisfied. Nonetheless, the framework suggested here—a focus on the developmental stages of the family—may survive as a way of integrating newer, more solid findings, framing more solid hypotheses and developing better methods. As for the last, Mills-Koonce et al. (2007) and Choe et al. (2014) provided a look at the future of the role of genetics in a developmental family neuroscience; the former used the family as the unit of genotyping with genetic data collected from at least two members in each family and the latter presages a more precise timing of when, in the development of family relationships, genetic effects have their most significant influence. The framework we propose here can keep molecular genetics focused on the family and on how these molecular techniques may enlarge our knowledge of how the family unfolds over time and across generations and how it shapes and is shaped by each of its members.

Fitting Family Interventions to the Family

The field is indebted to the early publications in this field for their perspicacity, three of them reviewed here. However, it

is time to move on to other strategies to take full advantage of the molecular genetic investigation of the family. As we noted, clinically efficacious interventions are a poor way to model naturally occurring variation in family process. Moreover, post hoc genotyping of already completed trials—even where the genotyping is nearly complete for all subjects—can produce misleading results, especially where there is a genetic main effect on the liability or pathology to which the intervention is addressed. In such an instance, the apparent sensitivity of individuals (or families) with a presumably sensitive genotype under study cannot be separated from the ceiling effect of the treatment. The apparent sensitivity of the genotype may just reflect a familiar clinical truth: sicker patients get more out of treatment than those who are less so. In fitting a specific treatment to a particular family genotype there is no substitute for a prospectively designed randomized trial, planned from the start, with blocking on the genotype in question such that those with and without the genotype are equally sick or equally likely to become so.

Since genotype is a blocking variable, all subjects must be genotyped before randomization with careful attention to whatever sampling bias such a requirement may inadvertently produce. Although contemporary techniques such as urn randomization might help it should not be necessary. The theory of differential susceptibility marshals empirical evidence buttressed by evolutionary reasoning to posit a set of genes that confer plasticity on individuals (and perhaps their families). The scientific task of fitting family interventions to family genotypes provides a test, in the most practical terms possible, of the mettle of this theory. Because of their for-better-or-for-worse quality, these genotypes should be untroubled by main effects but, if the theory is true, should predict more sizable treatment effects, which should become clearly apparent in a blocked design. During an early stage of a new branch of science inquisitive exploration, even playful exploration without rigorously derived prior probabilities, should be encouraged. The exuberance with which family researchers have embraced PCR has, in some instances, exemplified this productive vein in science. Fitting a treatment to a person or to a family with serious troubles or with liability for future troubles, on the other hand, is a serious business. Suppose genotype A proves sensitive to the treatment but genotype B does not; replicated results from well-designed clinical trials would rationally lead to recommending against the treatment for genotype B. A family-based use of molecular genetics—as we have reviewed it here—offers notable potential for this fitting process. However this evolving research paradigm should conform to well-established practices for other clinical trials. These include placing the measures including genotyping, and including expected outcomes in the lockbox of clinicaltrials.gov. It is entirely conceivable that such a study is already on the drawing board if not already under way.

Family Research Listening to Quantitative Genetics

Common Genes and Covariances

We have reviewed abundant evidence that there are substantial genetic influences on most measures of family relationships including parent–child, marital, and even sibling relationships. Equally abundant evidence suggests that many of these genetic influences are shared with those that influence such important measures of individual adjustment such as depression, antisocial behavior, social responsibility, autonomy, and cognitive motivation and achievement. These are evident in relatively short periods of developmental time where, for example, negative parenting might be assessed during early adolescence and child delinquency in later adolescence. These effects of common genes are also apparent across generations as in the case of parental alcoholism and offspring impulsive behavior. Every model of family influence prior to the use of genetically informative designs is potentially misspecified. While we have already belabored the point this circumstance is also the case for molecular gene–environment interactions where presumed environmental effect on adjustment could be attributable, in whole or in part to evocative gene–environment correlation for genes not measured in the study (or unknown and hence unmeasurable) or to passive gene–environment correlation.

We re-emphasize here that genetic studies have effectively delineated family subsystems that appear to have a decisive impact on the development of its members by dint of social, not genetic, mechanisms. In our review, marital and siblings systems stand out here but the genetically informed literature also clarifies where parent–child relationships are associated with child adjustment for environmental, not genetic, reasons.

Must every study, then, be a twin or an adoption study? No. But family researchers from here on out must think genetically (Reiss, 2010) and read the genetic literature pertinent to the problem they are studying. Further, in considering interpretations of their findings they need to include the possibility of genetic influences on covariances they report. However, genetically informed studies need to be included somewhere in an extensive program of research. We think twin and adoption studies should be accessible resources for the field of family studies and

research funding should be available for their establishment and maintenance just as government funding has helped distribute high density EEG and MRI facilities, each piece of equipment available for the use of many nearby researchers. However, genetically informed designs can be used even in the pilot phases of a family research project. Let us suppose, for example, that a researcher has a novel idea about a parent–child interaction pattern than increases the child's liability for anxiety disorders. The researcher might consider trying out this novel idea on adoptive families in the initial study. Recruiting adoptive families is much easier if they do not have to be linked to the birth parents of the adopted child. If our investigator gets a positive finding on the first go-around then the investigator has identified a potentially salient attribute of parent–child relationships and already knows, using this design, that its covariance with child symptoms cannot be attributed to passive gene–environment correlation. Another option for this investigator is to use a sibling design; it allows for an immediate distinction: are the observed effects due to differences *among* families (either genetic or shared environment) or differences within families (nonshared or genetic). There are other compelling reason for prioritizing sibling designs including the important effects of sibling socialization and for studies of adult development, a topic to which we return below.

Evocative Gene–Environment Correlation and the Pathogenesis of Heritable Disorders

We have reviewed several quantitative genetic (Burt et al., 2005; Larsson et al., 2008; Neiderhiser, Reiss, Hetherington, & Plomin, 1999; Reiss et al., 2000; Tucker-Drob & Harden, 2012) and molecular genetic studies (Propper et al., 2012) that suggest as a novel mechanism by which genetic influence is expressed in behavioral disorders. A heritable disposition in the child evokes a response from a parent that, in turn, amplifies the child's disposition that evokes an even more vigorous parental response. These reciprocal effects may cycle back and forth until a clear pathological outcome is noted in the child (such outcomes from these reciprocal processes are also possible in the parents; see Gross, Shaw, & Moilanen, 2008). All of this process can be hidden in estimates of the heritability of a disorder as determined by, for example, twin designs or even newer methods of estimating heritability based on correlated patterns of genotypic similarity between pairs of genetically unrelated individuals who are similar in any measured phenotype (Yang, Lee, Goddard, & Visscher, 2011). All these heritability estimates say to us that genotypic differences among individuals lead to phenotypic differences—somehow and some way. As noted, the way might be entirely through conventional pathways from DNA to RNA to proteins relevant for fetal, child, or adult brain function (or other organs relevant for individual differences in behavior such as the adrenal gland). Or there could be an outside-the-skin mechanisms. Here the intermediate behavioral phenotypes are heritable characteristics that *evoke distinctive social responses*. That is, these heritable characteristics are likely to induce the same reactions in other family members across families so that they are detectable as a reliable and heritable social signals.

We have cited two papers from the same adoption study that illustrate how this reciprocal process may work for the early the development of conduct problems (Fearon et al., in press) and for ADHD symptoms (Harold et al., 2013). The Fearon paper illustrated how between family differences might blunt this process: families with happy marriages somehow cancels mother's role in this reciprocal process with salutary effects on the child's development of self-control.

But within-family differences may also matter. For example, the heritable properties that elicit warmth in mothers are uncorrelated with those that evoke warmth in fathers (Reiss et al., 2000); to be detectable these differences in response—shaped by either role or gender of the parent—must generalize across families (at least in the sample studied) to be detectable. But it seems likely that families may react to a range of aversive behaviors in children—each determined by a different gene set—in comparable ways: each elicits a negative response. The gene-variants we reviewed in molecular studies of evocative processes in children suggested that effects of many different genes do converge on negative parenting. To follow the logic here it is the response of the family to a diverse set of heritable signals in the child that plays a decisive role in the outside the skin mechanism of the expression of genetic effects in behavioral syndromes. The family may make fine distinctions—as in the case of mother or father differences in warm responses to their adolescent offspring or lump many genetically distinct effects on child's characteristics together as functionally equivalent in odiousness or attractiveness.

John Loehlin presented a method for tracking how the family may lump or discriminate among these heritable genetic signals (Loehlin, Neiderhiser, & Reiss, 2005). In a reanalysis of the data from the nonshared study by Reiss and his colleagues, he used a genetically informed factor analysis to suggest that the same genetic factors that elicit warmth from parents suppress conflict negativity (or vice versa). That is, so far as the family's response is concerned

all the heritable features leading to either warmth or negativity shape a continuous dimension of family reaction with warmth on the high end and negativity on the low end and this dimension of reaction—initially influenced entirely by the child's genotype but shaped by the family's reaction—is, in turn, distinctively related to child's autonomy and negatively related to the child depression and antisocial behavior. However, the child factors that elicit monitoring and control are uncorrelated with those eliciting the continuous dimension of warmth-negativity. This dimension, with high monitoring and control at the upper end is distinctively related to sociability and cognitive achievement in the adolescents; these positive attributes are unrelated to the genetically elicited warmth-negativity dimension. While highly preliminary these data do suggest that, where families are integral to the outside the skin mechanism of gene expression, they may recode the genetic information that resides in the heritable characteristics of the child.

Siblings and Adult Development

Adult development is as important to the field of developmental psychopathology as is child development. An emerging pattern of data from quantitative genetics seems to have much to say about these processes. While specific nonshared influences have been identified in early development their magnitude has not only be less than expected from the twin and adoption studies reviewed by Plomin and Daniels (1987). Moreover, in early development these influences were transitory and their shifts, even over short periods of time, accounted for much of the instability of measures of child adjustment over time. The picture looks quite different as individuals age. The nonshared influences become stable and efforts to identify them have successfully centered on marriage although sibling differences in occupational experience, exogenously caused health problems or even residential location are also candidates for large-scale effects. A major base for this interest in nonshared environment in adult development comes from the meta-analyses of Briley and Tucker-Drob already cited (Briley & Tucker-Drob; Tucker-Drob & Briley, 2014) which clarifies the increasing importance of stable nonshared influences, across development, in two large domains of personal functioning: cognition and personality.

Currently, one of the most astonishing initiatives in behavioral science is the U.S. Health and Retirement Study that follows a large number of individuals from midlife until advanced old age or death. This seminal study has spawned many other comparable surveys in Europe, Asia, the Middle East, Africa, and Latin America. All of them are searching for ways to characterize patterns of aging and for the influences that shape those patterns over time. Quantitative genetics, though early in its exploration of this domain, provides an impudent suggestion for these very large studies. The fundamental questions about aging may not be estimates of factors accounting for *differences among individuals*. Rather the question about trajectories of aging might be reframed: what factors account for *difference and similarities between siblings* in the same family over the life course? However, the quantitative genetics literature we have reviewed suggests optimism for the discovery of the potential sources of these differences—above and beyond marriage. Except in the rare case of MZ twins (they are likely to be present in only 1 of approximately 80 cases in a random sample of aging individuals) these differences could be attributable to genetic differences among ordinary siblings. Or they could be due to critical differential experiences such as a good marriage for one or a bad marriage or no marriage for the other. We think a sibling difference in life course is a productive approach to adult development but rigorous estimates of the role of genetic differences among siblings will depend on oversampling twins. Several large-scale survey studies provide precedent (e.g., Rowe, Jacobson, & Van den Oord, 1999; South & Krueger, 2008).

There is, of course, another reason for studies of midlife and aging to sample subjects by sibling pairs. We have already reviewed data suggesting that the reciprocal environments that siblings build for themselves appears to have a sustained influence on the development of each at least through the transition to adulthood. In their reviews of sibling studies, Tucker-Drob and Briley found that stable, shared environmental influences persisted across the life span (Tucker-Drob & Briley, 2014). Do reciprocal sibling relationships play a significant role in the persistence of these stable shared environmental influences? Do these reciprocal sibling environments still bear the imprint of much earlier parent–child relationships?

SUMMARY

We have sketched a history of rapprochement between genetics and the social sciences in the study of the family. There are many domains in the study of the family that have been inalterably changed by this rapprochement: a heightened interest in differences between families in the sensitivity of members to one another, early steps in

embedding the study of family processes in a genuine transactional neuroscience, the prospect of a better fit between families and family-level interventions design to reduce problems they already have or to prevent them from occurring in the first place, a clearer recognition that genetic relatedness among family members influences observed associations between characteristics of parents and of their children, a new etiological model of developmental psychopathology focusing on the role in the expression of genetic influences on psychopathology through reciprocal relationships of genetically influenced evocative behavior in the child and the response of the parent, and finally, a perspective on sibling-based sampling and analysis in the study of adult development and aging. We hope geneticists are also listening to the results of this rapprochement to better appreciate the circumstances under which specific gene variants are expressed or not expressed and to include in their investigations the outside-the-skin mechanisms reviewed here.

INTRODUCTION

The progressive biologization of developmental science in general and the science of developmental psychopathology in particular in the past several decades has been tightly linked to technological, methodological, and statistical advances in developmental biology and genetic epidemiology. Predictably, this biologization has been accompanied by a rapid increase in the number of multidisciplinary projects conducted and published by the field. For example, at the time of the writing of this chapter, a quick SCOPUS search limited to the subject area of psychology using a combination of search terms "genes"/"molecular genetics" AND "development" returned almost 3,000 results, with 240 reports published in 2013 alone—a sixfold increase compared with the total number of publications with the same keyword 20 years ago. Even more impressive, perhaps, is that the linear relationship between year of publication and number of published reports indexed by SCOPUS over the same period can be described with a point estimate of Pearson's $r = .91$ ($p < .000001$)—a large effect size rarely seen by developmental scientists in their own data!

Whether or not this accelerating increase in the amount of generated and published data will result in a better understanding of the complex relationships between human genetics and development partly depends on the accessibility of these data (in terms of both acquisition and interpretation) to its main consumers, that is, to developmental scientists. In 2012, the US National Institutes of Health launched an online educational initiative for behavioral and social scientists called Genetics and Social Science: Expanding Transdisciplinary Research (http://www.nchpeg.org/bssr/), aimed at providing accessible coverage of the core concepts and issues in the field of genetics. Nevertheless, in their own teaching and collaboration experience, the authors of this chapter have been faced with the virtual absence of a concise, integrative, state-of-the-art overview of the basic methodological issues and advances in human genetics as applied to the study of the development and manifestation of complex traits and common disorders in general and neurodevelopmental disorders in particular. Most of the published treatments of these topics and methods are relatively isolated in

The writing of this chapter was supported by grants R01 DC007665, R21 HD070594, and P50 HD052120 from the US National Institutes of Health and grant No 14.Z50.31.0027 from the Government of the Russian Federation. Grantees undertaking such projects are encouraged to express freely their professional judgment. The chapter, therefore, does not necessarily reflect the position or policies of the aforementioned funding agencies, and no official endorsement should be inferred.

their scope and highly technical, thereby reducing their utility for interdisciplinary researchers that frequently do not have formal training in molecular genetics, genetic epidemiology, bioinformatics, and biostatistics. Therefore, the current chapter aims to fill this gap in the literature by providing an accessible and comprehensive overview of molecular genetics methods that would hopefully aid the new generation of developmental scientists in both digesting the rapidly growing number of reports on molecular genetic studies in the field and potentially serving as a starting point for designing their own projects.

This chapter is organized as follows. First, we will provide a brief overview of the basic concepts of molecular cell biology, thus setting the necessary background for presenting molecular genetics methods. Then, we will review several types of genetic variation and corresponding genotyping methods and research designs used in genetic linkage and association studies (with an emphasis on microarray genotyping and genome-wide association studies). We will then turn to the discussion of the current state of affairs with respect to the growing appreciation of the role of the structural variation in the human genome in human development and its consequences for the debate between those who attribute complex trait variation in humans to frequent or common vs. rare genetic variants. We will then turn to DNA sequencing methods, starting with the original Sanger sequencing and following with the next-generation DNA sequencing methods. After a brief discussion of gene expression profiling methods that builds on the information presented in previous sections (i.e., microarray and sequencing platforms), we will conclude with a set of comments pertaining to current and future utilization of molecular methods in the developmental sciences.

BASIC CONCEPTS

The focus of this chapter is on the methods used for acquiring information about the genetic make up of an individual (or a group of individuals) and study designs that are aimed at gaining knowledge about the etiology of a particular trait (typical and atypical) or a syndromic trait constellation. Before describing these methods, however, we need to establish what exactly the substrate for genetic information is, where it is located, and how it is transmitted and used to build a living organism. To minimize the technicality of this overview, we therefore refer the interested reader to other sources for more in-depth treatments of the relevant issues (Alberts et al., 2002; Laird & Lange, 2011; Russell, 2009; Wu, Ma, & Casella, 2007; Ziegler, König, & Pahlke, 2010).

With the exception of red blood cells (erythrocytes) that lack cell nucleus, every human body cell contains a full set of information about the primary structure of the genetic makeup of the individual. This information is stored in thread-like structures made of *deoxyribonucleic acid* (DNA) and other proteins. DNA, the main carrier of genetic information, is a large two-stranded molecule composed of a *backbone* that is formed by an alternating repeated pattern of a sugar group (deoxyribose) and a phosphate group, and organic *nucleobases* (or, simply, bases). The primary bases of the DNA are purines (guanine [G] and adenine [A]) and pyrimidines (thymine [T] and cytosine [C]). A structural unit of a single strand of DNA consists of one sugar group, one phosphate group, and a base, and is called a *nucleotide*. Recall, however, that DNA is a double-stranded molecule. The two strands are connected by a hydrogen bond between two opposing bases on the complementary strands comprising a DNA molecule: adenine always bonds with thymine (A-T rule), and cytosine always bonds with guanine (C-G rule). The specificity of these pairings is regulated by the dimensional[1] properties of the DNA bases and is frequently referred to as *complementary base pairing* rule since one can infer the sequence of one strand if the other one is known. The resulting DNA molecule resembles a twisted ladder described as a double helix.

Human DNA is structured into 23 *chromosomes* that function in cells. Each chromosome has a centromere and two arms, a short one (p arm) and a long one (q arm), that end with telomeres. Of these, 22 are autosomes consecutively labeled from 1 to 22 roughly according to their length: chromosome 1 is the longest with a length of ~248.9 million base pairs (bp); 21 is the shortest with ~46.7 million bp (http://www.ncbi.nlm.nih.gov/projects/genome/assembly/grc/human/data/). The remaining twenty-third chromosome is either an X or a Y sex chromosome, around 156 and 57.2 million bp long, respectively. Human sex cells (gametes—egg and sperm cells) contain a single set of 23

[1]Purines have a two-ring structure and are larger (wider) than pyrimidines that only have one ring. The formation of stable hydrogen bonds between DNA bases depends on the distance between strands, the size of the bases, and their geometrical properties. Correspondingly, purine-purine, pyrimidine-pyrimidine, and noncomplementary purine-pyrimidine pairings locally disrupt the DNA structure leading to DNA instability and are disfavored.

chromosomes and are termed to be *haploid* (k = 23). Most human somatic cells, however, are *diploid* (k = 46): they contain a double set of chromosomes, with one inherited from the mother and other one—the father, for the full diploid set of 44 autosomes and 2 sex chromosomes. Thus, while a haploid set of human DNA is approximately 3 billion bp long, the complete diploid set of genetic information is twice this length.

The genetic information necessary to make an entire organism[2] is stored in the linear sequence of DNA nucleotides and is used to guide protein synthesis. Proteins consist of polypeptide chains of repeating amino acids. Twenty different amino acids found in human proteins are encoded by triplets of DNA nucleotides called *codons* (e.g., the GUU sequence codes for amino acid called valine, while CGU codes for arginine). The three-letter code can be used to generate 64 different codons, but since there are only 20 amino acids that need to be encoded, the genetic code itself is considered degenerate (i.e., more than one codon can code for a particular amino acid). According to what is frequently referred to as the central dogma of molecular biology, protein synthesis follows a particular path, the DNA → RNA[3] → protein pathway. The first step in this pathway is called *transcription*. While the DNA is located in the cell nucleus, protein synthesis takes place in the plasma. Correspondingly, the first step requires transcription of DNA into a single-stranded messenger RNA molecule (mRNA) that carries the information to the plasma. During transcription, the DNA sequence is read by RNA polymerase (RNAP), an enzyme that is used to produce mRNA[4]—a template that will be used for the actual protein synthesis during the second phase called *translation*. This second step takes place in ribosomes in the cell plasma, and includes decoding the transcription-generated RNA to produce an amino acid or polypeptide chain that is then modified (folded) into the actual active functional protein.

The full sequence of DNA is called the *genome*. For a long time, the researchers' attention was focused on the amino-acid coding regions of the genome which contain codon sequences that initiate and terminate transcription, and whose transcripts undergo translation to produce a functional protein product—*genes*. These coding genic regions are separated by stretches of non-coding intergenic DNA. A gene can be formally defined as "a locatable region of genomic sequence, corresponding to a unit of inheritance, which is associated with regulatory regions, transcribed regions, and/or other functional significance region" (Pearson, 2006, p. 401). This recent definition underscores the shift from coding regions per se to regions that have at least some functional significance. At the time of the writing of this chapter, the latest human genome build (i.e., a public release of an assembly of contiguous reference DNA sequences in a chromosomal order that is representative of the human genome; the latest build has been released in 2014 and is called the Genome Reference Consortium human genome build 38 or GRCh38; http://www.ensembl.org) included 20,389 coding genes, accounting for about 1% of the total human genome length. However, the results of the Encyclopedia of DNA Elements (ENCODE; http://www.genome.gov/10005107), a public research project focused on identifying all functional elements in the genome, suggested that ~80% of the genome might have a biochemical function (The ENCODE Project Consortium, 2012), and that the distinction between genic and intergenic DNA regions is not clear-cut, but rather complicated by such phenomena as the existence of previously ignored transcription of regulatory elements and the presence of transcribed but non-protein-coding RNAs and pseudogenes (Gerstein et al., 2007; Mattick, 2004).

The transmission of genetic information from parents to their offspring involves the transfer of the genetic information into parental gametes during meiosis, and the fusion of parental gametes during zygote formation. Since meiosis is a special form of cell division that includes only one round of the duplication of genetic material but two rounds of cell division, each diploid progenitor cell gives rise to four haploid gametes. Thus, at the beginning of this process, a diploid progenitor cell contains a double set of

[2]Note that genetic information encoded in the DNA molecule is not only sufficient to make an entire organism, but is also transmittable (from parent to offspring), replicable (in order to be transmittable), and exhibits significant variation (which can be mapped to at least some facets of phenotypic variance within species). We will turn to these points later in the chapter.

[3]The RNA (ribonucleic acid) molecule, like DNA, is composed of a chain of nucleotides. However, it is typically a less stable single-stranded molecule. Unlike DNA that contains thymine as a complementary base to adenine, the complementary base to adenine in RNA is not thymine, but rather uracil (U), an unmethylated form of thymine.

[4]mRNA is not the only kind of the RNA molecules resulting from transcription and not the only one RNA molecule that participates in translation. Other RNAs (i.e., ribosomal rRNA and transfer tRNA) also partake in protein synthesis as supporting or regulating elements.

genetic material with each of the pair homologous chromosomes coming from one of the parents. Homologous chromosomes are similar in length, centromere location, and gene composition and position but are not necessarily fully identical as one is coming from the mother, and the other one—the father. After the DNA is duplicated, the cell contains four sets of the genetic material, and homologous chromosomes form connected pairs called bivalents. At this stage, it is possible for maternal and paternal chromosomes to exchange portions of genetic material during a process known as *crossing over*. After two rounds of meiotic division, four haploid gametes are formed. Chromosomal crossing over results in the recombination of maternal and paternal *alleles* (i.e., genetic variants) on the same chromosome and increases genetic variability among gametes. Importantly, the probability of a crossing-over occurring between two genomic segments at specific locations (loci) depends on the distance between these segments (i.e., segments and genes located closer to each other have a lower probability of being separated during crossing over than segments located further apart from each other—in the extreme case, on different chromosomes). This results in the deviation of the observed frequencies of *haplotypes* (combinations of alleles) from their expected frequencies in the population, the phenomenon referred to as *linkage disequilibrium* (LD). Two loci are considered linked if they are jointly transmitted from parent to offspring more often than under independent inheritance. Generally, genetic segments and genes that are located close together on the same chromosome and undergo recombination in less than 50% of meiotic events are considered to be linked, whereas genes and segments that are located on different chromosomes or at different ends of the same chromosome with crossing over happening in approximately 50% of meiotic events are considered to be inherited independently. We will return to the importance of the idea of linkage and linkage disequilibrium for molecular genetic studies of human traits in the next section.

The possibility of inheriting different alleles on the maternal and paternal DNA strands at the same genetic locus highlights the presence of genetic variability across individuals. In general, although different individuals can be said to have the same set of genes, they usually (with the exception of monozygotic twins) do not share the same exact sequence of DNA nucleotides. In diploid cells, the combination of alleles at a particular locus defines the *genotype* at that locus (e.g., if an individual has inherited the A allele from the mother and the G allele from the father, they have an AG genotype at that locus). If the two alleles are the same on both chromosomes, an individual is said to be homozygous at this locus, whereas different alleles form a heterozygous genotype. Variation in the human genome is a consequence of different types of mutation events that alter the base sequence composition of the DNA. These include large events during cell division that lead to deletions, insertions, duplications, translocations, and inversions of relatively large chromosomal segments and smaller events that typically occur during DNA replication, such as point mutations (i.e., substitution of one nucleotide for another). Generally, a locus is considered polymorphic if the mutant (minor or less frequent) allele is present in the referent population (e.g., individuals of European ancestry) at the frequency of at least 1% while the referent wild-type (major or more frequent) allele is found with the complementary frequency. The corresponding variation in the DNA sequence at that locus is called a *polymorphism*.

The human genome contains several types of genetic variation and corresponding polymorphisms. These include the *single nucleotide polymorphisms* mentioned above (SNPs; the most prevalent type of genetic variation, with 97,535,033 validated SNPs reported in the most recent build of the public SNP database dbSNP 144. (http://www.ncbi.nlm.nih.gov/projects/SNP/snp_summary.cgi), *short tandem repeats* (repetitions of a pattern of one or more nucleotides adjacent to one another otherwise known as micro- and mini-satellites), short insertions and deletions of genetic material (so-called *indels* that generally range in size from 1 bp to 1,000 bp or 1 kilobase pair, kb), and *copy number variants* (deletions, duplications, translocations, inversions, and insertions of genetic material that are typically over 1 kb long). Prior to the technological advances in molecular genetics, only large (generally over 3 million bp or 3 megabases, Mb, in size) and rare types of structural variations that affected quantity or structure of chromosomes were identified, as they were detectable using microscopic techniques. Over the course of the past two decades, however, a large number of smaller, frequent, or common (>1% frequency) variants has been discovered and described. We will now turn to the most commonly employed study designs in molecular genetics of human traits, methods used to genotype the main types of variants described already, and inferential (including statistical) procedures that underlie the inference about the involvement of a particular genetic variant or a gene in the etiology of human traits.

MOLECULAR GENETIC STUDY DESIGNS AND GENOTYPING

Linkage Studies and Short-Tandem Repeat Polymorphisms (STRPs)

The vast majority of complex human traits, from height (Silventoinen et al., 2003) and insomnia-related symptoms (Hublin, Partinen, Koskenvuo, & Kaprio, 2011) to child language development and literacy-related skills (Grigorenko, Ngorosho, Jukes, & Bundy, 2006; Kovas et al., 2005) to adolescent psychopathy (Tuvblad, Bezdjian, Raine, & Baker, 2014) to patterns of resting EEG connectivity (Schutte et al., 2013), exhibit significant heritability, with the contribution of genetic factors estimated in behavioral studies to generally range from 30% to 80% with a median estimate around 50%. Establishing familiality and heritability[5] using behavioral genetics methods and designs such as twin studies, the analysis of familial trait aggregation (i.e., the extent to which the trait is overrepresented in families where there is at least one affected proband), and segregation (i.e., the establishment of the mode of inheritance or genetic model of the trait) are important steps in the discovery of the genetic architecture of a trait. These steps are typically followed by the application of molecular genetics methods to locate genomic regions and identify genetic variants contributing to the trait, with the goal of revealing main genetic factors that play a role in its development and manifestation. For so-called simple, *Mendelian traits* characterized by relatively low prevalence, Mendelian patterns of inheritance (autosomal dominant, autosomal recessive, and X-linked), and high penetrance (i.e., probability of observing the phenotype given the presence of the mutation) of single-locus genetic variants, the past three decades of research have been extremely fruitful with respect to the discovery of genes underlying these traits and accompanying disorders (Botstein & Risch, 2003). The molecular bases of more than 3,500 such rare disorders have been identified to date, accounting for approximately 50% of the estimated 7,000 monogenic diseases (Boycott, Vanstone, Bulman, & MacKenzie, 2013). Among them are such somatic disorders as cystic fibrosis (Online Mendelian Inheritance in Man, http://www.omim.org; MIM#219700; caused by mutations in the *CFTR* gene located on chromosome 7q31[6]) and developmental disorders such as DiGeorge syndrome (MIM#188400; caused by a deletion of 1.5–3 Mb region of chromosome 22q11.2 that contains, among others, the *TBX1* gene) or Charcot-Marie-Tooth syndrome (MIM#606482; caused by mutations in the *DNM2* gene located on chromosome 19p13.2).

The success of Mendelian gene discovery is largely dependent on the methodological advances that transformed statistical linkage analysis as a behavioral analysis tool to investigate familial segregation of traits into a molecular analysis tool (that involves positional cloning with molecular techniques) used to establish the location of the segments of the DNA shared by related and phenotypically similar individuals. This revolutionary change has been brought on by the technological advances that made the genotyping (i.e., evaluating the exact state) of polymorphic genetic markers (i.e., DNA sequences with known physical/chromosomal locations) accessible to researchers. Initially, these markers were *restriction fragment length polymorphisms* (RFLPs; highly locus-specific markers with alternative alleles associated with restriction fragments[7] that differ in size), followed by short *tandem repeat polymorphisms* (STRPs). STRPs are represented

[5]Familiality refers to the familial aggregation (clustering) of the trait. For example, developmental disorders of language are considered to be familial since prevalence of these disorders is higher in first-degree relatives of probands affected with the disorder than in families of unaffected children (Tallal et al., 2001; Tomblin, 1989). Heritability, on the other hand, refers to the proportion of the total trait variance attributable to genetic factors. In most cases, heritability is estimated as narrow-sense heritability that reflects "the degree to which the genes transmitted from parents determine the phenotype of their children" (Tenesa & Haley, 2013, p. 141). For example, heritability estimates from twin studies suggest that childhood depression symptoms are 30–80% heritable (i.e., 30–80% of the variance in these symptoms could be attributed to additive shared genetic effects). Every heritable trait is also familial, but not every familial trait is heritable.

[6]Each arm of a chromosome is divided into regions called cytogenetic bands. These regions correspond to the patterns of staining (light and dark areas) of chromosomal regions that can be detected under a microscope and are labeled consecutively starting from the centromere out toward the telomeres. Cytogenetic bands (e.g., 22q11) can be further subdivided into subbands (e.g., 22q11.1).

[7]Restriction enzymes can recognize specific nucleotide sequences and cut DNA at specific locations called restriction sites. An RFLP probe *hybridizes* with (i.e., attaches itself to) one or more fragments of the cut (or digested) DNA samples separated by gel electrophoresis based on their size, producing a blotting pattern (e.g., visualized on an x-ray film) specific to a genotype at a particular locus. Mutations in the genome (e.g., SNPs, indels) change the relative positions of restriction sites and the length of DNA segments between them, making them amenable to genotyping through this method.

by repeating sequences[8] of typically 1–6 nucleotides that are abundant in the human genome and, due to their elevated mutation rate, are highly polymorphic (e.g., with an average of 6–8 alleles estimated for European populations; Calafell, Shuster, Speed, Kidd, & Kidd, 1998). By themselves these polymorphisms mostly do not have functional significance as they are biased away from the protein-coding regions of DNA (Metzgar, Bytof, & Wills, 2000) due to potentially high disruptiveness of non-triplet (tri- and hexanucleotide, i.e., STRPs in multiples of three) STRPs that cause frameshift mutations (i.e., changes in the grouping of codons that affect which amino acids are coded for by the codons that occur after the mutation) and result in the alteration of protein structure and function. However, STRPs have been invaluable with respect to their utility in locating genomic regions affecting a variety of traits and remain the most frequently employed markers in linkage studies.

Recall that linked genetic loci are transmitted together from parent to offspring more often than expected under independent inheritance. In so-called parametric[9] or model-based linkage analysis used to study Mendelian traits, the investigator is interested in the recombination fraction between multiple loci genotyped in familial samples. The analysis of the segregation of these markers in pedigrees reveals their relative position on the genome and is used to map trait loci. Given the highly polymorphic nature of STRP markers and their relatively low genotyping error rate, it is possible to efficiently trace the transmission of DNA segments through the pedigrees. The co-inheritance of the same haplotype by individuals affected with a Mendelian disorder but not by the unaffected individuals (i.e., co-segregation of the phenotype and the haplotype) in extended pedigrees and nuclear families serves as primary evidence for the involvement of the particular genomic location in that phenotype. Parametric linkage studies specify several parameters to calculate the primary linkage statistic, logarithm of the odds (LOD) score, such as disease allele frequency and mode of inheritance, marker allele frequencies, and marker maps. The parametric linkage analysis itself is based on the maximization the LOD score[10] function to provide an estimate of the recombination fraction between STRP markers and the disease locus (and, correspondingly, an estimate of the position of the disease locus).

Linkage studies frequently follow a two-staged approach where the first scan is performed using multiple markers spaced 5–10 centimorgans (cM[11]) apart followed by a higher-density scan that is focused on the region for which initial evidence for linkage has been obtained. Given that the resolution of linkage studies is relatively low (1–10 cM), they might identify from a few to a few hundred genes predicted to be relevant for the trait and located within about 1 cM (or approximately 1 Mb) from the linkage site, depending on the pattern of the cross-overs in the region (Botstein & Risch, 2003). This two-staged approach, for example, has been successfully used to establish the linkage of a severe speech and language disorder to the locus labeled SPCH1 and located on chromosome 7q31, followed by the identification of *FOXP2* as the causal gene for the autosomal-dominant Mendelian speech and language disorder in a single three-generational UK pedigree (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998; Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001). Although there are several examples of successful linkage mapping of Mendelian disorders using single extended

[8]Genotyping STRPs typically requires the polymerase chain reaction (PCR) amplification of the STRP region using primers that flank a particular STRP. The size of the amplified region depends on the number of repeats and, as in the case of RFLPs, gel electrophoresis can be used to separate DNA fragments of different size and establish the STRP genotype. Multiplexing (i.e., co-amplification of multiple STRPs in a single PCR reaction) facilitates genotyping of multiple STRPs at the same time, and in this case genotyping relies on using automated laser-induced fluorescence detection methods that label alleles with fluorescent dyes (fluorophores, same or different, depending on the overlap in allele size) attached to one of the primers for each of the STRP markers (for an overview of the current methods, see Guichoux et al., 2011).

[9]Parametric linkage assumes that the models describing the trait and the genetic marker are known. Nonparametric linkage relies on fewer assumptions about these models and their precise specifications.

[10]The LOD score is based on the comparison of the likelihood of the null hypothesis (no linkage) to the likelihood of the alternative hypothesis of linkage given certain model parameters. Positive and large LOD scores provide evidence for linkage. An LOD score of 3 is equivalent to $p = .0001$ or the odds of linkage of a thousand to one that the two loci (or a marker and the disease) are linked and inherited together. Although this value has been used as the cut-off for a long time in linkage studies, more recent work points to the LOD value of 3.3 as being more appropriate for controlling type I error rates in genome-wide linkage studies with multiple markers distributed across the whole genome at a certain density level.

[11]Centimorgan are units of genetic distance between chromosomal positions that are based on the evaluation of the frequency of crossing over (recombination) events between them (i.e., 1 cM equal 1% recombination, or, in physical distance, ~1 Mb).

pedigrees such as the KE family mentioned above (e.g., Asher, Morell, & Friedman, 1991; Sobreira et al., 2010), most linkage studies employ samples of multiple families to increase power to detect linkage. The statistical power of linkage (both parametric and non-parametric—see below) studies depends on several factors such as locus heterogeneity (i.e., more families are needed to detect signals that are coming from more than one locus involved in the etiology of the trait), recombination fraction between the trait and the marker locus (the further apart they are, the more families are required), correctness of the specification of allele frequency (and, for parametric linkage, other model parameters), diagnostic classification accuracy, presence of phenocopy (i.e., when a phenotype caused by nonhereditary factors matches or is very similar to a phenotype caused by genetic mutations), and genetic marker heterozygosity (or informativeness).

Note that parametric linkage analyses that specify modes of inheritance are best suited for locating loci involved in single-gene Mendelian disorders, especially in cases when there are few ungenotyped individuals in a family and the specification of the phenotype is unambiguous. When the trait is polygenic, common, *complex*, or quantitative in nature, however, it typically does not conform to a specific mode of inheritance, and parametric LOD score analyses are ill suited for establishing linkage in this situation. Correspondingly, nonparametric linkage analyses methods have been developed to account for this uncertainty in model parameters, relax them, or even remove the necessity to specify them unambiguously (e.g., remove the mode of inheritance assumption and decrease variant penetrance since complex traits and disorders are commonly thought to involve multiple genes and variants of small(er) effect sizes). This approach assumes that affected related individuals should show an increased sharing of haplotypes that are Identical by Descent (IBD[12]) in regions close to the involved genes independent of the specific mode of inheritance; that is, phenotypically similar related individuals should have similar alleles for a marker located close to the genes contributing to the trait.

A common design for a nonparametric linkage study is to evaluate allele sharing in sibships, in particular, affected sib pairs (for binary traits). When the IBD status for alleles for a marker can be determined (i.e., parents were genotyped and their genotypes at a particular locus can distinguish between children's IBS and IBD alleles), the observed proportion of sib pairs sharing 0, 1, or 2 IBD alleles can be compared with the expected proportions (see footnote 6) using a chi-square test or one-sided tests that compare proportion of sib pairs who share 2 alleles IBD with the expected proportion of 25% or compare average IBD sharing with the expected proportion of 50%. However, in the majority of cases, the IBD status cannot be determined unambiguously for either part of the sample or the whole sample (e.g., if the markers are not sufficiently polymorphic or the parents have not been genotyped). Several methods have been developed to allow for this uncertainty in linkage analysis. Among these are methods that take into account partially informative[13] matings from extended families (Sandkuijl, 1989), and multipoint methods utilizing information from multiple genetic markers at the same time to estimate the IBD distribution at each marker (Kruglyak & Lander, 1995). The pairwise sib-pair method can be extended to include larger sibships, and alternative pairwise IBD sharing analysis methods were developed to perform linkage analyses with multiple affected relatives of different degrees of relatedness (Gudbjartsson, Jonasson, Frigge, & Kong, 2000; Kruglyak, Daly, Reeve-Daly, & Lander, 1996).

So far we have mostly been discussing linkage in the context of binary traits such as disease status (affected vs. unaffected). However, many (if not most) traits of interest to developmental scientists are fundamentally continuous or quantitative in nature. These traits can be analyzed in quantitative trait linkage paradigms, and loci identified in studies that are based on these paradigms are frequently referred to as *quantitative trait loci* (QTLs). For sib-pair designs, early methods included regressing the squared difference between quantitative trait values of siblings on the estimated proportion of IBD alleles with the expectation that trait similarity in the presence of the linkage of this trait to a particular gene should be related to higher proportion of IBD alleles shared by siblings at the marker close to that gene (Haseman & Elston, 1972).

[12] Alleles are considered Identical By State (IBS) if they are represented by the same variant of a polymorphic locus. Alleles are considered IBD if they are not only IBS but also if they are inherited from a common ancestor. Two individuals (related or not) can share 0, 1, or 2 alleles IBS. While two unrelated individuals by definition share no alleles IBD, the expected proportion of shared IBD alleles in pairs of related individuals depends on the type of the relationship based on the principle of random segregation of gametes combined with the number of meiosis events that separate the two relatives in a pair (e.g., MZ twins are expected to share 2 alleles IBD at a given locus, while siblings are expected to show a distribution of 0 (25%), 1 (50%), and 2 (25%) alleles IBD).

[13] That is, when the parental genotype is not known but genotypes available for other family members can be used to calculate the probability distribution of the missing genotype.

More recent methods include extensions of the regression method that also incorporate additional information contained in mean-corrected cross-product of trait values (i.e., sibling covariance; Xu, Weiss, Xu, & Wei, 2000) and variance component methods that partition trait covariance between different relatives into the estimated IBD sharing component and the kinship component (Almasy & Blangero, 1998; Sham, Purcell, Cherny, & Abecasis, 2002). Keeping the sample size constant, variance component methods have the highest power when the number of pairs of relatives is maximized by studying fewer but larger families as opposed to more but smaller families (Williams & Blangero, 1999).

Cost-efficient whole-genome linkage studies that employ 400–800 STRP markers (sufficient to cover the whole genome) replaced early linkage studies that used numbers of markers an order of magnitude smaller in 1990s. Since then, a multitude of positive findings for simple Mendelian disorders have been reported. More recently, less polymorphic but extremely high density markers, single nucleotide polymorphisms (SNPs; see next section), have also been proposed for linkage studies. Yet the utility of linkage analyses for complex traits remains severely limited by their low genomic resolution, power constraints due to large sample size requirements (Risch, 2000), and cost and validity considerations specific to family-based designs, especially in the context of complex developmental traits. Although several approaches to increase the power of linkage studies of complex traits have been suggested, such as multivariate analyses that capitalize on the simultaneous interrogation of related phenotypes typical of complex cognitive traits (Marlow et al., 2003), developmental phenotypes that limit the age band where a particular phenotyping method is efficient remain a problem for these designs. Moreover, traditional mapping methods that focus on single time-point quantitative phenotype measures neglect the developmental nature of these traits and the dynamic pattern of their genetic control (Wu & Lin, 2006). We mention this developmental limitation here but would like to note that it is not specific to linkage studies and can be extended to genetic association studies in general (see next section). In addition, it is worth noting that sample ascertainment for linkage studies is rarely population-based and, correspondingly, traits that are characterized by locus heterogeneity (i.e., when a trait is influenced by multiple mutations at different unrelated chromosomal loci) might produce family-specific linkage signals that complicate the interpretation of linkage findings with respect to the general population (Teare & Barrett, 2005).

Candidate Gene Association Studies and Single Nucleotide Polymorphisms (SNPs)

In contrast to linkage studies, the goal of genetic association studies is to establish an association between the genotype at a particular locus and a particular trait. Although the distinction between linkage and association is subtle, it is crucial for understanding the differences between the two approaches for identifying the genetic bases of human traits. Genetic association studies assume that the *same allele* is associated with the trait in a similar fashion in the population, while linkage studies allow different alleles to be linked with the disorder or trait in different families, as long as the location of the genomic segment harboring these alleles shows evidence for linkage. Most genetic association studies are performed using DNA samples collected from unrelated individuals genotyped using markers that provide a much finer resolution than the RFLP or STRP markers traditionally used in linkage studies—single nucleotide polymorphisms (SNPs).

SNPs are single base-pair substitution polymorphisms that are typically less polymorphic than STRPs (i.e., most SNPs only have two alleles; see the NCBI database of SNPs called dbSNP, http://www.ncbi.nlm.nih.gov/SNP/). They represent around 90% of the variation in DNA and are found at the frequency of approximately 1 SNP per 1 kb of the human genome. They are found at a slightly higher frequency in intergenic compared with genic DNA, and among those that occur within coding genome segments, slightly less than half are synonymous (i.e., the base pair substitution does not change the coded amino acid) with the rest being nonsynonymous (i.e., missense, resulting in identifiable alterations of protein structure or nonsense, when the protein is rendered nonfunctional due to truncation introduced by a premature stop codon). SNPs that are located outside of the coding regions might also have regulatory and transcription-altering functions, although for the majority of these markers their functional impact and regulatory potential is unknown.

SNP genotyping and association analysis has become the leading tool for trait gene discovery due to their abundance in the human genome, low mutation rates, and simplicity of methods for SNP genotyping. We already briefly covered one such method: the RFLP genotyping touched upon in the previous section can actually be used for SNP genotyping when the restriction cut occurs for one allele but not the other, resulting in different segment lengths corresponding to each allele. The utility of this method is limited by its inapplicability to the majority of SNPs and the low degree of automatization of the process. There are several

alternatives available to researchers, and the choice of the genotyping platform largely depends on the scale of the study (i.e., ranging from platforms that genotype one to several thousand to several million SNPs). Below we will first describe two genotyping platforms used to interrogate several to several thousand SNPs to set the stage for the further discussion of SNP genotyping platforms in the later sections of the chapter in the context of genome-wide association studies.

One of the most frequently used methods for SNP genotyping in human association studies is allele-specific oligonucleotide hybridization (ASO). This method discriminates between SNP alleles by hybridizing complementary synthetic oligonucleotides (i.e., short single-stranded DNA molecules) to the target DNA segment. Allele discrimination in ASO genotyping relies on the labeling of allele-specific products with different fluorescent dye labels that are then read using fluorescent readout systems. For example, the TaqMan® assay (Life Technologies, Applied Biosystems) is based on the ASO method coupled with 5' nuclease activity of Taq polymerase during the PCR reaction (Shen, Abdullah, & Wang, 2009). TaqMan probes are labeled with a fluorescent reporter dye on one end (5') and a common nonfluorescent quencher on the other end (3') that eliminates background fluorescence of the intact probe. Each TaqMan assay uses two allele-specific probes and a pair of PCR primers. The hybridization of the probe during PCR results in the separation of the dye and the quencher, promoting fluorescence. Allele detection in this case is based on the Forster resonance energy transfer (FRET) analysis. FRET technique measures changes in fluorescence during dye excitation due to the transfer of energy in the donor-acceptor complex. In the absence of the quencher, the fluorophore dye, excited at a particular wavelength, emits light while returning to its ground state, while the presence of the quencher permits the transfer of energy from the excited fluorophore to the quencher without the emission of light. SNP genotyping typically uses cyanine dyes Cy3 (dark pink) and Cy5 (blue) for allele discrimination. The simplicity of TaqMan Assay chemistry lends it to automation and millions of assays have been developed, but low SNP multiplexing (i.e., genotyping of more than one SNP in parallel in the same assay/reaction) and high cost of dual-labeled probes limits the application of this genotyping method to projects that recruit large samples that are then genotyped using a large number of markers.

In contrast, Illumina GoldenGate Assay (Illumina, Inc), a highly multiplexing (i.e., simultaneously interrogating 96 to 3,072 SNPs) microarray platform, is based on the allele-specific primer extension (ASPE) and ligation method (Fan et al., 2006; Shen et al., 2005). In broad strokes, the increasingly popular microarray technology relies on using a small solid support surface with attached immobilized target DNA sequences (probes) to which the complementary amplified and labeled sample DNA (i.e., the DNA that is being genotyped) hybridizes. The hybridization signal is then read and interpreted with respect to evidence for a particular genotype. Illumina's microarray genotyping platforms are designed so that three oligonucleotides are synthesized for each SNP: two allele-specific oligonucleotides (ASOs) that are used to distinguish the SNP alleles, and a locus-specific oligonucleotide (LSO) that hybridizes 1 to 20 bases downstream from the ASO site. ASOs and LSOs contain target sequences for a set of universal PCR primers, and the LSOs also contain SNP-unique address sequences complementary to capture sequences attached to ultra-small silica beads. These silica beads are placed in microwells etched out of optical fibers or a silicon wafer. After the oligonucleotides have hybridized to the sample DNA, the ASO with a 3' end base complementary to the base at the SNP site is extended by polymerase and ligated to the corresponding LSO, forming a PCR template. The templates are amplified using the set of primers common to all SNPs, of which two are labeled with either Cy3 or Cy5 fluorescent dyes (but each anneals to only one of the two ASO sequences), and the third one anneals to a LSO common sequence. These reactions generate allele-specific PCR products that hybridize (using LSO to recognize a particular SNP site) to the beads carrying LSO-complementary oligonucleotides. The resulting hybridization signal is composed of the ratio of Cy3 and Cy5 fluorescence and is used to determine the genotype at each SNP site (i.e., equal intensity corresponds to the heterozygote, while the ratios of 1:0 and 0:1 correspond to the two alternative homozygote states). Note that genotyping based on indirect fluorescent signals is essentially a bioinformatic inference problem, and, although generally robust, is not immune to errors and depends on such parameters as the quality of the DNA sample, technical errors during sample and library preparation and handling, the specifics of SNPs selected for genotyping, and the accuracy of the algorithms used for SNP calling.

Both of the platforms described above are aimed at establishing the genotype (or allelic state) for each of the person in the study sample at each of the interrogated SNPs. These genotypes are represented by combinations of alleles that are labeled according to their frequency (typically the more frequent allele is considered the major

allele, and the less frequent one is labeled as the minor allele) in the current or the referent sample. Commercial genotyping platforms rely on prior knowledge about the sequence of the human genome and interrogate known sites of variation. Recall that a locus is considered polymorphic if the frequency of the minor allele (MAF) is at or above 1% in a particular population. However, it is certainly possible for an individual to carry private (i.e., found only in a particular family) or rare mutations that are missed by commercial platforms due to their low frequency (and novel mutations that have never been described and, correspondingly, could not have made it to the commercial SNP genotyping platforms). We will return to this point later in the chapter when talking about structural variants and rare variants identified using next-generation sequencing approaches. For now, we would like to concentrate on the main design considerations for candidate gene association studies.

Case–Control Designs, Single SNP, and Haplotype Association Testing Strategies

When the researcher is interested in the association between one (or several) SNPs and a binary or a quantitative trait, the simplest design strategy is to recruit either two ascertained groups of individuals that differ with respect to the binary trait (affected cases and unaffected controls) or a sample of individuals that exhibit significant variation in the quantitative trait. When the DNA from cases and controls is genotyped for a set of SNP markers of interest, straightforward association analyses can be employed to detect association signals separately for each marker. These include methods familiar to most behavioral scientists such as logistic regression that models log odds of disease as a linear function of the genotype/allele status and chi-square tests of association that test for the independence of disease status and genotype/allele frequencies with a standard 2 (cases + controls) × 3 (two homozygotes and the heterozygote) contingency table.

It is now widely accepted that the contributions of genetic factors to disease risk for complex disorders are roughly additive with the heterozygotes' risk estimated to be in-between that for the two homozygotes. Special statistical procedures have been developed to account for this additivity and improve statistical power compared with the general class of tests mentioned above. For example, the Cochrane-Armitage test (Armitage, 1955), also known as the proportion trend test, evaluates the hypothesis of zero slope for the line fitted to the three genotypic risk estimates—in this case the risk is estimated as the proportion of cases to the total sample of cases of controls harboring 0, 1, or 2 risk alleles. The choice of the particular association testing strategy, however, is not straightforward, as for some associations the nature of the relationship deviates from assumptions behind the employed statistical tests—for example, if the relationship significantly deviates from the additivity assumption (as in the case of overdominance when the two homozygotes have similar risk estimates that are also different from that for a heterozygote), the Cochrane-Armitage test will have low to null power to detect the true association. There are several strategies for overcoming this limitation, including calculating test statistics for all possible models (i.e., additive, dominant, and recessive effects) and choosing the maximum test statistic, or using Bayesian procedures (Balding, 2006).

For quantitative traits, association methods based on the extension of generalized linear model (GLM) approaches such as linear regression or analysis of variance (ANOVA) are frequently used to test for association under the assumption of additive genetic effects. These association tests typically require the distribution of the trait values to approximate normality for each genotype, and for each genotype group to have similar trait variances. In situations when the assumption of normality is violated, mathematical transformations of trait data such as log-transformation or quantile normalization can be used to approximate normal distribution. Score tests for binary outcomes like the Cochrane-Armitage test and linear regression approaches for quantitative traits can also incorporate covariates in the analysis, for example, to adjust for participants' gender and age.

One of the important concerns in genetic association studies is the presence of *population stratification*. Allele frequencies for a multitude of genetic variants vary both within and between different populations. Correspondingly, the detection of an association signal can be influenced (in both directions—by producing spurious associations and masking true association signals due to loss of statistical power) by the presence of differences in baseline allele frequencies between the populations from which cases and controls are sampled that have nothing to do with the trait of interest but rather with systematic differences in these populations' ancestry. In fact, population stratification is one of the most widely acknowledged reasons for nonreplication of genetic associations (Cardon & Palmer, 2003). In the ideal case, population stratification should be controlled by careful sample matching between cases and controls, and several methods (e.g., matching on such variables as geographic proximity, physical characteristics, self-reported family ancestry) have

been proposed to address this issue at the level of study design planning. Most frequently, however, the researchers supplement these procedures with statistical analyses of background genetic differences between cases and controls. These methods range from simply detecting background differences in genetic makeup between the populations by evaluating an independent set of multiple SNP markers that are unrelated to the markers of interest (Pritchard & Rosenberg, 1999) to more advanced methods such as *structured association* methods that assign individuals to population subclusters and perform association analyses within these clusters or use cluster membership as a covariate in the analyses (Pritchard, Stephens, & Donnelly, 2000), and *genomic control* methods that control for the inflation of test statistic caused by stratification (Devlin, Roeder, & Wasserman, 2001). When properly applied (e.g., by genotyping a recommended set of at least 25 additional SNPs) in situations when population stratification is not extreme, genomic control efficiently corrects for population stratification with minimal loss of statistical power (Dadd, Weale, & Lewis, 2009).

Note that the methods mentioned in the previous paragraph require genotyping multiple SNPs at unlinked or independent loci. So far we have been discussing association testing for single SNPs. However, in the vast majority of cases, the researchers genotype more than one SNP (e.g., multiple SNPs within a single candidate gene or in a candidate region). Independent testing of multiple SNPs in the same study introduces two problems. First, testing multiple SNPs separately leads to the statistical problem of multiple testing, well known to behavioral scientists as inflating Type I error rate. Standard multiple comparisons correction procedures such as the Bonferroni correction are overly conservative given that SNPs are frequently not fully independent from each other (i.e., are in linkage disequilibrium) and other methods that adjust for multiple comparisons in association studies have been developed. We will discuss these methods in the later paragraphs in the context of the extreme version of this problem specific to genome-wide association studies.

Second, such independent testing ignores the wealth of information conveyed by the combinations of SNPs reflected in haplotypes—specific combinations (or sequences) of alleles that occur together more frequently than expected by chance in regions of highly correlated genetic material with limited recombination. These regions are called linkage disequilibrium blocks and contain haplotypes consisting of SNPs that are in the high degree of linkage disequilibrium with each other due to shared ancestry (The International HapMap Consortium, 2005, 2007). Haplotype analyses reduce the burden of multiple testing by reducing the actual number of statistical tests performed. However, haplotype analyses can also capture complex interaction effects, such as when mutations that occur at different sites within the same gene on the same chromosome (in *cis* position as a haplotype) interact to create super alleles that have large multiplicative effects on the trait and disease risk (Drysdale, 2000; Tavtigian et al., 2001).

When haplotype phase (i.e., whether and which alleles observed for adjacent SNPs for a given individual are located on the same chromosome because they were inherited together as a haplotype from the same parent) is known, haplotype association testing is relatively straightforward and relies on extensions of methods used for SNP allele testing (e.g., by comparing haplotype frequencies in cases vs. controls). In case–control studies, however, the information about haplotype phase is typically unavailable as genotyping platforms produce unphased observed genotypes for individuals in the sample, and their parental genotypes are also typically unknown. Correspondingly, haplotype analysis in case–control studies requires statistical haplotype inference and reconstruction using likelihood-based or Bayesian methods followed by haplotype association testing (Schaid, Rowland, Tines, Jacobson, & Poland, 2002; Stephens & Donnelly, 2003; Sun, Greenwood, & Neal, 2007). For example, in an iterative two-staged approach of Schaid and colleagues (2002), haplotypes are inferred by computing estimates of probabilities of all possible haplotype pairs consistent with each individual's genotypes; these estimates are used as weights to update regression coefficients in association analysis in the GLM-based score testing framework that evaluates the presence of global (omnibus) haplotype effects and effects of specific haplotypes on binary, as well as quantitative traits.

Family-based Designs

Genetic association testing strategies described in the previous section rely on recruiting and genotyping samples of unrelated individuals. These case–control and case-cohort designs became the de facto standard in the field of complex trait genetics after linkage mapping fell out of favor. That does not mean, however, that studies of genetic underpinnings of complex traits exclusively use samples of unrelated individuals. A complementary class of study designs, called *family-based designs*, relies on using sets of genotyped relatives of various familial configurations to test for genetic associations between a trait and a set of SNP markers. These designs offer important advantages

over case–control studies: i.e., they are very robust against population stratification, simultaneously test for linkage and association, and offer unique strategies for battling the issues of multiple testing and genotyping quality control (Laird & Lange, 2006).

One of the simplest family-based designs is that of family trios which requires genotyping an affected proband and both of their parents. A specific non-parametric analytic strategy, called the transmission disequilibrium test (TDT), has been developed for these designs and tests the null hypothesis of no linkage and no association by evaluating the observed and the expected (under Mendelian laws) number of transmitted alleles (Spielman, McGinnis, & Ewens, 1993). For each marker, the TDT only utilizes data from informative families with at least one heterozygous parent and evaluates whether a particular allele is excessively transmitted to affected offspring (i.e., by comparing the numbers of transmitted vs. nontransmitted alleles), thus providing evidence for both linkage and association of that allele and the trait. Given that TDT is nonparametric, it does not require the specification of the genetic model or even the distribution of the trait. It is, however, inapplicable when parental genotypes are missing or when the analysis is focused on larger (so-called general) pedigrees.

The generalization of the trio-based TDT analytic strategy is realized in the widely used family-based association testing (FBAT) approach that permits using different configurations of relatives and missing data (e.g., nuclear or extended families with multiple affected and unaffected siblings that provide within-family controls), while preserving the nonparametric nature and robustness of the association testing found in TDT. FBAT represents a general class of family-based association tests that evaluate test statistics expressed as the covariance between an arbitrary function of offspring's genotype (genotype transmissions) and an arbitrary function of offspring's phenotype (a residual-trait deviation measure such as residuals from the sample mean offspring trait values); the details about the complex statistics underlying this method are presented elsewhere (Horvath, Xu, & Laird, 2001). Importantly, the FBAT approach and its extensions can not only handle different configurations of familial structures, but also work with covariates, are efficient with quantitative and time-to-onset traits, and permit multi-phenotype and multi-marker association testing (Lange, DeMeo, & Laird, 2002; Lange, DeMeo, Silverman, Weiss, & Laird, 2004; Lange, Silverman, Xu, Weiss, & Laird, 2003).

Other extensions of the TDT test include the affected-family-based controls (AFBAC; Thomson, 1995) method that uses data from all rather than just heterozygous parents (although it loses its immunity to population stratification) and the recently developed generalized family-based association test for dichotomous traits (GDT) that utilizes data from all possible discordant pairs of relatives in the family with resulting statistical power being higher than for other frequently employed tests of association (Chen, Manichaikul, & Rich, 2009).

As noted above, one of the main advantages of family-based designs is their robustness to population stratification. Genotyping parents also facilitates establishing haplotype phase, crucial for haplotype analyses, and the analysis of imprinting or parent-of-origin and mother–child genotype interaction effects (Cordell, Barratt, & Clayton, 2004; Weinberg, 1999). Another advantage of these designs is specific to childhood disorders where recruiting appropriately matched controls is more difficult than the affected child's parents (Laird & Lange, 2006). However, these designs have an important limitation. Although family-based designs are particularly efficient in establishing linkage and association for rare Mendelian disorders, for common disorders and complex traits their power is generally lower than that of case–control designs, while genotyping cost and recruitment time requirements are generally higher than that for case–control studies (McGinnis, Shifman, & Darvasi, 2002). Nevertheless, family-based designs might still experience a rise in popularity in the context of the analysis of next-generation sequencing data, and recent advances in analytic techniques (albeit parametric) permit using hybrid designs that utilize both population-based and family-based samples simultaneously (Zheng, Heagerty, Hsu, & Newcomb, 2010).

Candidate Gene and SNP Selection Strategies

So far we have been discussing genetic association studies in general, without reference to the specific genes or polymorphisms within them. However, candidate gene association studies typically focus on a more or less well-defined set of genes and SNPs within those genes that interest researchers. Several factors influence the selection of candidate genes and SNPs for a genetic association study, ranging from the number and nature of tested hypotheses to sample size to expected effect sizes (these issues will be covered in later sections). Multiple strategies are available for candidate gene selection, although assessing the candidacy potential of a particular gene with respect to a complex trait is an inherently imprecise and difficult task (Hattersley & McCarthy, 2005). When evidence for significant linkage to a particular genomic region

has been obtained, the researchers can select a set of SNPs and genes that are located under the linkage signal peak. This *positional* strategy thus focuses on candidate susceptibility genes that account for linkage peaks obtained in prior genetic linkage scans. Although intuitively appealing, this strategy has significant limitations as identified and replicated linkage regions are frequently relatively large and, given the general power and resolution limitations of linkage studies, are likely to miss multiple candidate genes located in other regions. The positional strategy for candidate gene selection can be used in isolation or in conjunction with other strategies, including the statistical strategy that prioritizes genes implicated in the trait or the disorder (or a related trait and disorder) in previous association studies or meta-analytical investigations (see later sections of the chapter).

Candidate genes might also be selected for association analysis using prior knowledge about the *biological function* of the protein encoded by the gene and the information about the *expression* of that gene in tissues relevant for the trait (e.g., in specific brain regions) at appropriate developmental periods. The utilization of the biological function information about the gene is an efficient strategy for candidate gene selection if and when the pathophysiology of the disease/disorder or the pathways involved in the development of the trait is known. This strategy can be augmented by using information from *pharmacological* studies that identify proteins implicated in the action of the disease- or trait-modifying drug or *animal model* studies that identify candidate genes that influence a phenotype similar to the human phenotype of interest in the model animal.

The subjectivity of candidate gene selection procedures, coupled with high non-replication rates of candidate gene association studies (Ioannidis, Ntzani, Trikalinos, & Contopoulos-Ioannidis, 2001), led to the development of a variety of computational tools that attempt to address or at least minimize problems caused by the lack of the background knowledge about the molecular underpinnings of complex traits (Zhu & Zhao, 2007). These in silico tools augment and integrate several of the identified strategies of candidate gene selection (sometimes also called candidate gene prioritization) with the goal of arriving at a multivariate strategy that would more likely result in an accurate candidate gene identification than an isolated use of just one strategy. These computational prioritization tools rely on the extraction, filtration, and complex statistical analysis and integration of heterogeneous data sets and resources available in a variety of public databases that are typically organized according to the principles of biological ontology (anatomical, cell/tissue, developmental, gene, and phenotype ontology). Many of the existing gene prioritization methods rely on two sources of input: 1) a list of candidate genes for prioritization (from a single locus, multiple loci, or even the whole genome), and 2) prioritization criteria (e.g., involvement in a disease or a certain pathway) in the form of biological keywords or seed genes that have already been linked to the trait or related traits (Brunner & Oti, 2007). These tools and computational strategies generally produce lists of candidate genes by *filtering* the initial lists into smaller subsets (e.g., based on the combination of the information about gene function, association data from genome-wide association studies, protein–protein and pathway interactions) or by *ranking* the input genes (Moreau & Tranchevent, 2012). The limitation of the filtering approach is the relatively strict nature of the filtration strategies that sometimes lead to false negative results when the true candidate gene is filtered out as failing one or more of the filtration criteria. An alternative strategy is to rank the candidate genes from least to most likely to be involved in the etiology of the trait without the application of strict filters. These methods include text mining of publicly available sources (e.g., publication abstracts in MEDLINE), similarity profiling that identifies candidate genes based on their similarity to the known genes relevant to the trait or respective biological processes, and *network analytic* methods that rely on the application of methods such as random walks or diffusion kernel to networks (e.g., a true protein–protein interaction network or an integrated functional linkage network) to identify trait-relevant nodes in preestablished networks through which information is propagated. There are multiple recently published excellent reviews of these (and other) methods available to researchers, with several accessible tutorials on web-based tools the interested reader is welcome to consult (Moreau & Tranchevent, 2012; Patnala, Clements, & Batra, 2013; Tranchevent et al., 2011). However, the application of these methods in a situation when little or no prior knowledge about the etiology of the trait and the pathways involved in related developmental processes is available remains challenging, and only a subset of human genes have been sufficiently annotated to be informative in such analyses.

Once the candidate gene or a set of candidate genes have been selected, the researchers typically face the issue of choosing polymorphisms within these genes. SNP selection for candidate gene studies, like the selection of candidate genes, can rely on the evaluation of the functional effects of SNPs. Recall that SNPs can be classified according to their functional class. A natural strategy is to select those SNPs within a gene that have identifiable consequences for the

structure and, correspondingly, the function of the protein products of that gene. In this case the evaluation of the association is performed in the context of the functional impact of the SNP on the biological pathway relevant for the trait. When there are multiple relatively frequent non-synonymous SNPs per gene, it is common to include several or all of these SNPs in the pool of candidate SNPs. The evaluation of the functional effects of SNPs might promote SNP selection by providing information regarding the degree to which a particular SNP is damaging obtained in experimental studies and analytically. Similarly to candidate gene prioritization frameworks, multiple in silico SNP effect analysis tools have been proposed, generally falling into two classes of sequence evaluation vs. structure evaluation algorithms (Mah, Low, & Lee, 2011). Sequence evaluation algorithms are more frequently used than structural algorithms since dimensional structural information is currently unavailable for most proteins, and evaluate the effects of SNPs on the function of the protein based on such parameters as the extent of change in amino acid residues (sequence homology) in evolutionarily conserved (and, therefore, assumed to have important functions) loci and their physiochemical similarity. Structural analyses, on the other hand, predict the functional effects of SNPs based on their impact on the three-dimensional protein structure, for example, by focusing on protein stability. Recently developed tools integrate sequence and structure information, as well as other prioritization-related data (such as network, pathway, and association information).

Researchers might also want to include SNPs in the *regulatory* gene elements (e.g., promoters and TF[14] binding sites), regions that can have long-distance effects on gene function (e.g., enhancer regions), and regions coding for microRNAs—small (~22 nucleotides long) noncoding RNAs that are extensively involved in post-transcriptional gene expression regulation (Ameres & Zamore, 2013). All of these elements are involved in multiple mechanisms that govern gene expression (Ameres & Zamore, 2013; Riethoven, 2010). Therefore, SNPs can disrupt or alter gene expression by influencing these elements, sometimes in a cell-type and tissue-specific manner (Dimas et al., 2009). Recently, a class of elements called *expression quantitative trait loci* (eQTL) has been discovered by establishing associations between variants located in these elements that can either be proximal (*cis*) or distal (*trans*) with respect to the location of the gene with the actual levels of that gene's expression (Dixon et al., 2007; Goring et al., 2007). Emerging evidence points to the pivotal role of eQTLs in complex traits—e.g., it has been found that SNPs associated with complex traits are much more likely to be located in eQTLs compared with SNPs located in other regions (Nicolae et al., 2010), and, correspondingly, point to the regulatory (rather than, for example, disruptive) nature of the variants associated with complex traits and common disorders.

Note, however, that commercial SNP genotyping platforms rely on using known SNP sites with a certain frequency threshold (i.e., >1% MAF in the population) that also satisfy several additional constraints necessary for high-quality genotyping (e.g., the unambiguity of the surrounding sequence is pivotal for successful target hybridization), and genotyping the full set of all discovered SNPs within a gene is impractical both from a statistical viewpoint and for cost reasons (it is, however, becoming increasingly possible with the application of next-generation sequencing methods; see further chapter sections). Given that the human genome has a linkage disequilibrium-laden correlated structure candidate gene association studies frequently employ the *tag SNP* selection strategy. Thus, loci demonstrating significant levels of linkage disequilibrium can be evaluated for association with a trait using so-called common tag SNPs that are correlated with other SNPs in the region because of the shared history and therefore tag common SNP haplotypes, removing the necessity to genotype SNPs at all possible loci. The presence of linkage disequilibrium and the availability of common tag SNPs for genetic association studies implies that it is possible to detect an association between a tag SNP and a trait without the tag SNP having any direct functional relationship with the trait and without directly genotyping the causal variant. Therefore, an important distinction for genetic association studies is that between a *direct association* and an *indirect association* that arises due to the correlated structure of the genome and the corresponding redundancy in the information provided by closely located SNPs. Differentiating between the two classes of association phenomena is an important issue for genetic association studies and frequently relies on the extensive characterization of the functional impact of the SNP on a trait or further fine-mapping (e.g., by using next-generation DNA sequencing) of the region around the SNP for which association has been demonstrated.

The selection of tag SNPs is possible in situations when the patterns of linkage disequilibrium between common variants at a particular locus are known for a given population. Fortunately, large-scale genome research

[14]Transcription factors (TF) are proteins that initiate and regulate transcription (and, therefore, gene expression) by binding to specific DNA sequences.

projects such as the International HapMap Project that focuses on discovering common patterns in the variation of the DNA sequence in the human genome (The International HapMap Consortium, 2005, 2007) provide such high-resolution genome-wide data for samples of varying ancestries: e.g., over 90% of the common (MAF > 5%) SNPs in non-African populations and around 80% of the common SNPs in Yoruba populations are highly correlated with at least one SNP in HapMap-produced data set of over 3.7 million SNPs with an oversampling of nonsynonymous SNPs.

Researchers are typically interested in obtaining the smallest possible set of tag SNPs with minimal loss of information based on pairwise correlations between SNPs or correlations of multiple SNPs indexing haplotypes. Some studies show that the reduction in the number of genotypes required to capture the common variation using tag SNPs is around 46–65% when the SNPs are chosen to capture all of the SNPs in the reference set, with a further reduction of 36–55% when the selection criteria are relaxed and without noticeable decreases in statistical power to detect true association signals, with even greater efficiency for multimarker methods (de Bakker et al., 2005). Correspondingly, several computational tools have been developed to optimize the process of tag SNP selection for candidate gene association studies using data produced by the International HapMap as well as other projects (Xu, Kaplan, & Taylor, 2007) for single as well as multiple populations simultaneously (Liu, Wang, & Wong, 2010; Patnala et al., 2013; Sicotte, Rider, Poland, Dhiman, & Kocher, 2011). However, although common tag SNPs can efficiently capture common variation in the human genome, they are much less efficient at predicting rare variants with MAF below 5% (Zeggini et al., 2005), and researchers should be aware of this limitation while designing candidate gene association studies.

An example of a successful implementation of a candidate association strategy can be found in a recent report on the genetic bases of adolescent substance abuse by Trucco, Villafuerte, Heitzeg, Burmeister, and Zucker (2014). Trucco and colleagues examined the associations between *GABRA2*, a gene previously implicated in substance abuse and conduct disorder in adults, and rule breaking as a potential mechanism mediating the effects *GABRA2* on substance and alcohol abuse risk in the developmental context. *GABRA2* is characterized by a strong LD structure, resulting in two common haplotypes specific to this gene. These haplotypes have been tagged in the study by three SNPs genotyped using the TaqMan platform for each of the 518 participants. The results were consistent across three SNPs and indicated that variation in *GABRA2* was more strongly associated with rule breaking in mid–late but not early adolescence, with over 70% of the total effect of *GABRA2* on substance abuse attributable to mediating rule breaking (which prospectively predicted substance abuse in the sample). This study represents not only a successful candidate association study that interrogated the candidate gene identified for a complex trait in adult samples but also, notably, explicitly modeled cascading developmental processes and their genetic regulation (i.e., using path modeling).

Genome-Wide Association Studies and High-Density SNP Microarray panels

The ability of common SNPs to tag genetic variants in linkage disequilibrium with them lies at the heart of the principle of *genome-wide association studies* (GWAS). In contrast to candidate gene association studies, GWAS studies are hypothesis-free in the sense that instead of depending on hit-or-miss candidate gene and variant selection, they are aimed at interrogating the whole genome. GWAS studies were made possible by the combination of advances in human genetics such as the completion of the Human Genome Project[15] (International Human Genome Sequencing Consortium, 2001, 2004), the deposition of a large number of SNPs to public databases, the initiation of the HapMap projects, and the rapid development of commercially-available high-throughput microarray genotyping platforms by Illumina and Affymetrix in the mid 2000s. Initially, these platforms aimed at using the microarray approach (described in previous sections) to genotype approximately 100,000 SNPs with MAF > 5% per sample spread across the whole genome and tagging other variants in linkage disequilibrium with them.

Current instantiations of Illumina's and Affymetrix's GWAS microarray panels include 10–50 times more SNPs than the number of SNPs used in the first published GWAS that evaluated associations between 116,204 SNPs and age-related macular degeneration in 96 cases in 50 controls (Klein et al., 2005). For example, Illumina currently offers a family of BeadChip-based microarray panels that evaluate from 715,000 SNPs per sample

[15]Coordinated by the National Institutes of Health and the U.S. Department of Energy, the Human Genome Project was the international consortium-based research program aimed at establishing the precise genomic location and DNA sequence of human genes. Its completion in 2003, 13 years after the start of the project, marked the key milestone in the science of human genetics.

(HumanOmniExpress-24) to over 4.5 million SNPs per sample (HumanOmni5Exome). In addition to including more SNPs, some of these arrays also (1) capitalize on information obtained in the 1000 Genomes Project[16] and large-scale sequencing projects, permitting genotyping of rare SNPs with MAF between 1% and 5% as opposed to only common SNPs with MAF >5% in previous generations of panels, (2) oversample exonic SNPs, boosting the power and resolution of GWAS studies to detect associations with SNPs located in coding gene regions, (3) include markers for other types of genetic variation (e.g., indels and CNVs; see later sections), and (4) allow for panel customization with the option of adding up to thousands of custom markers that specifically interest the researchers in specific studies.

Recent studies comparing the efficiency, coverage, and cost–benefit ratios (Ha, Freytag, & Bickeboeller, 2014) for different genotyping platforms suggest that while genome coverage for these platforms is slightly lower than advertised by the manufacturers and varies by study population, their tagging efficiency is still relatively high, and techniques like the imputation of unobserved genotypes based on the markers genotyped on the microarray are likely to prove advantageous for GWAS studies. Several overviews on the design of GWAS studies focusing on the evaluation of the prospective sample size and power as related to researchers' budgetary constraints, research questions and hypotheses, and choice of genotyping platform have been published and can be used as practical guides for choosing a particular genotyping platform (Ha et al., 2014; Nelson et al., 2013; Spencer, Su, Donnelly, & Marchini, 2009). Given the availability of these resources, we would like to instead focus on a set of design (and interpretation) issues beyond the choice of genotyping platform that are relatively specific to GWAS studies.

Most GWAS studies adopt a *case–control* approach, while recruiting large samples of cases and controls that are genotyped using high-throughput platforms mentioned above. Since GWAS studies typically evaluate hundreds of thousands to millions of SNP markers, they are faced with the necessity to perform the corresponding large number of statistical tests that dramatically increases the Type I error rate. Traditionally, researchers have used a relatively arbitrary cutoff of $p < 5 \times 10–^{7}$ put forward by the Wellcome Trust GWAS publications (The Wellcome Trust Case Control Consortium, 2007) or standard Bonferroni adjustments (α / number of genotyped SNPs) to declare an association statistically significant. However, Bonferroni adjustments are overly conservative in the context of the correlated structure of the human genome, and several alternatives that correct for non-independence between tested SNPs have been proposed. These include techniques that correct *p*-values based on the direct genotype-based calculation of the effective number of independent tests (Duggal, Gillanders, Holmes, & Bailey-Wilson, 2008; Gao, Becker, Becker, Starmer, & Province, 2010) and permutation testing (Han, Kang, & Eskin, 2009; Johnson et al., 2010).

Performing and correcting for multiple comparisons in the GWAS context means a dramatic power reduction for detecting associations, especially when the signal to noise ratio is high. This issue is especially pronounced when searching for indirect genetic associations with complex, polygenic traits that exhibit significant allelic (i.e., when multiple different polymorphisms in the same gene are associated with the trait) and locus (i.e., when multiple genes and genomic loci are implicated) heterogeneity, and when phenotyping is imprecise. Although the aforementioned first published GWAS study included ~150 individuals, currently performed GWAS studies generally employ much larger samples. For highly heritable polygenic traits with a strong genetic component such as height or Crohn's disease susceptibility, effect sizes for common SNPs are generally small and vary in the range of .07% to 1.96% of explained phenotypic variance (Park et al., 2010). A recent analysis of published disease- and trait-associated SNP associations corroborates these estimates with an observed range of odds ratios (ORs) from 1.04 to 29.4 and a median of 1.33 (Hindorff et al., 2009). Such small effect sizes require inordinately large samples to be detected, especially for variants with low MAF: for example, over 10,000 cases and 10,000 controls would be required to detect an association between a dichotomous trait and a disease variant with an OR of 1.3 at MAF < 10% with 80% power at $p < 10^{-6}$ (Wang, Barratt, Clayton, & Todd, 2005). While power increases with larger effect sizes and variant MAF for binary traits, GWAS studies still typically require samples on the order of 2,000 to 3,000 cases and controls to detect significant associations using currently available genotyping platforms (Spencer et al., 2009). It is worth noting that statistical power is slightly higher for detecting GWAS associations with quantitative rather than binary traits under some conditions (Yang, Wray, &

[16]The 1000 Genomes Project launched in 2008 with the goal of arriving at a refined, detailed catalog and map of human genetic variation by discovering >95% of genetic variants of up to 1% MAF across the genome, estimating their population frequencies and linkage disequilibrium patterns by performing DNA sequencing of 1,000 human genomes.

Visscher, 2010). Other factors such as the heritability of the trait, disease prevalence, the number of causal variants, the presence of epistatic (gene by gene or GxG) interactions, the degree of LD between the typed marker and the causal variant, the case/control proportion in the study sample, and the presence of covariates also all influence statistical power, and extreme care must be exercised at the stage of GWAS study design to address these issues.

Over 2,000 GWAS studies have been published since 2005, and curated catalogues have been constructed to facilitate dissemination of GWAS findings (Welter et al., 2014). Although GWAS studies have produced an array of results for a variety of traits, several issues have become apparent once these vast amounts of data have been accumulated. First, although multiple susceptibility loci have been identified for many complex traits, many were likely missed due to power limitations mentioned previously and characteristics of individual GWAS studies. Second, nonreplication and false association issues of genetic association studies, when extended to large-scale GWASes, are severe (Ioannidis, 2007; Lazzeroni, Lu, & Belitskaya-Levy, 2014), thus requiring extensive and careful validation in carefully designed replication studies, transforming a GWAS study into a two-stage design where association signals detected in the *discovery* cohort are validated in the *replication* cohort. This strategy can be augmented by GWAS association results prioritization strategies (Cantor, Lange, & Sinsheimer, 2010; Hou & Zhao, 2013) that optimize further gene, SNP, and sample selection. Third, when pooled together, disease- and trait-associated SNPs typically explain well under 10% of the phenotypic variance of complex traits (Visscher, Brown, McCarthy, & Yang, 2012). When compared with heritability estimates from behavioral genetic studies, these results suggest that trait-associated SNPs explain only a minor fraction of the heritability estimated in behavioral genetic studies. The remaining, unexplained portion has been correspondingly called *missing heritability* (Manolio et al., 2009), and this issue has received a lot of attention in the literature in the recent years. Several factors have been proposed to account for the missing heritability of complex traits, ranging from the acknowledgment of the important role of rare and structural variants (see following sections of this chapter) to the suggestions that missing heritability does not imply the presence of missing/undetected genetic variants but rather an overestimation of heritability in studies that ignore interactions among genes, their variants, and corresponding etiological pathways (Zuk, Hechter, Sunyaev, & Lander, 2012).

One interesting approach to increasing statistical power in genetic association studies, put forward in the psychiatric genetics literature, is to shift attention from direct behavioral phenotypes (e.g., disease status or performance levels) to intermediate phenotypes that are more proximal to the etiology of the trait than syndromic phenotypes. These so-called *endophenotypes* can be, for example, metabolic (e.g., peripheral hormone levels), neurophysiological (e.g., resting state EEG power), neuroanatomic (e.g., volumetric measures), or neurocognitive if the latter are proximal to the trait (e.g., phonological working memory measures in studies of developmental language disorders). Componential, quantitative endophenotypes reduce the complexity of end-point behavioral phenotypes and provide an intermediate link between biological and behavioral-syndromic levels of analysis (Cannon & Keller, 2006). The evident increase of interest in endophenotypes of complex disorders and traits was accompanied by both theoretical and methodological changes in the approaches to these traits that emphasized multivariate, dimensional and continuous investigations of multiple elements or facets of complex traits (Insel et al., 2010), in particular neurodevelopmental traits and disorders (Grigorenko et al., 1997; Smith et al., 2010).

Until now we have been describing ideal situations where, aside from design, power and interpretation issues, genetic association studies (including GWAS studies) have been otherwise properly conducted. Yet, there is an additional layer of complexity to such studies related to the technical aspects of DNA sample type, collection and handling, genotyping errors and quality control procedures. Although behavioral scientists undoubtedly recognize the complexity of the application of genetic methods, we would like to bring the attention of the reader to these issues to further facilitate their recognition and appreciation of the multi-layered uncertainty that is fundamental to modern molecular genetics methods.

High-throughput genotyping platforms have specific requirements for the volume, concentration, and quality of DNA samples submitted for genotyping. Correspondingly, in many studies, genomic DNA isolated from whole (venous) blood samples has been used as the preferred sample type. Collecting blood samples from development populations, however, might be challenging due to the complexities and potential complications of phlebotomy procedures. Inexpensive and easy to use saliva collection kits such as Oragene DNA Saliva kits (DNA Genotek, Inc) have been proposed as a viable alternative to standard procedures that typically yield ~8 ml of

anticoagulant-preserved whole blood per sample. DNA yields from saliva samples are typically lower than those from blood samples, and protein contamination rates are higher (Abraham et al., 2012). However, several studies have demonstrated that despite a slight drop in genotyping quality for saliva samples, concordance rates between blood and saliva samples are very high, and saliva samples perform well both in small-scale and large-scale genotyping projects (Abraham et al., 2012; Bahlo et al., 2010; Philibert, Zadorozhnyaya, Beach, & Brody, 2008).

Once the sample type has been selected, sample collection for large-scale projects typically takes place at multiple data collection sites. Multiple confounding issues can arise at this stage if cases and controls are overrepresented at different sites, genotyping for them is performed using different genotyping platforms and/or on separate sets of sample plates. Analyses of existing data sets demonstrated the presence of significant batch effects during genotyping that led to spurious associations due to confounding case–control status with such variables as experimental order, sample type, and confounding of family member status in family trios with plate sets that masked true genetic differences between families (Lambert & Black, 2012). Such effects are far from trivial and sometimes lead to the retraction of potentially high-impact publications, as has been the case with the New England Centenarian Study of human longevity GWAS published in and subsequently retracted from *Science* (Sebastiani et al., 2010) due to spurious associations attributable to combining data from multiple genotyping platforms. These issues are directly related to the principles of experimental design, and corresponding precautions can be taken to prevent confounding by using such procedures familiar to most scientists as blocked randomization.

Most current GWAS studies, however, rely not only on careful study design and procedures for *quality assurance* but also on the application of a complex set of procedures for *quality control* (Weale, 2010). Although the rationale behind each of these procedures is beyond the scope of this chapter, it is worth mentioning that it is common to assess the quality of genotyping per sample and per genetic marker (typically filtering out markers and samples with a genotype call rate below 95%), evaluate concordance between reported gender and gender inferred from genotypic data (i.e., based on the X chromosome heterozygosity) and between technical replicates, remove markers with low MAF (i.e., below 5%) and markers that show evidence for Mendelian segregation errors (one of the benefits of adopting a family-based design), assess population stratification using methods such as principal components analysis (PCA), and evaluate genetic markers for their deviations from Hardy-Weinberg equilibrium.[17] Given the complexity of genetic association study (including GWAS) design, execution, analysis, and interpretation, a special set of reporting guidelines called STREGA (Strengthening the Reporting of Genetic Association Studies) has been developed to facilitate reporting transparency and ease of interpretation (Little et al., 2009). In our view, these guidelines can also be used to facilitate optimal study design by bringing all of the above issues (and more) to the attention of researchers, funding agencies, and reviewers.

GWAS studies of developmental psychopathology traits are relatively scarce (Addington & Rapoport, 2012) and findings from these studies have been mixed. For example, although eight GWAS studies of ADHD have been performed, none have identified variants that would survive corrections for multiple testing. However, a recently published study used a two-stage GWAS approach with 607 adult ADHD cases and 584 controls in the discovery and 2104 ADHD cases and 1901 controls in replication samples, obtained suggestive evidence for the involvement of *FBX033* in ADHD and frontal gray matter volume (Sanchez-Mora et al., 2015).

Augmenting Genetic Association Studies Using Recent Statistical Developments: Mixed Models, Chip Heritabilities, Gene-Based Associations, and Meta-analytic Approaches

Some of the quality control procedures and adjustments can be performed in a GWAS setting simultaneously with statistical analysis. A particularly efficient method for adjusting for population structure confounders such as population stratification and familial relatedness (including so-called cryptic relatedness which arises when related samples are included in a population-based genetic association study) is the application of a set of analytical procedures known as *linear mixed models* (Kang et al., 2010; Listgarten et al., 2012; Zhou & Stephens, 2012). These models generally treat a genetic effect (e.g., number of minor alleles for a SNP) as a fixed effect in a regression model that also includes an additional random effect that models genetic relatedness (genetic covariance)

[17]Hardy-Weinberg equilibrium (HWE) describes the relationship between genotype and allele frequencies where there are no selection forces (such as mutation, selective survival or genetic drift) influencing a particular locus in a stable population. In the context of GWAS, departures from HWE can indicate genotyping errors.

between individuals in the study sample. In the GWAS context, available SNPs are used to calculate measures of genome-wide similarity between pairs of individuals (e.g., a kinship matrix) that capture the probabilities that these pairs share causal alleles and estimate their contribution to the phenotype. Developed explicitly for the application to complex quantitative traits, these methods are generally computationally intensive but are extremely efficient at controlling for a variety of confounding factors, sometimes in an SNP-specific (rather than sample-specific) manner, thereby reducing both Type I and Type II error rates.

Although these methods present a viable alternative to standard association testing approaches, they do not solve other GWAS issues such as missing heritability. Several recently developed methods that are gaining popularity in the complex trait genetics literature are aimed at addressing the missing heritability issue by estimating the proportion of phenotypic variance captured by all of the information provided by high-throughput genotyping technologies, rather than relying on single-SNP testing. This estimated proportion is called *genetic heritability* or *chip heritability*. For example, genome-wide complex trait analysis (GCTA) has been proposed as method for the polygenic modeling of complex traits (Yang, Lee, Goddard, & Visscher, 2011). Under the assumption that individuals who are more genetically similar should also be more phenotypically similar, GCTA utilizes genome-wide SNP data to estimate genetic relatedness between pairs of individuals in the sample. It estimates chip heritability by using the extension of linear mixed models to partition phenotypic variance into additive genetic variance explained by all SNPs, additive–environment interaction effects, and residual variance. However, this approach is not applicable when gene-gene interactions or dominance effects are at play, and effectively assumes that every genetic variant affects the trait and effect sizes are normally distributed. For some traits, however, it might be more realistic to assume that a proportion (but not all) of SNPs affect the trait of interest, and methods based on sparse regression models (e.g., Bayesian variable selection regression models) have been developed for such situations. Given that for the majority of traits the true genetic architecture is unknown, hybrid *polygenic modeling* approaches that combine the linear mixed modeling and Bayesian sparse regression modeling have been developed (Zhou, Carbonetto, & Stephens, 2013). Hybrid polygenic models allow for both a small number of large effects and a large number of small genetic effects to be estimated simultaneously, with the balance between the two inferred directly from the data. They are not only efficient at estimating chip heritabilities when combinations of larger and smaller effect size SNPs are at play, but also can be used to predict disease risk and quantitative trait values. Of note is that these methods are new, and few empirical reports have been published to date.

Two other classes of analytical procedures have been proposed to increase the yield of GWAS and candidate gene association studies. While polygenic modeling approaches are aimed at estimating the contribution of all of the (genome-wide distributed) genotyped SNPs to the trait, *gene-based tests* are aimed at evaluating the association between a trait and all markers within a particular gene (Li, Gui, Kwan, & Sham, 2011; Liu et al., 2010). This approach is especially powerful when a gene contains more than one causal variant, each of which is only marginally associated with the trait. Gene-based tests effectively combine the effects of all of typed SNPs in a gene and estimating a test statistics that is adjusted for non-independence between these SNPs. While genetic variants can exhibit different allele frequencies, LD structure, and heterogeneity in different populations, gene-based analyses might produce more consistent and replicable findings across populations than single-marker analyses. Gene-based tests are not only efficient in candidate gene studies, but also in the GWAS context, particularly by reducing the multiple comparisons burden as tens of thousands (number of evaluated genes) rather than hundreds of thousands or millions of statistical tests are performed. Extensions of gene-based testing procedures include the incorporation of functional information on SNPs that are assigned a prior weight based on their involvement in specific pathways and protein-protein interaction networks.

Another approach to evaluating the robustness and increasing the power for detecting genetic associations is to perform a genetic association *meta-analysis*. Even with relatively large samples, for the majority of complex traits the yield of reported and replicated genetic associations has been relatively modest. While GWAS studies typically employ a two-staged design where each of the stages is analyzed individually, there is a growing appreciation of the utility of directly combining statistical evidence for associations from multiple samples both within the same GWAS study and across published GWAS data sets (Begum, Ghosh, Tseng, & Feingold, 2012). Meta-analytic procedures, familiar to most behavioral scientists, offer an important toolset for detecting small effects that are consistent across multiple studies and cohorts, and revealing heterogeneity between studies and samples. They are especially relevant for so-called mega-analyses of association studies that are based on multitudes of individual studies performed within research consortia formed specifically to

increase statistical power. Genetic meta-analyses typically use straightforward statistical methods for combining (weighted or unweighted; e.g., using Fisher's method or a weighted Z-score method) *p*-values or effect sizes within either fixed or random effects models (Nakaoka & Inoue, 2009). Although powerful, meta-analytic techniques require special care with respect to ensuring the validity and robustness of the application of study exclusion and inclusion criteria, similarity of phenotype definition, interchangeability of SNP coding, consistent application of data cleaning procedures across data sets, and genotype imputation when studies differ with respect to the genotyping platform, as well as meta-analysis model selection.

The development of the approaches covered in this section of the chapter is reflective of the maturation of genetic association research in general and GWAS research in particular as a field that has moved beyond simple association testing, and has already contributed to disease- and trait-related gene and variant discovery. For example, Kornilov et al. (2015) performed a GWAS study of developmental language disorder in a small sample ($n = 359$) from an isolated population with an increased prevalence of the disorder using a mixed linear modeling approach. Although no individual SNP reached genome-wide significance, a gene-based analysis identified a gene statistically significantly (after correction for the number of genes for which the tests have been performed) associated with a part of the quantitative multivariate language phenotype in the population, *SETBP1*. Although the functional significance of this gene is currently unknown, several independent case study reports also indicated that *SETBP1* haploinsufficiency (i.e., when only one copy of the gene is functional) is associated with expressive language deficits in children. Yet the methods described in this section have only rarely been applied to developmental traits, and although for other complex traits (mostly a variety of somatic disorders) the accumulation of data led to a certain level of awareness of both benefits and limitations of common variant genetic association testing, psychological, psychiatric, and developmental genetics still lives in the pre-GWAS era or, optimistically, the GWAS era, compared with the post-GWAS era status for other traits.

STRUCTURAL VARIATION IN THE HUMAN GENOME AND COPY NUMBER VARIANT (CNV) ASSOCIATION STUDIES

Although SNPs represent most of the interindividual variation in the human genome, other types of variants have been receiving increasing attention in the last decade. These include structural genetic variants such as insertions, deletions, duplications, inversions, and translocations of genomic segments and segmental duplications. The field of human genetics has been extensively characterizing genetic variants at the nucleotide (e.g., SNPs) and karyotype levels (e.g., by studying aneuploidies), but structural variants that are smaller than ~3 Mb have generally been poorly characterized with respect to their number, distribution, size, allele frequencies, and functional impact.

The human genome contains several types of structural genetic variants that are frequently (albeit relatively arbitrarily) classified according to their size. Small insertions and deletions called *indels* represent the smallest class of structural genetic variants and generally range in size from 1 bp to 1 kb. Although initial estimates of the number of indels in the human genome were around 400,000 indels (Mills et al., 2006), with an average density of one indel per ~7 kb of genome, more recent data from the 1000 Genomes Project indicated that the human genome might contain over 1,000,000 indels combined over different populations (1000 Genomes Project Consortium, 2010). Indel density in the human genome is correlated with SNP density, and approximately a third of indels are found in the coding regions of the genome, thus potentially having important functional effects on the affected genes.

Structural variants that involve duplication or deletion of DNA segments over 1 kb long are called *copy number variants* (CNVs), and when structural variants of this size do not involve changes in the amount of genetic material (e.g., as in the case of inversions where the DNA sequence is flipped around with no actual gain or loss of genetic material), they are called *structural variants* (SVs). The distribution of CNVs and SVs across the human genome is not uniform: for example, as deletions are frequently associated with loss of protein function, they tend to be evolutionarily biased away from genes, and CNVs in general are biased away from ultraconserved genomic regions that are known to be under strong selection (Cooper, Nickerson, & Eichler, 2007). Structural variant frequency declines with variant length, with most (Shen et al., 2013; Wong et al., 2007; Zogopoulos et al., 2007) of the structural variants being classified as low-frequency (.50% to 1–5% MAF) or rare (< .50% MAF), and variants found at higher frequencies are called copy number polymorphisms (CNP); correspondingly, the human genome is estimated to have fewer CNVs and CNPs (e.g., ~20,000 estimated by the 1000 Genomes Project) than indels or SNPs. Note that, although SNPs vastly outnumber structural variants, given the size of the latter, the cumulative sum of base pairs that can be affected by them can actually be larger than the sum of base pairs affected by SNPs, thus

representing the second major source of genetic variation among individuals.

Like SNPs, structural variants can be benign or damaging with respect to their impact, and functional effects of this type of genetic variation are diverse. Gene expression association analyses revealed that CNVs account for 17.7% of the total genetic variation in gene expression levels (Stranger et al., 2007), and CNVs that directly lead to the increase or decrease of number of copies of a particular gene can affect that gene's transcript abundance (i.e., the amount of gene transcription product) and gene dosage. SVs, on the other hand, can disrupt transcription by creating breakpoints within transcripts, and large SVs can result in the alteration of the spatial distribution of chromosomes in the nucleus, thereby affecting important regulatory genetic interactions. CNVs, indels, and SVs located in regulatory regions might also disrupt gene expression, and these effects have been observed for loci that are sometimes millions of bp away from the target gene. The specifics of these effects partly depend on the location of the variant and the type of the regulatory element affected by it (i.e., activator or repressor). Likewise, structural variants located in noncoding regions can modulate transcription and even produce more severe effects like chromosomal fragility.

Our understanding of the landscape of structural variation in the human genome and its role in human traits has been limited in part due to the technological challenges specific to methods used for structural variant discovery (i.e., identification of the variant in a population, its validation, and characterization at the sequence level) and genotyping. CNV discovery and genotyping has relied greatly on the development of microarray approaches, primarily array *comparative genomic hybridization* (array CGH) and SNP microarrays, and in both cases the evaluation of the copy number state is done by comparing probe signal intensities to those of the reference sample. Array CGH relies on comparative and competitive hybridization of two samples labeled with different fluorophores to a set of targets, typically represented by long oligos or bacterial artificial chromosome (BAC) clones (Oostlander, Meijer, & Yistra, 2004). The fluorescence intensity signal ratio (Cy3:Cy5) between the two samples is normalized, converted to a $\log_2$ ratio, and the latter serves as the main source of information for copy number inference: increase in this ratio is indicative of the increase (or gain) in a copy number relative to the reference, while a decrease is indicative of a copy number decrease (or loss). The initial resolution of CGH studies was low and allowed for the evaluation of copy number states for variants larger than 1 kb. Commercially available whole-genome CGH arrays manufactured by Roche NimbleGen and Agilent Technologies rely on evaluating signals from multiple (i.e., 3 and more) consecutive probes to infer copy number state for each region and can genotype structural variants that are ~500 bp long. Although the CGH method is not sensitive to structural variants that do not alter the amount of genomic materials (i.e., SVs such as transversions), it is currently the leading method for CNV detection in clinical settings that previously relied on karyotyping, especially in the contexts of searching for the potential causes of unexplained neurodevelopmental disorders (Miller et al., 2010).

SNP microarray panels discussed in the previous sections have also been suggested as a method for structural variant genotyping (Cooper, Zerr, Kidd, Eichler, & Nickerson, 2008). Unlike for CGH, in this case hybridization is performed using one sample rather than two, and total normalized intensity as well as allelic intensity ratios are used for CNV inference to compare the copy number state of the tested sample with the aggregated intensity estimates of another individual or, more typically, a group of individuals (e.g., all of the genotyped individuals in a study sample). Although recent instantiations of these microarray panels include (nonpolymorphic) probes that specifically tag common CNVs and indels (especially in regions with low SNP density or coverage), in general the signal to noise ratio for CNV detection is lower for SNP panels compared to that of CGH panels (Alkan, Coe, & Eichler, 2011; Greshock et al., 2007), frequently leading to false positives (i.e., a discovery of the CNV that is not further validated using methods such as quantitative PCR). Microarrays have important limitations with respect to structural variant detection. For instance, copy number differences are evaluated with respect to the reference used to design the probes, and no information is available with respect to the actual location of duplicated or deleted regions or the position of structural breakpoints; in addition, single-copy gains are harder to detect than losses, and, as mentioned above, SVs that do not affect copy numbers are undetected by microarray panels. Furthermore, analysis of copy number states in and around repeat-rich and duplicated regions of the human genome is challenging given that microarray platforms rely on the assumption that each location is diploid in the reference, which might or might not be true, and is important given that CNVs actually correlate with segmental duplications in the human genome (Itsara et al., 2009). In addition, microarray CNV genotyping and discovery rely on the application of computational copy number detection

algorithms (Colella et al., 2007; Wang et al., 2007), which, while performing well with large CNVs, are not as accurate in detecting small structural variants, and multiple algorithms have been shown to differ with respect to identified variants with concordance rates between different algorithms sometimes falling below 50% and validation rates below 70% (Pinto et al., 2011).

Alternative methods for structural variant genotyping that overcome some of the aforementioned limitations of microarrays are single-molecule methods and next-generation sequencing. The former include cytogenetic methods like fluorescence in situ hybridization (FISH), fiber-FISH, and spectral karyotyping. These methods provide visualization of alterations of genomic structure at the single molecule level and have been used for structural variant discovery in the past. However, the fact that these methods are low throughput and have low resolution limits their application to several individuals and large structural aberrations (generally 500 kb to 5 Mb). Recently developed visualization techniques such as optical mapping and nanochannel visualization provide a more fine-grained analysis of genome structure and detect multiple types of structural variants (including complex rearrangements) and their locations but their application is also highly limited by a low throughput; these methods are reviewed elsewhere (Alkan et al., 2011; Das et al., 2010; Levy-Sakin & Ebenstein, 2013; Yamada et al., 2011).

Structural variant association study designs and analytical approaches are generally very similar to those described in this chapter for SNP-based studies. They rely on the recruitment of samples of cases and controls (less frequently—population-based samples to study associations with quantitative traits) and testing for association between the structural variant (typically a CNV) alleles (e.g., the number of copies) and the trait, either in a candidate–gene or whole-genome fashion. Given their high potential for being functionally damaging, CNVs are important vehicles for both studying candidate genes and identifying new trait-related genes.

Recall, however, that although they are collectively common and account for a significant proportion of human genetic variation, most structural variants are individually rare. In fact, structural variants in disease association studies have become synonymous with *rare variants*. In the previous sections we called GWAS studies hypothesis-free. This is not entirely correct given that GWAS study design, technologies used for genotyping, and statistical considerations guiding the analysis of GWAS studies are rooted in the common disease/common variant (CDCV) hypothesis. CDCV assumes that complex traits are primarily influenced by small to moderate effect size and low penetrance variants that are common in the population (Reich & Lander, 2001). Although initially promising, this approach has faced serious criticism in light of the landscape of findings from GWAS studies published in the last decade, most importantly the failure of common variants identified as disease susceptibility loci or QTLs to account for the major portion of genetic variance in the corresponding trait or provide evidence for their functional involvement in that trait's etiology. Correspondingly, the common disease/rare variant (CDRV) predicts that multiple rare variations in the DNA with high penetrance are the major (or at least complementary to common variants) contributors to complex trait variance and manifestation (Schork, Murray, Frazer, & Topol, 2009). Several arguments have been put forward to support CDRV. For example, it has been argued that population-level processes such as purifying selection and random genetic drift regulate the frequency of deleterious genetic variants, and rare genetic variants with recent (i.e., past 2 centuries) mutational history are more likely to contribute to common disease etiology than older common variants (Pritchard, 2001).

Much like the way recent GWAS polygenic modeling studies provide some support for the CDCV hypothesis, structural variant and DNA sequencing studies published in recent years have been pivotal in providing evidence for CDRV. The debate between the two has not been resolved, and the authors of this chapter would like to emphasize that recent attempts to reconcile the two are more likely to result in advances in our understanding of the genetic architecture of complex traits (Gibson, 2012; Schork et al., 2009). One approach is to evaluate the relative contributions of the two types of variants to the trait. A complementary approach would also seek to provide a theoretical and mechanistic account of how common and rare variants operate together, for example, by extending the well-known threshold-dependent response model to incorporate both types of variants. In this case, complex traits are regulated by a large number of polymorphisms that modulate biochemical traits contributing to the overall phenotypic trait, and individuals at the extremes of the continuous liability conferred by these polymorphisms exhibit disease states when additional risk is conferred by rare variants, the variable effects of which are conditional on the background liability (Gibson, 2012).

The digression in the previous two paragraphs and the distinction between the two classes of genetic variants is important for understanding the most commonly used structural variant association designs and problems

specific to this class of genetic association studies. CNPs with relatively high MAF can be analyzed in a relatively straightforward fashion in case–control association studies by comparing CNP frequencies in cases and controls, and the usual association study validity (e.g., as related to population stratification) considerations also apply in this case. If the analysis is performed using SNP microarray-derived data, quality control procedures developed for SNP data (e.g., call rate thresholding) are supplemented by strict quality control procedures that attempt to account for the high signal-to noise ratio of microarray-based intensity data and imprecisions in CNV detection (e.g., by adjusting probe data for batch effects and so-called genomic waves that affect probe signal intensities, and evaluating consensus between CNV calling algorithms; Diskin et al., 2008).

Another concern in CNV association studies is related to the difficulties in locating structural breakpoints specific to a particular structural variant: both true heterogeneity (i.e., presence of overlapping but not fully identical CNV segments associated with the trait) and genotyping/inference errors (i.e., when the same CNV is identified as having somewhat different start–end points for several samples) confound CNV association studies. Several strategies have been proposed to account for this issue by integrating CNVs in a study sample in a way that evaluates the boundaries between different CNVs and, for example, treats all common and unique CNV segments in the study sample as separate copy number variant regions (CNVRs). Since CNV association studies are relatively new in the field, comprehensive tools that perform CNVR detection and association analyses in an integrated fashion have only appeared recently (Forer et al., 2010; Kim et al., 2012). These tools also incorporate CNV association testing strategies for quantitative traits, most of which are based on familiar GLM techniques such as linear regression.

CNV association studies can also be performed in a family-based setting using designs similar to the ones used by SNP association studies, e.g., by using family trios or extended pedigrees. These data can be analyzed by recoding CNV data as pseudo-SNPs (and assigning minor allele counts to each sample based on the deviation from reference copy number) and using corresponding analytic techniques such as TDT. However, this two-step procedure (copy-number assignment and association testing), common to case–control CNV GWAS studies, has been criticized for artificial discretization of distributed intensity values and loss of power. Correspondingly, the FBAT approach that has been extended to CNV data in the GWAS context uses normalized probe signal intensities instead of assigned copy numbers to test for association between the trait (binary, quantitative, time-to-onset, and multivariate) and each marker (Ionita-Laza et al., 2008). Other association testing techniques for family-based designs based on variance component analysis for quantitative traits (Eleftherohorinou et al., 2011) or the further refining of the FBAT approach (Murphy et al., 2010) have also been proposed.

Family-based designs offer an important advantage over case–control CNV association designs as they permit evaluating the de novo (noninherited) status of CNVs when parental CNV genotypes are available. Determining the de novo status of a structural variant can be performed both after and during CNV calling (Chu et al., 2013). The popularity of the de novo or spontaneous/sporadic framework for CNV analysis is illustrative of the recent attention to the high per-generation genetic mutation rate in humans. For example, on average a newborn is expected to have ~70 new single nucleotide mutations in their genome with most of these mutations seemingly being of paternal origin (Keightley, 2012; Lynch, 2010). Although structural variants have not been precisely evaluated for their mutational properties yet, some estimates suggest that their mutational rate is lower than that of single nucleotide variants, and decreases with size. For example, new large CNVs over 100 kb long are estimated to occur once every 42 births (Itsara et al., 2010). However, de novo CNVs affect a significantly higher number of base pairs (16–50 kb) overall than single nucleotide variants (61 bp) per birth (Campbell & Eichler, 2013), and their deleterious potential is very high. As we mentioned above, CNVs became nearly synonymous with rare variants in genetic association studies, and in some cases the researchers' attention is exclusively focused on the role of rare de novo structural variants in the etiology of complex traits and disorders.

Although structural variant association studies are subject to the same statistical concerns and limitations as SNP studies, some of the issues are extremely pronounced in GWAS CNV investigations. Given the significant overlap in analytical approaches used for SNP and CNV association testing in the case/control setting, statistical power for CNV association tests can be evaluated using general power calculation tools. Recall that power is in part related to the frequency of the minor allele. Given their overall low frequency and genotyping issues that decrease power to detect CNVs described earlier, structural variants in general and CNVs in particular become difficult to detect in smaller-*n* studies (Wineinger & Tiwari, 2012). For example,

for single-marker tests, sample sizes above $n = 4{,}000$ might be required to detect an association even with higher MAF CNPs (Barnes et al., 2008).

Evaluating the impact of CNVs on a trait can be boosted by employing different collapsing methods, for example, by using CNV burden testing that evaluates the differences in estimated overall CNV frequencies or cumulative CNV length (burden) across different length bands between cases and controls. This powerful strategy can be augmented in a candidate–gene fashion by evaluating burden estimates for specific gene sets, such as for genes implicated in the candidate (or related) pathways and networks. In recent years, CNV burden has been linked to a host of developmental outcomes. For example, in one study individuals with intellectual disability and combined intellectual disability and multiple congenital anomalies have been found to harbor more large (>1 Mb) CNVs than control individuals or individuals with autism or dyslexia (Girirajan et al., 2011), and similar findings have been recently reported for ADHD (Yang et al., 2013).

DNA SEQUENCING: FROM SANGER SEQUENCING TO HIGH-THROUGHPUT NEXT-GENERATION SEQUENCING TECHNOLOGIES

So far we have been discussing genotyping methods and study designs that largely rely on the availability of genetic markers with known genomic locations and allele frequencies estimated for populations of different ancestries. In the case of linkage studies and in most cases of GWAS investigations, the statistical (linkage/association) signal is indicative of the location of the potentially causal variant which by itself is neither known precisely nor genotyped. Under these conditions, the causal mutation can be identified if the precise order of nucleotides in the DNA sequence is established for the candidate region. The Human Genome Project, the largest public scientific collaboration project in biology that took 13 years and $3 billion to complete, resulted in the publication of the working draft of the full sequence (also called the *reference sequence* or *human genome build*) of human genome (International Human Genome Sequencing Consortium, 2001, 2004), which revolutionized genetic science in terms of our knowledge about evolution, the number, location, and structure of human genes, the proteins they code for, and noncoding elements, led to the emergence of new fields such as proteomics (concerned with the identification and quantification of protein content in different organs and even cellular organelles) and directly or indirectly led to the development of technological, computational, and analytical tools that form the basis of the modern genetic science (Hood & Rowen, 2013).

The Human Genome Project relied on a combination of DNA sequencing technologies, most importantly the golden standard method of DNA sequencing based on Sanger's chemistry, developed in the 1970s (Sanger & Coulson, 1975; Sanger, Nicklen, & Coulson, 1977). Modern implementations of Sanger or first-generation DNA sequencing methods (e.g., methods that combine Sanger sequencing with capillary electrophoresis), albeit being faster, cheaper, and more automated these days, rely on the same sequencing approach. Sanger sequencing begins with the amplification of the target region of an unknown DNA sequence (called a *template*). A synthetic primer that is complementary to a region of the template is then hybridized to the single-stranded template, forming a double-stranded region that serves as a starting point for DNA chain extension by a DNA polymerase. The latter extends the sequence beyond the primer using complementary base pairing. A key element of Sanger sequencing is the addition of a small amount of dideoxynucleotide triphosphates (ddNTPs) to the reaction mix that also includes normal deoxynucleoside triphosphates (dNTPs). dNTPs (nucleotides) are standard building blocks of the DNA molecule, while ddNTPs lack a hydroxil group at the 3' position of the sugar that forms a phosphodiester bond between two nucleotides. The incorporation of a ddNTP into the growing DNA chain effectively leads to the termination of chain extension. In the solution where the same DNA chain is continuously synthesized, chain termination due to ddNTPs occurs randomly at all positions where the ddNTP nucleotide can be added to the chain. Thus, one reaction produces a set of synthetic products (*sequencing ladders*) of varying lengths, which can be separated according to their molecular weight. Four separate reactions are performed—one for each type of the nucleotide (A, T, C, and G). Originally, determining the actual genotype at each locus using the Sanger method relied on radioactive labeling of ddNTPs read via autoradiography of the sequencing gel that contained four adjacent lanes (one per nucleotide type). Radioactive labels were replaced with fluorescent labels and automated laser-induced fluorescence detection methods in the 1980s and 1990s. Current Sanger capillary sequencing methods use four different fluorophores in a single reaction; the sorting of DNA fragments by their molecular weight is performed using capillary electrophoresis, and less DNA is required for sequencing reactions due to multiple rounds of primer extensions coupled with the development of more sensitive detection

systems. Although Sanger sequencing remains the gold standard for targeted DNA sequencing, the application of this method in large-scale human projects (i.e., with a large number of individuals or multiple long DNA fragments) is limited by its relatively high cost and low throughput.

Modern sequencing platforms outperform Sanger sequencing by a factor of 100–1,000 in terms of daily bp throughput while reducing the cost of sequencing to .10–4% of Sanger sequencing costs when sequencing long (over 1 Mb) regions (Kircher & Kelso, 2010). These methods are typically referred to as *next-generation DNA sequencing* to reflect the paradigmatic change associated with the advent of commercially available high-throughput sequencing solutions in mid 2000s. For example, the 454 sequencing platform (Roche, Base) was the first non-Sanger technology to sequence an individual human genome (Wheeler et al., 2008). Unlike Sanger sequencing, this approach relies on pyrosequencing (Rothberg & Leamon, 2008) and can be used to sequence the whole genome or target regions of the genome. During DNA library preparation for pyrosequencing, the DNA that has been cut into short (1–1.2 kb) fragments is separated into single strands, and ligated to universal adapter primers. These adapter-ligated fragments are joined with microscopic beads (about 1 micron in diameter, with ~1 fragment per bead), which are then captured within droplets of oil–water emulsion, amplified using a PCR reaction (so that each droplet contains millions of copies of the original DNA fragment immobilized on the bead surface), and deposited into the picotiter plate (i.e., a plate that contains multiple wells that act as small test tubes) that contains fixed-location wells that can hold up to 1 bead each. Pyrosequencing reactions are then performed by sequentially washing single-nucleotide reagents and reaction enzymes over the plate (separately for each nucleotide). The actual sequencing relies on the detection of primer extension DNA polymerase activity using the so-called enzymatic cascade that generates light through the release of inorganic pyrophosphate when a specific (to the reaction) nucleotide is incorporated in a growing DNA strand. The pyrophosphate is converted to ATP by the enzyme sulfurylase, and a chemiluminescent enzyme, luciferase, then converts luciferin to oxyluciferin using ATP as a substrate. Light emission is monitored using cameras with fiber-optic bundles glued to a charge-coupled device (CCD). The emission is recorded at each step of the reaction and processed offline to infer the genotype at each nucleotide position.

Illumina's Genome Analyzer (also refer to as Solexa sequencing technology) is based on the four-color sequencing-by-synthesis approach that uses reversible terminator-based chemistry similar to that of Sanger sequencing (Bentley et al., 2008). For this platform, the DNA library also consists of adaptor-flanked fragments that are nevertheless shorter than those used with the 454 platform (generally up to several hundred bp). The DNA template is amplified using a bridge PCR method. In bridge PCR, both forward and reverse primers complementary to the adaptors' sequences are hybridized to a solid surface (*flow cell*) that contains eight independent channels. The immobilized DNA is then amplified to form spatially condensed clusters that contain multiple (~1,000) copies of the original template fragment in the form of arched single-stranded molecules. The resulting molecules are used as templates for DNA polymerase-based extension reactions that incorporate fluorophore-dyed terminator dNTPs into the synthesized DNA strand. Once a terminator dNTP has been incorporated, a CCD camera captures the fluorescent signal produced by laser excitation to identify the terminator nucleotide. The terminator group and the fluorophore are then removed for the next synthesis cycle (i.e., to determine the identity of the next base pair).

Both 454 sequencing and Genome Analyzer platforms can be used to sequence the whole genome by cutting it into smaller fragments and sequencing each of the fragments in parallel in the same reaction (*massively parallel sequencing*). This approach, called next-generation whole-genome sequencing (WGS), can be used effectively in three different applications: mutation discovery for Mendelian diseases that involve studying multiple affected individuals, discovery of the genetic architecture of complex traits and disorders, and clinical diagnostics of childhood disorders (Goldstein et al., 2013). The first two cases generally utilize designs familiar to the reader from the linkage and association sections of this chapter. Thus, DNA sequencing can be performed using samples of unrelated individuals that represent cases–controls or extremes of the quantitative phenotype variation continuum; allele frequencies can then be compared between the two cohorts at all genotyped loci that exhibit variation. In family-based designs, samples of related individuals are used to both detect mutations within the shared regions of the genome in extended pedigrees and reveal de novo mutations in family trios. Given the high cost of DNA sequencing, some studies only sequence affected individuals. Although causal mutations (i.e., for certain Mendelian disorders) can be identified based on their functional annotation and sharing among only the affected individuals, such studies sometimes utilize borrow controls from public repositories of sequencing data that have become available recently.

In this case, causal variant identification relies on multistep variant annotation (e.g., by obtaining information on the functional class and predicted effects of the variant) and filtration (e.g., by excluding common variants and mutations found in populations reportedly unaffected by the disorder in question). Note that DNA sequencing methods not only detect single nucleotide variants but also are capable of discovering small structural variants (indels), although the latter represent a certain bioinformatic challenge.

While Sanger sequencing is primarily used for targeted region sequencing (i.e., to sequence genes and regions under the linkage peaks or around significant association signals), WGS studies are similar to GWAS studies in the sense that they adopt a hypothesis-free approach by interrogating the whole genome. Given the high cost of next-generation sequencing in the context of association studies, however, targeted rather than whole-genome applications of next-generation sequencing have become popular in recent years. These applications and designs use DNA sequence capture chemistry to isolate regions of interest that are then subjected to sequencing. One of the most popular applications of targeted next-generation sequencing is whole-exome sequencing (WES) that is aimed at sequencing only the coding regions of the DNA by performing exome capture reactions prior to sequencing. Given the cumulative abundance of rare coding variants of potentially high functional impact in the human genome and the coding nature of most mutations underlying Mendelian disorders, WES has recently become the state-of-the-art tool for Mendelian disorder gene discovery (Bamshad et al., 2011).

Next-generation sequencing studies rely not only on an impressive set of recent technological but also on computational developments that permit analysis of extremely large data sets. Recall that massively parallel sequencing means that a multitude of genomic fragments are sequenced in parallel. For example, Illumina's HiSeq 2000 systems that are frequently used for WGS/WES applications are based on the Solexa method described above and generate 600 Gb of data in 12 days; these data include 3 billion ~100 bp reads per run. The generation of raw sequencing reads is only the first step in what became one of the most computationally intensive bionformatic paradigms in biological science. After extensive data preprocessing aimed at removal of low-quality reads, read trimming and removal of adapter sequences, the reads needs to be aligned to the reference genome. Since the reference sequence of the human genome is available, millions of short reads of unknown location generated by DNA sequencing platforms can be aligned (or mapped) to the reference genome. A variety of tools have been developed (Li & Homer, 2010), and their use typically requires both a certain expertise in bioinformatics and the availability of computational resources (e.g., a computing cluster). Most alignment algorithms construct reference genome indexes, read sequence indexes, or both. These indexes are then used in conjunction with statistical inference algorithms that find the part of the genome that corresponds to each read. Additional quality control procedures are typically employed after the reads have been aligned and sorted according their location, and are aimed, for example, at increasing the quality of indel detection by performing local realignment (or de novo assembly) for regions that contain indels. The third essential step is called variant calling and is performed on multiple overlapping aligned reads (e.g., typically with a goal of obtaining ~20x coverage at each genomic location). At the time of the writing of this chapter, a comprehensive bioinformatics pipeline developed by the Broad Institute at MIT has become the gold standard in WGS/WES variant calling. This pipeline uses a freely available Genome Analysis Toolkit (McKenna et al., 2010) to perform variant calling using HaplotypeCaller, an algorithm that uses a combination of de novo assembly and a Hidden Markov Model to identify possible haplotypes in the data and assign sample genotypes. GATK has been shown to outperform other variant calling tools in the majority of current human applications of next-generation sequencing methodologies (Ghoneim, Myers, Tuttle, & Paciorkowski, 2014; Liu, Han, Wang, Gelernter, & Yang, 2013).

Once the genotypes have been assigned to samples, the data produced by DNA sequencing can be analyzed using statistics similar to those developed for single nucleotide and structural variants described in the section on association studies. Given the large amount of data produced by WGS/WES studies (e.g., an individual genome is expected to have ~20,000 departures from the reference sequence), next-generation sequencing studies heavily rely on variant filtration, annotation, and prioritization to reduce the search space for the causal variant. Some of these methods use algorithms we referred to before when describing the evaluation of the functional impact of SNPs in association studies; these and other algorithms are frequently used in combination with each other to integrate data on the predicted effects of the genetic variant (e.g., using amino-acid substitution and phylogenetic conservation analysis; Hu et al., 2013) with other data such as the similarity between the phenotype in question with that of genetically modified model organisms (e.g., mouse; Robinson et al., 2014), or the presence of the variant in public databases or linkage

data (Zhang et al., 2013). Over 200 tools have been developed in the past decade for the analysis of WGS/WES data. A comprehensive overview of these tools is available elsewhere (Pabinger et al., 2014).

The statistical power of classic single-marker association tests is low for rare genetic variants, and while large samples (similar and exceeding those for GWAS studies) are required for studies of complex traits and common disorders, they are currently unattainable given the high cost[18] of next-generation sequencing. A new generation of statistical tests for rare-variant association testing has been developed to address the needs of next-generation sequencing studies. These methods include region- and gene-based multimarker tests that collapse rare variants into genetic scores (burden tests) and are useful when many rare variants are causal and produce effects in the same direction, and variance-component or random-effects methods that evaluate distributions of (weighted) aggregated score statistics of individual variants instead of collapsing them. These are more useful in case the region contains multiple non-causal variants and variants have different directions of association (Lee, Abecasis, Boehnke, & Lin, 2014; Moutsianas & Morris, 2014). Specific association methods have been developed for family-based sequencing studies, and these methods have been shown to outperform population-based association methods in case of dichotomous traits, while population-based tests offer higher power for continuous traits (Ionita-Laza, Lee, Makarov, Buxbaum, & Lin, 2013).

While low statistical power remains the main limitation of next-generation sequencing studies of human traits and disorders, the reader should in general be cautious when interpreting results from WGS/WES studies. First, technical errors can dramatically affect the false positive rate of next-generation sequencing studies. For example, one of the biggest technical challenges of next-generation sequencing is the presence of multiple repetitive DNA segments in the human genome that lead to ambiguities in read mapping and variant detection (Treangen & Salzberg, 2012). Second, variant filtration typically requires some sort of decision criteria to be imposed on the data set, and the researcher risks excluding the causal variant from the search set. Third, certain types of genetic variants of particular interest to researchers such as loss of function variants or variants located in regulatory regions are actually enriched for artifacts (MacArthur et al., 2012) or have low sequence coverage (Wang, Wei, Lam, & Wang, 2011), and, correspondingly, higher coverage (e.g., 60x coverage) and cost are required to accurately infer the genotype. Fourth, the same population ancestry and stratification concerns that apply to GWAS association studies also apply to WGS/WES studies. Fifth, current implementations of next-generation sequencing are limited with respect to their ability to accurately detect structural variants larger than indels (Zhao, Wang, Wang, Peilin, & Zhao, 2013). Finally, unlike the field of GWAS studies that has seen the emergence of study design, genotyping, analysis, replication, and reporting standards in recent years, the field of next-generation sequencing at the moment lacks these community-approved standards (Pulit, Leusink, Menelaou, & de Bakker, 2014), which significantly complicates the interpretation of next-generation sequencing studies that have already produced an extraordinary amount of data.

Next-generation sequencing revolutionized the field of genetics, and this technology offers the field of developmental psychopathology a new tool for identifying the genetic architecture of complex traits in a comprehensive fashion. For example, Sanders and colleagues (2012) performed a WES study of de novo single nucleotide mutations in 238 families from the Simons Simplex Collection, a cohort of pedigrees with at least one child affected with autism spectrum disorder (ASD), two unaffected parents, and (in 200 families) an unaffected sibling. This study estimated that disruptive de novo mutations are found in 14% of probands with ASD and showed that rare non-synonymous disruptive mutations in brain-expressed genes (in particular, *SCN2A, KATNAL2*, and *CHD8*) are associated with ASD with effect sizes similar to those for previously identified large CNVs. WGS/WES studies are rising, slowly replacing (or at least augmenting) GWAS studies of complex traits, and while the challenges outlined in the previous paragraph limit the utility of WGS/WES-generated data, next-generation sequencing is likely to become the new standard in molecular genetic studies of complex traits, signifying the transition to the post-GWAS era or next-generation sequencing era. In this section, we reviewed only two out of several commercially available next-generation sequencing platforms, and the interested reader is welcome to further familiarize

[18]The arrival of Illumina's HiSeq X Ten ultra-high-throughput sequencer in 2014 marked a milestone in DNA sequencing prices, which have been dropping since the advent of next-generation sequencing platforms: i.e., the cost decreased to ~$1,000 per genome (compare with $100,000,000 in 2001 and ~$50,000 in 2010; van Dijk, Auger, Jaszczyszyn, & Thermes, 2014). It is important to note, however, that this estimate is based on projected sequencing of 18,000 genomes per year over a four-year operational period, and only several HiSeq X Ten sequencers have been installed worldwide at the time of the writing of this chapter.

themselves with these platforms by referring to specialized sources (Harismendy et al., 2009; Mardis, 2013).

The next-generation sequencing era will likely be replaced by the next-next (or third-) generation sequencing era grounded in recently developed technologies that do not rely on the amplification of DNA fragments that leads to polymerase errors during library construction, preferential amplification of certain regions over others, and dilution of DNA modifications (e.g., DNA methylation). Single-molecule next-next-generation sequencing approaches such as nanopore sequencing (detection of DNA bases based on their effect on an electrical current or optical signal during the passing of the molecule or the bases through small natural or synthetic nanopores) can potentially overcome some limitations of next-generation sequencing platforms by offering affordable, quicker, and accurate (e.g., due to the absence of the amplification step and longer resulting reads) solutions for DNA sequencing (Schadt, Turner, & Kasarskis, 2010). These methods will likely bring a host of new methodological and analytical challenges with them. Until that time has come, however, current WGS/WES studies rely on next-generation sequencing platforms and approaches described above.

GENE EXPRESSION PROFILING

As we mentioned in the beginning of this chapter, variation in gene expression underlies such key developmental processes as cellular proliferation, differentiation, and plasticity in response to both external and internal factors. Recall that the first stage in protein synthesis, transcription, results in the synthesis of an mRNA molecule that is used as a template at the translation stage. Thus, the concentration of a particular RNA product is indicative of the level of the expression of the corresponding gene in the studied tissue. The full set of gene transcripts (transcribed from genomic DNA) in a cell at a particular stage of development and their quantity is called a transcriptome, and gene expression analysis (also called *transcriptome* profiling) has become one of the most widely applied methods in developmental biology. The main objective of gene expression analyses is to establish patterns of differential gene expression between different samples that might be obtained from the same group of individuals (e.g., different areas of the brain in a within-subject design) or from several groups of individuals (e.g., comparing peripheral blood gene expression levels in individuals who were or were not exposed to toxic stress in a between-subject design). Correspondingly, genes that are found to be differentially expressed between the two samples are likely involved in one or more etiological pathways for the trait.

The majority of gene expression studies rely on the microarray technology that we covered in the SNP genotyping section (in fact, we indirectly mentioned this method when touching upon eQTLs—expression microarray data remain the main source for endophenotypic data on gene expression). Library preparation for such studies requires using RNA to synthesize a complementary DNA (cDNA) molecule that is more stable than the RNA molecule during a process known as reverse transcription. Oligonucleotide probes that are located on the microarray are partially complementary to the most unique regions of each studied gene, and the evaluation of gene expression is based on the analysis of laser-induced fluorescent signals emitted by the fluorophore-labeled amplified cDNA hybridized to the microarray surface. For example, Affymetrix GeneChip Tiling Arrays, one of the most commonly used platforms, uses multiple probes (a probe set containing 11–20 pairs of probes—each pair includes a perfect match probe and a mismatch probe that is created by changing the middle base of the perfect match probe; it is used to measure nonspecific binding and correct for technical artifacts) per gene to arrive at the aggregate signal indicative of transcript abundance in a particular sample. Note that probe intensity confounds the true hybridization signal with other signals (e.g., from cross-hybridization, nonspecific binding, or system noise), and preprocessing methods that adjust for background noise (e.g., by subtracting the mismatch probe intensities from perfect match intensities) and batch effects are necessarily applied to the signal before further analyses.

Gene expression microarray studies rely on the comparison of normalized expression patterns between different samples. For a long time, fold change (the A/B ratio where A and B are intensity levels for a particular gene transcript for two samples) has been used as the main statistic to identify differentially expressed genes with relatively arbitrary fold change value (e.g. >2) cutoffs. However, this approach can produce biased estimates of gene expression and is insensitive to differential expression of genes that have extremely high as well as extremely low expression values (intensities), and inferential statistical methods such as the two-sample t-test (as well as its robust modifications that are less sensitive to outliers) have been proposed to evaluate differences in average expression levels between samples. Like GWAS studies, gene expression studies face the familiar problems of multiple comparisons and low statistical power (e.g., requiring ~32 samples per group to detect a twofold change in the 75% least variable genes

at 90% power and $p = .001$; Wei, Li, & Bumgamer, 2004; note that the current cost for a whole-genome microarray expression profiling is ~$500–750 per sample), and similar approaches have been taken to account (correct) for multiple comparisons or reduce the number of tests by analyzing differential expressions of sets rather than individual genes. For example, the Gene Set Enrichment Analysis (GSEA) focuses on sets of genes that share a common biological function, genomic location, or regulation (Subramanian et al., 2005) instead of identifying individual genes that are differentially expressed in two or more samples. In addition to partially ameliorating the multiple comparisons problem, GSEA has a number of other advantages over single-gene analyses such improved signal-to-noise ratio and its ability to identify and formally evaluate changes in pathways and processes relevant to the studied phenomenon.

In addition to microarray methods, sequence-based approaches have been developed as a method for gene expression profiling. These include early methods that used Sanger sequencing of cDNA and, most recently, RNA sequencing (RNA-Seq). RNA-Seq methods rely on the application of existing high-throughput sequencing technologies (e.g., 454 sequencing reviewed above) to cDNA libraries. RNA-Seq approaches, compared with microarrays, have low background signal given successful mapping of cDNA to the reference transcript sequence and, correspondingly, detect expression levels in the greater dynamic fold range; they are also more accurate at quantifying expression levels, leading to a higher degree of reproducibility (Marioni, Mason, Mane, Stephens, & Gilad, 2008; Wang, Gerstein, & Snyder, 2009). However, sample library preparation and RNA/cDNA fragmentation procedures involved in it can produce specific biases with respect to expression quantification, and special care should be exercised during sample library construction and data analysis to account for these biases.

Transcription levels are typically inferred using the total number of reads mapped onto gene exons normalized by the length of exons that can be uniquely mapped (Morin et al., 2008). Like next-generation DNA sequencing studies, RNA-Seq studies face a number of bioinformatic challenges such as the necessity to perform extensive quality control procedures (e.g., to correct for sequencing platform biases), dependence of statistical power on read depth which is related to both gene expression level and its length (i.e., longer transcripts typically have larger numbers of reads at the same expression level), with appreciable effects on the results of expression profile comparisons (Bullard, Purdom, Hansen, & Dudoit, 2010; Tarazona, García-Alcalde, Dopazo, Ferrer, & Conesa, 2011). Like DNA sequencing studies, RNA-Seq studies in human also greatly depend on the availability of the reference genome builds and the accumulating data regarding the spectrum of transcripts found in human cells. The presence of alternative transcripts (i.e., when the same gene gives rise to multiple transcripts/proteins due to a process known as *alternative splicing*) and problems aligning reads spanning exon junctions significantly complicate the mapping stage of the RNA-Seq studies; correspondingly, instead of the reference genomic DNA sequence, these studies sometimes use de novo assembly of transcripts or specific exon junction-modified sequence libraries to map the raw reads. Read mapping, normalization, expression level summarization and analysis of differential expression represent the main stages of bioinformatic analyses of RNA-Seq data, and multiple alternative computational approaches and tools have been proposed to tackle issues specific to RNA-Seq studies. These tools are comprehensively reviewed elsewhere (Bullard et al., 2010; Oshlack, Robinson, & Young, 2010; Soneson & Delorenzi, 2013).

Gene expression studies investigate expression levels in specific tissues (e.g., whole blood or brain gray matter). This specificity is one of the key features of expression studies, but it calls for extra care during study design, sample preparation, data analysis, and interpretation of results. Human expression studies that focus on complex neuropsychiatric and developmental phenotypes depend on the availability of relevant tissue samples. A natural strategy in this type of study is to examine differential gene expression in tissues relevant for the phenotype—that is, the brain. However, that requires justification of the selection of particular brain regions for the analysis that itself is based on data obtained from post mortem brain samples. In addition to ethical and practical concerns associated with obtaining these samples, such studies face the issue of post mortem RNA stability, and ensuring RNA integrity in these progressively degrading samples is of pivotal importance for precise expression quantification (Birdsill, Walker, Lue, Sue, & Beach, 2011). In the absence of post-mortem samples, it would be tempting to evaluate global differential gene expression patterns between two samples using whole blood samples, as peripheral blood is easier to acquire. However, whole blood gene expression levels are not perfectly correlated with gene expression levels in central nervous system tissues (Sullivan, Fan, & Perou, 2006). Correspondingly, researchers should be extra careful when interpreting results obtained from peripheral

blood samples, especially with respect to genes that are not expressed in either brain or blood, or, in general, show differential expression between blood and brain. Sample type selection represents just one of multiple issues in studying gene expression in developmental populations.

The human transcriptome is dynamic and its temporal dynamics reflect regulatory (re)organization of gene expression throughout the lifespan, which is especially pronounced in the human brain prenatally and neonatally (Colantuoni et al., 2011; Kang et al., 2011). The dynamic nature of the transcriptome, coupled with its tissue specificity (e.g., high variability between different brain regions and even different cortical layers) effectively requires researchers to carefully examine the hypothesis space generated by the combination of these factors and their research question. However, as the field matures, refines its methodology and produces enough publicly available data (e.g., as is realized in the BrainAtlas, http://www.brainspan.org, a public resource for spatiotemporal expression patterns across anatomical brain structures and different developmental stages), it will likely significantly advance our understanding of the biological machinery underlying both typical and atypical development.

FUTURE DIRECTIONS

Within the next few years (or at least for the duration prior to the publication of the next volume of this Handbook), the applications of molecular-genetic findings in the developmental science in general and developmental psychopathology in particular will likely only grow in popularity. Therefore, it is particularly important that the field introduces high standards for the design and methods employed in such studies.

Combining different methodologies in the same study, although challenging and costly, will likely generate a more comprehensive view of the molecular genetic architecture of developmental psychopathology traits. This statement applies to the combination of different phenotyping methods (e.g., by augmenting binary disease phenotypes with quantitative subphenotypes or endophenotypes such as neuroimaging data), as well as molecular genetic methods (e.g., by combining GWAS and WGS/WES methodologies to increase resolution and power).

It is also important, as it is in studies of somatic disorders, to encourage different groups interested in the same phenotype, either typical or atypical, to homogenize the methods used for generating both the phenotypic and molecular data used in the developmental sciences. Finally, the field should exercise high standards for the procedures followed when both original and secondary (partially or completely) analyzed data are available for independent meta- and mega-studies. Homogenization of phenotyping, genotyping, and analyses enables big science projects like the formation of large consortia that are aimed at investigating the genetic etiology of traits based on the pooled data from multiple populations and research groups—a crucial advantage given that small sample sizes remain one of the main obstacles in trait-associated genetic variant discovery.

CONCLUSION

The main goal of this chapter was to provide the readers with a succinct yet comprehensive sampling of the molecular genetics methods used to study human traits, in particular developmental and developmental psychopathology traits. These methods range from the discovery of the regions of the genome shared by individuals affected with a particular disorder to the quantification of the degree to which a particular gene (or genes) is expressed in a particular tissue. This variety of methods can be applied in a targeted (candidate) or a whole-genome fashion, and the choice ultimately depends on researchers' agendas and prior knowledge about the phenotype and its genetic and molecular etiology. We attempted to build our narrative to familiarize developmental researchers with this complex methodological toolbox in a non-technical way. Given the scope of the field, however, interested readers are welcome to consult with a variety of original research and review sources referenced in this chapter. In this section of the chapter, we would like to offer several brief concluding remarks.

Although the title of the chapter (correctly) assumes that all of the reviewed molecular genetics methods can be used to study human development, the extent to which they can be applied to developmental phenotypes in general, and developmental psychopathology in particular, has been limited for multiple reasons. Recruiting developmental populations for interdisciplinary, biologically oriented studies and characterizing them with respect to complex phenotypes is inherently a difficult task, undermined by uncertainties in and costs of phenotyping, issues that deserve a methodological treatment in their own separate chapter. Perhaps even more difficult is the integration of multiple levels of analysis that such studies demand.

As the fields of developmental science and developmental psychopathology are just crystallizing, it is not surprising that comprehensive frameworks for such integration are yet to be developed.

The research methods and studies reviewed in this chapter point at their complexity but also at their heterogeneity with respect to the establishment of gold standards in the field. For example, GWAS studies are probably familiar to most researchers interested in the genetic architecture of complex traits, and although the accumulation of evidence produced by these studies has been rapid, the field has had enough time to reflect upon its methodological but also theoretical limitations and challenges. On the other hand, DNA and RNA sequencing studies that use next-generation sequencing approaches have had a much shorter history, and the authors of this chapter can attest to the significant amount of methodological inconsistencies across these studies. These inconsistencies are in part related to the field's responses to the technological and computational/analytical challenges it is only now becoming familiar with. They are likely to be at least partially resolved in the near future, and public data sharing, although plagued with its own problems (e.g., ethical concerns), will likely play a pivotal role in this process. Crucially, however, most of the progress in complex trait genetics has been tied to studies of somatic disease or adult psychopathology rather than psychological phenotypes and developmental psychopathology. In that respect, the field is open to the new generation of developmental scientists and the interdisciplinary studies that will necessarily capitalize on this progress but that will also face their own challenges.

For better or for worse, molecular genetic methods for the research of complex phenotypes have been embedded into the developmental sciences just as strongly as any method in the neighboring sciences. This, of course, assumes that whatever rigor is characteristic of the utilization of these methods in their native disciplines, such as genetics or genomics, the same should be exercised in the developmental sciences. This, of course, does not assume that there should not be a certain amount of reasonable adaptation of these methods with regard to how and why these methods should be utilized in developmental sciences, but rather that their adaptation should be carried out with caution and with direct and indirect references to the lessons learned from the utilization of these methods in their native disciplines, genetic epidemiology and genetics and genomics.

One of the most important steps in our progress toward understanding the molecular underpinnings of human development via molecular genetics methods is the facilitation of cross-talk between specialists trained in complementary albeit compartmentalized subfields that serve as the foundation for the emergent fields mentioned above. To this end, it is our hope that we have succeeded in providing an overview that can be used as a starting point for the new generation of developmental scientists, but also for seasoned researchers coordinating (or hoping to coordinate) such interdisciplinary research.

INTRODUCTION

Both genes and environmental events have long been recognized for their significant contribution to the development of behavior, and in turn, phenotypic variation among individuals. Recent work with animal models of early-life stress, depression, and addiction along with human studies focused on infant behavior and stress have revealed that genes and the environment are inextricably linked by epigenetic factors, whereby the environment can create biochemical changes that affect gene activity (Branchi, 2009; Champagne, 2010; Dudley, Li, Kobor, Kippin, & Bredy, 2011; Wong, Mill, & Fernandes, 2011). This revelation has afforded a new framework for our understanding of how psychological and social-contextual factors can interact with our biology. These factors have given us too a valuable measure informative of norms and aberrations present at the molecular level. Furthermore, these factors give us a mechanism to understand how risk and protective factors can leave their mark on our genome and a route through which behavior could arise. The birth of epigenetics research thus has major implications for the field of developmental psychopathology and its tenets (Cicchetti, 1993, 2006; Sroufe & Rutter, 1984).

In this chapter, we discuss key studies that have helped define our current understanding of epigenetics in the development of behavior. We draw on work using animal models with relevance to developmental psychopathology and studies in which the translation of these findings has been made to humans. As the development of behavior is a process that extends throughout the life span, a central theme that is also explored in this review is that epigenetic regulation of genes is not a process exclusive to developing organisms, but is an active process that continues throughout life into senescence. Throughout our chapter and within the conclusion, we also raise several questions that need to be addressed in order to advance our understanding of the link between epigenetics and behavioral outcomes.

EPIGENETICS: THE BASICS

Before discussing studies of relevance to the field of developmental psychopathology, it is necessary to understand some basics of epigenetics. In a cell's nucleus, DNA is

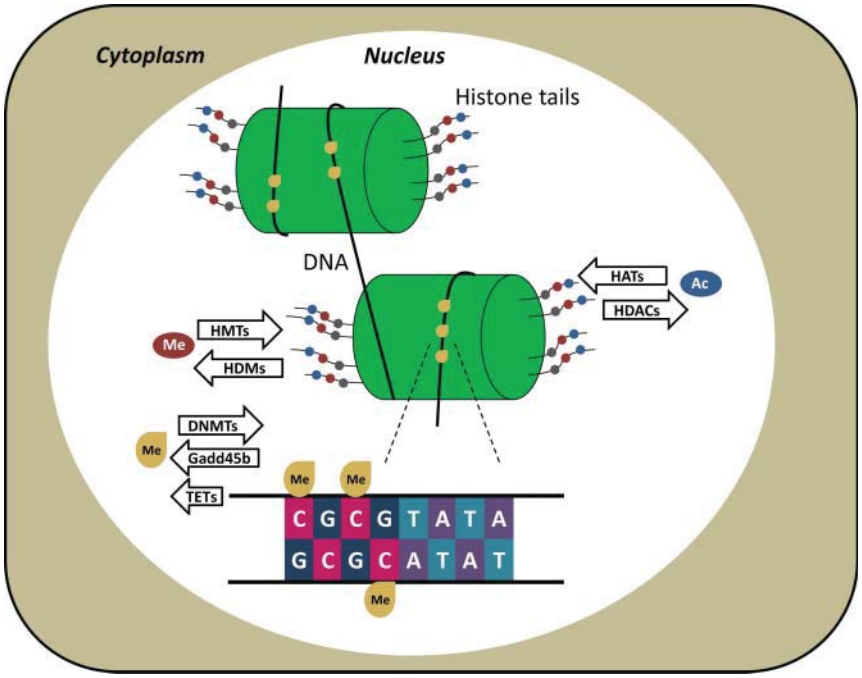

Figure 11.1 In the nucleus, DNA is wrapped around histone proteins, forming a DNA-protein complex called chromatin. DNA-histone interactions occur at the N-terminal tail of histones. On these tails reside many sites for epigenetic marking, including acetylation (Ac-blue), methylation (Me-red), and phosphorylation (P-gray). Acetylation occurs when there is the addition of an acetyl group via an enzyme called histone acetyltransferase (HAT). Deacetylation occurs when the acetyl group is removed by enzymes called histone deacetylases (HDACs). In a similar fashion, methyl groups can be added via histone methyltransferases (HMTs) or removed by histone demethylases (HDMs). Within the bottom portion of the figure is a schematic of DNA methylation, in which methyl groups (Me-tan) can be added to cytosine-guanine dinucleotides by DNA methyltransferase (DNMTs) enzymes. Gadd45b and TETs can facilitate active DNA demethylation. See footnote 1.

wrapped around histone proteins, forming a complex called chromatin (Figure 11.1). An easy way to consider histones is to think of them as spools and of the DNA as the thread that wraps around them. The backbone of DNA is negatively charged so it wraps around the positively charged histones. Without the histones (spools) to wrap around, DNA could not fit inside a cell nucleus.

To help determine whether DNA is accessible for gene transcription, chemical modifications to histones and the DNA strands themselves govern whether chromatin structure is in a state permissive for gene transcription (open and less tightly packaged, a structure referred to as euchromatin) or not (closed and tightly packaged, or heterochromatin). The histone proteins have amino acid tails that protrude beyond the DNA, and these amino acid residues are prone to chemical modifications that include acetylation and methylation (Berger, 2007). Histone acetylation, or the addition of acetyl groups to lysine residues on a histone tail, is a process catalyzed by enzymes called histone acetyltransferases (HATs). CREB binding protein (CBP) is one known HAT regulating chromatin structure. The addition of an acetyl group neutralizes the positive charge on histones, thereby decreasing the interaction with the negatively charged phosphates of DNA. This helps remodel (loosen) chromatin to a state permissive for gene transcription. Histone acetylation is rapid and reversible in an experience-dependent manner, but it too can be long-lived. Histone deacetylases (HDACs) are enzymes that remove the acetyl groups and reverse the effects of HATs. These help drive the state of chromatin back to a more closed form permissive to silencing gene activity. As an aside here, HDACs have much structural diversity and because of this are receiving research attention as possible targets of therapeutic interventions to increase gene activity.

Though far less studied in the behaviors we will review in this chapter, we are learning that histone methylation likewise is a crucial regulator of behavioral change and this modification can either suppress or activate gene transcription depending upon which amino acid residue of the histone is targeted and the degree of methylation that occurs. For example, up to three methyl groups can

be added to lysines, producing mono-, di-, and trimethylation patterns (Akbarian & Huang, 2009). H3K4 di- and trimethylation and H3K9 monomethylation are associated with gene transcription whereas H3K27 di- and trimethylation and H3K9 di- and trimethylation are linked with gene suppression. Histone methylation is catalyzed by enzymes called histone methyltransferases (HMTs), whereas enzymes called histone demethylases (HDMs) catalyze demethylation. Together, histone modifications help regulate gene activity by integrating numerous responses to signal biochemical cascades and repelling/recruiting chromatin remodeling and transcription factors making gene loci either more or less available to transcriptional modulation (Berger, 2007; Kouzarides, 2007).

DNA methylation is another epigenetic process that affects gene activity, and as will become clear in later sections, is an epigenetic factor that has really emerged as a leading candidate biological pathway linking gene–environment interactions to long-term and even multigenerational trajectories in behavioral development. DNA methylation often occurs at cytosine residues of cytosine-guanine (CG) dinucleotides, sequences that are highly underrepresented in the genome but often clustered within so-called CpG islands located within gene regulatory regions. DNA methyltransferases (DNMTs) are enzymes that catalyze the transfer of a methyl group, and de novo DNMTs (DNMT3a and DNMT3b) methylate previously unmethylated CG sites in DNA (Moore, Le, & Fan, 2013). The maintenance DNMT isoform (DNMT1, though it appears to regulate de novo methylation in some cases) perpetuates methylation marks after cell division, regenerating the methyl-cytosine marks on the newly synthesized complementary DNA strand that arises from DNA replication (Moore et al., 2013). The predominant view in the literature is that methylation of DNA is associated with suppression of gene transcription. The precise molecular processes through which this occurs are complex, but in essence methylated cytosines in turn can bind repressor proteins, including the methyl-binding domain protein MeCP2 and HDACs (Moore et al., 2013). DNA methylation (and deacetylation of histones) promotes a higher affinity interaction between DNA and the histone core, ultimately blocking access for transcriptional machinery and thus suppressing gene transcription.

It is important to note that while most evidence indicates that DNA methylation is associated with reduced gene activity, a handful of studies have indicated that DNA methylation can also be associated with transcriptional activation (Chahrour et al., 2008; Uchida et al., 2011). Regardless of suppressing or activating gene activity, DNA methylation is recognized as one of the most stable epigenetic processes affecting gene expression. As for a way to remove the methyl groups, historically in the epigenetics field, demethylation has been viewed largely as a passive process in differentiated cells, whereby multiple rounds of cell division without DNMT-mediated re-methylation is necessary to erase epigenetic marks. The idea of whether there is active DNA demethylation in post-mitotic cells, such as neurons, has been controversial. Our current understanding of active DNA demethylation is via a DNA repair-like mechanism catalyzed by Gadd45b (Ma, Guo, Ming, & Song, 2009) or oxidation by ten-eleven translocation (TET) proteins (Guo, Su, Zhong, Ming, & Song, 2011; Williams, Christensen, & Helin, 2012). A demethylase, MBD2, may also be responsible for active DNA demethylation in some cases (Detich, Theberge, & Szyf, 2002).

Though histone modifications and DNA methylation have been the most-studied epigenetic mechanisms in regards to behavior to date, increasing evidence is showing that genes (and behavior) can also be epigenetically regulated by noncoding RNAs, or RNA transcripts that have no apparent protein product. For example, microRNAs (miRNAs) are small, single-stranded RNAs with around 22 base pairs that can silence gene expression through mRNA degradation, inhibition of translation, and destabilization (Bartel, 2009). While at present we do not have a complete picture of the role of noncoding RNAs in gene regulation and behavior, it is becoming increasingly clearer that dysregulation of noncoding RNA-epigenetic pathways has relevance to understanding behavior and disease etiology (Bredy, Lin, Wei, Baker-Andresen, & Mattick, 2011; Sato, Tsuchiya, Meltzer, & Shimizu, 2011).

EPIGENETIC FACTORS AND OUTCOMES ASSOCIATED WITH PRENATAL ENVIRONMENTAL EVENTS

The intrauterine environment has long been recognized for its major contributory role in optimizing growth and development of an individual, and environmental events within this context are well recognized for their ability to affect behavioral development. For example, exposure of pregnant women to war-related stressors (including dietary restrictions) in the 1940s has been associated with an increase in prevalence of schizophrenia (SZ) and anxiety disorders in their offspring (Susser, Hoek, & Brown, 1998; van Os & Selten, 1998). Maternal emotion and psychological distress during pregnancy have been shown to predict

children's later emotional behavior (O'Connor, Heron, Golding, Beveridge, & Glover, 2002). Though such data (and numerous others) provide compelling evidence that early-life factors can predispose individuals to particular behavioral outcomes over the life course, it has not been until the past decade or so that empirical evidence has yielded a plausible mechanism for this notion.

Beginning in the early to mid-2000s, work using rodents where the prenatal environment could be experimentally altered began to provide direct evidence that one way prenatal events could alter developmental trajectories was indeed through bona fide epigenetic changes to genes. By altering nutritional cues within the prenatal environment while holding all other environmental factors and animals' experiences constant, researchers began to establish causality between prenatal nutritional exposure and phenotypic outcome (Waterland, 2006; Waterland & Jirtle, 2003). In these classic studies, pregnant Agouti mouse dams were provided dietary supplements comprised of methyl donors (e.g., methionine and folate). Offspring born to mothers who had not been fed the special methyl-donor diet had developmental outcomes characterized with yellow coat colors and overeating tendencies. In contrast, offspring born to mothers who had been fed the special diet had brown coat colors and did not overeat. The difference in developmental outcomes between the cohorts of mice was shown to be attributable to DNA methylation differences at genes controlling coat color and feeding behavior.

Since this seminal work, studies focusing on the developmental origin of health and disease have continued to identify links between early nutrition, epigenetic processes, and phenotypic outcomes. Additional work in rodents provides further empirical evidence of epigenetic factors linking maternal over-nutrition to adverse health outcomes in her offspring. For example, consumption of a high-fat diet during pregnancy has been shown to produce offspring that prefer sucrose and fat in adulthood, a phenotype that is accompanied by DNA hypomethylation (mean less methylation) and increased expression of several reward-related genes (including those encoding for the mu-opioid receptor and dopamine reuptake transporter) within the nucleus accumbens or prefrontal cortex, brain epicenters of appetite and reward (Vucetic, Kimmel, Totoki, Hollenbeck, & Reyes, 2010). Individuals who were prenatally exposed to famine during the Dutch hunger winter of 1944–45 have been shown, 6 decades later, to have less methylation of DNA associated with an important imprinted gene regulating body growth (insulin-like growth factor 2 [Igf2]) compared with unexposed, same-sex siblings (Heijmans et al., 2008). A recent study in Gambia has suggested DNA methylation patterns in first generation offspring differ depending on season of conception, in a context where diet varies greatly according to season (Waterland et al., 2010). Finally, mothers who reportedly consumed an unbalanced diet during pregnancy (one that has been linked to elevated blood pressure and cortisol in offspring) have offspring that display altered methylation of genes involved in cortisol regulation and body growth (11β-hydroxysteroid dehydrogenase type 2 [HSD2], glucocorticoid receptor [GR], and Igf2 [Drake et al., 2012]).

A growing body of work has also established epigenetic factors in pathways responsible for the negative impact of environmental toxins on current and subsequent generational offspring. During embryogenesis, exposure to the endocrine disruptor Vinclozolin (achieved by exposing gestating females) causes epigenetic programming of the germ-line that has transgenerational consequences for behavior and disease for future generations. For example, behavioral studies performed on Vinclozolin-exposed F3 generation animals show increased anxiety-like behaviors, hyperactivity, and impulsivity that coincided with alterations in gene expression networks within the amygdala (Skinner, Anway, Savenkova, Gore, & Crews, 2008). In more recent work from this line of research, investigators have shown that a single exposure to Vinclozolin likewise alters male descendants' (three generations removed) response to chronic restraint stress experienced during adolescence (Crews et al., 2012). Specifically, males with only the experience of adolescent stress (no prenatal fungicide exposure) show lower anxiety levels in an open-field test, whereas males with the cumulative experience of Vinclozolin in their lineage (i.e., their ancestors were exposed) and adolescent stress show higher levels of anxiety in the same test. Observations based on their study design are consistent with a two-hit model where exposure to chronic stress during adolescence (second hit) clearly influences subsequent brain development and behavior but they themselves are altered by ancestral exposures and epigenetic programming (first hit).

In 2008, a seminal investigation highlighted the role of epigenetic mechanisms in the maladaptive effects of prenatal stress on adult hypothalamic-pituitary-adrenal (HPA) responsivity and behavior (Mueller & Bale, 2008). Researchers found that adult males born to mothers who had been subjected to gestational stress exhibited marked changes in expression of the corticotropin-releasing factor (Crf) and GR genes, increased HPA-axis responsivity, and a depressive-like phenotype (anhedonia for example). CRF is secreted by the hypothalamus in response to stress, with

consequent secretion of adrenocorticotropin from the anterior pituitary and glucocorticoids from the adrenal gland. Examination of the Crf gene in these adults indicated that the prenatal stress regimen had significantly reduced methylation of specific cytosines with the regulatory region of the Crf gene in both the hypothalamus and amygdala. Reduced methylation parallels their observation of increased Crf gene expression, which together contributed to the depressive-like phenotype present in the offspring.

Additional work in rodent models has been consistent in showing the ability of psychological stress experienced directly by the mother to render epigenetic consequences on offspring. For example, restraint of the mother produces high levels of Dnmt1 and 3a (genes encoding enzymes that are responsible for adding methyl groups to DNA) mRNA in the frontal cortex and hippocampus of her male offspring (Matrisciano et al., 2012). This same study showed that prenatally stressed mice also displayed increased methylation of DNA associated with synaptic plasticity genes (including reelin) and several schizophrenic-like behaviors, including hyperactivity, deficits in social interaction, altered prepulse inhibition, and memory capacity. Restraint stress of pregnant rats has also been associated with changes in methylation of a placental and fetal gene (HSD2) whose product helps protect the fetus against the damaging effects of stress hormones (Jensen Peña, Monk, & Champagne, 2012). Further, variations in the magnitude of the same stressor can produce dramatically different epigenetic consequences. One group has shown that offspring of dams who had been briefly subjected to the stress of being on an elevated platform showed higher levels of global DNA methylation in their frontal cortex and hippocampus (Mychasiuk, Ilnytskyy, Kovalchuk, Kolb, & Gibb, 2011). In contrast, offspring of mothers that had spent much longer time on the platform showed a dramatic reduction in global DNA methylation levels.

As discussed in an earlier section, increasing evidence shows that genes (and in turn behavior) can also be epigenetically regulated by miRNAs. A recent study has provided a link between stress during gestation and long-term alterations in miRNA regulation in offspring (Zucchi et al., 2013). In this study, pregnant rats were exposed to a stressful environment twice daily from gestational day 12 to 18. The two stressors consisted of exposure to restraint for 20 minutes and forced swimming for 5 minutes. Investigators then assessed whether their stress regimen produced any changes in frontal cortex miRNA expression in dams or changes in whole brain miRNA expression of male offspring. They found alterations in miRNA expression in the frontal cortex of dams that correlated with stress-induced behavioral alterations (a decrease in total time spent tail-chasing antepartum compared with nonstressed dams). Specifically, gestational stress caused a downregulation of many miRNAs that are related to stress responses, metabolism, hormonal regulation, and neurological diseases, including miR-329, miR-20a, miR-500, miR-181, and miR-186. Prenatal stress also upregulated several miRNAs, including miR-24–1, which play a role in destabilization and translational inhibition of target mRNA. Significant changes were also observed in the brains (whole) of male offspring. Downregulation occurred in miRNAs that target genes that are related to neurodevelopment, stress responsivity, and brain pathologies. Upregulation also occurred in miRNAs that play a role in cell signaling and stress response, miR-98 (alters neural inflammatory responses), and miR-219 (a putative marker of SZ and bipolar disorder [BD]). While these observations cannot be directly linked to the changes in antepartum behavior observed, they nonetheless demonstrate the capacity of stress experienced by the dam to alter both her and her offspring's miRNA levels.

Fascinating evidence is beginning to emerge demonstrating that simply watching another individual experience stress can also render epigenetic consequences for offspring. Specifically, one report has shown global DNA methylation (frontal cortex and hippocampus), gene expression, and behavioral alterations in offspring of pregnant rats that were housed with another female who was repeatedly subjected to stress outside of the homecage (Mychasiuk et al., 2011). In this study, pregnant Long-Evans rats (during gestational days 12–16) were housed with another female rat that underwent elevated platform and bright light stress (30 minutes twice daily). Female offspring (10–13 days old) prenatally exposed to stress entered significantly less squares in an open field test, indicative of either locomotor deficits or their hesitation to explore novel environments. Investigation of global DNA methylation patterns in bystander-stressed offspring showed an increase in methylation within the frontal cortex and the hippocampus. A total of 558 genes were differentially expressed between the stressed and nonstressed control offspring, including genes involved in biological processes controlling neural development and function. These data effectively illustrate the ability of bystander stress to impact methylation levels within multiple brain regions (with distinct differences between sexes that we did not discuss here).

Our first hint that methylation status of the human genome is equally sensitive to maternal stress and emotion came in 2008. In this study, it was shown that infants

born to mothers that reported high levels of depression and anxiety during their third trimester of pregnancy exhibited increased methylation of the human GR gene (Nr3c1) promoter in cord blood cells (Oberlander et al., 2008). Increased methylation was also associated with increased HPA stress reactivity (change in cortisol levels from baseline) in response to novel visual stimuli at the 3-month visit. These data provided seminal evidence consistent with the notion of fetal programming of the infant's HPA axis by maternal mood. Since that study, this same group has also shown the programming capacity of maternal depressed mood on behavior and development that involves epigenetic changes within the serotonergic system. Specifically, increased maternal depressed mood scores have been associated with decreased maternal (peripheral leukocytes) and infant (umbilical cord) serotonin transporter (SLC6A4) promoter methylation (Devlin, Brain, Austin, & Oberlander, 2010). More recent work has shown an association between extreme psychosocial stress experienced while pregnant and methylation of the GR gene in newborns (Mulligan, D'Errico, Stees, & Hughes, 2012). In this study, war stress (vs. material deprivation or mundane stress) experienced by mothers in the Democratic Republic of Congo had the strongest correlation with birth weight, able to account for 35% of variance in birth weight. Birth weight and stress were also strongly correlated with GR methylation (the higher stress, the greater methylation and lower birth weight).

Together, the studies reviewed in this section indicate that nutritional factors, environmental insults, and life stress during pregnancy are risk factors for a wide range of behavioral outcomes in offspring. More importantly, these studies provide compelling evidence that DNA methylation (or demethylation) is a mechanism whereby prenatal stressors and environmental events could give rise to behavior, including altered stress responsivity and depression. As we discuss in the next section, we have also learned that epigenetic factors are at play during early-life development outside of the womb, and are thus recognized as a mechanism whereby early-life environmental events can create biochemical changes that dictate gene activity and the development of behavior.

EPIGENETIC FACTORS AND OUTCOMES ASSOCIATED WITH EARLY-LIFE POSTNATAL ENVIRONMENTAL EVENTS

The programming capacity of early environmental events outside the womb has become equally clear over decades of research. For example, children and adults with a history of early abuse or neglect show high rates of depression, anxiety, substance abuse and have impaired social functioning and deficits in cognitive performance (Cicchetti & Toth, 2005; De Bellis, 2005; Heim, Shugart, Craighead, & Nemeroff, 2010). One neural impact long presumed responsible for these outcomes is experience-induced changes in the function of the HPA axis. Indeed many clinical studies have demonstrated that early-life stress canalizes HPA axis function, as indicated by hypo- or hypercortisolism and the dysregulation of the circadian rhythm of cortisol production typical of children and adults with a history of maltreatment (Carpenter et al., 2009; Gunnar, Quevedo, & De Kloet, 2007; Rogosch, Dackis, & Cicchetti, 2011). HPA axis dysregulation is also a prominent symptom in adults with a history of child maltreatment and the diagnosis of major depressive disorder or posttraumatic stress disorder (PTSD) (Bauer, Wieck, Lopes, Teixeira, & Grassi-Oliveira, 2010; De Bellis & Thomas, 2003). Nonhuman primate models of early-life adversity likewise demonstrate the negative impact of early-life stress and maltreatment on the HPA axis, showing for example that separation of infants from their attachment figure can provoke increased activity of the HPA axis (Gunnar et al., 2007; Howell & Sanchez, 2011). Variable foraging paradigms that disrupt mother–infant interactions (approximating a neglectful caregiving environment for the infant) yield offspring that are more fearful and have high levels of CRF as well as alterations in noradrenergic and serotonergic function (Gunnar et al., 2007). Together, these observations suggest that epigenetic programming of HPA axis regulation is one way in which early-life environmental events could render an individual with lifelong altered stress responses and increased susceptibility to later-emergent stress- and mood-related psychiatric disorders.

In 2004, investigators brought forth the first direct evidence in support of this notion. At the same time, these data challenged the previously held view that epigenetic mechanisms are static and unresponsive to the environment outside of periods of embryonic development and cellular differentiation. Data they presented indicated that methylation of DNA associated with the GR, a gene underlying stress-responsivity through its regulation of HPA activity, was directly associated with the type of caregiving experienced during the first postnatal week (Weaver et al., 2004). Specifically, they showed that adult male rats that had been reared by nurturing mothers that exhibited high levels of pup licking and grooming (LG) had low levels of methylation of DNA associated with the

GR gene within their hippocampus, while adults who had been raised by less nurturing (low LG) mothers exhibited hypermethylation of GR DNA. These observations were consistent with GR gene expression patterns and anxiety-related behavior of the animals. Animals with low methylation had higher expression of the GR gene and exhibited less stress-responsivity and anxiety-like behavior (less fearful response to stimuli, decreased defensive response, and a more modest HPA response to a stress challenge), while animals with higher methylation had lower gene expression and increased anxiety-like behavior.

It is important to point out here that DNA methylation changes often occur in conjunction with other chromatin changes, including histone acetylation. Histone acetylation at the ninth lysine (K9) residue of histone 3 is a marker of active chromatin, and adult offspring of high-LG mothers when compared with offspring of low-LG mothers had higher acetylated K9 levels. Then through a series of cross-fostering studies, they were able to demonstrate that the levels of GR promoter methylation were a direct product of the mother's behavior during the postnatal period. These data were key in providing an association between the levels of caregiving behavior and DNA methylation of the GR gene promoter. Finally, in an effort to help establish a causal link between the observed epigenetic modifications, gene expression patterns, and adult behavior, they demonstrated that pharmacologically manipulating methylation patterns, via treatment of adult animals with a HDAC inhibitor (trichostatin A), removed group differences in DNA methylation, histone acetylation, and behavior.

Another way to examine the ability of incant-caregiver interactions to program the HPA axis is to separate infant rodents from their mother for a specified period of time. Since rodent pups are dependent on their mother for survival, separation from the mother produces an array of responses, including alterations in HPA activity (Faturi et al., 2010). We have learned that behavioral outcomes in separated infants are also in part due to epigenetic programming of the HPA axis (Murgatroyd et al., 2009). In this study, mice as far as 1 year out from the last infant separation experience were shown to have hypomethylation of arginine vasopressin (AVP) DNA in their paraventricular nucleus (PVN). The product of the AVP gene is a hypothalamic component that induces the synthesis and release of adrenocorticotropin from the pituitary. The lower levels of DNA methylation inversely correlated with AVP expression, as well as reduced binding of MeCP2, a DNA methyl-binding protein typically associated with gene suppression. They found that these molecular effects occurred in parallel with increases in corticosterone secretion (in response to an acute stress challenge and under basal conditions) and memory deficits in an inhibitory avoidance task. AVP antagonism was shown to partially reverse the phenotype. Overall, these results indicate that an early-life stressor activates a key group of stress regulating neurons that are part of the HPA axis, leading to stables changes in MeCP2 function and programing of a key gene involved in the stress regulatory pathway. Since this study, infant separation has been shown to produce less methylation of CG sites associated with the Crf promoter within the PVN, an effect that coincides with heightened plasma corticosterone response to an acute stress challenge (Chen et al., 2012).

Akin to the rodent literature, the human GR gene appears equally responsive to early-life environmental events. For example, increased methylation of GR and ribosomal RNA genes (and a corresponding decrease in transcript levels) have been found in hippocampal samples derived from adult males who committed suicide and had a history of childhood abuse (Labonté, Suderman, et al., 2012; McGowan et al., 2009; McGowan et al., 2008). In another study linking the effects of early-life adversity with epigenetic modification of the human GR gene, parental loss, childhood maltreatment, and disruptions in parental care were found to be associated with increased GR promoter DNA methylation (as determined from leukocyte DNA) and attenuated cortisol responses to a stress challenge (Tyrka, Price, Marsit, Walters, & Carpenter, 2012). Additional work has shown that childhood sexual abuse and its severity show a positive correlation with GR methylation (Perroud et al., 2011). In this study, GR methylation was explored in individuals with Borderline Personality Disorder (BPD), Major Depressive Disorder (MDD) or individuals with a co-morbidity of MDD and PTSD. While the severity of childhood sexual abuse and the number of maltreatment types correlated positively with GR methylation in all of these individuals, those with BPD who experienced repeated sexual abuse with penetration and other abuses showed the highest methylation percentage. This is yet another example linking childhood maltreatment, epigenetic changes, and adult psychiatric disorders.

If we return to rodent models, the broad array of phenotypes affected by maternal care in the rodent model of high vs. low LG, including hippocampal-dependent memory, sexual behavior, fear-like behavior, maternal care, and alterations in drug-seeking behavior (Kaffman & Meaney, 2007) would suggest the ability of early-life events

to epigenetically program a multitude of genes and brain systems. Subsequent research has shown that this is indeed the case. Maternal care has been shown to influence levels of cytosine methylation of the estrogen-receptor alpha (ER-α) gene promoter in the medial preoptic area, an area intimately associated with maternal behavior (Champagne, Weaver, Diorio, Dymov, Szyf, & Meaney, 2006). Activation of ER-α supports maternal behavior expression, and expression of this gene is regulated by a signaling cascade known as the Janus kinase-Stab5b pathway. Lower levels of ER-α gene DNA methylation, increased binding of Stab5b, and increased expression of ER-α were found in adult female offspring of high-LG mothers. These animals showed high levels of licking and grooming towards their own offspring, as well as displaying an arched back nursing position toward their offspring. The opposite was found for adult offspring of low LG mothers. Reminiscent of the outcome regarding fear- and anxiety-like behaviors, variations in maternal care also confer differences in future mothering behavior via epigenetic mechanisms. LG maternal behavior has since been shown to affect γ-aminobutyric acid (GABA) inhibitory circuits, as males that are raised by low-LG mothers have reduced hippocampal levels of the rate-limiting enzyme in GABA synthesis called glutamic acid decarboxylase (GAD1) which is associated with increased methylation of GAD1 promoter DNA (Zhang et al., 2010). Epigenetic changes in this model are known to occur on a much broader genome-wide scale within the hippocampus (McGowan et al., 2011).

Work in other models likewise demonstrates the ability of early-life experiences to epigenetically alter multiple genes and brain regions. For example, infant male rats experiencing repeated separation from their mother and nest environment show altered hippocampal methylation and expression of estrogen receptor (ERβ) DNA (a gene that encodes a receptor responsive to estrogen) (Wang, Meyer, & Korz, 2012) and increased methylation (and therefore reduced expression) of the hippocampal synaptic plasticity gene reelin (Qin et al., 2011). With some of our own work, we have provided a link between caregiver maltreatment, altered DNA methylation patterns of the Brain-derived neurotrophic factor (Bdnf) gene, and aberrant behavioral outcomes (Roth, Lubin, Funk, & Sweatt, 2009).

A known stressor of rat mothers is resource deprivation (nesting material), and we and others have used this to elicit aberrant caregiving behaviors (Ivy, Brunson, Sandman, & Baram, 2008; Raineki, Moriceau, & Sullivan, 2010). In our laboratory, we use this stressor in conjunction with a within litter design to examine the ability of adverse caregiving to alter DNA methylation. We employ three experimental conditions: normal maternal care, cross-foster care, and caregiver maltreatment. The normal maternal care condition consists of leaving infants in their home cage with their biological mother in the room in which they were bred (infants are however briefly handled for marking and weighing purposes). The cross-foster care condition consists of placing infants in a different room and in a different apparatus with a lactating dam. This female is given an hour to habituate to the chamber before receiving infants. She is also given adequate amounts of bedding so that she may nest and nurture infants. The caregiver maltreatment condition consists of placing infants in a different room and apparatus with a lactating dam. This female is not given time to habituate to her new surroundings and is not provided adequate bedding to construct a nest. Infant rats are repeatedly exposed to their designated conditions for 30 minutes daily from postnatal day one through seven. Nurturing caregiving behaviors that we see in the normal care and cross-foster conditions include frequent observations of infant grooming, anogenital licking (to void their bladder), and nursing. Adverse caregiving behaviors displayed in the maltreatment condition include infant dragging, dropping, roughly handling, and active avoidance of the pups (Figure 11.2a). Dams within this condition also spend less time crouching over or nursing the infants and decreased amounts of licking and grooming.

In some of our earliest work with this model (Roth et al., 2009), we first explored the capacity of our maltreatment conditions to alter Bdnf gene expression. We found that this was the case, as adult animals that were exposed to the maltreatment condition during infancy had significantly less Bdnf mRNA in their prefrontal cortex (as a whole) than controls (either normal or cross-foster care). We then explored whether DNA methylation could be involved. We showed that normal adults (i.e., adults with a history of normal infancy) had either no or very little CG dinucleotide methylation within an important regulatory region of the Bdnf gene (DNA associated with exon IV). This was in sharp contrast to the adults who had experienced maltreatment during infancy, where sequencing of that same regulatory region revealed that the same CG dinucleotides were all highly methylated (Figure 11.2b). Next, to establish that the methylation changes were contributing to the gene deficits, we showed that chronic treatment with a DNA methylation inhibitor called Zebularine was able to rescue the adult maltreatment-caused deficits in Bdnf gene expression. Zebularine treatment also lowered methylation levels in maltreated animals.

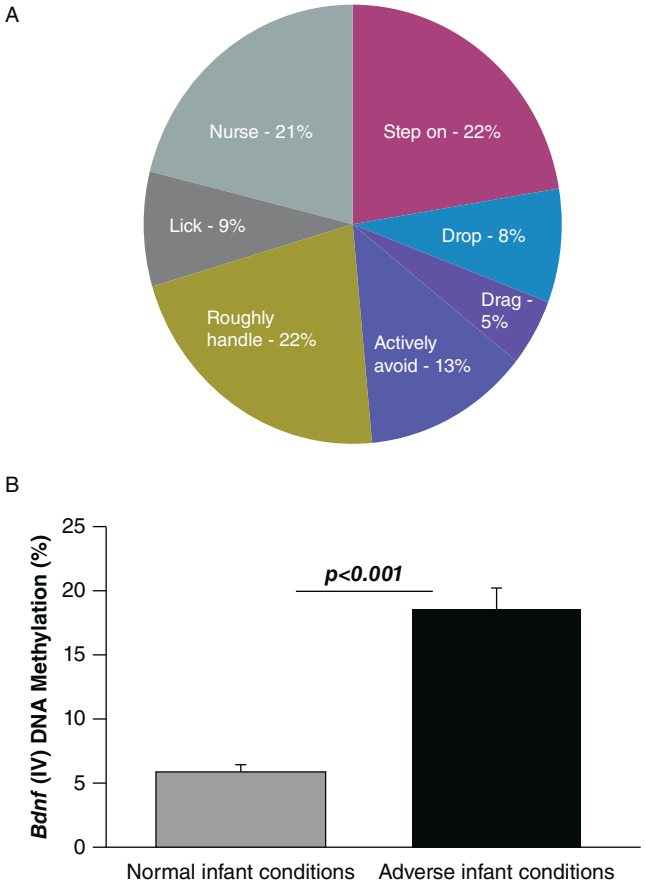

Figure 11.2 Assessment of caregiving behaviors within our maltreatment condition (A) indicates that infants experienced an adverse caregiving environment characterized by maltreatment and low levels of infant licking or nursing. Three months removed from the last experience of maltreatment, (B) adults were found to have significant methylation of Bdnf DNA in their prefrontal cortex. Data recreated from Roth et al., 2009, pp. 761. See footnote 1.

Maternal and social isolation in infant macaques has been linked to hypermethylation of the serotonin transporter gene (Kinnally et al., 2010), and the impact of chronic and unpredictable infant separation on depressive-like behaviors in mice and in their subsequent offspring has been linked to the DNA methylation profile of several stress-related and behaviorally relevant genes (Franklin et al., 2010). In this latter study, litters were exposed to repeated bouts of maternal separation three hours daily during the first two weeks of life. Additionally during separation, mothers were subjected to unpredictable stress. Investigators found that separation (and stress of the mother) led to depressive-like behaviors that were not just present in males that experienced the early-life stress regimen, but in their offspring that were never subjected to any stress and had been raised under normal conditions. For example, when exposed to the forced swim test, offspring spent more time floating indicative of depressive-like behavior. Anhedonia, the inability to experience pleasurable stimuli, is a behavior commonly displayed in depressed individuals. Stressed offspring in their study likewise consumed decreased amounts of sucrose. In parallel, DNA methylation patterns that were present in the germline (sperm) and brains of the male mice that had directly experienced the early-life stress (i.e., the fathers) were present in the brains of the offspring.

Epigenetic regulation of gene loci other than the GR gene has too been linked to childhood experiences. For example, antisocial behavior in females with a history of childhood sexual abuse coincided with both genotype and hypermethylation of DNA associated with the promoter region of the gene encoding the serotonin transporter (Beach, Brody, Todorov, Gunter, & Philibert, 2011; Vijayendran, Beach, Plume, Brody, & Philibert, 2012). Children (male and female) aged 7–10 years and raised in institutional care, in comparison to children of the same age but raised by their biological parents, show greater methylation of DNA associated with a number of genes involved in controlling serotonin and glucocorticoid biosynthesis, immune responses, and cell-signaling pathways involved in memory formation (Naumova et al., 2012). Adolescent and adult DNA methylation levels, including those of genes known to play an important role in cell-signaling pathways within the brain, have been linked to parental stress levels during early childhood years (Borghol et al., 2012; Essex et al., 2013). Further, male individuals with severe abuse during childhood have been shown to exhibit genome-wide changes in hippocampal DNA methylation, including hypermethylation of over 200 gene promoters and hypomethylation of around 100 gene promoters, many of which are involved in neural plasticity (Labonté, Yerko, et al., 2012).

As one final point for this section, a review of the literature suggests that epigenetic changes could underlie why developing males and females have different susceptibility to early-life stress or outcomes associated with stress. Because of existing methylation patterns at certain gene loci during development, stress has the potential to differentially affect males and females. For example, DNA methylation of the ER-α gene is higher in female rodents than males at postnatal day 1 (Schwarz, Nugent, & McCarthy, 2010). Epigenetic regulators are known to differ between sexes early in development, providing another route for stress to differentially affect the sexes. For example, mRNA and protein levels of DNMT3a (Kolodkin & Auger, 2011) and MeCP2 (Kurian, Forbes-Lorman, & Auger, 2007)

within the infant amygdala are higher in females than in males, but by postnatal day 10 these sex differences have disappeared. Dnmt3a is highest in the female and male cortex at postnatal day 10, while Dnmt1 is highest after weaning (PN25) (Westberry, Trout, & Wilson, 2010). Within the MPOA, gene promoters involved in sexual differentiation of the brain show differential epigenetic patterns between males and females at both an embryonic and early postnatal stage (Matsuda et al., 2011). It stands to reason that future epigenetic studies need to incorporate both sexes to fully elucidate the role that DNA methylation plays in sex-specific development of behavior.

EPIGENETIC FACTORS AND OUTCOMES ASSOCIATED WITH EVENTS LATER IN LIFE

In the previous sections we focused on epigenetic alterations that are known to occur in response to environmental factors and events experienced within the intrauterine or caregiving environments. In parallel to developmental studies, research efforts aimed at understanding molecular mechanisms underlying memory processes, drug addiction, and stress outcomes have illustrated that the adult central nervous system (CNS) is likewise sensitive to environmentally driven epigenetic alterations. Evidence suggests that both DNA methylation and histone modifications provide a mechanism for gene-by-environmental interactions throughout the life span.

The process of turning learned information into memories that can be stored and retrieved for the long haul involves gene expression. A diverse series of studies in rodents have demonstrated an important role of epigenetic regulation in learning-induced gene expression. Making the case that histone acetylation is an important process for learning and memory are studies showing that contextual fear memory formation is associated with acetylation of histones within the hippocampus (Levenson et al., 2004), and that mice deficient of the HAT CBP have both deficits in synaptic plasticity and long-term memory capacity (Korzus, Rosenfeld, & Mayford, 2004; Oliveira, Wood, McDonough, & Abel, 2007). The ability to extinguish a conditioned fear memory has been linked to histone acetylation changes within the prefrontal cortex (Bredy et al., 2007), and the beneficial effects of environmental enrichment on restoring learning and memory capacity in cognitively impaired mice have been shown to be mediated by increased hippocampal and cortical histone acetylation (Fischer, Sananbenesi, Wang, Dobbin, & Tsai, 2007). Finally, additional work has shown that in addition to histone acetylation at memory-linked genes there is a complex pattern of histone methylation changes (Gupta et al., 2010).

The capacity of DNA methylation to regulate synaptic plasticity and memory in adult animals has become apparent. In some of the earliest work, investigators reasoned that if DNA methylation remains an active process in the mature brain then it should be able to orchestrate gene–environment interactions relevant to learning and memory. We have learned that this is indeed the case and that both DNA methylation and demethylation are active processes involved in regulating gene expression in long-term memory formation. For example, seminal studies along these lines showed that shortly after fear conditioning (within 1–2 hours), adult rats within their hippocampus had decreased methylation of DNA associated with memory-related genes (Lubin, Roth, & Sweatt, 2008; Miller & Sweatt, 2007), while increased methylation of DNA was associated with memory suppressor genes (Miller & Sweatt, 2007). Demethylation corresponded with active gene transcription, while methylation corresponded with gene suppression. A follow-up study demonstrated longer-lived (30 days) experience-induced changes in cortical DNA methylation (and thus gene expression) following the contextual fear-conditioning paradigm (Miller et al., 2010). Pharmacological agents that alter DNA methylation have been shown to both alter DNA methylation in adult CNS tissue and block hippocampal synaptic plasticity (Levenson et al., 2006) and hippocampus-dependent memory formation (Lubin et al., 2008). Other studies have shown that disruption of other epigenetic regulators including MeCP2 (Adachi, Autry, Covington, & Monteggia, 2009), DNMTs (Feng et al., 2010), and Gadd45b (Sultan, Wang, Tront, Liebermann, & Sweatt, 2012) can also alter plasticity and memory.

Regulation of gene expression is also recognized as a molecular basis of addiction, and epigenetics are increasingly being explored for their contributory role to this process. Acute administration of cocaine has been shown to increase striatal histone acetylation on genes known to play a critical role in cocaine-related behaviors, while chronic cocaine exposure has been found to hyperacetylate these same gene promoters for several weeks (Kumar et al., 2005). Histone methylation has been shown to occur at several gene promoters in the nucleus accumbens after chronic cocaine exposure (Renthal et al., 2009). Further attention in this line of work has turned to characterizing the role of epigenetic regulators, including DNMTs, in the morphological (dendritic spine plasticity in the nucleus

accumbens) and behavioral outcomes (cocaine preference) that may underlie cocaine addiction (LaPlant et al., 2010; Maze et al., 2010).

A growing literature base is providing compelling evidence that epigenetics can help explain how adulthood stressors can leave their marks on genes. In adult rodents it has been demonstrated that either acute or chronic restraint stress (Hunter, McCarthy, Milne, Pfaff, & McEwen, 2009) and chronic social defeat stress (Tsankova et al., 2006) evoke robust changes in hippocampal histone methylation. Social defeat stress is also known to be associated with a lasting decrease in methylation of Crf DNA and a concomitant increase in Crf expression in the hypothalamus of animals that develop social avoidance behavior (Elliott, Ezra-Nevo, Regev, Neufeld-Cohen, & Chen, 2010). Mice in this study that did not develop social avoidance after exposure to defeat stress did not show these epigenetic modifications. Stress-susceptible (inbred BALB/c) and stress-resilient (C57BL/6) male mice are known to show behavioral differences following chronic exposure to mild stressors, and differences in their phenotypes have been attributed to differential patterns of glial cell-derived neurotrophic factor (Gdnf) DNA methylation (Uchida et al., 2011). Specifically, while both strains of mice were shown to display increased methylation of the Gdnf promoter (in the nucleus accumbens) following chronic stress, stress-susceptible mice (BALB) showed additional epigenetic changes that led to repression of Gdnf transcription, including gene promoter interactions with HDACs. Mice that adapted to chronic stress (B6) showed other epigenetic changes permitting Gdnf transcription. These studies provide the first glimpse that there are epigenetic attributes of stress resilience versus stress susceptibility.

In collaboration with David Diamond's group, we have explored the ability of repeated exposure to predatory and social instability stress to alter DNA methylation in adult rodents (Roth, Zoladz, Sweatt, & Diamond, 2011). In this study, rats were randomly assigned to stress or no-stress groups. Rats in the stress group were placed in plastic DecapiCones, which immobilized them. They were then placed in a Plexiglas enclosure and taken to a cat housing room. Within this room, they were placed in a cage with an adult female cat for one hour. The Plexiglas enclosure prevented any direct contact between the rat and the cat, and to promote cat gustatory behavior toward the rat, cat food was smeared on top of the rat's enclosure. Rats in the stress group were exposed to two of these stress sessions separated by a 10-day period. Predictability was controlled by conducting one exposure during the light cycle and one during the dark cycle. Rats in the stress group were also exposed to unstable housing conditions, beginning on the day of the first cat-stress session. Rats in the stress group were housed with a different cage mate daily, and no rat in the stress group had the same cage mate for a period longer than 2 days across the whole 31-day stress period. This psychosocial stress regimen produces rodents that show learning and memory deficits, increased anxiety-like behavior, and glucocorticoid abnormalities weeks to months following the initiation of the stress regimen (Zoladz, Conrad, Fleshner, & Diamond, 2008; Zoladz, Fleshner, & Diamond, 2012).

As depicted in Figure 11.3, we found that these behavioral abnormalities coincided with significant methylation of the Bdnf gene, interestingly the same loci affected by our early-life stress regimen (Roth et al., 2011). Specifically, we found increased methylation of DNA associated with Bdnf exon IV in the dorsal DG and dorsal CA1 of stressed rats, but decreased methylation in ventral CA3. Overall, Bdnf DNA methylation in the dorsal hippocampus was differentially affected by psychosocial stress when compared with the ventral hippocampus. Bdnf mRNA levels were suppressed in CA1, and our data are consistent with the notion that increased methylation is one way that transcriptional repression occurs after psychosocial stress. These data also provide insight into mechanisms likely contributing to increased anxiety-like behaviors and cognitive impairments seen in humans that are maintained for long periods of time after a traumatic experience has occurred.

The ability of acute stressful experiences to evoke epigenetic modifications in humans has been demonstrated in a laboratory setting using the Trier social stress test (TSST). This is a very effective stressful experience for participants, and in this test subjects have to perform a public speech after a period of anticipation as well as perform mathematical problems in front of a panel of interviewers. One group has reported a short-lived increase in methylation of the oxytocin receptor (OXTR) gene in blood samples from male and female TSST participants (Unternaehrer et al., 2012), while another group has reported greater methylation of the NR3C-1 gene after the TSST in females (Edelman et al., 2012).

Together, data from studies reviewed in this section have provided us with a new framework in trying to understand how psychological and social-contextual factors can interact with our biology even outside of sensitive periods of development. These data also tell us that experiences do not have to be confined to early-life developmental periods in order to evoke DNA methylation changes. Whether

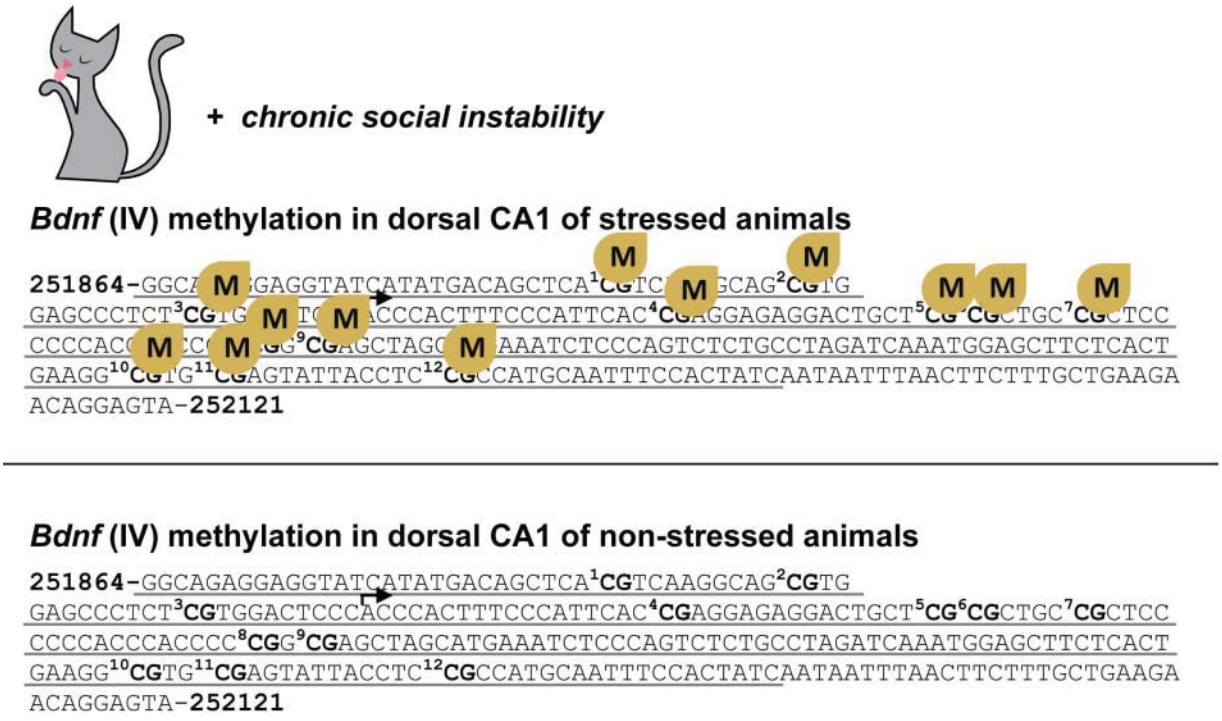

Figure 11.3 Direct bisulfite sequencing analysis in the hippocampus of adult rats that had experienced the psychosocial stress regimen (chronic social instability and repeated exposures to a predator stimulus) revealed significant cytosine methylation (compared with controls) across 12 cytosine-guanine dinucleotide sites within DNA associated with exon IV of the Bdnf gene. See footnote 1. *Source:* Data recreated from T. L. Roth, P. R. Zoladz, J. D. Sweatt, & D. M. Diamond, Epigenetic modification of hippocampal Bdnf DNA in adult rats in an animal model of post-traumatic stress disorder, *Journal of Psychiatric Research, 45*, 922, 2011.

sensitive periods early in life truly represent heightened periods of vulnerability to these types of changes is an issue that has not been systematically addressed. Expression profiles of Dnmt1, 3a, and 3b provide one piece of evidence that this may be the case. Though these genes are detectable in neurons throughout the life span, some of their expression profiles peak (e.g., Dnmt3a) during the early postnatal period (Brooks, Marietta, & Goldman, 1996; Feng, Chang, Li, & Fan, 2005; Goto et al., 1994). Worth considering in the context of this discussion is the possibility that there is a larger gene pool at play during sensitive periods (such as in early postnatal development or adolescence), while instead a much more limited gene pool is responsive to later-life factors. Adding further complexity to this discussion is evidence that experiences do not always translate into immediate changes in DNA methylation, but that changes can emerge after an appreciable delay. For example, we have found some changes in Bdnf methylation that emerge several months after infant maltreatment (Blaze, Scheuing, & Roth, 2013). Further, DNA methylation patterns naturally change with maturation and aging processes (Numata et al., 2012; Siegmund & Connor, 2007). These phenomena then likely have significance in terms of stress incubation and direct versus indirect trajectories leading to later behavior change or the onset of psychiatric disorders.

EPIGENETIC FACTORS ASSOCIATED WITH BEHAVIORAL DISORDERS

Drawing on data from both developmental and adult studies, it is clear that our genome is susceptible to epigenetic modifications, providing a layer of genetic regulation that is sensitive to a lifetime of experiential and environmental factors. The studies we have reviewed up to this point also make the argument that epigenetic changes have functional relevance in terms of behavior. Additional support for this notion came from several known intellectual and psychiatric disorders that have been associated with altered epigenetic marks. At this point the association (i.e., a causal link) between aberrant epigenetic marking of the genome and manifestation of these disorders that we will review here remains speculative for many reasons, several which are listed here. For example, it is difficult to distinguish

preexisting methylation patterns (heritable changes) from those that may have developed in response to a particular life event. Without baseline epigenetic measurements in individuals prior to the development and diagnosis of a disorder, it is also difficult to distinguish epigenetic patterns that led to versus those that developed from having the disorder. Drawing on evidence from the animal work previously reviewed, what we can say is that these types of disorders represent intriguing candidate disorders that might be associated with epigenetic changes triggered during development (or later in life). Another point to keep in mind is the extent to which peripheral measures of DNA methylation (obtained from blood samples or cheek swabs) capture the complexity of methylation alterations present in their brain.

Accumulating observations are consistent with the hypothesis that epigenetic marking of genes could underlie aspects of cognitive dysfunction and psychopathology. This seems especially true in regard to psychiatric disorders that are associated with early-life stress and abnormal brain development and function. In this section, we will discuss three instances of human intellectual disabilities as examples where epigenetic mechanisms have been implicated in developmental delay and cognitive disabilities: Rett syndrome (RS), Fragile X syndrome, and Rubinstein-Taybi syndrome (RTS). We use them to help us illustrate that epigenetically based disruptions are known to lead to particular behavioral outcomes. We will then summarize evidence linking the presence of DNA methylation alterations with SZ, PTSD, mood disorders, and Alzheimer's disease (AD).

Rett Syndrome

RS, estimated to be the second leading cause of intellectual disabilities in women, was first described in 1966 by Austrian pediatrician Andreas Rett (1966) and is an X-linked disease that affects about 1 in 15,000 females by ages 2–18 years of age (Ellaway & Christodoulou, 2001). Development during the first few months of life is normal in RS patients, with symptoms first appearing between 3 months and 3 years of age. The trademark of RS is a display of continuous, stereotypical hand movements, such as wringing, washing, clapping, or patting, which appear after the loss of purposeful hand movement. Other signs of RS include decreased growth (including microcephaly), abnormal respiration, gait ataxia, autism, seizures, and other neurologic dysfunctions. Studies have indicated that in a percentage of patients they have a mutation of MeCP2 (Amir et al., 1999). The role that MeCP2 might play in the symptoms and memory deficits observed in RS is still unclear, but strains of MeCP2-deficient mice have been shown to display several of the characteristics of human RS (Chen, Akbarian, Tudor, & Jaenisch, 2001; Guy, Hendrich, Holmes, Martin, & Bird, 2001; Tate, Skarnes, & Bird, 1996), and overexpression of MeCP2 has been found to actually enhance long-term memory formation and the induction of hippocampal LTP (Collins et al., 2004). These results suggest that levels of MeCP2 are coupled to cognitive performance, and are consistent with the idea that loss of functional MeCP2 protein could play a role in cognitive deficits associated with RS.

Fragile X

Fragile X syndrome is one of the most commonly inherited learning disabilities. It is associated with distinct physical and behavioral features and causes learning disabilities that range from mild to extremely severe, with most patients showing IQs in the range of 50 (Turner, Webb, Wake, & Robinson, 1996). Two genes have been associated with Fragile X: FMR1 and FMR2. The FMR1 mutation is due to an expansion of trinucleotide repeats (CGG), where normal levels of FMR1 are produced if the FMR1 gene contains between 50–200 repeats; however, levels of FMR1 decrease if the number of CGG repeats exceeds 200. (Ashley et al., 1993). Decreased gene expression occurs via mechanisms including aberrant methylation of DNA and formation of restrictive chromatin structure. The FMR2 gene undergoes a similar hypermethylation and transcriptional silencing due to expansion of a CCG repeat (Gecz, Gedeon, Sutherland, & Mulley, 1996; Gu, Shen, Gibbs, & Nelson, 1996).

Rubinstein-Taybi

RTS was first described in 1963 (Rubinstein & Taybi, 1963) and is an inherited, autosomal dominant disease that has been mapped to chromosome 16p13.3, which contains the gene for the transcriptional co-activator CBP (Petrij et al., 1995). Several studies have shown that RTS patients have a variety of mutations in CBP. As discussed in an earlier section, CBP is a HAT that facilitates histone acetylation. Animal models of RTS, with mutant CBP alleles, exhibit deficits in numerous long-term memory tasks and forms of hippocampal synaptic plasticity (Alarcon et al., 2004; Korzus et al., 2004; Oike et al., 1999; Tanaka et al., 1997). The important implication of this work is its suggestion that altered HAT activity is causative of at least part of the cognitive deficits associated with RTS.

Schizophrenia

SZ is a disorder of cognition that is defined by positive symptoms including delusions, hallucinations, and disorganized thoughts and by negative symptoms such as poor motivation, social withdrawal, and apathy. With the onset of SZ occurring typically after adolescence, the environment is thought to play a key role in its etiology. Common observations in the cortex of individuals with SZ include increased Dnmt1 expression and decreased expression of reelin and GAD1 (Guidotti et al., 2007; Ruzicka et al., 2007; Veldic, Guidotti, Maloku, Davis, & Costa, 2005; Veldic et al., 2004, 2007). Deficits in reelin and GAD1 levels have been attributed to altered methylation levels (Abdolmaleky et al., 2005; Connor & Akbarian, 2008; Grayson et al., 2005; Huang & Akbarian, 2007). Daily injections of methyl donors are known to recapitulate hypermethylation of reelin and GAD1 in mice, as well as alter social recognition and prepulse inhibition behaviors (Tremolizzo et al., 2002, 2005). When mice are given subcutaneous injections of valproate, a histone deacetylase inhibitor that can also affect methylation levels, expression of reelin and GAD1 are rescued. Recent genome-wide epigenetic approaches on cortical tissue from SZ patients suggest there are many additional gene loci with altered DNA methylation, including other gene families related to GABAergic and neurotrophic (Bdnf) function (Connor & Akbarian, 2008; Mill et al., 2008). Peripheral measures of DNA methylation implicate epigenetic marking of the monoamine oxidase A (MAOA) gene promoter (Chen, Zhang, Zhang, Shen, & Xu, 2012), DNA associated with several serotonin receptors (Abdolmaleky et al., 2011; Carrard, Salzmann, Malafosse, & Karege, 2011; Ghadirivasfi et al., 2011), and the catechol-o-methyltransferase (COMT) gene (Abdolmaleky et al., 2006; Lott et al., 2012; Melas et al., 2012; Nohesara et al., 2011). Finally, a genome-wide analysis of DNA methylation on peripheral blood DNA samples obtained from monozygotic twin pairs discordant for major psychosis showed numerous loci with DNA methylation differences between twins discordant for SZ and BD (Dempster et al., 2011).

Posttraumatic Stress Disorder

PTSD is a psychiatric disorder that results from exposure to significant trauma**.** Peripheral measures of methylation show strong associations between child abuse, total life stress, methylation of DNA associated with genes related to immune function (such as the cytokine INFγ), inflammation (inflammatory gene IL-6), plasticity (Bdnf), and the diagnosis of PTSD (Smith et al., 2011; Uddin et al., 2010). The Bdnf methylation changes we have shown to take place in the rodent model of PTSD (Roth et al., 2011) are a nice parallel to these reports. In another rodent model of PTSD, there is evidence that methylation of the disks large-associated protein (DIgap2) gene is altered in the hippocampus of PTSD-like rats (Chertkow-Deutsher, Cohen, Klein, & Ben-Shachar, 2010). It is thought that this gene plays an important role in the molecular processes that are involved in the adaptation to traumatic events.

An interaction between methylation status of the SLC6A4 (Koenen et al., 2011) or MAN2C1 (Uddin, Galea, et al., 2011) genes and the number of traumatic events experienced has been reported in PTSD. In humans, Koenen and colleagues found that after controlling for SLC6A4 promoter genotype, people with more traumatic events were at an increased risk for PTSD, but only with decreased SLC6A4 DNA methylation. Individuals exhibiting higher methylation were protected against PTSD. MAN2C1 is a gene that has been implicated in T-cell functioning. When methylation differences were assessed using whole-blood derived gene expression levels in individuals with PTSD and those without PTSD, MAN2C1 showed significant methylation in association with the number of potentially traumatic events experienced (PTEs). Assessment of serum DNA methylation patterns in genomic repetitive elements (LINE-1 and Alu) of US military service members predeployment and postdeployment and with or without PTSD diagnosis suggest DNA methylation operative as a resilience or vulnerability factor (Rusiecki et al., 2012). LINE-1 and Alu are repetitive elements found throughout the human genome that were previously classified as "junk DNA" but now recognized for their role in modification of gene expression.

There is also emerging evidence of a so-called double hit model, in which having a genetic risk allele and promoter DNA methylation may more accurately capture the molecular risk of PTSD. For example, 9-repeat allele carriers of the dopamine transporter (SLC6A3) gene show an increased risk of lifetime PTSD when in conjunction with high methylation present in the SLC6A3 promoter (Chang et al., 2012). Methylation of genes within the pituitary adenylate cyclase-activating polypeptide (PACAP) system, a system responsive to cellular stress and implicated in neurotrophic function, also appears to predict a PTSD diagnosis. Females with high plasma PACAP levels and greater methylation of the PACAP receptor

gene (ADCYAP1R1) also containing a polymorphism show strongest PTSD symptoms and physiological fear responses (Ressler et al., 2011).

Suicide and Mood Disorders

Epigenetic phenomena have similarly been associated with suicide and depression. Postmortem work with brain tissue (including the frontal cortex, amygdala, and PVN) of individuals who committed suicide or had been diagnosed with major depression has shown significant Dnmt mRNA alterations (Poulter et al., 2008), increased Bdnf DNA methylation (Keller et al., 2010), and altered methylation patterns of numerous genes that are known to play a role in neuronal growth, brain development, and cholinergic transmission (Sabunciyan et al., 2012). The findings of altered levels of Dnmt mRNA (Higuchi et al., 2011) and Bdnf DNA methylation (Fuchikami et al., 2011) have likewise been replicated from peripheral measures in patients with major depression. Other findings in depressed patients include increased methylation of genes involved in brain development and metabolic processes (Uddin, Koenen, Aiello, Wildman, de los Santos, & Galea, 2011) and decreased methylation of genes, such as the inflammatory gene IL-6 (Uddin, Koenen, et al., 2011).

Alzheimer's Disease

AD is a neurodegenerative disease that occurs in individuals that are typically 65 and older, and it is a disease that profoundly impacts thinking and memory skills and is characterized by mild to severe dementia (loss of cognitive function). The major neurobiological hallmarks of this disorder are extracellular plaques and intracellular tangles (Mattson, 2004). Aberrant DNA methylation patterns have been reported in both normal and pathological aging, including observations of global hypermethylation and increased methylation of memory targets such as Bdnf in AD patients (Bakulski et al., 2012; Bollati et al., 2011; Keleshian, Modi, Rapoport, & Rao, 2013). In aged rats (not a model of AD, but a model of the natural decline in cognition that occurs with aging), it has been shown that decreased mRNA levels of genes important for synaptic plasticity and memory formation are attributable to hypermethylation (Penner, Roth, Barnes, & Sweatt, 2010; Penner et al., 2011). Altered chromatin plasticity and histone acetylation are too presumed to be involved in cognitive aging and AD, as cognitive impairments in mouse models of AD can be rescued by increasing histone acetylation either via pharmacological manipulation or through exposure to environment enrichment (Fischer et al., 2007).

EVIDENCE OF EPIGENETIC TRANSMISSION OF PHENOTYPES

Another fascinating tenet in behavioral epigenetics research is the idea that the heritable nature of epigenetic changes could allow information acquired during one's lifetime to be passed on to offspring. This is a provocative idea that was initially met with large skepticism, but studies continue to emerge at a rapid pace providing compelling evidence that this actually occurs. Providing some of the strongest evidence of the phenomenon of germ-line epigenetic inheritance, including altered stress responses for 3 to 4 generations removed from the initial environmental insult, are studies exposing pregnant dams to endocrine disruptors (Crews et al., 2012; Skinner et al., 2008) or high fat diets during gestation (Dunn & Bale, 2011), which we have previously discussed.

The observation of nongenetic transmission of caregiving phenotypes has been present in the literature for some time (Francis, Diorio, Liu, & Meaney, 1999; Maestripieri, 2005). For example, Dario Maestripieri used a cross-foster paradigm to explore genetic versus epigenetic determinants of maternal abuse in macaques (Maestripieri, 2005). The offspring that were born to nonabusive mothers were cross-fostered to abusive mothers after birth (control–abuse) and infants that were born to abusive mothers were cross-fostered to nonabusive mothers (abuse–control). These groups were compared with groups of nonabusive and abusive mothers that raised their own offspring. Females exposed to maltreatment exhibited the same abusive behaviors toward their own offspring. In contrast, females exposed to a nurturing caregiving environment did not show any abusive behaviors toward their offspring. Abusive behaviors were significantly different from behaviors seen from nurturing mothers independent of the maternal phenotype. These results suggest that transmission of infant abuse in the macaque is transferred through an epigenetic process rather than a genomic process. Direct epigenetic evidence for a similar phenomenon has come from work in the high- versus low-LG model carried out by Frances Champagne. As pointed out in an earlier section, infant experiences with nurturing mothers (high LG behavior) decreases methylation of DNA associated with ERα gene in the MPOA, producing increased

gene expression and responsivity to hormonally primed maternal behavior (Champagne et al., 2006). As a consequence of these epigenetic modifications, offspring and grand-offspring from high LG mothers become high LG mothers themselves (Champagne, 2008; Champagne & Meaney, 2007).

As experiences in the nest provide a powerful learning environment that serves to program later maternal behavior, we have also explored whether our early-life experience regimen affects maternal behavior of females, and whether the observed epigenetic modifications might be transmittable across a generation (Roth et al., 2009). We found that females with a history of maltreatment (maltreated females) showed the same types of abusive behaviors toward their own offspring that they had experienced themselves as infants, and that the epigenetic modifications acquired in one generation were even transmitted to the next generation of infants. Specifically, 8-day-old offspring (both males and females) derived from the maltreated females had significant methylation of Bdnf DNA in both their prefrontal cortex and hippocampus in comparison to offspring derived from normal-treated females (females who had experienced a normal infancy). The final question we posed in this study was whether the intergenerational inheritance was due to the mother's caregiving behaviors (maltreatment), or was it due to some biological component (i.e., the patterns were not completely erased between generations). A cross-foster design allowed us to address whether DNA methylation alterations were due directly to the mother's caregiving behaviors. Surprisingly, cross-fostering experiments (where offspring born to maltreated females were cross-fostered to normal females and vice versa) suggested that the inheritance was not simply a reflection of the postnatal experience, but likely reflected some unidentified prenatal component.

In an earlier section, the ability of infant separation to produce lasting changes in depressive-like behaviors and methylation of the Crf gene (Franklin et al., 2010) was discussed. From this same study, anxiety and depression-related behaviors, as well as methylation changes, were also found to be present in offspring and grand-offspring derived from males that had experienced the initial separation (Franklin et al, 2010; Weiss et al, 2011). This is an important observation because in rodents once mating is confirmed, males are usually removed from the cage and do not provide care of offspring. Subsequent studies from this line of work have revealed deficits in cognition and social interaction transmitted through the F3 generation (Franklin et al, 2011). Stress-related behaviors induced by social defeat can also be transmitted from the father (Dietz et al., 2011). In a study from Eric Nestler, adult male mice that were exposed to chronic social defeat stress and control mice were bred with normal female mice (females that never experienced any type of stress). Offspring were assessed for anxiety- and depressive-like behaviors using the elevated-plus maze, novel environment response, sucrose preference, and forced swim test. Chronic exposure to social defeat produced social avoidance behavior in fathers. Their offspring too showed greater amounts of social avoidance, even with a submaximal defeat paradigm that normally would not produce a defeated mouse. Furthermore, defeated offspring showed reduced preference for sucrose and decreased latencies in immobility in the forced swim test.

The ability of disruptions in social hierarchy structure during adolescence to have transgenerational implications has been reported by Larry Feig's group (Saavedra-Rodríguez & Feig, 2013). Social instability was achieved by changing cage mate composition twice a week for a 7-week period beginning in early adolescence. Control groups remained housed with the same cagemates throughout the course of the experiment. Mice from stressed and control groups, along with their offspring, were tested on the elevated plus maze, the open field test, and for social interaction. Two months after the end of the stress treatment, females showed increased anxiety-like behaviors in both the elevated plus maze and often field tests. When social behaviors were explored by introducing an unfamiliar same-sex juvenile into a test apparatus, both stressed males and females spent little time interacting. Future generations (from stressed and control parents) were tested on the same behavioral tests. First generation females, like their mothers, spent significantly less time in the open arms of the elevated plus maze and a significant decrease in locomotor adaptation to a new environment (open field test). When social behaviors were explored, female offspring also interacted less with a stimulus animal, just like their stressed mothers. Social interaction behavior in male offspring was not affected. Elevated corticosterone levels were also found in first generation female, but not male, offspring from stressed parents. Finally, cross-fostering experiments indicated that the transmission of the anxiety phenotype was not caused by postnatal caregiving behaviors, and additional experiments demonstrated that fathers could transmit the anxiety and defective social interaction phenotype to F2 and F3 daughters.

TRANSLATIONAL IMPLICATIONS

Throughout the chapter we have discussed the translational relevance of data from animal studies where appropriate. Two additional points we would like to expand upon here are the utility of epigenetic modifications as biomarkers and epigenetic therapy in the treatment of cognitive and mental dysfunction.

As epigenetic alterations are widely known to play an important role in cancer (DNA methylation and histone modifications are found in different human cancerous tumors), they have been long recognized as potential biomarkers for screening, diagnosis, and treatment targets of various cancers (Kristeleit, Stimson, Workman, & Aherne, 2004; Pan, Lu, & Huang, 2007; Seligson et al., 2005). A challenge in translating results from many of the animal studies we have reviewed in this chapter to humans concerns access to relevant tissues since there is accumulating evidence that epigenetic modifications occur with incredible specificity across tissue and cell types (Davies et al., 2012; Iwamoto et al., 2011; Ladd-Acosta et al., 2007). What we do know at this point is that a growing body of work has noticeably demonstrated a link between peripheral-DNA methylation profiles, exposure to adversity, and a risk for and even current diagnosis of psychiatric disorders. For example, analysis of whole blood (Borghol et al., 2012; Naumova et al., 2012) and lymphocyte (Beach et al., 2013; Vijayendran et al., 2012) samples from individuals exposed to various forms of early-life adversity have consistently revealed aberrant methylation patterns that are present on a genome-wide scale. There is evidence of similar stress-induced changes in DNA methylation states detectable in buccal tissue and saliva samples (Essex et al., 2013; Yang et al., 2013). Together, this would suggest system-wide changes, arguing for the utility of peripheral DNA methylation measures as a marker of stress-induced changes that are present on many tissue/systems levels (Gavin & Sharma, 2010).

Further, there is evidence indicating a parallel relationship between blood-DNA methylation profiles. For example, it was shown in one study that methylation patterns of the rodent COMT gene were directly correlated in peripheral blood mononuclear cells (PBMCs) and the PFC (Ursini et al., 2011). Mice chronically exposed to synthetic glucocorticoids show correlations in blood and brain (hippocampus) methylation of DNA associated with the Fkbp5 gene (Ewald et al., 2014). In one of the largest cross-tissue and interindividual comparison of blood and brain methylation patterns in humans, investigators found strong correlations between DNA methylation for blood and brain tissue were present (Davies et al., 2012). Finally, parallel patterns of methylation in T cells (derived from blood) and PFC tissue of rhesus macaques subjected to differential rearing have been reported (Provençal et al., 2012).

A point of optimism that emerges from the literature is that the dynamic nature of DNA methylation (and other epigenetic modifications for that matter) affords an opportunity to perhaps correct aberrant epigenetic marks. This has given birth to what is called epigenetic therapy, where investigators use drugs like zebularine, sodium butyrate, and trichostatin A to relax chromatin structure in order to provide gene transcription accessibility. Indeed the ability of these drugs to correct epigenetic patterns was first recognized in cancer treatment. For example, when a drug combination of 5-aza-2'-deoxycytidine and Zebularine were administered to both murine and human leukemic cells this reactivated a tumor suppressor gene (via demethylation) and decreased tumor growth (Lemaire, Momparler, Bernstein, Marquez, & Momparler, 2005). Further, the drug cocktail increased the life span in mice with leukemia (Lemaire et al., 2005).

The scope of application of epigenetic therapy has continued to be broadened to include possibly enhancing cognition and treating specific symptoms of various psychiatric disorders. HDAC inhibitors have been successfully used to reverse deficits in synaptic plasticity, learning and memory, and stress-related behaviors in rodents (for a review see Abel & Zukin, 2008). We and others have successfully modified patterns of DNA methylation in the adult brain that were associated with early-life experiences (Roth et al., 2009; Weaver et al., 2004). Whether these strategies are capable of altering the epigenome and behavior patterns of humans is not known. Studies, though, are beginning to reveal the incredible sensitivity of human epigenetic states to traditional pharmacological and behavioral therapies proven effective in treating psychiatric disorders.

Consistent with the neurotrophin hypothesis of depression (stress and depression are associated with decreased Bdnf, which can be restored via antidepressant treatment), antidepressant treatment has been shown to restore Bdnf and histone modifications associated with Bdnf IV DNA in depressed patients that showed a positive response to treatment (Lopez et al., 2013). Another study has shown that lithium and valproic acid, two of the most widely used mood-stabilizing compounds for treatment of BD, reduce methylation of DNA associated with the Bdnf gene in

bipolar patients (D'Addario et al., 2012). The final study we will highlight here has demonstrated that a psychotherapeutic approach can be effective at modifying epigenetic states (Perroud et al., 2013). Specifically, BPD patients that underwent a 4-week treatment regimen of intensive dialectical behavior therapy and showed a positive response to the treatment also showed a decrease in Bdnf DNA methylation. Nonresponders, on the other hand, did not show a change in methylation status and instead maintained significantly higher methylation than controls. Further, the changes in methylation states over time were significantly associated with changes in several cognitive measures, including depression scores and impulsivity. Together, the studies reviewed in this section argue for the utility of peripheral measures of DNA methylation as a general biomarker of altered epigenetic states and even as a biological indicator of treatment response.

FUTURE DIRECTIONS

Discoveries to date in rodent and nonhuman primate models make a convincing argument that epigenetic mechanisms underlie cause–effect relations in regard to neurobehavioral development and later stress-driven abnormalities. Results from many animal studies have been translated to humans. As applied to human development and psychopathology, epigenetic studies in humans have likewise provided compelling evidence that DNA methylation alterations are a biological substrate through which a variety of factors can alter the human genome. Though early studies utilized a candidate gene and brain region approach to identify specific sites of DNA methylation changes, more recent studies have begun to utilize a genome- and system-wide approach. Data from these types of studies are telling us that the impact is not limited to a single gene or brain region, but that epigenetic changes are occurring genome-wide and throughout the brain and body. This tells us then that there are epigenetic consequences for gene networks, with functional implications for disruptions at the circuit level.

Despite the fact that our knowledge concerning the ability of experiences to epigenetically modify our genome is progressing, we still have much to learn. Throughout the chapter we have tried to bring up outstanding issues in the field when relevant to particular topics we reviewed. Here we discuss a few others.

Though we can easily say environmental factors have direct effects on gene expression and behavior via alterations in DNA methylation, one of the most important questions for future studies to address is how environmental factors drive these changes. We do know that postmitotic neurons express the enzymatic machinery necessary for modifying chromatin and DNA methylation states (Brown, Weaver, Meaney, & Szyf, 2008; Feng et al., 2005; Ma et al., 2009), providing a susceptible basis for environmentally driven epigenetic modifications. Brain region, and cell-type specificity for that matter, would require qualitative, quantitative, and spatial arrangement of mechanisms capable of orchestrating responses to similar stimuli, which appears also to be in place. In the hippocampus for example, isoforms of Dnmt are known to vary by subregion (Brown et al., 2008) and cell-type (Feng et al., 2005; Siegmund & Connor, 2007). The physical link (i.e., signaling cascades), however, between an environmental stimulus and a change in DNA methylation remains unclear, but hypotheses are developing. In the model of high versus low LG behavior in rats, it is thought that maternal behavior triggers a signaling cascade that involves a serotonergic-mediated increase in cAMP, recruitment of the transcription factor nerve growth factor-induced protein A, and recruitment of CBP and a candidate demethylase (MBD2) to the GR promoter (Hackman, Farah, & Meaney, 2010; Weaver et al., 2007). In the maternal separation model that showed changes in epigenetic programming of AVP (Murgatroyd et al., 2009), separation is thought to depolarize hypothalamic neurons, triggering phosphorylation of MeCP2 (via calmodulin kinase II, which converts it from an inhibitor to an activator of transcription), and demethylation of AVP.

In the last few years there has been the discovery of 5-hydroxymethylcytosine (5hmC), an epigenetic modification that may serve as a intermediary between a methylated and demethylated cytosine, and regardless of its exact role is now commonly considered a sixth base within the genome (Münzel, Globisch, & Carell, 2011; Song & He, 2011). Conventional methods used for mapping DNA methylation, such as bisulfite sequencing, do not differentiate a methylated cytosine from a hydroxymethylated cytosine. The exact role of 5hmC in the brain is not clear, but there is evidence that its role is distinct from that of DNA methylation, and several laboratories have now made the connection between TET proteins and cognition. For example, though able to form a normal associative fear memory, TET1 knockout mice are impaired in their ability to extinguish the memory (Rudenko et al., 2013). Overexpression of TET1 (using a viral-mediated approach) leads to increased 5hmC in hippocampal tissue that impairs hippocampal-dependent fear memory formation (Kaas et al., 2013). Further, we are beginning to see evidence

of changes in 5hmC associated with early-life stress and disease. Maternal deprivation in rhesus macaques has been shown to induce DNA hydroxymethylation changes at numerous gene loci within the prefrontal cortex, including the promoter region of genes that are involved in neurological functions and psychiatric disorders, including REST, MAPK1, and SLC6A4 (Massart et al., 2014). These data tell us that we have an additional epigenetic marker responsive to life events, which may too mediate the impact of such events on brain development and function. Additionally, postmortem data are beginning to strengthen the idea that alterations in brain 5hmC have relevance to brain and psychiatric disorders, including AD (Chouliaras et al., 2013) and SZ (Kato & Iwamoto, 2014). Further research is certainly necessary to fully understand the role of 5hmC in mediating behavioral trajectories.

The final point for further research that we bring up here is that involving telomeres. There is increasing evidence that chromatin modifications are important regulators of telomeres, and as telomere length continues to be implicated in health and disease outcomes it seems critical to understand the link between epigenetics and telomeres. Telomeres are TTAGGG repeats located at the ends of chromosomes. One common analogy that is helpful when picturing telomeres is to compare them to the clear, plastic caps on the end shoelaces. Their main role is to maintain the stability of the chromosome (Blackburn, 1991; Blackburn, 2005). An enzyme called telomerase assists in the maintenance of telomere length, and telomeres shorten every time cells divide. Telomeres are known to shorten with age, and this shortening is influenced by epigenetic regulation and exacerbated by stress (Aubert & Lansdorp, 2008; Blasco, 2007). For example, telomere length is reduced in mothers caring for chronically ill children (Epel et al., 2004). Shorter telomeres have been found in those who had a greater number of childhood adverse events (Tyrka et al., 2010), spent a significant amount of time in institutional care (Drury et al., 2012), or were exposed to violence (Shalev et al., 2012). Asok and colleagues recently showed that high-risk children have greater amounts of telomere attrition when compared with low-risk children, and that longer telomere length was associated with higher parental responsiveness in high-risk children (Asok, Bernard, Roth, Rosen, & Dozier, 2013). All of these studies support the notion that a reduction in telomere length is a biological outcome associated with early-life stress. Given that chromatin structure affects regulation of telomeres, another important piece in the puzzle to solve is how epigenetic changes driven by stress might in turn drive (or be a result of) telomere dysregulation.

CONCLUDING REMARKS

In summary, studies have revolutionized our understanding of the biological changes that occur with environmental adversity, social stress, and traumatic experiences. Work in both animal models and humans have contributed fascinating insight into epigenetic factors that serve as a rich source for interactions between our environment and static genome. Continued elucidation of the regulatory role of epigenetic processes in aspects of normal and abnormal brain development stands to reveal substantial information regarding the molecular processes underlying cognitive and psychiatric disorders, and importantly, routes for more effective treatment strategies.

INTRODUCTION

Overview of Chapter

The observation of multifinality and equifinality in the development of psychopathology has long been a source of intrigue to psychologists (Cicchetti & Rogosch, 1996). In the case of the former, it has been observed that the same environmental input can have a number of different outcomes depending on the individual. For instance, although it is noted that environmental stress contributes to a range of psychiatric disorders, including major depression and post-traumatic stress disorder, only a subset of individuals exposed to such stress will actually go on to develop disorders. Moreover, when disorder does occur, some individuals appear to react to stress with externalizing behaviors, whereas others develop internalizing problems. Further, some individuals appear to be strongly impacted by environmental stress, whereas others exhibit resilience and achieve positive outcomes in such environments (Masten, 2001). In the case of equifinality, one final end point may be the result of multiple different developmental origins. For example, different types of environments and

Large portions of this chapter are based on Bogdan, Hyde, & Hariri, *Molecular Psychiatry*, 2013; Hyde, Bodgan, & Hariri, *Oxford Handbook in Molecular Psychology,* 2013; Hyde Bogdan, & Hariri, *Trends in Cognitive Science*, 2011; Munoz, Hyde, & Hariri, *Journal of the American Academy of Child and Adolescent Psychiatry*, 2011; Hyde 2015, *Development and Psychopathology*; and Swartz & Monk, 2013, *Handbook of Developmental Psychopathology*. Thus this chapter draws heavily on these sources in combining the ideas and text of these works to provide a more integrated and comprehensive description of the neurogenetics of developmental psychopathology. The work was supported in part by a postdoctoral fellowship provided by the National Institute of Child Health and Human Development (T-32 HD07376) through the Center for Developmental Science, University of North Carolina at Chapel Hill, to JRS. We wish to thank Martha Alves and Hailey Dotterer for their helpful assistance in preparing the chapter.

life events that vary in their nature, timing, and duration (e.g., childhood maltreatment, loss of a loved one, natural disasters) could all have the same outcome: the onset of major depression, demonstrating that there are likely many pathways to the same outcome. The key to understanding these processes is tied to the study of how individual differences interact with, modify, and increase or decrease responsiveness to environmental influences.

A large volume and wide variety of psychological research has documented that individual differences in dimensions of personality, mood, cognition, and environmental experience critically shape complex human behavior and confer differential susceptibility for psychopathology across development (Belsky & Pluess, 2009; Ellis & Boyce, 2011). The integration of neuroscience and psychology has shown that many of these individual differences in personality, mood, cognition, and experience are associated with differences in the brain, including its structure (Kempton, Salvador, Munafò, et al., 2011), connectivity (Thomason & Thompson, 2011; Whitfield-Gabrieli et al., 2009), activity at rest (Jang et al., 2011; Pizzagalli, 2010), and activity during tasks (Hariri, 2009). Moreover, associations between brain structure and function and complex behavior are not "just" correlational: experimental designs, including direct chemical (Bigos et al., 2008) and electrical (De Raedt et al., 2010; Holtzheimer & Mayberg, 2011) manipulation of these neural circuits have been shown to cause behavioral changes. Thus, much current research is aimed at understanding the neural correlates and brain mechanisms involved in the development of psychopathology.

In this chapter we ask where individual differences in brain structure and function arise from and how we can understand the role of genetic background in shaping neural structure and function, particularly as it interacts with experience across development. Specifically, we refer to *neurogenetics* as a discipline that will improve understanding of a complex etiological chain that starts with variability in genes, interacts with variability in experience, with this interaction mediated by the brain at multiple levels of analysis, and is ultimately expressed as behavior or more specifically as cognition, mood, or personality, that may increase risk for maladaptive outcomes, such as psychopathology. Such mechanistic knowledge can facilitate the development of better (and etiologically-based) diagnoses and ultimately lead to novel treatments targeting specific links identified within these complex pathways (Charney et al., 2002; Hasler & Northoff, 2011; Kupfer & Regier, 2011). In other words, by understanding how our genetic background interacts with experience to affect our brain, a deeper, more nuanced, and more complete understanding of psychopathology can emerge, leading to improved treatment and prevention.

An initial step to develop a mechanistic understanding of complex behavior is to identify sources of individual variability in neural signaling pathways (e.g., neurotransmitter systems) and to understand how such variability influences brain function and behavior. Because differences in neurotransmitter availability and function ultimately shape variability in emergent neural pathways, developing links between brain chemistry and circuitry is critical for understanding the biological basis of behavior and psychopathology. Building on nonhuman animal research (Holmes, 2001), positron emission tomography (PET) ligand (Buckholtz et al., 2010), and pharmacologic challenge (Bigos et al., 2008) studies, molecular genetics provides noninvasive and cost effective tools to tap into variability in brain chemistry through the identification of common DNA sequence variation, referred to as polymorphisms. These polymorphisms allow for the modeling of individual differences in brain chemistry and neural signaling pathways, and represent the first step in a cascade that leads from genetic to neural to behavioral differences (Bigos & Weinberger, 2010; Hariri, 2009; Meyer-Lindenberg et al., 2006). Thus, in the first part of this chapter, we provide a detailed overview of neurogenetics, including an outline of the variety of techniques incorporated within a neurogenetics framework and a discussion of how neurogenetics research is contributing to our understanding of these complex molecular signaling cascades.

In the second part of this chapter, we discuss how areas of research and techniques within neurogenetics map onto concepts from *developmental psychopathology*. Guided by a *developmental neurogenetics* framework (Hyde, 2015), we highlight emerging findings from studies that have examined youth internalizing disorders, including anxiety and depression. We discuss interactions between well-established neural underpinnings of internalizing disorders (i.e., corticolimbic circuitry and functioning) with genotype and environmental adversity. More importantly, we outline potential biological mechanisms that can account for interactions between gene, brain, and environment that may ultimately lead to the behavioral outcome of depression or anxiety among some youth. In addition, we discuss potential treatment implications that arise from neurogenetics. Finally, we discuss current challenges in neurogenetics and next steps in research on developmental neurogenetics.

A Brief History of Imaging Genetics and Neurogenetics

The systematic investigation of how common genetic variation maps onto individual differences in behaviorally and clinically relevant brain function was pioneered at the turn of the century by Daniel R. Weinberger and a small group of colleagues at the National Institute of Mental Health. Weinberger and colleagues were specifically interested in advancing our understanding of the molecular genetic architecture of common psychiatric disorders, particularly schizophrenia, which twin studies had demonstrated to exhibit a high degree of heritability. However, rather than attempting to link common genetic variation directly to clinical diagnosis as had been the convention in psychiatry, Weinberger and colleagues focused their association studies on neural phenotypes that were simultaneously more proximal to any molecular effects of polymorphisms and represented intermediate biological processes associated with core disease symptoms and pathophysiology. In other words, Weinberger and colleagues began to systematically map the biological pathways that lay between any given genotype and an emergent behavioral or clinical phenotype (Hariri & Weinberger, 2003).

In the earliest imaging genetics studies, neuroreceptor mapping techniques, such as single-photon emission computerized tomography (SPECT), were employed to map common variation positioned to affect gene expression onto observable in vivo differences in protein availability (e.g., Heinz, Goldman, et al., 2000; Heinz, Jones, et al., 2000). These studies were followed quickly by those using fMRI to map common variants onto variability in brain function associated with core symptoms and pathophysiology (e.g., Bookheimer et al., 2000; Egan et al., 2001; Hariri et al., 2002). Through these earliest studies, imaging genetics emerged as a simple yet powerful approach that not only provided the missing links between genes and disorder but, through illumination of these links, also offered novel targets for treatment. Imaging genetics further introduced a remarkable era of replication in genetic association studies by focusing on relatively homogeneous neural phenotypes rather than heterogeneous behavioral and clinical phenotypes. The almost parallel emergence of gene–by environment (GxE) interaction research in psychiatry (Caspi et al., 2002; Caspi et al., 2003) demonstrated that the ultimate effect of genetically driven variability in brain function on psychopathology likely reflects the moderating role of specific environments through which these pathways can be expressed as relative risk or resilience (Belsky et al., 2009; Grishkevich & Yanai, 2013; Manuck, 2009).

While the value of imaging genetics in advancing the treatment and, possibly, prevention of mental illness was readily and rapidly adopted by the psychiatric community, the approach was initially regarded as little more than a curiosity by neuroscience. However, the application of imaging genetics to illuminate the importance of specific pathways in the emergence of individual differences in a broad range of cognitive and affective brain functions has garnered increasing recognition by even basic scientists (Hariri, 2009). As detailed below, in this broader application of imaging genetics, common polymorphisms of demonstrated importance for specific biological pathways are used to efficiently model emergent variability in brain chemistry and, in turn, test the modulatory effects of this chemistry on cognitive and affective processes supported by discrete neural circuits (Erickson et al., 2013; Forbes et al., 2009; Nikolova, Singhi, Drabant, & Hariri, 2013).

Across disciplines, imaging genetics has now become a widely and commonly employed tool for identifying the biological pathways through which individual differences in behaviorally and clinically relevant brain function emerge and contribute to trajectories of risk and resilience for psychopathology. It is positioned to inform the development of animal models to deepen our understanding of these pathways at the molecular and cellular level (e.g., Chen et al., 2006; Papaleo et al., 2008) and, likewise, translate discoveries from animal models into humans (e.g., Gunduz-Cinar et al., 2013; Joeyen-Waldorf et al., 2012; Wellman et al., 2013). Imaging genetics is further positioned to quickly and efficiently launch detailed investigations of the next generation of candidate genes as they are identified using genome-wide association studies (GWAS) and genomic sequencing (e.g., Bigos et al., 2010). Moreover, MRI-based measures of behaviorally and clinically relevant brain structure, function, and connectivity are increasingly becoming the target phenotypes in GWAS (e.g., Jahanshad et al., 2012; Jahanshad et al., 2013). Thus, imaging genetics is now poised, not to simply map biological pathways for existing genetic associations with behavioral and clinical phenotypes, but rather to drive discovery leading to follow-up association studies with targeted behavioral and clinical phenotypes of biological pathways.

WHAT IS NEUROGENETICS?

Neurogenetics is a discipline that integrates techniques from genetics, neuroscience, and psychology, and attempts to link variability at specific sites on the genome (i.e., polymorphisms) to variability in protein expression and

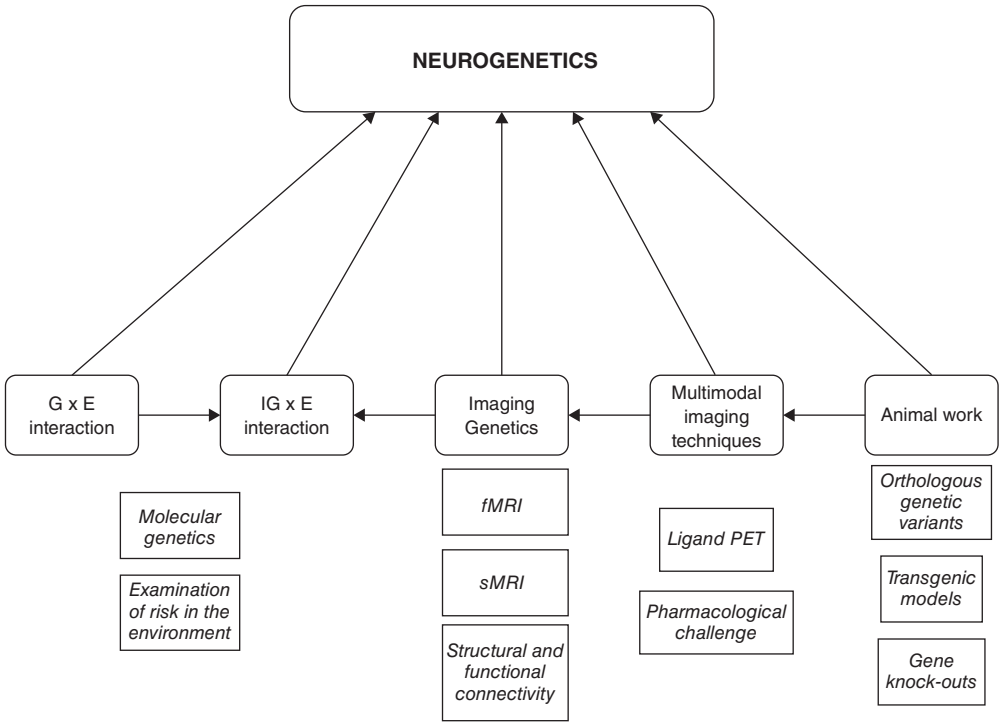

Figure 12.1 Conceptual summary of neurogenetics, a discipline that incorporates several approaches to understand the impact of genes on brain structure and function and subsequent behavior. The core technique within neurogenetics is imaging genetics, which links variability in functional genetic polymorphisms to differences in brain structure and function, particularly using MRI. However, neurogenetics also leverages nonhuman animal models and multimodal and pharmacologic challenge MRI studies to specify complex molecular signaling pathways and, more directly, to experimentally probe neural chemistry. More recently, models within a neurogenetics framework have also incorporated the influence of experience within an imaging gene–environment (IGxE) interaction framework. Through this variety of techniques, neurogenetics is helping to specify the molecular pathways from gene to brain to behavior.

function, brain structure and connectivity, and, ultimately to individual differences in behavior and risk for psychopathology (Bogdan, Hyde, & Hariri, 2012; Hariri, 2009). A significant advantage of neurogenetics is the emphasis it places on integrating evidence from multiple approaches, in particular the combination of (1) *imaging genetics*, (2) other approaches that more precisely examine neurochemistry (e.g., nonhuman animal work, PET studies, pharmacological challenge), and (3) the effect of the environment on behavior (e.g., *GxE interaction studies;* Figure 12.1). In the first half of this chapter, we describe the key elements incorporated within neurogenetics and we examine advantages and ongoing challenges of this approach.

Imaging Genetics

The core of neurogenetics is imaging genetics, a technique that aims to link variability in genes to variability in brain structure and function.

Why Study Genes in the Context of Developmental Psychopathology?

Genes have an unparalleled potential impact on all levels of biology. In the context of disease states, and particularly behaviors as they deviate from normative patterns, genes are fundamental to our understanding of mechanisms. Whereas most human behavior cannot be explained by genes alone, and certainly much of the variance in aspects of brain information processing will not be directly genetically determined, variations in a genetic sequence that impact gene function likely contribute a substantial amount of variance to these more complex phenomena. This conclusion is implicit in results garnered from twin studies that have demonstrated heritabilities of 40–70% for aspects of cognition, temperament, and personality (Plomin, Owen, & McGuffin, 1994). Psychiatric illnesses also cluster within families, suggesting a highly heritable component to disease susceptibility (Moldin & Gottesman, 1997; Weissman, Leckman, Merikangas, Gammon, & Prusoff, 1984; Williamson et al., 1995). Genes, therefore,

have the potential to identify underlying mechanisms of variability in behavior and disease risk, which may be particularly salient in relation to child and adolescent psychopathology that appears at least similar to, and in some cases, *more* heritable than adult psychiatric disorders (Beaudet, 2007; Coolidge, Thede, & Jang, 2001; Lichtenstein & Annas, 2000; Rhee & Waldman, 2002). Within this context, imaging genetics represents the ability to understand the neurobiological mechanisms through which genes can impact variability in emergent behavioral phenomena.

The classic approach used in genetic association analyses involves the use of candidate genes. A candidate gene is a gene whose variation is suspected of being directly associated with an observable behavioral or clinical (i.e., disease-related) property of an individual (called a phenotype). Within a candidate gene approach, the first step is to identify a genetic polymorphism that potentially impacts the function of a behaviorally or clinically relevant biological process. Next, deviations in the frequency of one gene variant (i.e., an allele) in populations expressing the phenotype are determined. Ideally, the genetic variation should have an impact on the molecular or cellular function of the gene or protein (i.e., be a functional variation), and the target phenotype should be stable, robust, and quantifiable. Within an imaging genetics framework, target phenotypes are usually physiological responses of the brain during specific behavioral processes (e.g., amygdala reactivity when viewing threatening facial expressions) or some other measure of brain structure (e.g., gray matter volume or integrity of white matter tracts connecting relevant brain regions) or function (e.g., brain activity at rest or network connectivity during a specific task).

Why Link Genes to Functional Neuroimaging?

Previous investigations of candidate genes have attempted to link functional polymorphisms directly to behavior. Findings from these studies however, have been weak and inconsistent (e.g., variation in the serotonin transporter—the 5-HTTLPR short allele—and negative emotionality; Malhotra & Goldman, 1999). One explanation for these weak and inconsistent findings is the considerable inter-individual differences in dimensions of observed behavior, as well as subjectivity and error in behavioral measures, which necessitate daunting sample sizes to detect even small gene effects (Glatt & Freimer, 2002). In addition, and perhaps more importantly, variability in genes needs to affect a myriad of levels of change to have any measureable influence on behavior. Put another way, gene effects are not expressed directly at the level of behavior, but rather are mediated by effects on molecular and cellular cascades, which may bias information processing in brain circuitries, ultimately mediating behavioral responses to environmental challenge. Thus, for genetic variability to affect behavior, it must also affect brain function at some level. An efficient and effective tool that can be used to explore the impact of these potentially brain-relevant genetic polymorphisms is provided by functional neuroimaging, including fMRI, EEG, and PET. These different imaging techniques enable quantification of activity within specific brain regions during cognitive and emotional tasks performed by a participant. The assumption is that imaging techniques can identify neural pathways through which genetic polymorphisms contribute to the emergence of variability in behavior and thereby risk for psychopathology.

Basic Principles Involved in Imaging Genetics

Three basic principles have been articulated for imaging genetics studies (Hariri, Drabant, & Weinberger, 2006; Hariri & Weinberger, 2003; Munoz, Hyde, & Hariri, 2009): (1) selection of candidate genes; (2) control for nongenotype factors; and (3) selection of appropriate tasks for the subject to perform during functional imaging.

First, there is a need for well-defined functional polymorphisms (i.e., single nucleotide polymorphisms [SNPs] or other structural variants) in coding or promoter regions, which have been previously linked to specific physiological effects at a cellular level with known impact at distinct brain regions. Selecting variants that are *functional* and thus that have known neurobiological consequences (e.g., increases in serotonin signaling or decreases in transcription of a protein affecting neurotransmission) is important because of the emphasis placed by imaging genetics on specifying *mechanisms* through which genes impact brain and related behavior.

Second, there is a need to control for potential confounds. This need arises because potential genetic effects are still relatively small compared to the typically large effects of age, sex, IQ, and environmental influences (e.g., illness, injury, substance abuse). Indeed, because imaging genetics studies focus on a single or relatively few polymorphisms against a background of millions, studies must control for population stratification (Cardon & Palmer, 2003). Population stratification refers to differences in the genetic background of individuals that reflect their unique ancestry, and against which any relationship between specific genotypes and phenotypes can be tested. This point is important in relation to assessing specific diverse

populations who may be at greater risk for developing psychopathology. In particular, among populations marked by heterogeneity in ethnic or racial background, allele frequencies may differ markedly by ancestry, which introduces a major potential confound into studies (for a nuanced discussion of genetic ancestry, see Fujimura & Rajagopalan, 2011).

Third, to successfully identify functional correlates of genetic variation, studies need to choose well-characterized behavioral tasks for participants to perform during functional neuroimaging, which are both sensitive and specific to the brain process under investigation. The ideal tasks for imaging genetics studies are ones that have been established to robustly engage specific brain systems as well as tasks that display adequate variance across individuals. While such criteria increase the likelihood of identifying significant genetic regulation of interindividual variability in brain function and related behaviors, multiple genetic polymorphisms (many of which will be of small effect) acting in concert or opposition in the context of unique environmental challenges will ultimately account for the majority of variance in any given neural or behavioral phenotype (e.g., Buckholtz et al., 2007; Nikolova, Ferrell, Manuck, & Hariri, 2011).

Advantages of Imaging Genetics Studies

Imaging genetics studies have become more common over the last two decades as studies of the brain have become increasingly important in our understanding of the development of psychopathology. An imaging genetics approach offers several strengths in terms of advancing our understanding of the development of variability in brain structure and function as it may relate to complex behavior and psychopathology.

First, by connecting genetic variation to intermediate biological phenotypes (e.g., brain chemistry or circuit function), a plausible, observable, and testable mechanism is provided through which genes could influence behavior (Hasler & Northoff, 2011; Meyer-Lindenberg et al., 2006). For example, several studies have demonstrated a link between variability in the serotonin transporter gene—the short allele of the 5-HTTLPR—and increased amygdala reactivity to threat (Hariri et al., 2006; Hariri et al., 2002) and decreased functional connectivity between the amygdala and prefrontal regions of the brain (Pezawas et al., 2005). Given links between increased amygdala reactivity and anxiety and depression (Fakra et al., 2009; Price & Drevets, 2010), these studies have begun to address how and why variation in the 5-HTTLPR might affect risk for these disorders. In particular, studies examining these associations exemplify much of the promise of neurogenetics by combining different techniques that emphasize the brain as the mechanism that links genetic effects on behavior and genetic variability to differences in brain structure and function.

Second, when the target polymorphism being examined is of known functionality (e.g., altered gene transcription and/or function), it can serve as a proxy for individual differences in brain chemistry. In this way, polymorphisms can inform our understanding of molecular and neurochemical mechanisms through which differences in the brain arise at the genetic and molecular level (Hariri, 2009). For example, in the case of the 5-HTTLPR, the short allele has been linked to decreased transcription of the serotonin transporter gene (Lesch et al., 1996), which in turn affects the amount of serotonin transporter molecules, ultimately affecting the clearance of serotonin from the synapse. Adopting an imaging genetics approach thus emphasizes a multilevel account for biological mechanisms: not only do genetic polymorphisms represent heritable genetic influences, but they also model neurotransmitter differences that affect neuronal firing at synapses via the modulating effect of neurotransmitters.

Third, by focusing on dimensional and relatively objective intermediate phenotypes, imaging genetics research largely escapes the limitations of broad nosological definitions (e.g., *DSM-5* diagnoses), which are typically comprised of heterogeneous symptoms or behaviors and are often subject to methodological biases inherent in self-report (Hasler & Northoff, 2011; Meyer-Lindenberg et al., 2006). Imaging genetics is thus more consistent with the Research Domain Criteria (RDoC) approach now emphasized by the National Institute of Mental Health (Cuthbert & Kozak, 2013; Insel et al., 2010), modeling a multilevel understanding of complex behavior.

Challenges of an Imaging Genetics Approach

Although imaging genetics studies have contributed to our understanding of psychopathology, some major issues are worth noting as we look forward to the next generation of research. First, the majority of imaging genetics studies has established links between genetic polymorphisms and the brain but failed to demonstrate direct and meaningful links to behavioral outcomes (Hariri et al., 2002; Pezawas et al., 2005). As noted above, however, a major advantage of an imaging genetics approach is the modeling of the brain as a mediator linking genetic variability to variability in behavior. Recently, imaging genetics studies have begun to establish such meaningful links by modeling indirect pathways from genes to behavior via the brain

(Fakra et al., 2009; Furmark et al., 2008). Studies that demonstrate indirect pathways between gene and behavior through the brain, when no direct gene–behavior link exists (Fakra et al., 2009), emphasize the importance of using statistical approaches that can model indirect (mediated) pathways (Preacher, Rucker, & Hayes, 2007). Moreover, imaging genetics studies that are able to establish indirect effects highlight that there are important relationships between genes and behavior, even when large direct relationships are not evident. However, to date, very few imaging genetics studies have actually drawn out an indirect pathway from gene to brain to behavior, instead focusing mostly on gene to brain. More research is therefore needed that examines the brain as a mediator of gene–behavior pathways.

A second critical challenge within imaging genetics is to model even greater complexity of genetic effects on the brain. In particular, GxE interaction studies clearly demonstrate the importance of environmental experience in understanding the ultimate effects of genetic variation on behavior and thus the environment should be modeled in future studies (see the following IGxE description). Beyond issues relating to the effect of the environment, the effects of epistasis (i.e., GxG interactions) and the likely small influence of any *single* genetic polymorphism highlight the need for novel analytic approaches. Future studies are needed that investigate epistasis, that is GxG interactions (Buckholtz et al., 2007; Talkowski et al., 2008), cumulative genetic profiles (Nikolova et al., 2011), hypothesis-free imaging using genome-wide association studies (Liu et al., 2010), rare gene or copy number variants (Blakely & Veenstra-Vanderweele, 2011), or novel statistical approaches to integrate multiple genes into models (Gruenewald, Seeman, Ryff, Karlamangla, & Singer, 2006; Hizer, Wright, & Garcia, 2004). Further, beyond interaction effects (GxE, GxG), future studies that incorporate complementary techniques (e.g., neuroreceptor PET, pharmacologic challenge, animal models), or studies that approach the problem of modeling neural reactivity in novel statistical ways (e.g., graph theory: Astolfi et al., 2007; or machine learning: Pereira, Mitchell, & Botvinick, 2009), will better capture molecular mechanisms mediating genetic effects on the brain (Hariri, 2009; Ressler et al., 2011).

Other Relevant Techniques to Examine Neurochemistry Within Neurogenetics

Animal Models

An advantage of leveraging genetic polymorphisms in the context of brain phenotypes is that it allows for more effective synergy with animal models (e.g., transgenic mouse models, optogenetics), which in turn can advance a detailed understanding of the molecular and cellular mechanisms that ultimately link genetic variation to brain to behavior (Blakely & Veenstra-Vanderweele, 2011; Caspi, Hariri, Holmes, Uher, & Moffitt, 2010; Holmes, 2008). Animal models allow for many designs that cannot be carried out ethically in human samples. Typically nonhuman animal designs confer greater experimental control and more precise and in-depth measurement of molecular biological pathways. Within psychiatry, nonhuman animal research has traditionally modeled psychopathology and related intermediate behaviors by documenting changes in response to behavioral, environmental, or pharmacologic stimuli and/or changes following genetic manipulation. Because of the ability to manipulate and directly measure brain chemistry and gene function, studies using animal models can therefore target specific molecular mechanisms at specific developmental periods that might otherwise be inaccessible in human studies (e.g., Yu, et al., 2014). In addition, research employing nonhuman animal models offers unique opportunities to control both genetic background and environmental experience, neither of which is practical or ethically feasible in human studies (Holmes, 2008).

Both the presence of orthologous genetic variants and the development of novel manipulations (e.g., transgenic lines, optogenetics) provide researchers using nonhuman animal models with opportunities to identify specific molecular mechanisms for behaviors related to human psychopathology, which also represent potential novel treatment targets (Barr et al., 2003; Fenno, Yizhar, & Deisseroth, 2011; Holmes, 2001). Orthologous genetic variants, which are similar but not identical to human polymorphisms, allow for more direct comparison of nonhuman animals and humans based on shared genetic differences that confer similar effects on gene transcription and/or protein function. For instance, an orthologue of 5-HTTLPR exists in rhesus macaque monkeys (i.e., rh5-HTTLPR) and, like the human variant, the short allele of rh5-HTTLPR is associated with relatively decreased transcription of the gene (Bennett et al., 2002). This functional genetic orthologue has allowed researchers to examine how various factors, such as maternal separation (Barr et al., 2004) and chronic SSRI administration (Bogdan et al., 2011), influence behavior and brain chemistry in experimentally controlled settings (Barr et al., 2003). For instance, it has been shown that following maternal separation, monkeys carrying the rh5-HTTLPR short allele display greater anxiety, agitation, and exaggerated

HPA axis response (Barr et al., 2004; Caspi et al., 2010). Moreover, much like humans, rh5-HTTLPR short allele carriers have greater metabolic activity in the amygdala (Kalin et al., 2008) and demonstrate more risk-averse behaviors (Caspi et al., 2010; Watson, Ghodasra, & Platt, 2009).

Emerging neuroimaging work with rh5-HTTLPR has begun to establish the mechanisms through which these associations with behavioral outcomes might emerge. For example, results from human studies suggest that the behavioral consequences of the short 5-HTTLPR allele may arise via neurodevelopmental influences on brain morphometry (Canli et al., 2005; Pezawas et al., 2005), which has been confirmed in the rhesus model (Jedema et al., 2010). Moreover, the rhesus model also has confirmed human findings indicating that the effects of 5-HTTLPR on adult brain function and behavior appear to be mediated by downstream modulation of other serotonin signaling mechanisms (e.g., 5-HT_{1A} autoreceptor downregulation) (David et al., 2005; Oler et al., 2009). Thus, the availability of orthologous genetic variants allows for testing and validation of observed neurogenetics pathways of individual differences in behavior, genetic disease risk in the context of adverse environments and, perhaps most importantly, the discovery of specific molecular mechanisms mediating neurogenetics effects on behavior and psychopathology.

Similarly, transgenic mouse models have provided invaluable insight into the genetic and molecular components of complex behavior and related psychopathology. For example, serotonin transporter knockout mice (i.e., mice that have been genetically engineered to have an existing gene inactivated) have informed our understanding of how the short allele of 5-HTTLPR in humans may contribute to depression. A series of studies using a knockout mouse model have demonstrated that loss of serotonin transporter function results in a multitude of downstream effects, including regionally specific upregulation and downregulation of both presynaptic and postsynaptic serotonin receptors, which ultimately determine the modulatory effects of serotonin on neuronal signaling (Hariri & Holmes, 2006; Holmes, 2008; Kim et al., 2005). In addition, conditional transgenic models have furthered our knowledge of serotonin function. Unlike the constitutive (i.e., from birth) serotonin transporter knockout model, conditional transgenic models allow experimenters to control the exact *timing* of gene knockout. These transgenic models have demonstrated that similar differences in serotonin signaling (conferred by 5-HTR_{1A} autoreceptor negative feedback and not transporter reuptake) must occur early in development to alter adult brain function and behavior (Gross et al., 2002) and that the long term effects of signaling in these pathways may be specific to sensitive developmental periods (Yu et al., 2014). These results suggest that serotonin transporter function and the resulting effects on brain and behavior vary substantially across development.

Thus both monkey and rodent data suggest that the short allele of 5-HTTLPR appears to exert its influence on behavior and risk for depression through neurodevelopmental mechanisms that affect both downstream 5-HT signaling mechanisms and corticolimbic structure. Further, both of these processes appear to be exacerbated by stressful experiences. Convergent patterns across species help to detail the molecular mechanisms that shape the effects of 5-HTTLPR on brain chemistry, circuitry, behavior, and risk for psychopathology (Caspi et al., 2010), and thus demonstrate the utility of using nonhuman animal model research to inform our interpretation of neurogenetics studies in humans. As noted above, findings from imaging genetics studies are often built on a firm foundation in animal models and can be strengthened via a two-way exchange with this literature (Figure 12.1). Though studies of 5-HTTLPR correlations with amygdala reactivity are often cited in isolation, these studies were built on and informed by nuanced work in nonhuman animal models.

Multimodal Imaging

Because functional genetic polymorphisms appear to be a useful way of representing individual differences in brain chemistry and associated neural signaling pathways, neurogenetics can inform our ultimate goal of identifying the detailed and complex biological mechanisms that give rise to risk for psychopathology. However, to truly gain mechanistic knowledge, neurogenetics is strengthened by incorporating more direct assessment (e.g., ligand PET; Willeit & Praschak-Rieder, 2010) or manipulation (e.g., pharmacological challenge; King & Liberzon, 2009) of brain chemistry in humans and work from nonhuman animal research. The synergy of these different approaches within a neurogenetics framework allows for even more detailed and controlled assessment and manipulation of brain chemistry. The incorporation of a wider range of techniques to assess brain chemistry is a major reason this discipline is now more broadly referred to as *neurogenetics* instead of *imaging genetics*. The term neurogenetics deliberately emphasizes that a range of techniques are critical to this approach and that it is *not solely* focused on using imaging with genetics (Bogdan, Hyde, et al., 2012; Hariri, 2009). Indeed, although imaging genetics has contributed to our understanding of how molecular signaling pathways

affect brain structure and function, genetic variation is a distal and typically static indicator of these pathways.

Therefore, neurogenetics researchers have leveraged two other approaches to better define these pathways at a molecular level. Specifically, neurogenetics also includes the use of multimodal imaging. Multimodal imaging studies use positron emission tomography (PET) in combination with genetic polymorphisms and fMRI to directly probe in vivo neurochemistry (Fisher & Hariri, 2012; Fisher et al., 2009; Willeit & Praschak-Rieder, 2010). For example, work by Fisher, Hariri, and colleagues has used PET, fMRI, and molecular genetics approaches to link genetic variability to brain function, as well as *in vivo* neurochemistry. In particular, these researchers examined the serotonin 1A receptor, a major receptor in the serotonin system for providing homeostatic feedback on serotonin transmission (Hariri & Holmes, 2006). Using PET and fMRI, they demonstrated that the density of serotonin 1A autoreceptors accounts for 30–44% of variability in amygdala reactivity in healthy adults (Fisher, Meltzer, Ziolko, Price, & Hariri, 2006). As previous studies had identified a functional genetic polymorphism in the serotonin 1A receptor gene (the −1019G allele of HTR1A) (Lemonde et al., 2003), this group next examined how this polymorphism affected neural function by using fMRI in an imaging genetics study. They found that the serotonin 1A receptor gene functional polymorphism was related to individual differences in amygdala reactivity and subsequent trait anxiety (Fakra et al., 2009). Taken together, these studies build a molecular mechanism via which variation in the serotonin 1A receptor gene may affect receptor density, which in turn appears to affect amygdala reactivity, resulting in risk for greater trait anxiety. Further, this body of research exemplifies how multimodal neuroimaging, combined with imaging genetics, can begin to build a molecular account for the ways that genetic polymorphisms might affect complex neurotransmitter pathways (e.g., affecting receptors that affect feedback on the 5-HT system) and ultimately influence both neural functioning and subsequent behavior (Fisher & Hariri, 2012; Fisher & Hariri, 2013). Moreover, by leveraging PET with fMRI, neurochemistry can be examined in the same human participants that are undergoing fMRI scans.

Pharmacological fMRI

While multimodal studies involving PET enable direct observation of neurotransmitter binding levels in awake adults, *pharmacological fMRI* designs facilitate direct manipulation of circuits (Honey & Bullmore, 2004; Schwarz, Gozzi, Reese, & Bifone, 2007). More specifically, neural responses are examined after individuals are given drugs that target specific neurotransmitters systems. For example, studies have used acute administration of selective serotonin reuptake inhibitors in combination with fMRI to demonstrate that these commonly prescribed drugs have direct effects on amygdala reactivity (e.g., Bigos et al., 2008). These findings demonstrate that experimental manipulation of specific neural circuits can also cause changes in functioning. In this way, studies are beginning to specify how blocking of serotonin transporters affects amygdala reactivity acutely and chronically. Through PET and pharmacological challenge studies, neurogenetics researchers are thus able to observe more precise molecular mechanisms and experimentally manipulate these pathways. However, while the addition of multimodal neuroimaging and pharmacological fMRI are important components of a neurogenetics approach, these techniques are difficult to carry out ethically among children, and are therefore less helpful when examining younger populations or when asking questions about early development. At the same time, use of synergistic techniques within a neurogenetics framework, even among adults, and incorporation of converging findings from nonhuman animal models, helps lay a foundation for understanding these processes across development (e.g., Yu, et al., 2014).

Imaging Gene–Environment (IGxE) Interactions

As outlined in the previous sections, a neurogenetics approach, informed by nonhuman animal work, uses imaging genetics and other complementary techniques (e.g., multimodal and pharmacological fMRI) to build a more precise and multilevel account of individual differences from gene to neurotransmitter, to brain structure and function, and ultimately to behavior. Until recently, neurogenetics had been solely focused on delineating neurobiological contributions to behavior, and for the most part, had ignored potential environmental influences on these pathways. However, a number of other approaches have led to an expansion of neurogenetics to incorporate conceptualizations of the environment. First, the rise of the field of epigenetics has led to a greater *specification* of the molecular mechanisms through which experience is thought to affect gene transcription and translation (Meaney, 2010). Second, GxE interaction studies at the epidemiological level have continued to gain prominence within research on psychopathology development (Moffitt, Caspi, & Rutter, 2005, 2006). Finally, an increasing number of studies have demonstrated important links between individual variability in experiences and differences in brain

structure and function (Gianaros et al., 2008; Gianaros et al., 2007; Gianaros et al., 2011; Hackman, Farah, & Meaney, 2010; Tottenham et al., 2011; Tottenham et al., 2010). Thus, neurogenetics has evolved further in order to specify how the *environment* could affect and interact with complex biological pathways (Caspi & Moffitt, 2006). We describe this evolution of neurogenetics to incorporate assessments of the environment in detail below.

Considering the Environment: GxE Interactions

Why do some youth exposed to environmental stressors (e.g., abuse) go on to experience psychopathology, while others, exposed to the same stressor, are resilient? Inspired by models of differential susceptibility (Belsky & Pluess, 2009; Ellis & Boyce, 2011), GxE interaction studies have helped to specify why some individuals are more likely than others to succumb to risk. A GxE interaction occurs when the relationship between an environmental experience (e.g., exposure to trauma) and a phenotype (e.g., psychopathology) is contingent on individual differences in genetic makeup (i.e., genetic polymorphisms) (Caspi & Moffitt, 2006; Rutter, Moffitt, & Caspi, 2006). Alternatively, a GxE interaction is observed when the association between genetic makeup and a phenotype is dependent upon environmental experience. As such, GxE interaction research does not presuppose a main effect of either single polymorphisms or environmental experiences but rather emphasizes an interaction between genetic variation and experience.

Theoretical reviews have revealed several key principles for conducting GxE interaction research and evaluating the resulting patterns (Caspi & Moffitt, 2006; Moffitt et al., 2005). First, as in imaging genetics, researchers need to consider the broad heritability of the target behavior and then leverage knowledge generated in physiology and neuroscience to select polymorphisms in candidate genes that are of functional significance in the biological response to the environmental experience. Second, there needs to be evidence of variability in the response to the selected environmental experience, for which accurate measurement and, ideally, quantification should be available. Finally, there should be causal evidence linking the environmental experience with psychopathology if possible.

Because the concept of GxE interactions does not presuppose a large main effect of single genetic variants (or experiences) on behavior but rather emphasizes an interaction with experience, carefully conducted GxE interaction studies can be instrumental in addressing issues of "hidden heritability". Specifically, hidden heritability refers to the general failure of GWAS (and specific candidate genetic variants) to account for much of the variance attributed to heritable factors in quantitative studies (Maher, 2008), the generally weak penetrance of polymorphisms in candidate genes (Maher, 2008), and the lack of consistent replication in genetic association studies of psychopathology (Caspi & Moffitt, 2006; Plomin, 2005). There are therefore a number of advantages for neurogenetics to adopt a GxE interaction approach. First, a GxE interaction approach holds promise to confront the problem of the typically small effects in neurogenetics research, whereby inclusion of environmental factors may inform the effects of polymorphisms on a phenotype (Bogdan, Hyde, et al., 2012). Second, GxE interaction research provides face validity as it represents a more plausible model of development in which individual experiences and genetic background interact to influence relative risk rather than more simplistic models hypothesizing independent effects of particular genes or experiences.

The utility of a GxE interaction approach for the discipline of neurogenetics is exemplified by the influential work of Caspi and colleagues (Caspi et al., 2003), who demonstrated that the depressogenic effects of stress are contingent upon 5-HTTLPR genotype. Specifically, in these studies, a strong and positive relationship between life stress and depression was noted among short allele carriers of a 5-HTTLPR genotype. In contrast, long allele homozygotes of 5-HTTLPR genotype had little or no relationship between stress and depression. These findings have been well replicated (Caspi et al., 2010; Kaufman et al., 2004; Kendler, Kuhn, Vittum, Prescott, & Riley, 2005) and are supported by meta-analysis (Karg, Burmeister, Shedden, & Sen, 2011) and by extensive rodent and nonhuman primate models (Caspi et al., 2010).

For neurogenetics models, the prominence of the 5-HTTLPR genotype is of specific interest as this same allele, as described previously, was linked to amygdala reactivity in some of the first ever imaging genetics studies. This finding has also since been well replicated and further supported by meta-analytic studies (Hariri et al., 2005; Hariri & Holmes, 2006; Hariri et al., 2002; Munafò, Brown, & Hariri, 2008; Pezawas et al., 2005). Moreover, the confluence of these findings suggests that imaging genetics research would benefit from incorporating both the environment and GxE interactions to conceptualize relationships between gene, brain, and behavior. Indeed, GxE interaction research alone cannot reveal the specific biological mechanisms for risk (Blakely & Veenstra-Vanderweele, 2011; Caspi & Moffitt, 2006). Ultimately, for a genetic or environmental variable to affect behavior, it must "get under the skin" (Kendler, 2011; Meyer-Lindenberg,

2011; Rutter & Dodge, 2011): GxE interactions must be instantiated in the brain if they are to affect behavior and the development of risk and resilience. Thus the integration of imaging genetics with GxE interaction studies is critical to our understanding across both literatures, and fits well within a broader neurogenetics framework.

Integrating Imaging Genetics and GxE Interaction Studies

Both GxE interaction studies and imaging genetics studies examine potential relationships between genetic variation and individual differences in behavior or risk for psychopathology. In GxE interactions, the relationship is conditional on experience (i.e., statistical moderation). This conditional effect is necessary to unmask genetic effects (or vice versa). In imaging genetics, a biological mechanism is specified in which variability in brain structure or function enables a link to be drawn between genes and behavior (i.e., statistical mediation/indirect effects). The integration of these two approaches has been termed imaging gene–environment interactions (IGxE) (Hyde, Bogdan, & Hariri, 2011). IGxE informs our understanding of the conditional mechanisms through which genes, environments, and the brain interact to predict behavior and risk for psychopathology. Several recent reviews have demonstrated possible IGxE interactions within a neurogenetics framework, by combining findings from research in animal models, GxE interaction studies, and imaging genetics studies to explain the interactions of genetic variants with environmental variables to predict learning, memory, and psychopathology (Casey et al., 2009; Caspi et al., 2010; Meyer-Lindenberg, 2011). Though these reviews are exciting, empirical studies are only just beginning to test components of IGxE directly. We explore how these conditional mechanisms can be specified conceptually and statistically in single human neuroimaging studies and outline recent studies that have tested components of IGxE interactions.

First, the concept of IGxE can be modeled statistically using a moderated mediation framework (also called conditional indirect effects) (Preacher et al., 2007), in which mediated/indirect effects are moderated by a third variable. Within IGxE, any or all mediated imaging genetics paths (i.e., gene to brain, brain to behavior, and then gene to behavior via brain) may differ depending on the level of a moderator variable (e.g., presence or absence of childhood abuse). As shown in Figure 12.2, there are multiple ways that genetic, neural, environmental, and behavioral variables could interact, and each model yields answers to slightly different questions (see also Preacher et al., 2007). A particularly intuitive IGxE model is a GxE interaction in which the interaction term predicts behavior through its effect on brain function (Figure 12.2, path c). In this case

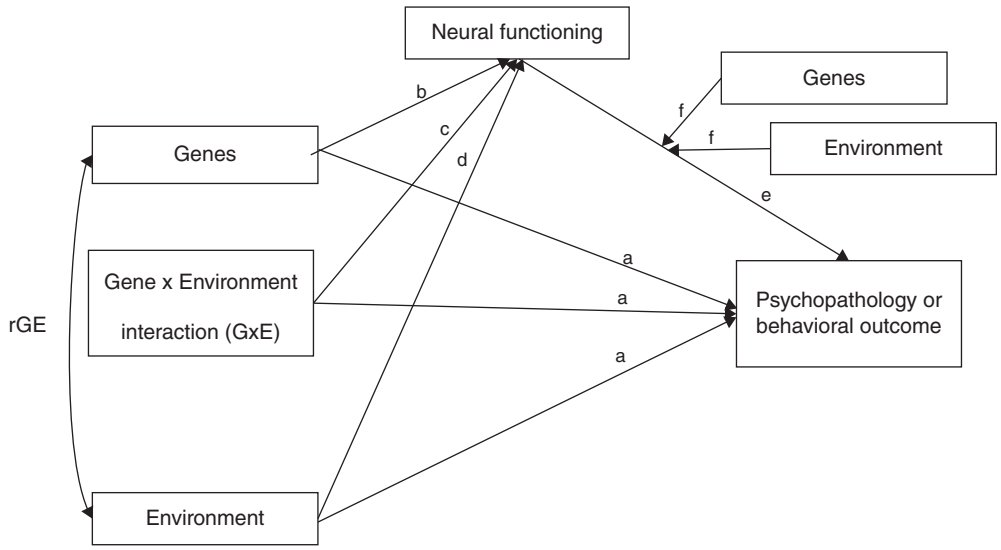

Figure 12.2 Theoretical model of IGxE. A theoretical model of IGxE highlighting how IGxE can be modeled conceptually and statistically. Relationships of the variables are shown for more traditional GxE and imaging genetics paths, as well as new paths possible in IGxE. The a paths model typical GxE relationships; b & e paths model traditional imaging genetics links; d paths show direct effects of the environment on neural functioning; c and e paths model GxE interactions predicting behavior via neural functioning; f paths represent further possible interactions—genetic variation or certain environments moderate associations between neural functioning and behavior. Within SEM models of continuous interactions, the covariance between a genetic variant and an environment is modeled and reflects the correlation (rGE) between specific genetic variants and the environment. *Source:* Adapted from Hyde, Bogdan & Hariri (2011).

there are direct effects of both genetic and environmental variables on brain function, but their interaction predicts nonadditive unique variance, which in turn predicts behavior.

A theoretical example of applying this IGxE interaction model is that increased amygdala reactivity is predicted by both the risk allele of the 5-HTTLPR polymorphism (Hariri et al., 2002), and early experiential risk (e.g., early child maltreatment, McCrory et al., 2013; or socioemotional deprivation, Tottenham et al., 2011). Individuals with the 5-HTTLPR polymorphism and relevant environmental experience could show a *synergistic* increase in amygdala reactivity, which could then further predict increased anxiety symptoms. Alternatively, a positive environment, such as parental warmth, could negate any relationship between genetic variation in serotonin signaling and amygdala reactivity and this lowered amygdala reactivity could then predict average levels of anxiety symptoms.

This example also underlies much of the potential of incorporating IGxE interactions within the discipline of neurogenetics. By combining the power of proximal intermediate phenotypes, evidence from animal models, and potential GxE interactions to clarify relationships, IGxE interaction research is able to provide further insight into the conundrum of hidden heritability. For example, if a genetic variant had no association with a neural or behavioral phenotype in the majority of circumstances, but a robust association in relatively rare environments (e.g., physical abuse), IGxE could potentially detect the association via proximal neural phenotypes. Finally, it is also important to note that within an IGxE model, we specify paths in which genes or experience moderate a brain–behavior link based on studies that support this type of statistical moderation. For example, individuals with a variant in a gene affecting endocannabinoid signaling were found to show greater correlation between reward-related brain reactivity and a measure of impulsivity (Hariri et al., 2009). Additionally, individuals with low social support had a greater relationship between their threat related neural reactivity and trait anxiety (Hyde, Gorka, Manuck, & Hariri, 2011). These studies suggest that the brain–behavior link may not be static across all environments or across different genetic backgrounds.

Within neurogenetics research, approaches that test a "full" IGxE model (i.e., GxE interaction predicts brain function, which in turn predicts behavior via a mediated pathway) are exciting but are only just beginning to emerge (e.g., Glaser et al., 2014). However, several studies have recently been published testing GxE interactions that predict brain function, a critical first step in this emerging field (Cousijn et al., 2010; Drabant et al., 2012; Gerritsen et al., 2011; Ursini et al., 2011). In the first study testing a portion of an IGxE interaction model, Canli and colleagues (2006) reported that the 5-HTTLPR genotype interacted with life stress to predict resting state activity in the amygdala. More specifically, this study found that short allele carriers had elevated amygdala activity at rest, but only among individuals that had experienced more life stress, providing a neural mechanism through which short allele carriers could be more susceptible to the environment at the neural level. In other words, the short allele was only related to amygdala activity at rest for those with greater experience of negative life events, demonstrating an interaction between genotype and environment in predicting brain function.

In a second example of recent research that has tested a portion of an IGxE interaction model, White and colleagues found that emotional neglect was related to threat related amygdala reactivity, but only among individuals with specific alleles of a gene coding for a protein (FKBP5) that affects hypothalamic-pituitary-adrenal (HPA) axis regulation (White et al., 2012). This result is particularly interesting when considered alongside the well-established roles played by both the HPA axis and amygdala functioning in a myriad of psychopathologies. Moreover, the findings of White and colleagues helps to elucidate why some youth with one risk factor (e.g., emotional neglect) may ultimately experience poor outcomes, while others appear relatively resilient. Overall, these and other studies (e.g., Bogdan, Williamson, & Hariri, 2012) are beginning to demonstrate that gene effects on the brain appear to be moderated by experience or vice versa, that experience effects on the brain are moderated by genotype, and that these interactions may affect risk for psychopathology through their effect on brain structure and function (Glaser, et al., 2014).

Challenges to Progress and Advances in the Emerging Field of IGxE

Like that of its parent strategies (i.e., imaging genetics and GxE interaction studies), the promise of an IGxE interaction model is not without ongoing challenges. First, the challenges noted in the imaging genetics section generally apply to IGxE interaction models. Second, incorporating the environment into models introduces additional complexity, including the need to consider carefully any definition of what an environment experience actually consists of (Manuck, 2013; Manuck & McCaffery, 2010). Typically, environment refers to both *experiential* phenomena (e.g., childhood abuse, divorce, or unemployment; Caspi et al., 2003) and *exposure* to

physical forces (e.g., toxins, natural disasters, and acts of violence; Franklin & Mansuy, 2010). However, experiential phenomena and physical forces differ crucially in the degree to which an affected individual contributes to the environmental trigger, little to none with physical forces but possibly a significant amount with experiential factors.

A wealth of research supports the notion that individuals vary in the degree to which they influence their own experiences. By extension, many "experiences" are likely to be correlated with genotype (Burt, 2008; Jaffee, 2011; O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998). "Experiences" that are influenced by an individual may reflect GxE correlation (rGE): the influence of genetically driven variability in behavior as a precipitator of specific experiential triggers (e.g., heritable difficult temperament resulting in harsh parenting, which in turn are both correlated with later antisocial behavior). Unfortunately, some GxE interaction studies may therefore be biased by rGE in that many of the "experiences" are exposures that could, to some degree, be precipitated by the individual and contingent on their genotype (Jaffee, 2011). Indeed, some GxE interaction studies may actually be finding latent GxG interactions.

Recently, several GxE interaction studies have sought to address the issue of rGE through novel designs such as behavior genetic approaches (Reiss & Leve, 2007). For example, adoption studies are able to separate the extent to which parents and children share genotype (Leve et al., 2010) and twin designs isolate ways that experiences differentially affect individuals with the same genotype (Jaffee et al., 2005). Studies have also addressed rGE by capitalizing on natural disasters (Kilpatrick et al., 2007) or natural experiments (Costello, Compton, Keeler, & Angold, 2003). Within these designs, GxE interaction effects can be explored in a context where individual genotypes are unlikely to be related to the experiential phenomenon (e.g., a hurricane). Studies using experimental manipulation in humans (King & Liberzon, 2009) and nonhuman primates (Bennett et al., 2002), as well as randomized controlled trial treatment designs (Brody, Beach, Philibert, Chen, & Murry, 2009) are also able to exclude rGE through experimental manipulation of experience.

A third challenge facing IGxE interaction models is that they require substantially larger samples than those typically available to have acceptable levels of power. Moderated mediation models require starting sample sizes in the range of 500–1000 subjects to examine the expected small to moderate effects of each variable (Preacher et al., 2007). Moreover, this sample size estimate does not include issues, such as low minor allele frequencies or environmental exposure rates, which could necessitate even larger samples. Though samples of this size might sound untenable, several large scale neuroimaging studies have emerged by expertly piecing together smaller convenience samples (Fennema-Notestine et al., 2007; Yan, Craddock, Zuo, Zang, & Milham, 2013), scanning larger and larger samples of individuals (Butterworth, Cherbuin, Sachdev, & Anstey, 2011; Nikolova et al., 2013; Satterthwaite et al., 2012), using data sharing, open access data (Jack et al., 2008; Marcus et al., 2007; Potkin & Ford, 2009; Yan et al., 2013) and consortium models (Fjell et al., 2012; Paus, 2010; Schumann et al., 2010; Thyreau et al., 2012; Toga, Clark, Thompson, Shattuck, & Van Horn, 2012), and carrying out neuroimaging meta-analyses (Jahanshad et al., 2014), all of which could be leveraged going forward to test IGxE interaction models. However, single studies with standard protocols (or multisite projects with standardized protocols), representative sampling, and coverage of key genes are likely to be the most effective strategies in testing these questions (Falk et al., 2013; Paus, 2010; Schumann et al., 2010).

Fourth, although GxE interaction research alone has increased the depth and complexity of our understanding of factors influencing the etiology of psychopathology, it is certain that even greater complexity exists in the form of GxExE and GxGxE interactions (Kaufman et al., 2004; Rutter & Dodge, 2011; Wenten et al., 2009; Cicchetti, Rogosh, & Oshri, 2011) and that these interactions will have a bearing on the questions that are addressed within IGxE models. For example, in an interesting GxExE study, the 5-HTTLPR genotype– x maltreatment interaction that predicted depressive symptoms in the original study by Caspi and colleagues (2003) was found to be *further* moderated by social support. Specifically, only short homozygotes carries for 5-HTTLPR genotype with both a history of childhood maltreatment *and* low social support showed increased depressive symptoms (Kaufman et al., 2004). This finding emphasizes the complex and multifaceted nature of the relationship between genes, experiences, and behavior, in which some experiences exacerbate risk (maltreatment), while others appear to be protective (high social support). In relation to a broader neurogenetics framework, this finding is also interesting when specifically considered alongside another recent study that found that the well-replicated positive correlation between amygdala reactivity to threat and trait anxiety was moderated by level of social support (Hyde, Gorka, et al., 2011), further emphasizing the complexity inherent in understanding gene–behavior links.

Fifth, it is important to understand that development plays a large role in the unfolding of gene–environment–

brain–behavior relationships. Few GxE interaction studies have examined whether or how findings vary by age or developmental stage (i.e., "Gene x Environment x Development" [GxExD] studies: Hyde, 2015; Vrieze, Iacono, & McGue, 2012). As with GxE studies, it is likely that development has important implications for findings from IGxE models. For example, many studied genetic variants (e.g., MAOA, 5-HTTLPR) appear to have their functional effect in utero or very early in development (Fowler et al., 2007; Jedema et al., 2010; Sibille & Lewis, 2006). In addition, environmental experiences differ in their impact depending on the developmental stage of the individual (e.g., types of stressors might differ for children and adults or there may exist particular sensitive periods for certain risks; Kendler & Myers, 2009; Sroufe & Rutter, 1984). Furthermore, epigenetic studies demonstrate that certain experiences might have a greater biological impact during "sensitive periods" of development (Meaney, 2010).

As emphasized above, IGxE findings may also vary by developmental stage, as experiences (e.g., parenting) will change forms, and their impact on biology and the impact of genotype may be affected by this progression of development (e.g., changes associated with puberty). Moreover, as the brain is changing across development, its relationship to genes and experience is likely to be moderated further (e.g., Yu et al., 2014). Thus, some IGxE findings may be specific to certain developmental periods but, without greater emphasis on development and using IGxE methods in children and adolescents, we are unable to test these hypotheses.

Sixth, as would be applicable to GxE interaction studies and imaging genetics studies, sampling is a major issue, that may be under-appreciated within this field, and especially within neuroscience. Most of the broad neuroimaging literature, which provides a foundation for both imaging genetics and IGxE models, is based on samples of convenience (e.g., college students in subject pools, community volunteers who respond to a flier). These kinds of samples are likely to vary across a number of important dimensions that could affect the consistency and replicablity of findings and distort the relationship between individual differences in brain and behavior (Chiao & Cheon, 2010; Henrich, Heine, & Norenzayan, 2010). Moreover, we know very little about whether or how brain–behavior or gene–brain links are moderated by culture, and even less about how IGxE links may vary based on ancestry (Chiao & Cheon, 2010). Thus, IGxE interaction studies that are thoughtful about sampling and *who* the study will generalize to are mostly likely to lead to "true" findings (for more details on this point see Falk et al., 2013).

Finally, just as GxE and imaging genetics studies have required researchers to bridge several areas and work in multidisciplinary teams, a neurogenetics framework and IGxE studies require even greater knowledge and collaboration. We hope that the conceptual models introduced through IGxE and neurogenetics will garner even greater appreciation for the work of colleagues in disparate fields (e.g., animal neurophysiology, biostatistics, epidemiology, experimental psychology, developmental psychopathology) and help to spur collaborations that will ultimately better specify the development of psychopathology.

Summary of Neurogenetics

In sum, neurogenetics is a discipline that incorporates a variety of approaches and aims to understand the impact of variability in genes on brain structure and function, and subsequent behavior. The core technique within neurogenetics is imaging genetics, which focuses on linking variability in functional genetic polymorphisms to differences in brain structure and function, particularly using MRI. However, neurogenetics also relies on nonhuman animal models to specify complex molecular signaling pathways involved in linking variability in genes to variability in neural signaling and is further complimented by multimodal and pharmacologic MRI studies that can more directly and experimentally probe neural chemistry in awake adults. More recently, models within a neurogenetics framework have also incorporated the influence of *experience* on molecular signaling pathways by using IGxE studies. Through this variety of techniques, neurogenetics is helping to specify the molecular pathways from gene to brain.

However, a major limitation of the field of neurogenetics to date has been its overwhelming focus on studying adult samples and a notable lack of attention being paid to development (though see Viding, Williamson, & Hariri, 2006). That noted, in the second part of this chapter, we turn to an emerging area of research examining youth internalizing disorders using neurogenetics (Swartz & Monk, in press). In particular, we focus on research evidence from studies that have used the different techniques outlined above to examine the development of internalizing disorders, and thus present a model of how neurogenetics can be applied to developmental psychopathology. We focus specifically on internalizing disorders in youth for two reasons. First, much of the foundational neurogenetics research in adults has focused on phenotypes most applicable to internalizing disorders, and thus reviewing similar results in youth can help highlight continuities and discontinuities. Second,

much of the neurogenetics research in youth has been focused on internalizing and thus this outcome provides more fertile ground for review.

DEVELOPMENTAL PSYCHOPATHOLOGY AND NEUROGENETICS

The field of *developmental neurogenetics* is still in its infancy (Hyde, 2015), but in the second part of this chapter, we outline research that highlights a need to more precisely examine the role of development in gene–brain–behavior associations. To begin, we examine how the concepts underpinning both neurogenetics and developmental psychopathology can be integrated within one framework. We outline key points advanced by developmental psychopathology, including its focus on designing ways to conceptualize and measure "disordered" phenotypes, the specification of mechanisms that link risk to outcomes, the importance of conditional relationships, and the concepts of equifinality and multifinality. We then discuss how neurogenetics research can benefit from incorporating these concepts from developmental psychopathology. Having laid out principles of *developmental neurogenetics,* as conceptualized as an integration of neurogenetics and developmental psychopathology (Hyde, 2015), we move into discussing the application of this approach to research that has examined youth internalizing disorders. We focus on brain regions of interest and the application of imaging genetics to internalizing disorders, discuss IGxE interaction studies to date, and outline specific genetic and biological mechanisms that will be the focus of future research.

Developmental Neurogenetics—An Integration of Developmental Psychopathology and Neurogenetics

Incorporating a developmental perspective within neurogenetics opens the field to a range of novel and interdisciplinary questions, the answers to which have great promise for yielding significant advances in our understanding of the development of psychopathology: how do genes interact with the environment to influence neural development? How does neural development and behavior transact with genes and the environment to alter gene expression and elicit environmental supports or risks? How can physiological mechanisms, such as epigenetic regulation, explain the transactional associations between genes, brain, and environment over time? Does the association between genes and neural or behavioral phenotypes change over development? How does neural development influence risk and resilience to the development of psychopathology? Can patterns of neural development predict the onset or course of psychopathology? Can the use of neural development (in contrast to neural activation in adulthood) as a mediator of GxE interaction effects lead to novel insights on the etiology of disorder? How can this knowledge be translated to inform preventive and treatment efforts? In the following sections, we highlight key principles within developmental psychopathology that will guide this research in the future (the points presented here are selected from a more thorough discussion of this topic in Hyde, 2015).

Phenotype—What and Who Are We Studying?

Developmental psychopathology has been at the forefront of designing ways to conceptualize and measure "disordered" phenotypes. Recent evidence suggests that psychopathology, at both a construct and measurement level, can be considered dimensional, rather than categorical, in nature (Krueger & Markon, 2011; Plomin, Haworth, & Davis, 2009). Further, various psychopathologies have high comorbidity and overlap with other psychopathologies (Krueger, 1999; Krueger & Markon, 2006) and diagnostic categories contain great heterogeneity in terms of symptoms, prognosis, and development (Clark, Watson, & Reynolds, 1995; Tsuang, Lyons, & Faraone, 1990).

Early pioneering work in children (Achenbach, 1966), demonstrated that many disorders could be mapped onto broadband meta-factors (i.e., internalizing and externalizing). Research in adults confirms these findings and highlights that much of the "problem of comorbidity" evolves from a meta-structure involving several broad domains (e.g., internalizing) each containing specific "disorders" as subfactors (e.g., anxiety, depression) that share general and specific risks (Krueger & Markon, 2006; Krueger, Markon, Patrick, Benning, & Kramer, 2007). Recent work even suggests that there may be a "p" meta-factor that indicates an overall latent risk for increased distress and greater liability to psychopathology across diagnoses (Caspi et al., 2013; Lahey et al., 2012).

Applying this meta-structure to neurogenetics is particularly important given that many neural and genetic risk factors seem to be rather broad in their effects. For example, in children and adults, amygdala reactivity has been linked to several different disorders, including anxiety (Fakra et al., 2009; Monk et al., 2008) and depression (Price & Drevets, 2010), as well as to externalizing disorders and psychopathy (Blair, 2010; Hyde, Shaw, & Hariri, 2013). Results have been similar for genetic variants, such

as the 5-HTTLPR, which has been associated with these same outcomes, although sometimes in opposite directions (Glenn, 2011; Karg et al., 2011; Sadeh et al., 2010; Sen, Burmeister, & Ghosh, 2004). When considered in the context of research examining the hierarchical nature of psychopathology, neural and genetic studies suggest that variability across many individual genes or brain structures predicts *multiple* disorders due to the shared etiological structure of disorders. Applying models of general (i.e., "p" factor, general internalizing factor) versus specific (i.e., depression, anxiety) factors as an outcome when undertaking neurogenetics studies may help identify which risk factors are general versus specific, or even *how* specific these risk factors are (see Figure 12.3).

More specifically, a general versus specific modeling approach may enable us to conceptualize genetic and neural variation as contributing to dimensions that may be shared or unique to various general psychopathologies, rather than as specific correlates or part of a single "etiology" for one disorder (Buckholtz & Meyer-Lindenberg, 2012). For example, in the case of the short allele of the 5-HTTLPR and high amygdala reactivity, these risk factors instead may contribute to *broad* risk for psychopathology, particularly internalizing liability. It may be that this risk is underpinned by a dimension of neuroticism, emotionality, or emotional dysregulation (Lahey, 2009). For example, having greater amygdala reactivity may make an individual more prone to being emotional, emotionally dysregulated,

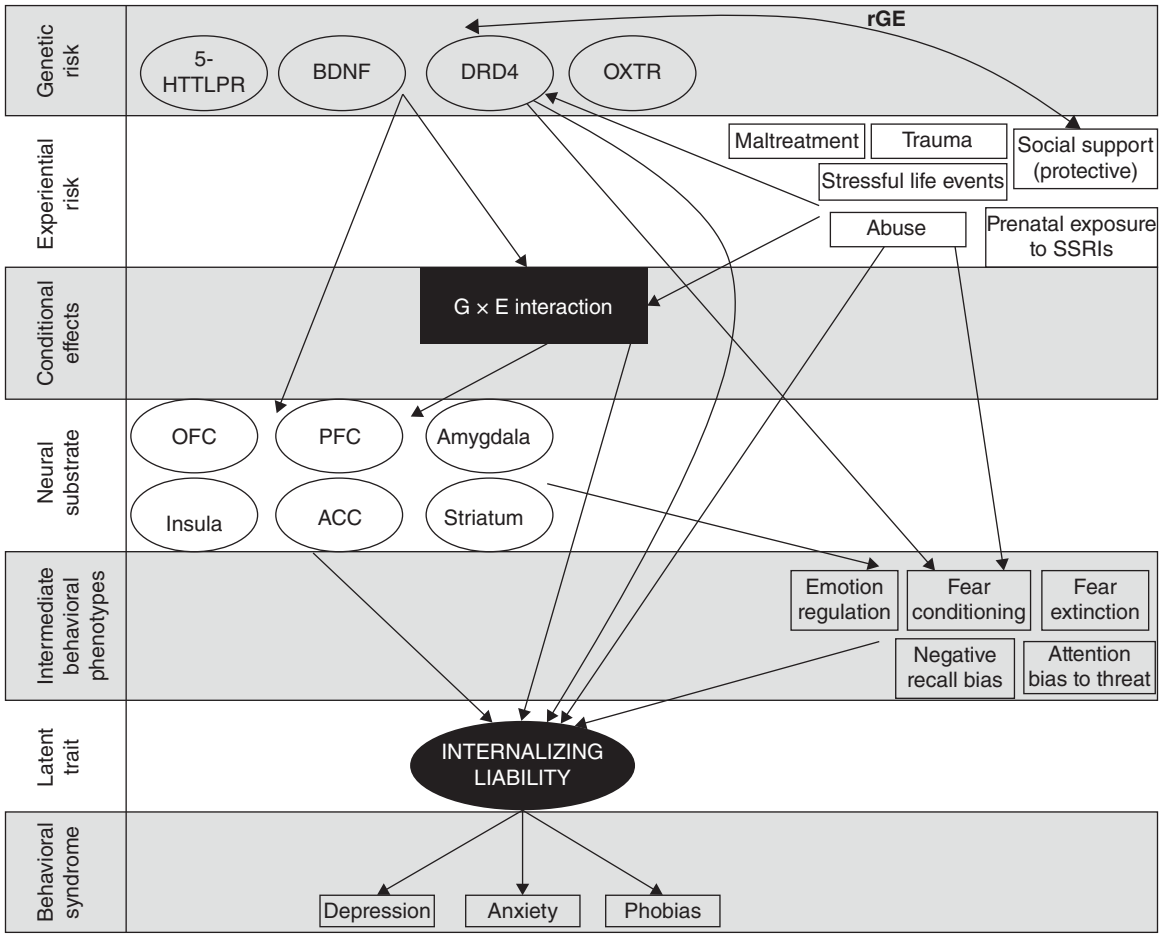

Figure 12.3 A hypothetical neurogenetics model of internalizing disorders in which levels of analysis are plotted on the y axis. Each level of analysis provides examples based on extant literature to date as outlined in this chapter but is not meant to be comprehensive. The arrows show direct and mediated pathways between genes and environment on both neural and behavioral outcomes, and between experiential and genetic risk (i.e., epigenetic effects). GxE interaction effects also have direct and indirect (via brain) effects on development of internalizing psychopathology. Not shown are reciprocal effects that theoretically operate in the opposite direction (e.g., the diagnosis of an internalizing disorder may affect the level of maltreatment or social support an individual receives). *Note:* OFC = orbitofrontal cortex; PFC = prefrontal cortex; ACC = anterior cingulate cortex.

or sensitive to emotional stimuli, which could then increase risk for anxiety and depression. Alternatively, this same risk of having high amygdala reactivity could be linked to some types of externalizing disorders that involve higher levels of emotion dysregulation (Pardini & Frick, 2013). In contrast, having very low amygdala reactivity and being low on emotionality could increase risk for other pathologies, such as psychopathy or callousness (Hyde, Byrd, Hariri, & Manuck, 2014; Hyde et al., 2013). In this case, basic neural functioning, when examined transdiagnostically and within a general-specific model framework, may explain why some disorders overlap and *how* they overlap (e.g., via greater amygdala reactivity and emotional reactivity) (Buckholtz & Meyer-Lindenberg, 2012).

At the same time, while a consideration of dimensional and hierarchical models provides a good fit to data, this approach ignores the usefulness of categories in clinical practice and the marked heterogeneity even within individual diagnoses (i.e., it focuses more on what disorders share at the broad level or which symptoms are important transdiagnostically, rather than addressing the heterogeneity within disorders). As such, while general-specific models can help us to uncover broad and general risk factors for psychopathology, we also need to identify why individuals have different symptom profiles within specific diagnoses. Further, identification of symptom profiles or other attributes of an individual may help to identify subgroups of individuals with a more similar development, course, and etiology of psychopathology, and even individuals that need different or tailored treatments. This idea of parsing down into smaller and more homogenous groups is akin to specifying a third level in the meta-structure of psychopathology.

Developmental psychopathology has long championed this kind of person-centered approach, which moves beyond variable-centered or dimensional analyses. This emphasis has important implications for neurogenetics because finding statistical relationships with a dimensional outcome can result in very different interpretations compared with those findings that arise from results with a small group of individuals who are particularly extreme on certain variables that are associated with etiology, development, or prognosis. Moreover, a person-centered analysis could help to uncover groups of youth that may look similar on one measure (i.e., diagnosis) but may differ in many important ways on other measures (e.g., symptom onset, duration, age of onset). In other words, those with a single diagnosis are not all the same, especially when we consider diagnoses within a developmental context. Neurogenetics research could therefore benefit from examining specific subgroups of more similar individuals together, which may produce more consistent and robust findings than studies that examine broad diagnostic classifications.

Complex Models

As highlighted throughout this chapter, neurogenetics tests a complex array of pathways from genes to proteins to neural circuits to brain function to behavior and each pathway is moderated by context. Developmental psychopathology has much to offer theoretically and empirically to neurogenetics studies in addressing these complex pathways. In particular, the application of multilevel (Cicchetti & Toth, 2009) and complex systems frameworks to understanding complex, reciprocal, and cascading pathways examining multiple levels of analysis has previously been written about extensively (Bronfenbrenner & Ceci, 1994; Sameroff, 1995, 2000, 2010). However, as ecological and complex systems theory is applied to a greater extent within neural and genetic studies, better models can be proposed and tested that contain multiple mechanistic (and interactive) pathways, reaching from molecules to cells to brain structures to traits to symptoms to outcomes, and with well-defined molecular mechanisms specifying both the genetic and environmental precursors to these processes (Beauchaine & McNulty, 2013; Buckholtz & Meyer-Lindenberg, 2008; Meaney, 2010; Roth & Sweatt, 2011).

A second example illustrating how theory and research in developmental psychopathology can help to address complex models is the recent advance in understanding conditional effects. As outlined in the first part of the chapter, an early and dominant model of psychopathology was a diathesis-stress model positing that some individuals had a latent propensity toward a certain psychopathology, which could be unmasked under certain conditions (e.g., high stress). Recent work in the field has brought greater nuance to this idea through the proposal and testing of models of differential susceptibility that posit that some individuals are more susceptible to their environment for better (vantage sensitivity) or worse (vulnerability factors or diathesis stress), or both (differential susceptibility) (Belsky & Pluess, 2009; Ellis & Boyce, 2011). These models focus on genes as markers for individuals who are most vulnerable to negative environments (Belsky & Pluess, 2009), those who may benefit the most from positive experiences (Pluess & Belsky, 2013), and those who are more sensitive to both good and bad environments (Belsky et al., 2009). Although empirical support for differential susceptibility and its range of effects has been limited to date (Cicchetti, Rogosch, & Thibodeau, 2012; Manuck, 2009), this type of modeling approach provides a useful framework for

neurogenetics research to consider interactions between genes, brain, and experience in the prediction of current and future behavior.

Developmental psychopathology also highlights significant complexity that exists in the form of further moderation of GxE interaction effects by genes or environment (Kaufman et al., 2004; Rutter & Dodge, 2011; Wenten et al., 2009; Cicchetti et al., 2011). Researchers have begun to address GxG interactions and the likely cumulative nature of different genetic variants by constructing cumulative genetic profiles (Nikolova et al., 2011; Purcell et al., 2009). This approach mirrors the major impact that cumulative risk models of environmental exposures made within developmental psychopathology (Sameroff, Seifer, Zax, & Barocas, 1987) showing that an accumulation of risk, be it genetic or environmental, is often more important than any single risk factor by itself in predicting poor outcomes (Appleyard, Egeland, Dulmen, & Sroufe, 2005; Sameroff et al., 1987). However, no studies to date have combined cumulative genetics models with cumulative experiential models.

Equifinality and Multifinality

Another important point of emphasis from developmental psychopathology relates to the concepts of equifinality and multifinality. Specifically, these concepts specify that children can arrive at the same point or diagnosis from many different risk factors (equifinality) and children with the same risk factors may end at very different points or diagnoses (multifinality) (Cicchetti & Rogosch, 1996). These concepts help to emphasize that many risk factors are not specific to one outcome, that there are likely multiple pathways and etiologies to any single disorder, and that the effects of risk on outcome are likely probabilistic. In an example of equifinality, multiple different risk factors can influence the development of the same behaviors. For example, a child with experiences of early abusive parenting versus a child with experiences of early warm parenting but later peer bullying, could both exhibit the same symptoms of depression in adolescence. Alternatively, as an example of multifinality, initial risk factors may lead to a wide array of different outcomes. For example, early maltreatment has been linked to both internalizing and externalizing outcomes, and as noted above, several similar neural and genetic profiles have been linked to a wide array of psychopathological outcomes.

Thus, it is important to highlight that the effects of genetic and neural variability are likely to be probabilistic, as highlighted by much of the research described so far. Understanding biological differences between groups high or low on certain psychopathologies only helps us understand *biases* toward certain behaviors. Any single experience, single gene, or functioning in a single brain area is unlikely to be deterministic or to be *the* major factor in the development of complex psychopathology. Rather, each risk, across all possible domains, is likely to bias an individual toward or away from risk via interaction with other factors. For example, studies of the serotonin system and the amygdala have shown that certain genes in the serotonin system (e.g., the short allele of 5-HTTLPR) and increased amygdala activity to threat are linked to anxiety and depression (Fakra et al., 2009; Hariri et al., 2006; Monk et al., 2008; Price & Drevets, 2010). However, many people with both increased amygdala activity to threat and with "risk" alleles in the serotonin system are neither depressed nor anxious (Hyde, Gorka, et al., 2011). Thus, these variables can simply be considered as one small part of a complex probabilistic chain. However, we must also consider that small risk factors or a "push" toward one outcome in a complex system can lead to larger changes (Kauffman, 1996; Sameroff, 1995). In the case of specific neural or genetic profiles, small pushes to a system (e.g., a slightly greater tendency toward or away from anxiety and attention to threat) in one direction may lead to developmental cascades toward or away from risk as the child and the environment begin to shape each other over time (Masten & Cicchetti, 2010). Thus, though the effects of many genetic and neural variables may be small and probabilistic, they may, in some youth and in some contexts, have larger effects due to their role in a developmental cascade over time.

The study of resilience in developmental psychopathology can also inform neurogenetics models (Masten, 2001; Rutter, 2006). Much neurogenetics research has focused on risk and maladaptive outcomes, but these same tools could be leveraged by positive psychology (Seligman & Csikszentmihalyi, 2000). Studies of resilience within a neurogenetics framework could help to identify neural and genetic profiles of individuals who do not go on to develop psychopathology, even under circumstances of great risk (e.g., child maltreatment, high stress) (Feder, Nestler, & Charney, 2009). Alternatively, these studies could help to identify factors that buffer the risk posed by "risky" genes or neural profiles.

Developmental Stage, Age, and the Unfolding of Processes Across Development

A major thrust when developmental psychopathology was first conceptualized was to add a clearer focus on the role of development to psychiatric conceptualizations of disorder.

Though neurogenetics is certainly poised to answer questions about development, much of the neurogenetics literature has focused on adults, with little work carried out among younger populations and very few studies testing the moderating role of development. However, there has been increased recognition across imaging and genetics research of the need for a developmental focus in neurogenetics (Viding et al., 2006). In particular, observations from a range of disciplines suggest that characterizing GxE interaction effects on neural and behavioral phenotypes requires the incorporation of a developmental perspective.

For example, Lenroot and Giedd (2011) have argued for the need to examine the interaction of age with GxE interaction effects, noting that twin studies in the area of quantitative genetics demonstrate that heritability estimates for brain development and psychopathology vary across different stages of development (see also Vrieze et al., 2012). Thus, the relationship between genes and phenotypes may *change* as a function of development due to factors, such as puberty, that trigger or change gene expression. Further, in the field of social genomics, Cole and colleagues (2011) provided a potential demonstration of *antagonist pleiotropy,* or the notion that the risk or protection afforded by a gene may be reversed by contextual factors such as developmental stage. Specifically, they demonstrated that a functional polymorphism in the promoter for the *IL6* gene associated with increased inflammation in older adults actually plays a protective role in adolescents, leading to decreased levels of inflammation in adolescents exposed to social stress. This study suggests that the effects of genes—and whether they can be considered "risky" or "protective"—depends on the developmental stage under investigation.

Also complicating the developmental picture is evidence suggesting that early influences can have latent effects that do not emerge until later stages of development, with several studies illustrating various considerations that researchers must make when considering development. For example, Ansorge and colleagues (2008) found that administering selective serotonin reuptake inhibitors (SSRIs) to mice during early postnatal development led to increased anxiety-related behavior that only manifested after the developmental period corresponding to puberty in mice. Moreover, this effect appeared to be limited to early developmental exposure to SSRIs, as administering SSRIs at a later stage of development had no significant impact on anxiety-related behavior. Thus this study emphasizes that some *exposures* will only affect these pathways when the exposure occurs during a sensitive period and that certain *outcomes* may only be observable after a particular developmental stage (e.g., Yu et al., 2014). In another example of developmentally sensitive effects, Petersen and colleagues (2012) found that the interaction between 5-HTTLPR genotype and stressful life events had the most robust effect on the development of anxiety/depressive symptoms measured in later adolescence at 16–17 years versus early adolescence. Thus, in this study the GxE interaction appears specific to a certain developmental stage for the *outcome*.

Finally, in a study that hypothesized specific biological mechanisms that could underlie these types of developmental stage-dependent effects, Casey and colleagues (2009) examined the effect of a valine-to-methionine substitution at codon 66 (Val66Met) in the brain derived neurotrophic factor (*BDNF*) gene. The Met allele of the Val66Met *BDNF* polymorphism is associated with decreased secretion of BDNF, a neurotrophic factor hypothesized to affect plasticity and changes in brain regions associated with learning, including both the hippocampus and amygdala. Given its association with learning and plasticity, the *BDNF* polymorphism may be linked to internalizing problems such as anxiety disorders, which are characterized by abnormal fear learning (e.g., overgeneralization of fear conditioning and reduced extinction of fear learning). In a demonstration of an age-dependent association between genotype and behavioral phenotype, Casey and colleagues observed that children with a Met allele of the Val66Met *BDNF* polymorphism exhibited differences in response latencies in a fear conditioning task relative to Val homozygotes, suggesting greater acquisition of fear learning in the Met group. In contrast, these effects appeared to be reduced in adolescents in the sample. The influence of the *BDNF* polymorphism on neural and behavioral phenotypes has been hypothesized to differ by developmental stage because expressed BDNF levels in the brain change over development, showing increases from childhood and peaking in young adulthood (Casey et al., 2009). Because expressed BDNF levels increase during adolescence, the association between the Val66Met *BDNF* polymorphism and fear-related learning may be altered during this developmental stage relative to childhood.

Taken together, the evidence from across these studies suggests that the association between GxE influences and neural function depends on both the developmental period in which an individual is exposed to a developmental influence (biological or environmental) and the stage of development in which the outcome is tested. Indeed, the influence of certain genes on neural function may be due to the emergent effects of these genes on brain development occurring specifically during the adolescent period. Given the potential latent effects of early developmental influences

on psychological outcomes, as well as the possibility that certain genetic polymorphisms may act differentially as risk or protective factors at different stages of development, it is critical as we move forward to consider the developmental stage of participants in neurogenetics studies both in terms of when *experiences* are measured (and when they occurred) and when *outcomes* are measured.

Summary

In sum, there appears to be promise in the integration of neurogenetics and developmental psychopathology (Hyde, 2015). First, the integration of these approaches points to a need to consider psychopathology, at the measurement and construct level, as both dimensional and overlapping in nature. Examining specific versus general correlates of genetic and neural variability may help to identify how these variables fit together and how they contribute to the development of psychopathology. Moreover, while evidence supports a dimensional and hierarchical approach, research is also needed that specifies these risk processes at a person-level by identifying groups of individuals that are more homogenous in development, symptoms, outcomes, or treatment response. Neural and genetic studies have already helped to support the notion that within some psychopathologies, there exist subgroups with unique or different correlates. However, neither broad nor person-centered approaches have yet to be applied to neurogenetics studies. Thus, further integration of these concepts into neurogenetics is needed to help uncover how neural and genetic processes might operate to predict broad and general outcomes, as well as specific subgroups of youth, within existing diagnoses. Moreover, by providing more accurate and broad or specific outcomes (with less error), we may help to increase the precision within neurogenetics studies.

Second, the emphasis in developmental psychopathology on adopting an interdisciplinary approach, particularly in its adaptation of ecological and complex systems models and its appreciation of complex interactions, can help inform changing views of the structure of psychopathology and maladaptive behaviors.

Third, studies of equifinality, multifinality, and resilience have provided important future directions for neurogenetics. In particular, now that studies have begun to establish more robust relationships between genetic and neural variables and psychopathology, a next major step will be to help define why these risks predict poor outcomes for only some people. In other words, what pathways contribute to "normal" functioning for many individuals with "risky" genetic or neural profiles? Why do some individuals that carry the 5-HTTLPR not have "elevated" amygdala reactivity? Why does elevated amygdala activity only predict heightened anxiety in the absence of social support? These questions have major treatment and prevention implications in identifying who is protected from the negative effects of risk and how they are protected. For example, if protective effects can be found in neural or environmental domains, then these variables can be targeted in interventions.

Fourth, as emphasized above, findings within neurogenetics research are likely to vary with developmental stage, as experiences will change forms and their impact on biology and the impact of genotype may be affected by the progression of development. Moreover, as the brain is changing across development, its relationship to gene and experience is likely to be moderated further. Thus, some findings may be specific to certain developmental periods. However, without greater emphasis on development and employing neurogenetics research in children and adolescents, we are unable to test these hypotheses (see next section on application of neurogenetics to the study of youth internalizing disorders).

NEUROGENETICS AND YOUTH INTERNALIZING DISORDERS

As outlined in the first part of this chapter, neurogenetics offers great potential for understanding the development of psychopathology by linking candidate genes to functioning of the neural circuitry associated with disorders, and specific environmental conditions under which such associations are likely to arise. Further, an integration of neurogenetics and developmental psychopathology provides a useful framework that guides a more nuanced understanding of the complex unfolding of interactions between gene, brain, environment, and behavior across the life course. An emerging body of literature has applied a neurogenetics framework to understanding the development of internalizing disorders in youth. We outline findings from studies that have investigated internalizing disorders among samples of both adults and youth, with research into adult internalizing disorders typically preceding or guiding studies of younger populations. We have chosen to focus our examples for how neurogenetics research can be applied to internalizing disorders, as the vast majority of research to date has been carried out in this area. In a final section we examine the next steps for research in this field and exciting new possibilities that could be borne out through developmental neurogenetics.

Brain Regions of Interest

Among adult samples, many studies have examined structure, functioning, and connectivity of corticolimbic circuitry. This circuitry includes cortical regions, such as the prefrontal cortex, and subcortical limbic regions, such as the amygdala. A reliable finding is that both major depressive disorder and anxiety disorders (e.g., social phobia and generalized anxiety disorder) are associated with altered functioning of corticolimbic circuitry (Price & Drevets, 2010). For example, one of the most consistent findings in the clinical neuroscience of internalizing disorders is heightened amygdala reactivity to threatening or negative stimuli in patients with anxiety or depressive disorders (Etkin & Wager, 2007; Groenewold, Opmeer, de Jonge, Aleman, & Costafreda, 2013; Hattingh et al., 2012). Greater amygdala activation to threatening stimuli is also associated with increased severity of anxiety symptoms (Phan, Fitzgerald, Nathan, & Tancer, 2006). The heightened amygdala reactivity seen in adults with these disorders is thought to arise from decreased regulation by prefrontal cortical regions, including the ventral and dorsal prefrontal cortex and the rostral anterior cingulate cortex. This notion is supported by evidence for decreased functional connectivity between the amygdala and prefrontal cortex in individuals with internalizing disorders (Etkin, Prater, Hoeft, Menon, & Schatzberg, 2010; Hahn et al., 2011; Lu et al., 2012; Prater, Hosanagar, Klumpp, Angstadt, & Phan, 2013).

Studies using diffusion tensor imaging, which assesses the microstructural properties of white matter tracts, also suggest reduced fractional anisotropy (FA) in white matter tracts connecting the prefrontal cortex and amygdala, including the uncinate fasciculus (Phan et al., 2009; Tromp et al., 2012). This reduced FA may indicate reduced myelination of this white matter tract in adult patients. Indeed, decreased white matter connectivity predicts reduced prefrontal cortex-amygdala functional connectivity in adult patients with generalized anxiety disorder, suggesting that this may contribute to reduced prefrontal cortex regulation of amygdala activity (Tromp et al., 2012). In sum, internalizing disorders in adults have been associated with increased amygdala reactivity as well as disruptions in structural and functional connectivity between the amygdala and prefrontal regulatory regions.

The amygdala and prefrontal cortex have been associated with a number of intermediate behavioral phenotypes linked to internalizing disorders. For example, both animal models and human neuroimaging studies suggest a consistent role for the amygdala in fear acquisition and conditioning, whereas the ventromedial prefrontal cortex is associated with extinction of fear learning via inhibition of the amygdala (Milad & Quirk, 2012). Thus, heightened amygdala activation and decreased connectivity between the ventromedial prefrontal cortex and amygdala could lead to increased fear conditioning and difficulty with extinguishing acquired fears. These intermediate behavioral phenotypes have been linked to a number of anxiety disorders (Lissek et al., 2013; Lissek et al., 2005). Likewise, given its role in detecting emotionally relevant stimuli in the environment, the amygdala has been linked to processes such as biasing attention toward threat (Pessoa & Ungerleider, 2004), and thus may play a role in the well-replicated finding of attention bias to threat in anxiety disorders (Bar-Haim, Lamy, Pergamin, Bakermans-Kranenburg, & van, 2007). Moreover, given the role of cortical regions in cognitive control and emotion regulation (Ochsner & Gross, 2005), reduced functional connectivity between the prefrontal cortex and amygdala may be associated with the emotion regulation abnormalities characteristic of internalizing disorders (Foland-Ross & Gotlib, 2012). Thus, the neural abnormalities identified in adult internalizing disorder patients are consistent with the intermediate behavioral phenotypes thought to contribute to the development and maintenance of these disorders.

Neuroimaging research with children and adolescents with internalizing disorders has broadly mirrored the work carried out among adults, and also provides evidence of corticolimbic dysfunction, although studies with samples of children and adolescents are still relatively uncommon. For example, paralleling findings for anxiety in adults, heightened amygdala activation has been observed in both children and adolescents with anxiety disorders (e.g., Monk et al., 2008). Interestingly, this finding appears to be highly dependent on the timing and context of the threatening stimuli. Specifically, brief presentation of threatening faces, tasks that require participants to rate their own subjective fear, or evaluation of threatening stimuli elicit heightened amygdala activation in youth with anxiety disorders relative to controls (Beesdo et al., 2009; Guyer et al., 2008; McClure et al., 2007; Monk et al., 2008; Swartz, Phan, Angstadt, Fitzgerald, & Monk, 2014). In contrast, presentation of threatening faces for relatively longer periods of time or rating of nonemotional aspects of faces (e.g., nose length) do not appear to elicit heightened amygdala reactivity in anxious groups (Beesdo et al., 2009; McClure et al., 2007; Monk et al., 2006; Swartz, Phan, et al., 2014).

In addition to explicit processing of threatening stimuli, implicit emotion processing tasks, including rating the gender of emotional faces, are also associated with

amygdala hyperactivity among children and adolescents with anxiety disorders (Blair et al., 2011; Thomas et al., 2001). As with adults, there is evidence of altered functional connectivity between the prefrontal cortex and amygdala among anxious youth, including decreased ventrolateral prefrontal cortex-amygdala connectivity when threatening faces are briefly presented (Monk et al., 2008) and increased ventrolateral prefrontal cortex-amygdala connectivity when rating the desirability of disliked and potentially threatening peers (Guyer et al., 2008).

Among adolescents with major depression, heightened amygdala activation has also been observed (Beesdo et al., 2009; Yang et al., 2010). In addition, depression among youth is associated with altered functional connectivity, including decreased medial prefrontal cortex-amygdala connectivity (Perlman et al., 2012) and increased subgenual anterior cingulate cortex-amygdala connectivity (Connolly et al., 2013; Perlman et al., 2012). Finally, decreased FA in the uncinate fasciculus has been observed in adolescents with major depression (Cullen et al., 2010), suggesting that, similar to adults, heightened amygdala reactivity may be associated with reduced regulation by the prefrontal cortex. Due to the central role that corticolimbic circuitry appears to play in the development of internalizing disorders, the majority of neurogenetics research in this area has thus aimed to characterize genetic influences on the structure and function of these brain regions.

Imaging Genetics and Internalizing Disorders

The genes involved in regulating serotonin signaling have been a focus of many imaging genetics studies of internalizing disorders in adults due to serotonin's role in modulating corticolimbic function and the therapeutic effects of pharmacological interventions, including selective serotonin reuptake inhibitors for treating anxiety or depressive disorders (Fisher & Hariri, 2013). In particular, the 5-HTTLPR has received a great deal of research attention. In earlier studies, genetic variation in the 5-HTTLPR was classified dichotomously as either the short (S) allele (decreasing expression of the serotonin transporter) or the long (L) allele. Subsequently, researchers identified an A to G SNP in the L allele, with the L_G genotype acting similarly to the S genotype in conferring reduced transcription of the serotonin transporter; whereas the L_A genotype is associated with increased expression (Hu et al., 2006). Thus, because some of the studies described include the S, L_G, and L_A allele classification, we use the terms low-expressing allele to refer to the S or L_G alleles, and high-expressing allele to refer to the L_A allele, rather than the traditional short vs. long dichotomy in describing this area in more detail.

As noted previously, the first imaging genetics studies examining the 5-HTTLPR were performed in adults and demonstrated that the low-expressing allele is associated with increased amygdala activation during the processing of threatening stimuli (Hariri et al., 2002), an effect confirmed through meta-analysis (Munafo, Brown, & Hariri, 2008). Additional research demonstrated that the low-expressing allele predicts altered connectivity between prefrontal regulatory regions and the amygdala (Pezawas et al., 2005) suggesting that the low-expressing allele may lead to decreased prefrontal regulation, which in turn results in heightened amygdala response. Using diffusion tensor imaging (DTI), the low-expressing allele of the 5-HTTLPR has also been associated with decreased FA in the uncinate fasciculus (Pacheco et al., 2009), suggesting that structural connectivity between the amygdala and prefrontal cortex may play a role in the effects of the low-expressing 5-HTTLPR allele. Thus imaging genetics findings in adults indicate that the low-expressing allele of the 5-HTTLPR predicts the same alterations in corticolimbic structure and function as seen in adult patients with anxiety or depressive disorders (though as noted previously this mediated pathway has not been directly tested).

In typically developing children and adolescents, the low-expressing allele of the 5-HTTLPR is also associated with increased amygdala activation to threatening or negative stimuli (Battaglia et al., 2012; Furman, Hamilton, Joormann, & Gotlib, 2011; Lau et al., 2009). For example, Battaglia and colleagues (2012) found that in adolescents, the low-expressing allele of the 5-HTTLPR was associated with increased amygdala activation to angry faces, which was associated with a greater number of social anxiety symptoms. In another example, Furman et al. (2011) found that among typically developing adolescent girls aged 10–15 years old, those with the low-expressing allele of the 5-HTTLPR displayed a faster time to peak in amygdala BOLD signal when focusing on a sad mood state relative to carriers of the high-expressing allele.

In addition to the amygdala, regions associated with other aspects of emotion processing have been linked to 5-HTTLPR genotype in samples of youth. For example, adolescents with the low-expressing allele of 5-HTTLPR demonstrated greater attention bias to subliminally presented fearful faces during a probe detection task, as well as increased activation in parietal regions associated with attention allocation (Thomason et al., 2010). In a separate study of 8-year-old children, the low-expressing allele of the 5-HTTLPR was related to increased activation in

the dorsal striatum and anterior cingulate cortex when viewing sad movie excerpts relative to carriers of the high-expressing allele (Fortier et al., 2010).

Taken together, studies conducted among typically developing children and adolescents indicate similar gene–brain relationships to those seen in adults. Specifically, the low-expressing allele of the 5-HTTLPR appears to be associated with heightened reactivity to threatening or emotional stimuli. In many of these studies (e.g., Battaglia et al., 2012; Thomason et al., 2010), heightened neural reactivity is associated with increased anxiety symptoms or behavioral phenotypes, such as attention bias to threat, that are reliably associated with clinical anxiety (Bar-Haim et al., 2007). In sum, findings from imaging genetics studies to date have described a pathway through which a common genetic variant is associated with patterns of neural functioning that are in turn associated with anxiety-related symptoms or behaviors. In this case, findings in youth have paralleled findings in adults, indicating that these pathways may develop early in life.

However, although findings appear to replicate across different ages, studies have typically paid little attention to development and its potential moderating effect on the magnitude of effects. This point is particularly interesting when considering that the brain areas implicated in imaging genetics studies (i.e., cotricolimbic circuitry) show protracted structural development into adulthood (Toga, Thompson, & Sowell, 2006). Indeed, several studies have now demonstrated that activation of these brain areas and their structural and functional connectivity varies across development (Casey, Tottenham, Liston, & Durston, 2005; Gee et al., 2013; Swartz, Carrasco, Wiggins, Thomason, & Monk, 2014). For example, a recent study demonstrated that, in response to emotional faces, amygdala-medial prefrontal cortex connectivity switched from positive to negative during the transition from childhood to adolescence and that this change in connectivity was paralleled by a linear decline in overall amygdala reactivity (Gee et al., 2013). Interestingly, Gee and colleagues hypothesized and found some support for the notion that this developmental change in connectivity could underlie normative decreases in anxiety from early childhood to early adolescence. Taken together, the findings from recent studies highlight the importance of considering development when replicating neurogenetics findings among youth and emphasize that there are really two separate, though related, questions to ask when adopting a neurogenetics framework, (1) do findings in adults show a similar pattern in children or adolescents, and (2) does age or developmental stage moderate findings?

Though much of the literature has focused on the first question, the second question may actually yield more useful findings in attempting to understand the development of internalizing disorders, and fits well within a neurogenetics approach to understanding psychopathology. For example, a recent study by Wiggins and colleagues (2012) demonstrated that carriers of the low-expressing allele of the 5-HTTLPR evidenced a cross sectional increase in amygdala activation with age from 9–19 years old whereas this developmental increase was not seen in high-expressing allele carriers. Moreover, in low-expressing allele carriers only, there was a negative association between functional amygdala-ventral medial prefrontal cortex connectivity and age. The findings from this study suggest that age may moderate the links between genotype and brain function, with the adult-like pattern of increased amygdala activation and decreased prefrontal-cortex amygdala connectivity in low-expressing allele carriers only being evident in older adolescents.

In another important example of developmental moderation of gene–brain–behavior relationships, Lau et al. (2009) compared the link between 5-HTTLPR genotype and amygdala function in children and adolescents with anxiety disorders relative to typically developing youth. In typically developing youth, Lau and colleagues found an expected association between the low-expressing allele of 5-HTTLPR and heightened amygdala activation to threatening faces relative to high-expressing allele carriers. However, contrary to the adult literature, children and adolescents with anxiety disorders with the *high-expressing* allele of 5-HTTLPR also had *heightened* amygdala activation compared with anxiety disorder patients with the *low-expressing* allele. Given the small sample size and the small number of participants in the high-expressing allele group, these results need replication in a larger sample. However, if replicated, the findings could indicate that genes have different associations with brain function in individuals who develop clinical disorders at a relatively young age compared with healthy peers or compared with normative samples of adults.

IGxE Interaction Studies in Youth

As described in the first part of this chapter, GxE interaction studies indicate that the influence of genes on psychological functioning depends on environmental context. Several recent studies have tested components of an IGxE interaction model and demonstrate that GxE interactions have implications for brain functioning. For example, research in adults has demonstrated that life stress

interacts with the low-expressing allele of 5-HTTLPR to predict increased amygdala activation to subliminally presented fearful faces (Williams et al., 2009), as well as baseline amygdala activation (Canli et al., 2006). In contrast, in a sample of 18-year-olds, Walsh and colleagues (2012) found that the low-expressing allele of 5-HTTLPR predicted increased amygdala activation to emotional faces but did not find support for an IGxE model, as childhood adversity did not interact with genotype or directly predict amygdala activity. At the same time, Walsh and colleagues did find that recent negative life events at age 17 had an additive effect in predicting heightened amygdala activation, indicating that both genetic variability and variability in experience influenced amygdala reactivity, though these effects did not appear to result in nonadditive interactions. The lack of observed effects of childhood adversity on amygdala function could be in part related to a broad definition of adversity in this study (e.g., childhood abuse, family dysfunction, occasional violence, lack of warmth, or lack of communication between family members), highlighting the need for close attention to be paid to both the operationalization and measurement of environmental stress.

Aside from difficulties relating to assessment of the environment, however, these preliminary three studies exemplify the utility of examining IGxE interactions within a neurogenetics framework, particularly in demonstrating how an IGxE framework might translate across developmental stages. Given the importance of identifying protective factors for youth psychopathology development, future research is needed to examine whether positive environmental influences also interact with genotype to influence amygdala activation in children and adolescents. For example, as described previously, Kaufman et al. (2004) found that social support moderated the relation between 5-HTTLPR genotype and child maltreatment. In contrast to maltreated children with the low-expressing allele of 5-HTTLPR who experienced positive social support, those who lacked positive social support showed high levels of depressive symptoms. Thus, future studies could test whether social support moderates the association between 5-HTTLPR genotype and amygdala reactivity, or the association between amygdala reactivity and report of depressive symptoms. In applying neurogenetics within an IGxE model in this way, future studies could more precisely examine potentially protective factors that buffer negative GxE interaction effects on the developing brain.

Beyond the Walsh et al. (2012) study that examined 18-year-olds, two other papers from the Teen Alcohol Outcomes Study (TAOS), a study of teens at genetic risk for psychopathology, have examined IGxE components in youth. Bogdan and colleagues built on an earlier study, previously described in this chapter, which examined a gene affecting HPA axis function (*FKBP5*) that moderated the link between emotional neglect and threat-related amygdala reactivity in this sample of teens (White et al., 2012). In the subsequent study, Bogdan et al. (Bogdan, Williamson, et al., 2012) examined a different gene related to another component of HPA axis function (the mineralocorticoid receptor) in this relatively large sample of children and adolescents aged 11–15 years old ($N = 279$). Results suggested that genetic variation in the mineralocorticoid receptor influenced threat-related amygdala reactivity. However, similar to the findings of White and colleagues (2012), prior childhood emotional neglect was also related to amygdala reactivity and also moderated the effect of this HPA-axis related genotype on neural reactivity (Bogdan, Williamson, et al., 2012). This study is thus a useful example of a how parts of an IGxE model could be tested among youth (see also Glaser et al., 2014). Moreover, these two studies demonstrate the thoughtful application of IGxE: the authors examined genes related to an important system (the HPA axis) associated with an experiential variable (early maltreatment) and brain region (threat-related amygdala reactivity), which has been implicated in many outcomes associated with early maltreatment and HPA axis dysregulation (e.g., depression, PTSD, anxiety disorders).

Overall the preliminary results from studies testing components of an IGxE model provide potential mechanisms that may help us identify the developmental pathways through which gene–environment interactions affect brain function. Hopefully in the future these interactions can, in turn, be linked to behavior and risk for psychopathology (i.e., Glaser et al., 2014). Specific findings relating to additive or interactive effects of stressful life events and maltreatment with genotype on amygdala activation suggest that increased amygdala reactivity to negative stimuli may mediate GxE interaction effects on the development of internalizing disorders.

Beyond 5-HTTLPR: Other Imaging Genetics Findings in Youth Applicable to Internalizing Disorders

The functional polymorphism in 5-HTTLPR has been one of the most extensively investigated candidate genes in imaging genetics studies. However, recent imaging studies in children and adolescents have also begun to examine associations between a number of other candidate genes

and corticolimbic functioning relevant to internalizing outcomes. For example, Lau et al. (2010) examined the Val66Met polymorphism of the *BDNF* gene in relation to amygdala response in adolescents with an anxiety or depressive disorder relative to typically developing controls. They found that the Met allele, which is associated with decreased neurotrophic function, predicted increased amygdala activation while rating subjective fear among adolescents with an anxiety or depressive disorder but not in controls.

Outside of genes affecting amygdala reactivity, another candidate gene that has been examined in relation to internalizing problems is a polymorphism of the dopamine receptor D4 subtype (*DRD4*) and its functional variant (7R+), which is associated with decreased dopamine signaling. Perez-Edgar and colleagues (2014) found that *DRD4* genotype and caudate activation moderated the link between early behavioral inhibition and adolescent anxiety. In this study behaviorally inhibited participants with the 7R+ genotype and stronger caudate activation to reward showed increased levels of anxiety in adolescence. Thus, genes and associated neural function may moderate associations between early childhood temperament and adolescent internalizing outcomes. These findings help us further identify a subset of individuals most at risk for internalizing problems via their early risk temperament and genetic or neural risk profile. Importantly, this study also identifies neural and genetic factors that may help to elucidate why not all children with "risky" early temperaments (i.e., behavioral inhibition) go on to demonstrate clinically significant levels of an internalizing disorder.

A third relevant candidate gene is a single nucleotide polymorphism in the oxytocin receptor gene (*OXTR*, rs2254298; G>A). Among adolescent girls, Furman, Chen, and Gotlib (2011) found that homozygosity for the G allele was associated with decreased amygdala volume. Furman et al. posited that this relationship may be due to decreased regulation of corticosteroids by oxytocin, which may then be associated with atrophy of the amygdala. Given that the G allele is found in higher frequencies in patients with depression, this study provides another example of a link between a gene and a neural structure (the amygdala) frequently implicated in depression, helping to delineate the developmental pathways through which risk genes may have their effects.

Although each of these candidate genes outlined above may explain a relatively small amount of variance in brain structure and function, cumulatively and in interaction with environmental stressors, they are likely to have greater predictive power in helping to determine which individuals are at risk for disrupted development of corticolimbic circuitry. For example, individuals with multiple genotypes associated with altered amygdala structure and function (the low-expressing allele of 5-HTTLPR, the Met allele of the Val66Met *BDNF* polymorphism, and homozygous G alleles in the rs2254298 polymorphism of the oxytocin receptor gene) may be at particularly high risk for the development of anxiety or depressive disorders, whereas individuals with only one of these risk alleles may be relatively buffered from this effect. Future research examining multiple genes and their associations with multiple regions (prefrontal cortex, amygdala, striatum) will be necessary to examine potential additive and interactive effects (e.g., Nikolova et al., 2011).

Finally, whereas studies described in this chapter have almost exclusively relied on a candidate gene approach to select functional polymorphisms with known effects on a neurotransmitter system or protein of interest, an alternative approach uses GWAS to search for genes that are associated with the functioning of a candidate neural region. Using this approach, a novel candidate polymorphism in the *DOK5* gene, which is associated with neuronal development, was found to be associated with amygdala activation in adolescents with bipolar disorder and among typically developing controls (Liu et al., 2010). Studies using GWAS and other related exploratory techniques could be used to identify other potential candidate genes that may be linked to corticolimbic function and the development of internalizing disorders. The downside to GWAS studies is that they require very large sample sizes, which are difficult and costly to collect when examining neuroimaging phenotypes.

Biological Mechanisms Underlying Neurogenetics and GxE Interaction Findings

As this chapter has highlighted, there is now evidence that the low-expressing allele of 5-HTTLPR interacts with childhood maltreatment or stressful life events to predict the development of depression in adolescents and adults (Caspi et al., 2003; Kumsta et al., 2010; Petersen et al., 2012; although see Laucht et al. (2009) for evidence of the high-expressing allele predicting greater internalizing problems in adolescents). As we have noted in previous descriptions of neurogenetics and IGxE, emerging research suggests that a major molecular pathway through which GxE interactions affect behavior is via brain chemistry (Hyde, Bogdan, et al., 2011). In particular, emerging research in epigenetics suggests a potential pathway through which environmental stress

interacts with 5-HTTLPR genotype to influence the development of internalizing disorders. For example, preliminary evidence suggests that DNA methylation of cytosine-phosphate-guanosine (CpG) sites in the promoter region of the 5-HTT gene may play a role in the previously observed GxE interactions in internalizing disorders (Beach, Brody, Gunter, et al., 2010; Kinnally et al., 2010; Kinnally et al., 2011; Philibert et al., 2007; Philibert et al., 2008). In particular, methylation of CpG islands in the promoter region of genes is thought to make the promoter region less accessible to transcription factors, decreasing the expression of the gene (for more extended reviews on this topic see Bagot & Meaney, 2010; Meaney, 2010; van IJzendoorn, Bakermans-Kranenburg, & Ebstein, 2011).

DNA methylation of the 5-HTT promoter region is one potential mechanism through which GxE interaction effects may occur. Research from the Iowa Adoption Studies has suggested that methylation of this region may be sensitive to environmental stressors, providing evidence that a history of child abuse is associated with increased methylation in the promoter region of the 5-HTT gene (Beach, Brody, Todorov, Gunter, & Philibert, 2010). Greater methylation at certain CpG sites in the serotonin transporter gene region has also been shown to be associated with decreased mRNA transcription, and a lifetime history of major depression (Philibert et al., 2008). Maltreatment thus appears to be associated with a molecular mechanism that decreases the transcription of the serotonin transporter, and there is a trend for this mechanism to be associated with a greater risk for having a lifetime history of depression.

Taken together, these studies provide preliminary evidence that early environmental stressors, such as child abuse, alter methylation levels of CpG sites in the serotonin transporter gene region. This altered methylation appears to result in decreased expression of the serotonin transporter, which could potentially affect corticolimbic development and function. Importantly from a neurogenetics perspective, these mechanisms may differ further by genotype. For example, in nonhuman primate work, Kinnally and colleagues (2010) found that the low-expressing allele of the rh5-HTTLPR was associated with increased methylation of CpG sites on the 5-HTT gene in macaques, which in turn was associated with decreased levels of serotonin transporter mRNA. This pattern of associations suggests that, similar to findings in humans, higher methylation leads to reduced serotonin transporter expression in nonhuman primates. Additionally, increased methylation was found to interact with early life stress (separation from mother or unpredictable food availability) to predict higher scores on a behavioral measure of stress reactivity (Kinnally et al., 2010; Kinnally et al., 2011).

This emerging body of research, when considered alongside pioneering research on rodents by Meaney and colleagues (e.g., McGowan et al., 2009; Meaney, 2010; Weaver et al., 2004), demonstrates potential neurogenetics mechanisms by which well-replicated GxE interactions appear to affect brain neurochemistry and function, and subsequent risk for psychopathology. Taken together, research from humans, nonhuman primates, and rodents suggests a potential pathway for epigenetic influences on the development of psychopathology. In particular, increased methylation of the 5-HTT gene leads to reduced transcription of the serotonin transporter (Philibert et al., 2008) and heightened stress reactivity in nonhuman primates (Kinnally et al., 2011). Importantly from a neurogenetics perspective, early environmental stress (e.g., child abuse) leads to increased methylation of the serotonin transporter promoter region, and methylation levels may be moderated by 5-HTTLPR genotype (Beach, Brody, Todorov, et al., 2010; Kinnally et al., 2010), thus providing a mechanism for a GxE interaction in which individuals with the low-expressing allele who are exposed to stressful life events are at increased risk for developing psychopathology.

These preliminary findings signal an exciting potential direction for future research. However, incorporating epigenetics into IGxE designs will require careful consideration of a number of theoretical and methodological concerns. First, although we can assume that DNA sequences assessed in adulthood have not changed from early development, the same may not necessarily be true for epigenetic modifications, given that they are subject to environmental influence (Houston et al., 2013). Thus, as noted throughout, although much of the research to date has examined experiences that occur in childhood (e.g., maltreatment), studies carried out in humans have typically not examined outcomes in youth, nor focused on childhood trajectories of these behaviors. Thus longitudinal work, especially with a developmental psychopathology focus on mechanisms and trajectories of behaviors, is needed to chart these complex molecular pathways across development and complex trajectories of behavior in youth.

Second, a major limitation of research to date is that methylation levels have been assessed peripherally in blood cells, which may not match methylation levels in the brain, especially given that methylation levels vary by cell type (Houston et al., 2013). As yet, it appears there is no straightforward association between peripherally measured methylation levels and methylation in the brain.

In particular, it is possible that the association between peripheral and central nervous system methylation levels could vary depending on the gene of interest, or the brain structure in which methylation levels are examined (Ursini et al., 2011).

Third, the mechanisms linking increased methylation of the 5-HTT gene to increased risk for psychopathology need to be further delineated. Although studies have shown that methylation of the 5-HTT gene alters mRNA transcription of the serotonin transporter gene, the developmental consequences of methylation for brain structure and function remain to be examined. Given the aforementioned limitations, progress in this area will require research that spans methodologies to triangulate a developmental pathway, while accounting for the strengths and limitations of each method. Animal research will clearly be important in this regard because it is possible to assess methylation levels in brain regions of interest, and test whether these match methylation levels assessed peripherally. Animal models, such as those used by Kinally and colleagues, also allow for experimental manipulation of environmental stress and rearing conditions (Kinnally et al., 2010; Kinnally et al., 2011). However, animal models necessarily limit the conclusions that can be drawn regarding complex human phenomena, such as social anxiety or depression. Postmortem studies in humans have also examined methylation levels directly in brain regions of interest and linked these to potential environmental stressors (e.g., McGowan et al., 2009). There are, however, a number of limitations to these studies, including the inability to assess the consequences of observed methylation levels for brain function.

An example of a research design incorporating a number of these proposed research directions examined a common functional variant in the gene regulating Catechol-O-methyltransferase (COMT), an enzyme that breaks down dopamine in the prefrontal cortex (Ursini et al., 2011). The *COMT* gene has a common functional polymorphism: Val158Met. The Val allele is associated with greater *COMT* activity, lower levels of prefrontal dopamine, and reduced prefrontal efficiency. In contrast, the Met allele is associated with less *COMT* activity via decreased thermostability, greater prefrontal dopamine, and, subsequently, increased prefrontal efficiency. This polymorphism may be an important candidate for GxE interactions because methylation at the region investigated in this study is possible on the Val allele, where there is a CpG site, but not on the Met allele (Wiers, 2012). Because *COMT* breaks down dopamine in the prefrontal cortex, greater methylation of the Val allele leads to reduced expression of *COMT*, leading to greater availability of dopamine in the prefrontal cortex and greater prefrontal cortex efficiency.

Incorporating research from animal models into their study, Ursini and colleagues demonstrated that *COMT* methylation levels measured peripherally in blood cells were significantly associated with *COMT* methylation levels in the prefrontal cortex in rats, suggesting that peripherally measured methylation levels correspond to those in the brain region of interest. Then, incorporating a human IGxE design, Ursini and colleagues examined the association between peripherally-measured *COMT* methylation levels, environmental stress, and prefrontal cortex function during a working memory task performed during fMRI scanning. In this portion of the study, they found that environmental stress predicted reduced methylation in Val/Val participants. Moreover, reduced methylation was associated with reduced working memory performance. The imaging component provided evidence that greater life stress and reduced *COMT* methylation were associated with decreased prefrontal cortex efficiency during the working memory task. When applying these findings to what we know about the genetic and molecular pathways affected by *COMT* variation, this study could be interpreted to show that methylation actually biased individuals toward the sequence-based variation conferring greater flexibility and adaptability via increased phasic dopamine signaling; stress-induced changes in methylation may then alter this bias and confer risk for psychopathology.

This study demonstrates how research can be integrated across a number of domains to better elucidate the processes through which genes and the environment interact to influence neural function, thus exemplifying much of the promise of neurogenetics. Using an animal model, Ursini and colleagues provided preliminary evidence that peripherally measured *COMT* methylation levels matched those in the region of interest (the prefrontal cortex). In humans, they demonstrated that environmental stress reduces *COMT* methylation (measured peripherally) and that reduced methylation coupled with greater stress is associated with prefrontal cortex function. Because methylation can only occur on the Val allele, this research has begun to indicate a potential pathway through which a GxE interaction may occur where the presence or absence of environmental stress has a stronger influence on Val allele carriers. Overall, these types of studies signal an important need for greater cross-talk and collaboration across a range of disciplines, as it is clear that no one method alone will be sufficient for identifying the mechanisms through

which GxE interactions influence risk and resilience in the development of psychopathology.

Summary of Research Examining the Neurogenetics of Internalizing Disorders

To summarize, neurogenetics studies have begun to elucidate a number of developmental pathways through which GxE interaction effects may contribute to the development of internalizing disorders (Figure 12.3). Studies have highlighted a number of genetic polymorphisms that affect neural development and neurotransmission, including polymorphisms in genes that influence the reception or secretion of serotonin, BDNF, dopamine, and oxytocin. These candidate genes can in turn be linked to the development and function of neural regions that are affected by the proteins these genes code for. For instance, the 5-HTTLPR genotype, which modulates serotonin reception, can be plausibly linked to altered function of corticolimbic circuitry, including reduced functional connectivity between the prefrontal cortex and amygdala. Administration of oxytocin has been shown to dampen amygdala activity (Kirsch et al., 2005), creating a potential link between *OXTR* genotype and amygdala function. BDNF is expressed in the amygdala, and thus *BDNF* Val66Met genotype may contribute to individual differences in plasticity and fear learning in the amygdala (Casey et al., 2009). Amygdala function, in turn, is linked to processes, such as fear conditioning and attention bias to threat, whereas prefrontal cortex-amygdala connectivity is associated with fear extinction and emotion regulation, all intermediate behavioral phenotypes associated with internalizing disorders. These neural phenotypes serve as key bridges between genetic variation and behavioral and psychological outcomes.

Additionally, environmental stress has been shown to interact with genotype to predict amygdala function (Canli et al., 2006), and environmental support has been shown to moderate the association between amygdala function and anxiety (Hyde, Gorka, et al., 2011). Thus, the environment interacts with genotype and neural function at multiple levels in this model, further elucidating the developmental pathways through which genes and environment interact to influence the development of psychopathology. However, despite the progress made to date, a developmental perspective has still been largely lacking from such explorations. As discussed above and illustrated by the relatively small number of studies described examining neurogenetics of internalizing in youth, the majority of imaging genetics research has been conducted in adults, which may be problematic for informing our theories of the development of psychopathology. When studies are conducted in adults, they are either performed in healthy controls (who may be relatively resilient to the development of psychopathology) or in adult patients (whose neural function may reflect the consequence of disorder rather than the cause). When studies have been conducted in children or adolescents, they often include a wide cross-section of ages and have generally not considered moderation of GxE interaction effects by development or developmental pathways. Thus, an important direction for future research will be to incorporate a developmental perspective into neurogenetics designs, particularly as outlined above considering points from developmental psychopathology.

FUTURE DIRECTIONS

Ongoing Challenges and Future Directions for Neurogenetics Research of Internalizing Disorders

To return to the questions posed at the beginning of this section, research in the nascent field of developmental neurogenetics as applied to internalizing disorders has demonstrated the importance of incorporating a developmental perspective into research. Initial studies, including those of Wiggins et al. (2012) and Casey et al. (2009), provide preliminary evidence for "age–genotype" interaction effects on behavioral and neural phenotypes, indicating that the association between a gene and a phenotype of interest will vary depending on *when* the association is measured. There are several reasons that we could see such developmental effects, each of which has important implications for future directions in this field. Many brain structures, including the prefrontal cortex and amygdala, undergo protracted development throughout adolescence and thus the association between genes and brain function may depend on age. For instance, several recent studies have shown that there are cross sectional linear *declines* with age in amygdala reactivity to emotional faces (Gee et al., 2013; Swartz, Carrasco et al., 2014). Thus, if amygdala reactivity is normatively higher in children, the association between genotype and phenotype may differ in children relative to other earlier or later developmental stages. If brain functioning can be measured and examined as a trajectory over time, we may be able to examine how individuals differ from the decreasing trajectory that occurs during adolescence or if variations from this trajectory predict maladaptive outcomes. Moreover, some

effects may be latent, or may be only activated after certain developmental stages, such as when puberty triggers changes in gene expression.

Casey and colleagues (2009) have proposed another mechanism through which "age × –genotype" interactions may occur: because expressed levels of proteins can vary over development, the effect of a genetic variation that decreases or increases expression of that protein may vary by developmental stage because the absolute levels of protein available vary by age. Thus, a genotype that codes for an "ideal" amount of protein expression in one environment at one developmental stage may not be ideal at another developmental stage. Thus, although relatively few IGxE studies that include an additional assessment of moderation by age have been conducted to date, initial theoretical and empirical considerations suggest that there is great promise in taking a developmental perspective to neurogenetics approaches.

A related question has been to pinpoint the biological mechanisms through which genes and the environment interact to influence development. Again, we have barely scratched the surface when it comes to addressing this question, but preliminary studies incorporating epigenetics have suggested a plausible pathway through which environmental stress can "get under the skin" and influence the development and functioning of the brain. This area of research is subject to some novel methodological difficulties given the lack of straightforward associations between peripherally measured methylation levels and methylation levels in brain regions of interest. However, these limitations also highlight the promise of a neurogenetics approach. In particular, studies of epigenetics will benefit greatly from the incorporation of animal models, imaging genetics, GxE approaches, and PET and multimodal imaging approaches to better link experience to the complex molecular pathways leading from gene to brain to behavior.

Other questions to date remain largely unanswered. In particular, we know very little about whether patterns of neural development in childhood or adolescence could be used to predict onset of disorder. Moreover, we are yet to examine whether knowing about neural development patterns, could better identify genetic risk markers that could be used to relatively inexpensively and noninvasively assess an individual's risk for the development of psychopathology. Given the current gaps in the literature, we outline several directions for future research that could lead to significant progress in this area: First, the reliance on cross-sectional research to date indicates a need for the mapping of neural development using longitudinal approaches. There are several large-scale longitudinal studies that have done such mapping in structural brain development (e.g., Gogtay et al., 2004; Shaw et al., 2008), but to date, only a handful of longitudinal studies have examined changes in brain function (e.g., Koolschijn, Schel, de Rooij, Rombouts, & Crone, 2011; Ordaz, Foran, Velanova, & Luna, 2013; Pfeifer et al., 2013). Mapping the longitudinal development of brain function, including amygdala reactivity and prefrontal cortex-amygdala connectivity, is an important first step in forming hypotheses about how development might moderate GxE interaction effects on neural function, or how trajectories of neural development could mediate GxE interaction effects on disorder onset. Additionally, studies that compare trajectories of typical brain development to trajectories of brain development in individuals at risk for disorder (e.g., individuals with a high number of risk alleles of candidate genes or heightened familial risk due to a family history of disorder) can help to highlight early markers of the boundary between adaptive and maladaptive brain development. This step will be important in determining whether altered patterns of brain development could be used as early indicators of risk for disorder. These future directions point to a need both for large-scale, longitudinal functional neuroimaging studies and the training of neuroscientists in statistical approaches for the analysis of large data sets and longitudinal measures of behavior and brain functioning (e.g., Nagin & Tremblay, 2001).

Second, a notable limitation of many imaging genetics studies conducted to date is that sample sizes have been too small to investigate moderation of effects by age, sex, or race/ethnicity. In general, these studies have analyzed all participants together, and when race/ethnicity is considered, the approach is usually to select for White/Caucasian participants or reanalyze results to ensure they hold in the subsample of participants that are White/Caucasian. Lacking the power to test for moderation effects of gender is problematic given the noted gender differences in internalizing disorders (and differential effects of pubertal hormones on brain development), with females tending to have higher rates of depression and anxiety from adolescence onward. Moreover, lack of power to test for differences across race/ethnicity categories is also problematic, given that allelic frequencies vary by race/ethnicity and may even have different or opposite effects in different groups. For instance, there is some evidence to suggest that the association between the 5-HTTLPR and brain function in Asian populations is opposite to that found in Caucasian populations, with the high-expressing allele predicting greater anxiety and reduced prefrontal

cortex-amygdala connectivity (Long et al., 2013). Thus, failure to take into account potential differences could mask significant effects or lead to conclusions that are not accurate for all racial/ethnic groups.

Treatment Implications

There is significant promise in using neurogenetics and developmental psychopathology to inform translational efforts (Bogdan, Hyde, et al., 2012; Hyde, 2014). For example, the promise of examining subgrouping and person-centered approaches to studies of psychopathology, particularly those examining neural and genetic correlates, is that if these studies identify a group of youth or adults with a distinct etiology (e.g., those with early-onset depression), then we may be better able to tailor interventions to these individuals (e.g., Hyde, Waller, & Burt, 2014). Moreover, if empirical studies identify factors (i.e., early anxiety symptoms, certain genetic polymorphisms) that predict a different course of a disorder, then these factors may be important in identifying those at highest risk early for preventative interventions (e.g., Dishion et al., 2008; Hankin, 2012). Genetic variation and brain function may also help to identify treatment response and thus be considered before interventions are even started (Bryant et al., 2008; Ising et al., 2007; Uhr et al., 2008). Thus, as medicine moves toward both a more tailored and personalized model of care at the individual level, and a more preventative model of care at the population level, identifying factors that delineate subgroups of individuals that need different treatments or that can be targeted earlier with preventative interventions will be increasingly important and may help to increase the effectiveness of both prevention and intervention models (Simon & Perlis, 2010; Willard & Ginsburg, 2009).

More specifically, by deconstructing the molecular mechanisms underlying gene–brain–behavior pathways, especially in collaboration with animal models and in vitro research, neurogenetics has the potential to inform novel therapeutic targets. For example, combining evidence from studies linking *HTR1A* rs6295 with anxiety through amygdala reactivity with prior work demonstrating effects of the polymorphism on the capacity for negative feedback inhibition, suggests that targeting 5-HT_{1A} autoreceptors, perhaps as an adjuvant to SSRI treatment, may produce greater clinical effect. In fact, a recent study in a transgenic mouse model of 5-HT_{1A} autoreceptor function demonstrated that reducing autoreceptor levels prior to SSRI administration converted nonresponders into responders (Richardson-Jones et al., 2010). Thus, neurogenetics research with *HTR1A* rs6295 has identified a novel therapeutic target (i.e., antagonism of 5-HT_{1A} autoreceptors) and a marker that could be used to individually tailor treatment (i.e., for C allele homozygotes).

Another example of how neurogenetics can inform treatment and prevention comes from research on TREK1, a background potassium channel. Inspired by a *TREK1* knockout mouse study showing that deletion of *TREK1* results in a depression resistant phenotype (Heurteaux et al., 2006), human studies have linked variation in the human *TREK1* gene (*KCNK2*) to depression (Liou et al., 2009), blunted striatal response to reward (a neural profile associated with depression; Dillon et al., 2010), as well as antidepressant treatment response (Perlis et al., 2008). More recently these findings have led researchers to develop antidepressant medications that antagonize TREK1. One such compound designed to inhibit TREK1 has been associated with a positive antidepressant response, hippocampal neurogenesis, and increased serotonergic signaling in rodents (Mazella et al., 2010). Though the potential of this novel treatment mechanism has yet to be tested in humans, it does further document how neurogenetics research can spur therapeutic advancements by identifying novel targets. These examples highlight the great potential of neurogenetics to inform targets for novel interventions and ways to better personalize psychiatric treatment. However, they also underline the importance of additional research in this area that is translational in nature.

Next Steps in Research

Drawing across this chapter, there are a number of important future steps arising for the next generation of research. In particular, there are several key methodological steps and developments needed in the tools we use to examine gene–brain–behavior links. Further, there are theoretical advancements needed in the way that we model complex and conditional relationships, including the effects of development, further moderation of GxE interaction by additional genes or environments, and the importance of incorporating epigenetic mechanisms into models.

First, there is need for imaging genetics studies to draw out indirect pathways from gene to brain to behavior, instead of focusing solely on gene to brain associations. In particular, we need research that examines the brain as a mediator of gene–behavior pathways longitudinally. As outlined, within a neurogenetics framework, this research will benefit from leveraging what we know from complementary biological techniques that probe the chemistry of the brain, including pharmacologic challenge studies and

animal models. We also need ways to increase sample sizes within imaging genetics research, which will support the testing of increasingly complex pathways, particularly if this can be done with repeated neuroimaging data collection across development. Looking ahead, neurogenetics will benefit from scanning larger and larger samples of individuals at a population level, using data sharing, consortium models, and neuroimaging meta-analyses. The use of larger sample sizes will also enable closer examination of the potential moderation of GxE interaction effects by sex or race/ethnicity, which are too often overlooked in studies that focus on homogenous subgroups, such as White/Caucasian participants. Failure to take into account potential differences according to gender or race/ethnicity may mask significant effects or lead to conclusions that are not accurate for all subgroups. As a field, we also need to be open for further collaboration with colleagues who are developing novel statistical modeling methods, including advanced computational and statistical techniques, as well as data mining approaches such as machine learning and graph theory. Finally, as we develop increasingly complex models that incorporate the influence of the environment in IGxE interaction studies, we need to be more precise in our operationalization of the environment. In particular, by incorporating an emphasis highlighted in developmental psychopathology on adopting an interdisciplinary approach, neurogenetics will benefit from the use of ecological and complex systems models that will help to inform changing views of the structure of psychopathology and maladaptive behaviors. Finally, by adopting more genetically informed designs we can begin to highlight which environmental effects are independent of genotype.

Second, from both methodological and theoretical perspectives, we need to be better at modeling increasingly complex conditional relationships, including GxGxE and GxExE. In considering the potential for further moderation of GxE interaction effects by genes, we will be able to build on a significant body of literature examining cumulative genetic profiles (Nikolova et al., 2011; Purcell et al., 2009). Likewise, modeling the role of the environment is usefully informed by cumulative risk models of environmental exposures within developmental psychopathology, highlighting the fact that an accumulation of "risk" is often more important than any one 'single' risk factor. Combining cumulative genetics models with cumulative experiential models is a key next step in neurogenetics research.

Third, a further source of complexity is the role of developmental stage (D) in influencing GxE and IGxE interaction effects (i.e., GxExD). As outlined, we believe that neurogenetics has much to gain from incorporating key tenets of developmental psychopathology to create an integrated developmental neurogenetics framework (see Hyde, 2015). Through the integration of these approaches, future next steps in neurogenetics research will involve an examination of broader liability for psychopathology (i.e., within a general-specific modeling framework), deconstruction of diagnostic classifications within a person-centered framework to identify even greater homogeneity with subgroups of individuals, incorporation of the concepts of equifinality and multifinality within models, and a focus on the temperamental, personality, or endophenotypic building blocks of psychopathology that serve as more objective outcomes with which to assess gene–brain–behavior links. Importantly, models from developmental psychopathology can inform modeling of these complex, multilevel questions and will help to guide efforts to examine the role of development in these processes.

In particular, future neurogenetics research needs to be more sensitive to potential developmental effects. First, studies are needed that include an examination of the effects of "age x gene" interactions within imaging genetics studies to determine whether the influence of genes on brain function varies at different ages or developmental stages. A second and related aim is for studies to examine how genes affect trajectories of brain development using prospective longitudinal designs. Longitudinal research on cortical thickness and IQ suggests that the trajectory of brain development can be more predictive of outcomes than the end points of development (Shaw et al., 2006). Thus, the association between genes and trajectories of brain development during childhood and adolescence may provide greater predictive power than that afforded by examining genes and brain function solely in adulthood (see also Casey et al., 2009). Indeed, although there is preliminary evidence from behavioral and health research of age x gene effects, we have barely scratched the surface on how these manifest as differences in the development of brain structure and function.

Third, in relation to neurogenetics research examining the development of youth internalizing disorders more specifically, there are some overlapping directions for future research that could lead to significant progress in this area. Importantly, there is a need for prospective longitudinal functional neuroimaging studies that can prospectively examine changes in brain function and whether trajectories of neural development mediate GxE interaction effects on anxiety or depression. In relation to a developmental

psychopathology framework, studies that examine individuals with high cumulative experiential or genetic risk are also needed. In addition, we are only just beginning to understand the full extent of the implications associated with epigenetic mechanisms and in particular, how environments interact with genotype to affect an outcome. However, the transmission of epigenetic markers from parent to offspring is a further source of risk for individuals, and one that precipitates examining environments, not just in the lives of individuals, but also that of their parents.

Related to this point is the need for research to move beyond a single candidate gene approach. As mentioned above, candidate genes only account for a small percentage of variation in neural phenotypes of interest. One approach, as we have suggested, is to incorporate cumulative genetic profiles (Nikolova et al., 2011) or to use statistical methodology to identify how individual genes fit with a neural or behavioral phenotype (e.g., Gruenewald et al., 2006). Likewise, using GWAS approaches with neural phenotypes (or developmental trajectories of neural phenotypes) as outcomes of interest has the potential to identify novel genetic polymorphisms that may provide additional predictive power. Ultimately, a more nuanced approach to characterizing genetic risk, environmental risk, GxE statistical effects, and neural development will hopefully lead to more precise characterization of the developmental processes through which genes and environment interact to influence risk or resilience for psychopathology, which will have important translational implications for the early detection of risk for disorder and early intervention and prevention efforts. Though these types of developmental neurogenetics models are relatively novel, they hold great promise and are an exciting new approach to understanding the development of psychopathology.

A central problem in development concerns origins; understanding how the multiple sources of information that direct the development of the organism originate and interrelate over time (Oyama, 2000). From its initial definition as "the study of the origins and course of individual patterns of behavioral maladaptation . . . however complex the developmental pattern may be" (Sroufe & Rutter, 1984, p. 18) the discipline of developmental psychopathology has directly addressed the need to understand the origins of mature forms of behavior in terms of developmental processes. Developmental psychopathology has served as a driving theoretical force in shaping the vast array of scientific disciplines that are directly concerned with development, with "the dynamic interplay of processes across time frames, levels of analysis, and contexts" (Carolina Consortium on Human Development, 1996). Recognition of the common focus on development across disciplines has given rise to what is known as developmental science and to a set of principles by which developmental science is defined. As stated by Magnusson and Cairns (1996) these principles include (1) an understanding of development as holistic and requiring an examination of reciprocity among systems across levels; (2) the contextually bound nature of development; (3) the role of novelty in development; (4) the centrality of time and timing in development, on multiple scales and metrics; (5) the problem of reductionism and the tendency to study one aspect of development in isolation; and (6) recognition of what is known as correlated constraint, or the organized and conservative nature of development. In combination, these principles describe an understanding of the person situated within time frames, levels of analysis, and contexts and offer insight into a developmental understanding of psychopathology.

EXPERIENTIAL CANALIZATION

In the application of general principles of developmental science to the study of developmental psychopathology, we focus on the holistic and contextually bound nature of development and the principle of correlated constraint. We are particularly interested in these principles as they relate to the psychobiological process referred to as experiential canalization (Gottlieb, 1991). The concept of canalization represents an attempt to formally describe the phenomenon of differentiation in development; the emergence of specific and well-ordered forms and behaviors from initially undifferentiated prior states. Canalization, as a descriptive term, contains no prior assumptions about the sources of information that direct the canalizing or shaping process in development. What is implied in the term, however, is the idea of a progressive narrowing of possibilities—of paths taken and foreclosed. As such, it is an apt term for describing the principle of correlated constraint, the constraining of development by the process of development itself. In research on psychological development, this constraining of possibilities is a central feature of cognitive and perceptual development. A canonical example is found in research on language development in infancy. With repeated exposure to a given language in infancy, the child gains experience discriminating phonetic contrasts common to that language while losing the ability to discriminate phonetic contrasts not encountered in that language (Kuhl et al., 1992; Werker & Tees, 1986). Simultaneously with such gain through loss in language development, however, infants acquire an increased ability to integrate sensory experience from multiple sources—visual, auditory, and affective—leading to the further tuning and elaboration of perceptual networks in response to experience (Pons et al., 2009).

As it is generally and historically understood, the concept of canalization describes inevitability or determinism in development; the assumption that information is present in the organism or in the environment that directs development to specific endpoints. As reviewed by Gottlieb (1991), canalization was first invoked by Holt (1931) to describe motor development from the prenatal to the early postnatal period. This initial use of the term was framed within learning theory and the shaping of behavior by conditioned responses. In keeping with the general tenor of psychological research in the first half of the twentieth century, this early use of the term was framed within the assumption that experience is responsible for the shaping of behavior, and that the process of development is shaped by general but ubiquitous experiences acting on initially diffuse and undifferentiated patterns of motor activity.

In contrast to the initial use of canalization from the perspective of learning theory and implied assumptions about the experiential source of the information in directing the development of the organism, a very different and more commonly understood view of the concept was subsequently proposed by Conrad Waddington. Waddington's conceptual model proposes genes as the primary source of information shaping the development of the organism. In contrast to a conception of development as a progressive narrowing or shaping of abilities by experience, the use of the term as associated with Waddington describes a developmental process that is resistant to the influence of experience and that is characterized by a self-righting tendency in response to variation in experience.

Distinct from both the learning theory and genetic interpretations of canalization, the meaning of canalization from the perspective of developmental psychobiology differs from the views proposed by Holt and Waddington (Gottlieb, 1991). It recognizes both biological and experiential influences across multiple levels of analysis and situates them within the individual's developmental history. The framing of canalization proposed by Gottlieb and Kuo (1965) integrates biological and experiential information to address the question of *how* development occurs. As such, it is concerned not so much with the ultimate origin or the endpoint of development as it is with the pathway, with the developmental trajectory and consequences for later development conditioned on earlier occurring developmental processes. Without positing a primacy to any particular source of information, biological or experiential, it proposes an understanding of psychological development as essentially probabilistic as opposed to predetermined, but one that can appear to be highly stable and resistant to change. Identifying the ways the different constituent components of development combine to create stability in physical and psychological development is the objective of the experiential canalization approach; this then allows for the identification of potential points of malleability and specific time points and variables that can be manipulated to bring about change in the developing system. In this way, the concept addresses the paradoxical nature of development as a process of change that is characterized by stability and resistance to change.

Perhaps the most direct illustration of the experiential canalization approach as the combined action of biological and experiential influences on development is seen in Gottlieb's research on the recognition of the maternal call in wood and mallard duck hatchlings. Gottlieb's embryological experiments indicated that the seemingly innate and instinctual tendency of hatchlings to identify and maintain proximity to conspecifics (duck mothers) is

dependent on prenatal experience. Specifically, in order to exhibit the prototypical imprinting behavior exhibited by hatchlings, it is necessary that the embryo experience its own hypersonic vocalizations. In the absence of this experience, imprinting can occur to a variety of species (Gottlieb, 1997). That is, the developmental system—including genetic, physiological, and environmental input, pre-, peri-, and postnatally—is plastic and open to canalization. Here, behavior can be considered a leading edge of development (Cairns, 1991), as the embryonic ducklings vocalization is the primary mechanism of development. That is, behavior organizes the components of the developmental system into a new and stable configuration and acts to maintain that configuration.

A related example in humans, referred to already, is the development of intersensory perception and perceptual narrowing in infancy. The integration of multimodal information occurring very early in development—prenatally and postnatally—provides the basis for the development of increasingly precise perceptual abilities, reducing the amount of information that must be processed in order to bring about a particular behavioral response to stimulation (Lewkowicz, 2000). Perceptual integration can provide for the facilitation or inhibition of sensory processing in one modality by another, for example enhanced auditory perception by the visual modality. From an experiential canalization perspective, the timing and type of modality specific stimulation is central to the process of perceptual development. Experience, primarily through temporal rate and frequency, drives a process whereby the organism acquires increasingly integrated and differentiated information about the world. The act of perceiving integrated information provides the basis for further and more differentiated integration of perceptual processes. Similar processes are also described in dynamic systems theory approaches to motor development, and the idea that as perception shapes action, so action shapes perception (Thelen, 1995).

A MODEL OF SELF-REGULATION DEVELOPMENT

To apply the experiential canalization model to self-regulation development, we look to prior thinking on self-regulation (Luu & Tucker, 2004; Posner & Rothbart, 2000) and define it as the volitional and non-volitional (conscious and non-conscious) management of emotional, attentional, and physiological responses to stimulation, both internally and externally generated, for the purposes of enacting intentional goal-directed, motivated behavior. In this broad definition, self-regulation includes influences at multiple levels of analysis ranging from the genetic to the neural and physiological to the behavioral and social-cultural. Here, self-regulation can be understood to be composed of a set of interacting processes with well-defined biological substrates that are hierarchically organized and integrated by development into particular forms and behaviors. A model of these components and their hierarchical organization is presented in Figure 13.1. This figure presents an architecture or architectonics of self-regulation that is open to the canalizing process of experience at each level. In this, it can be understood both as a model of influences on behavior at a given point in time as well as developmentally over time, as processes at one level influences the development of processes at multiple other levels, as in the general developmental psychobiological model in Figure 13.2.

At the top of the model in Figure 13.1, the fifth level, are the executive functions, defined as cognitive abilities associated with holding information in mind in working memory, the inhibition of highly automatic or prepotent responses to stimulation, and the volitional shifting of

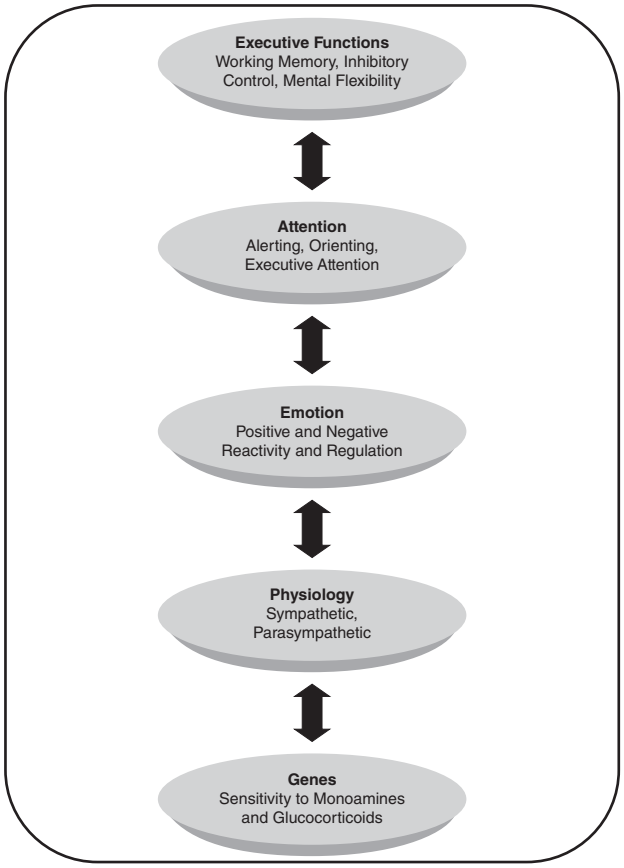

Figure 13.1 The architecture of self-regulation.

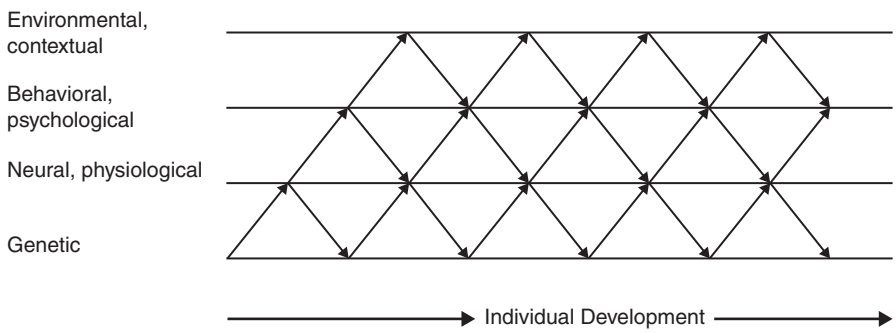

Figure 13.2 The developmental psychobiological model.

attention among distinct but related dimensions of a given stimulus. Executive functions are widely studied in typical and atypical development (Diamond, 2013). The construct originated in neuropsychological research to describe an array of cognitive and behavioral deficits in individuals associated with planning and decision making, primarily in the instance of damage to specific brain areas in prefrontal cortex (PFC; Fuster, 2008; Luria, 1973). Deficits in this set of cognitive skills in various psychopathologies have led to increased interest in executive functions and to their typical and atypical development.

Executive functions are one aspect of the volitional control of arousal and in some ways are synonymous with the motivated and intentional control of behavior. Importantly, for the model in Figure 13.1 and for a developmental model of psychopathology, however, executive functions are only one, and perhaps the least stable or most vulnerable aspect of the self-regulation system. Executive functions are, relatively speaking, chronometrically slow, volitionally effortful, and resource intensive aspects of cognition. Neurobiologically, executive functions are dependent on the integrity of prefrontal cortex (PFC) and the neural circuitry linking PFC with multiple brain regions, including limbic, temporal, and parietal areas. These brain areas that are interconnected with PFC and that both influence and are influenced by PFC, are those represented by the third and fourth levels in the model in Figure 13.1, namely emotional and attentional reactivity and regulation. The brain areas associated with attention include three networks that underlie three functionally, anatomically, and neurochemically distinct aspects of attention, namely altering, orienting, and executive attention, or the volitional control of the focus of attention. The alerting system is activated by norepinephrine originating in midbrain and involves specific areas of frontal and parietal cortex. The orienting system includes the temporal parietal junction, superior parietal cortex, and frontal eye fields and is activated by the cholinergic system. The executive system includes anterior cingulate cortex, insula, and basal ganglia and its primary neurotransmitter is dopamine (Petersen & Posner, 2012; Posner & Rothbart, 2007; Posner, Rothbart, Sheese, & Voelker, 2012). The brain areas associated with emotional reactivity and regulation include structures of the limbic system, notably the amygdala, anterior cingulate, and ventral, lateral, and medial areas of PFC (Davidson, 2000; Dolan, 2002; Ochsner, et al., 2004). All of these brain areas are activated by the above neurotransmitters as well as serotonin.

Activity in the circuitry that underlies reactivity in attention and emotion systems is chronometrically fast relative to executive functioning, and consequently stimulation can drive emotional and attentional responses in ways that shape brain development and support or undercut executive function abilities. The neural basis for this relation occurs in part through the activity of the neurotransmitters described above. The action of these neuromodulators is represented in the second level of the model in Figure 13.1 as the stress response. The stress response system includes the distinct but interrelated sympathetic-adrenal system and resulting levels of catecholamines, primarily dopamine and norepinephrine, and the hypothalamic-pituitary-adrenal (HPA) axis and its end product, the glucocorticoid hormone cortisol. Cortisol results from a cascade of activity in the hypothalamic-pituitary-adrenal (HPA) axis in which stimulation initiates the release of corticotropin releasing hormone (CRH) from the paraventricular nucleus of the hypothalamus leading to the secretion of adrenocorticotropic hormone from the pituitary and resulting release of cortisol from the adrenals. Circulating cortisol then feeds back on the HPA system to inhibit CRH and the resulting production of cortisol (Gunnar & Quevedo, 2007).

CRH also potentiates the sympathetic-adrenal system leading to complex interactions between the HPA axis and

the autonomic nervous system (ANS). Although, the time course of cortisol is slow, taking minutes to reach peak levels, cortisol has more rapid effects at the cell membrane occurring in a time frame of seconds rather than minutes. Studies focusing on physiologically faster actions of glucocorticoids have indicated ways the HPA axis interacts with the ANS (Groeneweg, Karst, de Kleot, & Joels, 2011). CRH facilitates catecholamine release, leading to what is termed a permissive effect of glucocorticoids on indicators of ANS activity such as heart rate (Sapolsky, Romero, & Munck, 2000). Here, interactions among the components of stress physiology are intricate and more research is needed on how they are related developmentally. One investigation of the combined effects of glucocorticoids and catecholamines on behavior in an adult rat model indicated that stress-induced elevations in dopamine are blocked by a glucocorticoid receptor antagonist and that this manipulation was associated with higher levels of working memory performance on a complex maze learning task following stress induction (Butts, Weinberg, Young, & Phillips, 2011). Also in a rat model, high levels of glucocorticoids acting at receptors in PFC both impair working memory and enhance memory consolidation for emotionally arousing events. Importantly, these effects are mediated by a membrane bound steroid receptor, not by activity within the cell nucleus, and dependent on levels of norepinephrine (Barsegyan, MacKenzie, Kurose, McGaugh, & Roozendaal, 2010).

More generally, the feed forward-feedback nature of the stress response system is central to higher and lower aspects of the self-regulation model. As levels of NE, DA, and cortisol rise, they potentiate activity in the emotional and attentional networks that influence executive function abilities. This activation is understood as signaling from limbic and brainstem structures to PFC that levels of stimulation are occurring that require effortful attention and control. That is, as neurotransmitters rise to moderate levels, they increase neural activity in PFC. At very high levels, however, hormone increase is associated with decreased activity in PFC and increased activity in subcortical brain areas associated with reactive responses to stimulation, the capture of attention, and also with robust formation of declarative memories of highly emotional events, the so-called flashbulb memory phenomenon (Diamond, Campbell, Park, Halonen, & Zoladz, 2007). As demonstrated primarily by the research of Goldman-Rakic (1995) and Arnsten (2009), the functional form of the relation of hormone levels to executive function abilities such as working memory is the classic inverted U-shaped curve first identified by Yerkes and Dodson (1908). The inverted U-shaped curve describes the well-known colloquial relation between performance and anxiety in which moderate levels of stress are understood to facilitate performance. Notably, however, in this model and in the original paper by Yerkes and Dodson describing it, moderate levels of stimulation in rats, operationalized as mild electrical shock, was associated with increased performance only on complex learning tasks. In contrast, performance on simple reactivity tasks, such as fear conditioning, was linearly and positively associated with stimulation; with simple tasks, the higher the increase in stress hormones, the better the learning, as in the emotional memory phenomenon.

The mechanism linking moderate stress with complex learning has to do with the fact that neural activity in PFC is sensitive to levels of catecholamines. At moderate levels of catecholamine increase, synaptic activity in PFC is increased and synaptic long-term potentiation, the process through which neurons communicate and form networks, takes place. At very high levels of catecholamine increase, however, the opposite occurs. Instead of increasing synaptic activity and LTP, synaptic activity in PFC is decreased, as neurons in this brain area work less well when exposed to high levels of catecholamines. (The loose analogy that is sometimes used is that of an internal combustion engine, in which an optimal mixture of fuel and oxygen are needed in order for combustion to take place. When the amount of fuel or oxygen is too great or too small, the mixture is difficult to ignite and combustion does not occur.) In other brain areas, however, notably those associated with emotional, attentional, and motoric reactivity to stimulation, such as a vigilant and hyper attentive state, the relation between catecholamine levels and synaptic activity is linear. That is, as catecholamines reach levels that lead to decreased activity in PFC, shutting down brain areas associated with complex cognition and reflective thinking, they are turning on brain areas associated with reactive and less reflective responses, namely the amygdala, a key structure in orchestrating automatic and nonconscious responses to stimulation associated with fear, anxiety, and vigilance to threat.

The Inverted U

The model of self-regulation presented here suggests that the concept of the inverted U can be applied to self-regulation generally. From a bottom-up perspective, as levels of emotion and attentional reactivity and associated neuromodulators rise they support effortful self-regulation through executive functions that are important for

performance and learning on complex tasks. And vice versa, from a top-down perspective, executive functions allow the organism to reflect on information and to direct attention and emotional arousal with cascading consequences through the levels of the model in Figure 13.1. In the model, when stimulation becomes overwhelming or underwhelming, or when top-down control is compromised in some way, bottom-up processes take over and lead to reactive behavior. That is, behavior is more directly under the control of highly learned responses and outside stimulation and less under the control of internally generated information and control—in a word, less reflective.

High levels of stimulation leading to a sustained stress response and rising catecholamine and glucocorticoid levels flip the brain from a top-down mode of control associated with PFC and reflective thinking to a bottom-up mode of control associated with the amygdala and reactive responses to stimulation (Arnsten, 2009). Such an aspect of brain function has clear benefits to survival and evolutionarily speaking is highly conserved across species. In times of threat, it is important for bottom-up processes to take control of attention, emotion, and motor responses to stimulation. The bottom-up form of control assists in the process of survival because it is faster from the perspective of neuronal activity than top-down control (see LeDoux, 1996, 2012). The mechanism by which neural activity is flipped from a top-down to a bottom-up mode of control is related to the types of neural receptors for catecholamines and glucocortioids that predominate in different brain areas and variation in their sensitivity to levels of these hormones. For example, a receptor for norepinephrine (NE), the alpha2 receptor, proliferates in PFC and has a high affinity for NE, meaning that it is active at low to moderate levels of NE and potentiates synaptic activity. Similarly, the dopamine D1 receptor is also present in PFC and sensitive to moderate increases in dopamine. The NE alpha2 and dopamine D1 receptors have complimentary roles in supporting working memory and are both sensitive to increase in NE and DA, respectively. At increases beyond a moderate level, however, they become inactive (Arnsten, 2009). In contrast, different types of receptors for NE are present in the region of the amygdala and hippocampus, the alpha1 and beta receptors, and they are less sensitive to increases in NE and become increasingly active as levels rise. Similar relations are observed for types of glucocorticoid receptors, and along with receptors for catecholamines, provide the neurobiological basis for the inverted U-shaped curve between stress and performance outlined previously.

Genetic Variation

Notably for understanding the hierarchical relation among levels of analysis in the model of self-regulation in Figure 13.1 at the base of the model are variants in genes, both single nucleotide polymorphisms and variable number tandem repeats that are associated with sensitivity to and variation in levels of the relevant hormones that act as neuromodulators in the neural circuitry that underlies self-regulation. For example, a variant of a single nucleotide polymorphism (SNP), the catechol-o-methyltransferase gene (COMT) has been widely studied, particularly as a potential contributing cause of schizophrenia. This gene is associated with the break down or catabolism of catecholamines, dopamine and norepinephrine, in PFC. Individuals who have a G to A substitution, resulting in a valine to methionine substitution at position 158, catabolize dopamine less efficiently than do individuals with the valine version of the gene. Individuals who are heterozygous for the gene display intermediate levels of dopamine catabolism relative to those who are homozygous for the valine or methionine version of the gene. The functional activity of the gene in relation to behavior is seen in the role it plays in regulating catecholamines, particularly dopamine in PFC. Given the relatively low density of synaptic dopamine transporters in PFC, dopamine removal from the synapse results more from the activity of enzymes that break down dopamine and norepinephrine into inert components than from the removal of dopamine from the synapse through cellular transporter mechanisms. Given the inverted U shape relation of catecholamines to synaptic activity in PFC, a number of studies have shown relations of COMT val158met genotype to executive functions.

Generally speaking, the form of this relation has been one in which individuals homozygous for the met version of the gene, meaning that they break down catecholamines less quickly, exhibit higher levels of working memory and executive cognitive task performance due to the increased presence of catecholamines in PFC. That is, consistent with the inverted U-shape relation between stress and performance described previously, moderately higher levels of catecholamines, in this case due to the benefit of a genetically conferred characteristic, should be associated with a higher level of executive function ability. Studies of the COMT gene and similar genes associated with catecholamine activity for the most part, however, have been carried out in laboratory contexts and have not taken into account where on the inverted U shape curve an individual may be situated, experientially speaking. Several studies,

however, note that expectations concerning the relation of the COMT gene to behavior must take into account the context and temperament of the individual, or what might be considered the initial starting point or background state of the brain prior to completing an executive cognitive task (see Tunbridge et al., 2007, for review). For example, pharmacological manipulation of catecholamine levels through amphetamine administration results in a higher level of performance among val carriers relative to met carriers (Mattay et al., 2003), an effect opposite from what would be expected under typically occurring conditions.

EXPERIENTIAL CANALIZATION OF SELF-REGULATION DEVELOPMENT

The experiential canalization model of self-regulation is one in which the developmental shaping of the self-regulation system over time is open to the combined influences of individual biology and experience at all levels, from the genetic to the social and cultural. In the model, it is therefore essential to take into account the history of the organism when examining one aspect of the individual, such as COMT genotype, in relation to any other. Clear examples of this point are seen in demonstrations of the relation of genetic background and early experience to risk for psychopathology in widely cited analyses from a longitudinal sample, a birth cohort, in Dunedin NZ (Caspi et al., 2002, 2003). Here, the relation of genes that regulate monoamine (MAOA) and serotonin (5-HTT) metabolism to later psychopathology were dependent upon the quality of early experience. Specifically, in the Dunedin sample, individuals carrying the version of the MAOA gene that confers less efficient metabolism of monoamines were increasingly likely to exhibit antisocial behavior as adults if they had experienced maltreatment in childhood (Caspi et al., 2002). Similarly, for individuals carrying the version of the serotonin transporter gene that confers less efficient metabolism of serotonin (lower serotonin transporter availability), the effect of stressful life events on depression was increased (Caspi et al., 2003). To be clear, in both of these studies, adverse early experience was a risk factor for later psychopathology for all individuals in the study. The risk associated with that experience, however, was even greater for individuals carrying the gene associated with less efficient metabolism of the relevant neurotransmitters (dopamine, norepinephrine, serotonin).

Although impressive in many ways, what is most notable about these findings is the idea that what is beneficial under advantageous circumstances is detrimental in adverse circumstances. That is, while the maintenance of catecholamines in the brain confers benefits to self-regulation and reflective thinking under low stress conditions, it is disadvantageous under high stress conditions. The neurobiological basis for the way in which acute stress affects psychological function and behavior by increasing catecholamines and flipping the brain from a more reflective to more reactive mode of control in the short run is well established. What is less clear, however, is the extent to which this neurobiology has long-term implications for psychological development and risk for the development of psychopathology, such as that in the examples above. Given the role of experience in brain development (Greenough, Black, & Wallace, 1987) and the formation of neural networks by processes of LTP occurring in response to experience (Hebb, 1949), it is conceivable that tendencies toward more reactive or more reflective modes of self-regulation could become increasing well established, potentially early in development that would be maintained behaviorally in a way that would have long term implications for psychological outcomes and risk for psychopathology.

Much more longitudinal research is needed to address this central point in the development of self-regulation, for which an experiential canalization approach focusing on stress and stress hormones can be helpful. The basis for such an approach is rooted in concepts of allostasis and cybernetics (Pribram, 1960). Decades of research on stress physiology have demonstrated that stress physiology adaptively adjusts as a cybernetic system to current and expected challenges. Unlike homeostatic systems that must maintain functioning within a relatively narrow band around a given set point to support the optimal functioning of the organism (e.g., body temperature around 98.6° Fahrenheit), stress response systems are allostatic, able to adaptively adjust set points and ranges in response to experience as needed. In this process of allostatic adjustment, the brain plays the key mediating role as it is shaped by experience to adjust physiologic systems to meet an expected future (McEwen & Gianaros, 2011). From the joint perspectives of allostasis and cybernetics, the self-regulation of behavior is a manifestation of physiological set points and accompanying cognitive representations of these set points (Luu & Tucker, 2004). Experience in concert with biological systems acts to establish increasing stability in patterns of behavior through its influence on stability in neural networks (Derryberry & Rothbart, 1997; Posner & Rothbart, 2007).

Numerous studies have confirmed that PFC is central to the regulation of stress response physiology and that levels

of catecholamines and glucocorticoids in part shape the development of this area of the brain (Holmes & Wellman, 2009). Consistent with the experiential canalization model of self-regulation, stress early in life is understood to shape the strength of connections between prefrontal and limbic structures that underlie self-regulation (Cerqueira et al., 2007). For example, a series of studies has shown that induced stress in adult rats leads to changes in the structure of neurons in PFC with consequent effects on attention and set-shifting executive cognitive types of abilities (Liston et al, 2006; Radley et al., 2006). These studies indicate that early stress can lead to the types of functional deficits that are observed in various forms of psychopathology and strongly indicate early stress as one potential contributor to the pathogenesis of psychiatric disorders through its influence on the development of self-regulation.

Available human data are consistent with the findings of stress manipulation studies in animal models and indicate the effect of stress hormones on PFC and executive functions. Pharmacological manipulations affecting glucocorticoids as well as catecholamine levels have demonstrated the role of these neurochemicals in executive function abilities (Alexander et al., 2007; Lupien et al., 2001). Of pressing interest are the various pathways through which naturally occurring chronic stress in individuals' lives may lead to self-regulation difficulties and to increased risk for psychopathology. Early life stress, primarily operationalized in terms of the adverse events usually associated with the experience of growing up in poverty, has been shown to lead to alterations in resting levels of stress hormones such as cortisol in children (Blair et al., 2011; Evans, 2003; Lupien et al., 2005). As well, early poverty has been associated at the molecular level with differential expression of genes associated with adrenergic and glucocorticoid function. In one study, genome wide transcriptional profiling found that low SES in childhood was associated with up regulation of genes associated with adrenergic neural receptor function and down regulation of genes associated with glucocorticoid receptor function in adulthood; a pattern consistent with an expected higher level of reactivity and less prototypically effective regulation of physiological reactivity in individuals experiencing poverty in early childhood (Miller et al., 2009).

Experiential Canalization as Life-Course Strategy

Implicit in the idea of the allostatic shaping of stress response systems is the notion of a tradeoff between short-term benefit and long-term disadvantage. Central to the experiential canalization model and also the related adaptive calibration model of stress response physiology (Del Giudice, Ellis, & Shirtcliff, 2012) is the idea that alterations to physiology occurring in response to stress are an adaptive and probabilistically normative response to conditions of disadvantage. Alterations to stress physiology and to the neurobiological self-regulation system in response to an expected environment, particularly early in development, are central to a developmental and evolutionary understanding of psychological and physical functioning. Evolutionary biological models across a variety of species indicate that, in conditions of high disadvantage and in which resources and support are low, effective strategies for garnering resources and for surviving to maturity and engaging in opportunities for procreation are optimized through the tuning of stress physiology to potentiate high reactivity and low reflective behavior. Although such reactivity may have some long term cost, the potential for surviving to realize this longer term cost is reduced in conditions of disadvantage. In contrast, in highly resourced and supportive environments, alteration of stress physiology in ways that support more reflective behavior with positive consequences for longer term benefit is advantageous. A well-resourced future is one that can best be utilized and optimized through planning and reflection on multiple possibilities.

The idea that development is shaped by environmental context in ways that are designed to maximize fitness within that context is observed across a variety of species from plants, to fish, to mammals. A notable example of the shaping of such a defensive response in development, persisting across generations, is seen in the modest example of the radish. High levels of damage by herbivores induce phenotypic changes in radish leaf production and in seed production in ways that make the leaves less appealing as a food source and as a result promote fitness in environments in which herbivory is high (Agrawal, 1999). A similarly modest example, in this instance in an insect, the water flea, exposure of the mother to the chemical signal of a predator induces morphological changes in offspring that render them less vulnerable to that predator over subsequent generations, even in the absence of any exposure during development of the offspring to that signal. In these examples, environmental programming of individual development is mediated through the mother, through what is referred to as the maternal provision. In a review of the literature on environmental programming, Cameron et al. (2005) provided several examples across a variety of species from plants to insects to mammals in which the experience of the parent induces a phenotypic change in the offspring, often for successive generations.

Sensitivity to Context

A key point implicit in the foregoing is the realization that the relation between one level of influence in the self-regulation model, such as genetic background associated with catecholamine metabolism, and experience extends beyond merely increasing risk for later psychopathology. The gene variant or stress response that confers risk in adverse circumstances may be the one that confers benefit in more advantageous circumstances. The recognition of such increased susceptibility to experience (Belsky & Pluess, 2009) or biological sensitivity to context (Boyce & Ellis, 2005), as this phenomenon is referred to is perhaps central to understanding how individuals who look very similar in certain respects may end up with very different outcomes. Such multifinality in development, the emergence of divergent developmental pathways and endpoints from similar starting points, is expected and may hold some promise for understanding processes of risk and resilience in developmental psychopathology. Fulfilling this promise will involve some understanding of the short and long term implications of the inverted U-shape relation between stress and self-regulation for psychological and behavioral development (Blair, 2010). It may be that any longer term effects on brain development and synaptic functioning are malleable and may offer clues as to how effects of early experience can be overcome by later experience. As well, it may be for some, that later experiences can exert disadvantageous effects despite early advantage.

An important point here concerns the fact that in samples demonstrating an association between a specific gene variant, be it MAOA or any other gene, and disadvantageous experience, the number of individuals with the relevant version of the gene and high adverse life experience are usually a small percentage of the total population (e.g., Caspi et al., 2002; Kim-Cohen et al., 2007). This indicates that the association between the specific gene variant and the adversity being examined can account for only a portion of the pathologic outcome being examined. That is, complementary to multifinality, there is also equifinality, or multiple ways individuals come to the same developmental outcome. Here, reported interactions between gene variants and environments in the prediction of outcomes are perhaps best seen as exemplary of the relation between biology and experience in the study of developmental psychopathology. Multiple genes are related to the activity of catecholamines and glucocorticoids and multiple types of experience can combine with those genes to lead to psychopathology or to resilience despite risk. Discerning common pathways among these heterogeneous influences is a complex undertaking but one in which psychobiological theory and understanding of self-regulation as a recursive feed forward and feedback driven system can provide a useful organizing framework.

Gene Expression

An overarching point essential to issues of multifinality and equifinality in development is that the recursive nature of the model in Figure 13.1 extends to the genetic level. That is, just as executive function processes can both control and be controlled by levels of arousal in emotion and attention systems, so do stress physiology and genes interact through processes of gene expression that shape and are in turn shaped by levels of stress hormones. The HPA axis cascade and action of glucocorticoids on relevant neural targets is generally physiologically somewhat slow, occurring over minutes or hours. Here, glucocorticoid effects on neural activity and structure are largely gene mediated, meaning that they affect processes in the cell nucleus and influence DNA transcription (de Kloet, Karst, & Joels, 2008; Joels & Baram, 2009). As such, the self-regulation model posits that experience shapes development in two directions: As experience acts on stress physiology to influence levels of circulating hormones, it is working "upstream" to affect emotion, attention, and executive function skills that work to regulate stress physiology. It is also working downstream, through cortisol to affect gene expression in ways that also affect levels of stress hormones and, consequently, reactivity and regulation of emotion and attention and executive functions. In theory, the feedforward–feedback loop of self-regulation is understood to be developing over time in response to experience, perhaps rapidly early in the life course, to establish set points or sensitivity for reactive as opposed to regulated responses to stimulation (Luu & Tucker, 2004). Experience and biology are understood to combine to determine the sensitivity of the self-regulation system.

The defining psychobiological model of a canalizing process in self-regulation development, although not necessarily referred to as such, is found in research on the effect of maternal behavior on development in a rat model. As shown in the rat, expression of a gene associated with glucocorticoid receptor density in the hippocampus is determined by specific types of maternal behaviors occurring within the first 8 postnatal days. Expression of this gene is associated with the ability to regulate hypothalamic-pituitary-adrenal (HPA) axis responses to

stress and, in turn, with self-regulation behaviors influenced by stress hormone activity. Specifically, offspring of rat mothers that lick and groom their pups frequently and nurse in an arched-back manner (LG-ABN) manifest reduced reactivity and enhanced regulation not only of glucocorticoid levels but also greater learning and memory and reduced avoidance in the face of novel and/or threatening stimuli (Liu et al., 1997; Liu et al., 2000). Notably from the perspective of experiential canalization and adaptive phenotypic plasticity, the high licking and grooming maternal behavior associated with glucocorticoid receptor gene expression in the hippocampus and increased cognitive and behavioral regulation in offspring is facilitated in resource rich environments but reduced in resource poor environments (Meaney, 2001). That is, to some extent the maternal behavior that offspring receive is influenced by the characteristics of the environment in which the mother is situated when conceiving and rearing her offspring. The idea here is that in high-resource environments, the mother rat would be foraging away from the nest for relatively short periods of time and therefore engaging in more of the LG-ABN behavior while in low resource environments the opposite would be true. Such an environmentally driven change in maternal behavior leading to changes in stress physiology and hence behavioral development of offspring is a canonical example of a canalizing process in development.

EXPERIENTIAL CANALIZATION OF SELF-REGULATION DEVELOPMENT AND RISK FOR PSYCHOPATHOLOGY

Understanding the distribution of genes and processes of gene expression in populations and the ways genetic background and gene expression are related to one another developmentally is a key scientific goal for research in developmental psychopathology and human development generally; one for which the experiential canalization approach can provide a useful theoretical framework. Important in this goal is an understanding of the relation of biology and experience to developmental outcomes within the model of self-regulation. Here, the model of self-regulation development describes what can be considered an endophenotype, or intermediate phenotype (Gottesman & Gould, 2003). The endophenotype describes combinations of physiological, anatomical, cognitive, and neural processes that are implicated in but by no means unique to psychopathology. The endophenotype is understood to encompass a well-defined and coherent set of processes and behaviors that in part characterize a given disorder. As such, it is well aligned with new directions in the identification and classification of mental disorders on the basis of genetics and brain structure and function as well as behavior referred to as Research Diagnostic Criteria (RDoC; Insel et al., 2010).

The self-regulation system provides an elaborated model of the intermediate phenotype that provides insight into interaction among processes at multiple levels of analysis and various pathways to the occurrence of a given disorder and means to treat it. In the clinical and developmental literature on psychopathology broadly, self-regulation is widely studied in the form of the regulation of emotion and attention and also executive functions. Many aspects of the components to the self-regulation model outlined above are the topic of extensive research in schizophrenia, attention-deficit/hyperactivity disorder, anxiety disorders, and depression. In keeping with the general idea that the study of typical and atypical development are mutually informative, the processes of the typical development of executive function, attention, and emotion from the experiential canalization approach, particularly in the context of high risk, whether from poverty, prior family history or both, can inform understanding of self-regulation in research in developmental psychopathology. To this end, we review research on the typical development of self-regulation, focusing on our own and others work with the aim of outlining ways developmental processes may increase risk for psychopathology or alternatively promote resilience in the context of risk.

Typical Development of Executive Functions

Definitions of executive functions have ranged somewhat widely within a circumscribed set of abilities from the more to less inclusive. Given the role executive skills in planning and problem solving and effortfully regulating aspects of cognition and motivation, some have argued for relatively inclusive definitions of executive functions that involve general planning and problem solving skills (Welch, Pennington, & Grossier, 1991). Others, in contrast, have focused more narrowly (Aron, 2008). Increasingly, however, the field has settled on the domain general cognitive skills of working memory, inhibitory control, and attention shifting as the operational and conceptual definition of executive control (Diamond, 2013). That is, cognitive control generally involves the integration of these skills in task performance. This is seen in widely used measures

of executive function (Davidson, Amso, Anderson, & Diamond, 2006; Zelazo, 2006) and has tended to be validated in studies examining the relation of executive function components to performance on comprehensive executive function tasks (Miyake et al., 2000).

A complete review of research on executive functions is not appropriate here; however, from the perspective of the experiential canalization model of self-regulation development and its application to developmental psychopathology, the protracted developmental course of executive function abilities and their association with prefrontal cortex, a slow maturing brain region (Gogtay, Giedd, et al., 2004), recommends these cognitive skills as potentially valuable indicators of experiential influences on development and on risk for and prevention of psychopathology. The genesis of the executive functions construct in the neuropsychological literature (Luria, 1963) and intense interest in executive functions in the instance of brain damage or dysfunction (Duncan, Burgess, & Emslie, 1995; Waltz et al., 1999) further illustrates the applicability of these cognitive abilities to a developmental understanding of psychopathology. In typically and atypically developing samples, studies of executive function have of necessity employed a variety of measures, primarily due to the restricted age range in which various measures can be used. This makes cross-study and cross-age comparisons difficult. As well, research on the development of executive functions has tended to be cross sectional and has focused on age-related change as well as issues relating to measurement and to construct definition and validity, including the differentiation of executive functions from other aspects of cognitive ability, particularly general intelligence (Blair, 2006). Longitudinal research on the development of executive functions in childhood or throughout the lifespan is relatively rare. Nonetheless, useful information about executive function development can be gleaned from several analyses (e.g., Anderson, 2002; Welsh, Pennington, & Grossier, 1991). Studies with older children and adults have examined typical tasks from the neuropsychological literature and found that performance on these batteries follows a trajectory in which ability increases steadily throughout adolescence into young adulthood. For example, Luciana and colleagues found in a cross sectional sample of 9–20-year-olds that recall-guided action of single units of spatial information develops until 11 to 12 years while the maintenance and manipulation of multiple spatial units develops until 13 to 15 years. More complex processing of information in which the individual must organize and structure information develops until ages 16 to 17 years (Luciana et al., 2005). Complex processing of information in working memory has also been found to develop into early adulthood (20–29 years) with age related declines becoming apparent in the 50–64 years range (De Luca et al., 2003).

Measurement of Executive Functions

Information about the typical trajectory for executive function abilities in younger children has been limited by the absence of measures appropriate for longitudinal use. Although there are a number of effective measures of executive functions for preschool children, variation in performance on these measures is usually restricted to a relatively narrow age range with pronounced floor and ceiling effects outside of that range. Carlson (2005) reviewed several widely used measures in early childhood research and found that most are adequate within a relatively narrow age range. Similarly, Espy and collaborators have shown that an attention shifting and inhibitory control task known as the Shape School tracks age related changes in abilities in a cross sectional sample of 3 to 6 year olds (Espy et al., 2006). Noting the need for measures that can be used longitudinally to examine within person change in executive function and that address the tripartite division of executive function into working memory, inhibitory control, and cognitive flexibility domains, Willoughby and Blair (2010) developed a battery of six executive function tasks appropriate for 3–5-year-olds. This battery, similar to analysis of other executive function batteries (Wiebe, Espy, & Charak, 2008), was found to indicate a single underlying factor of executive function. It also demonstrated longitudinal measurement invariance across the age range studied and good test–retest reliability (Willoughby et al., 2011). Notably, findings in a large longitudinal sample ($N = 1{,}292$) indicated rapid and substantial development in early childhood of 2.8 SD on average in executive function between ages 3 and 5 years (Willoughby et al., 2012).

The aforementioned studies provide some indication of the typical course of the development of executive function and indicate that the ability to process complex information continues to develop into young adulthood. There currently is not a complete normative picture of executive function development, however, against which atypical trajectories can be identified. Obtaining this information is a priority for research in psychopathology and for research on human development in the context of risk, generally. Deficits in executive function are one mechanism through which early adversity affects lifetime risk for mental as well as physical health disorders (Blair & Raver, 2012).

Atypical trajectories for executive function development in early childhood may provide some early indication of risk. An important step in obtaining normative information on executive function development has been the creation of what is known as the NIH Toolbox, which includes computerized versions of two widely used measures of executive function, the Dimensional Change Card Sort task and the Eriksen Flanker Task (Zelazo et al., 2013). Presumably normative information on these measures will be forthcoming and will provide a valuable resource for examining executive function deficits as potential indicators of risk for developing psychopathology.

In developing longitudinal measures of executive functions, however, it is important to note that executive function abilities may be highly vulnerable to a variety of insults and therefore less informative as a definitive indicator of risk for psychopathology. Executive functions can be affected by a variety of things, from the mundane (lack of sleep and lack of exercise; Chadock-Heyman et al., 2013; Davis et al., 2011) to the catastrophic (structural and functional damage to PFC and related circuitry; Duncan, Burgess, & Emslie, 1995). Unlike, for example, semantic memory or speed of information processing, aspects of cognition that are more stable, executive functions can be relatively variable within person. The openness of executive functions to insult small and large means that within person change and the stability of between person differences may be great. To a considerable extent, this aspect of executive functioning is a manifestation of the relation of these cognitive abilities to the lower level processes in the model in Figure 13.1. As noted by Luu and Tucker (2004, p. 125), "Disembodied concepts of executive functions may be particularly inappropriate when dysfunctions of executive control are invoked to explain pathologies of mood and motivation. Rather than a disorder of an external supervisory control, these pathologies suggest fundamental alterations in the internal goals and set-points guiding self-regulation." Executive functions are understood to be predictably variable due to influences on attention and emotion and stress physiology as a manifestation of self-regulation development.

Notably, the inherent variability in executive functions creates problems for traditional psychometric analyses by which the validity of psychological assessments is typically established. Test–retest reliability may tend to be low and correlations among assessments of putatively the same construct administered concurrently may correlate weakly or even not at all (Rabbitt, 1997; Willoughby & Blair, 2011). These measurement concerns and considerations in executive function research are seen most clearly in latent variable model analyses of executive function test batteries (Willoughby, Pek, Blair, & FLP Investigators, 2013). Latent variable modeling is an appropriate and widely used strategy for estimating and analyzing the common variance among a set of measures of ostensibly the same construct. Analyses of general mental ability and academic achievement are well-known examples of the utility of latent variable modeling to derive a single underlying construct. Task batteries of these constructs produce robust latent factors that account for upward of 70% of the variance in each of the individual measures (observed indicator variables) used to create the latent variable. Unlike test batteries for these constructs, however, executive function assessments in most latent variable analyses (e.g., Miyake et al., 2000; Willoughby et al., 2012) present low to moderate correlations among the observed indicators and as a result executive function latent variables usually account for only small amounts of variance in each of the indicator variables. This aspect of the task batteries places an upward limit on the reliability of the latent variables, referred to as maximal reliability, despite typically excellent global model fit (Willoughby, Pek, Blair, & the FLP Investigators, 2013). Excellent model fit in this instance cannot be taken as an indicator of the quality of the measurement of the underlying construct, raising questions about conclusions of the literature on executive function abilities using latent variable modeling.

The foregoing characteristics of executive function measures highlight the inherent weaknesses as well as strengths of the construct. On one hand, traditional psychometric standards for establishing reliability and validity indicate that the construct is somewhat problematic. On the other hand, part of the value of executive functions lies in their inherent instability. Here, theory and empirical evidence indicate that the construct may be most valuable because of its potential malleability and suggest novel methodologies to study it. To this end, executive function research could benefit from the application of innovative but underutilized methods focusing on within person change (Molenaar, 2008; Nesselroade & Jones, 1990). The application of what is referred to as a multivariate, replicated, single-subject, repeated measures design focusing on intraindividual variability as opposed to interindividual variability could provide the basis for a more accurate estimate of the typical course of the development of executive functions and the relation of this development to risk for psychopathology. Such idiographic research methods were developed to address the fact that traditional analytical approaches that address inter-individual variation cannot provide accurate information about within person change.

To appropriately model the complexity of development, for current purposes relations among various aspects of the self-regulation system as they relate to within person change, it is necessary to measure individuals, as many as possible, as repeatedly as possible, and to analyze the data to examine how variables combine within persons (Ram, Brose, & Molenaar, 2013). This approach allows for conclusions about trajectories and processes of change within an individual as well as identification of patterns of similarity among groups of individuals, empirically capturing the reciprocal, dynamic nature of development so forcefully outlined by Magnusson and Cairns (1996) and by an experiential canalization framework.

Executive Functions and Developmental Psychopathology

Issues relating to the measurement of executive function abilities and appropriate methods for the study of change are heightened by the fact that developmental studies have indicated deficits in executive functions across a variety of disorders including attention-deficit/hyperactivity disorder (ADHD; Biederman et al., 2007; Willcutt et al., 2010) and autism (Ozonoff & McEvoy, 1994). Studies have also established that executive function deficits are characteristic of major depression and schizophrenia (Tan, Callicott, & Weinberger, 2009). Although executive function deficits are neither necessary nor sufficient for the diagnosis of any psychiatric disorder, knowledge of executive function development and its biological and experiential determinants can likely provide valuable information to further understand psychiatric disorders and their pathogenesis. Consistent with the framework of the experiential canalization model in Figure 13.1, however, executive function deficits across various disorders or within a single diagnostic category could originate from multiple different sources of influence. Executive function deficits in and of themselves are perhaps too general to be of use on their own in identifying risk for and potential course of a given disorder. Knowledge of the processes that underlie the development of typical executive function abilities, however, will likely prove to be useful in diagnosing and treating subsets of individuals with a given disorder.

The specific etiology and course of psychopathology generally might be more readily discerned by considering the various levels in the model in Figure 13.1. Two examples are useful here: schizophrenia and ADHD. Both are characterized by executive function deficits and executive functions have been extensively studied in individuals with these disorders. More specifically, for present purposes, the COMT gene has figured largely in research on schizophrenia. Given the role of this gene in the activity of dopamine in PFC, it serves as a logical candidate for understanding the etiology of schizophrenia. The association of COMT with schizophrenia is, however, weak at best (Fan et al., 2005). This is not surprising given the complexity of processes affecting executive function as well as risk for schizophrenia, among which dopamine availability associated with the activity of a single gene is one small influence. Research on the COMT polymorphism, which has been voluminous, has revealed, however, the centrality of taking into account the background physiological state of the individual. Given the inverted U shape curve defining the relation between neurotransmitter levels and neural activity in PFC, it may be advantageous under conditions of stress or threat, or even moderately elevated stress, to break dopamine down more efficiently, as do individuals with one or two copies of the val allele of COMT. Therefore, research on one aspect of the individual, such as COMT genotype, might prove to be a risk factor or a protective factor in the case of schizophrenia or other disorders affecting executive functions, depending on a host of other characteristics of the individual. Although relations among this host of factors is undoubtedly complex, the experiential canalization approach provides a framework for incorporating this complexity and for discerning relations among levels of influence that lead to the disorder or to its absence despite substantial risk. Here, the principles of developmental science articulated by Magnusson and Cairns (1996) listed at the beginning of the chapter suggest the importance of focusing on the timing of individual experience and variation in rates of development of the various components of the self-regulation system. Application of single-subject, repeated measures designs to the well-established relations among COMT, catecholamine levels, and executive function abilities can address complex relations among influences on an intermediate phenotype associated with risk for psychopathology.

ADHD is also a complex disorder for which the experiential canalization approach is useful in discerning multiple etiologies and subtypes of the disorder. Prior models of ADHD have focused primarily on executive function deficits as its defining feature (Barkley, 1997; Nigg, 2001). Given the inherent complexity of executive functions and multiple pathways to problems with executive functions, however, identification of ADHD as a disorder of executive functions is too general and has required a focus on heterogeneity of subtypes and on bottom-up as well as top-down influences on cognitive ability and behavior. As outlined in the model of self-regulation, the bottom-up influences can affect top-down executive

control abilities. In ADHD research, this has been noted in a focus on sensitivity to reward and approach behavior (Nigg & Casey, 2005) as processes at the emotional and physiological levels that can override or subvert executive function abilities. Furthermore, the recognition of the multiplicity of influences and pathways in ADHD has resulted in a focus on the identification of heterogeneity in the disorder. That is, rather than taking a core deficit such as executive dysfunction as the sole focus of research on etiology, diagnosis, and treatment, investigators have turned to heterogeneity of psychological functioning in typically developing populations as a backdrop against which to understand heterogeneity in ADHD. This effort has pursued what is known as community detection, an approach to define clusters or communities of similarity among relevant measures of cognitive ability among a sample of children meeting criteria for ADHD and typically developing controls. Notably, the approach has yielded the insight that heterogeneity in ADHD is embedded in heterogeneity in typically developing children (Fair, Bathula, et al., 2012). As well, the heterogeneity in subtypes identified by community detection was observed in variation in functional connectivity in the brain for two of the most common ADHD subtypes (Fair, Nigg, et al., 2012). These results confirm to some extent the value of a focus in developmental psychopathology on both multi and equifinality and on the mutually informative relation between typical and atypical development. As well, these findings suggest the value of a developmental analysis as outlined in the seven principles enumerated in the introduction. It may be that distinct pathways to the disorder can be discerned early in development and that the timing and type of experience associated with each yield insights into its etiology and potential preventive intervention.

Application to the Study of Anxiety and Mood Disorders

A further illustrative example of the way in which an understanding of the hierarchical organization of influences on self-regulation is related to the study of psychopathology is found in its application to anxiety and mood disorders. Anxiety is an essential aspect of human functioning that has been conserved throughout evolution for its value in detecting and responding to threat. Executive functions, which enable the higher order processing of potentially threatening information, expands the link between detection and response, projecting it into the future and building upon past experience (Luu, Tucker, & Derryberry, 1998). For present purposes in the experiential canalization framework of self-regulation, this understanding of executive control, as one that is intimately connected with threat detection (emotional, reactive) highlights the reciprocal relation between bottom-up and top-down processes for understanding anxiety and mood disorders. Specifically, bottom-up pathways linking amygdala and anterior cingulate cortex (ACC) have been identified as critical components of individuals' regulation of fear and anxiety. Individuals prone to high levels of anxiety demonstrate clear differences in amygdala function, processing threatening versus nonthreatening stimuli differently than non-anxious controls in a bottom-up model of attention and emotion processing (Debiec, Diax-Mataiz, Bush, Doyere, & LeDoux, 2010; Dolan & Vuilleumier, 2003; Mogg & Bradley, 1998). Processing biases in depressed individuals' perception of emotionally negative stimuli have also been found to be associated with heightened activation throughout additional ventral components of the network linking amygdala, insula, ventral striatum, and ventral ACC (Mayberg, 2003; Phillips et al., 2003). Findings extend to pediatric samples of nonmedicated children and adolescents experiencing high levels of depressive symptoms (Roberson-Nay, et al., 2006; Yang et al., 2010).

These bottom-up processes of emotion regulation (ER) involved in responses to fear-evoking or threatening stimuli are, of course, tied to top-down processes involving PFC function (see Dolcos, Iordan & Dolcos 2011 for review). Specifically, executive functions can aid in modulating negative arousal as well as in interpreting and responding to emotionally negative stimuli (Ochsner, Bunge, Gross & Gabrieli, 2006; Ochsner & Gross, 2005; Posner & Peterson, 1990; Wang et al., 2008). Highly anxious individuals, however, have been found to show reduced executive functions, and consequently, difficulty in managing competing or conflicting cognitive demands relative to nonanxious controls (Bishop, 2009; Bishop, Duncan, & Lawrence, 2004: Rueda, et al. 2004). These differences have been hypothesized to play critical roles in anxious individuals' difficulty in accurately appraising both the emotional states and intentions of others, in socially positive as well as socially negative situations. While past work has largely focused on elucidating the links between greater proneness to reactive versus reflective profiles of self-regulation and profiles of behavioral disinhibition (e.g., higher risk taking behavior, higher delinquency and higher risk of substance use problems), newer research considers the ways that top-down processes are implicated as symptom (as much or more so than cause) in the development of anxiety, depressive disorders and broader-band internalizing difficulty (Buckner, Mezzacappa & Beardsley, 2003; Zucker, Heitzeg & Nigg, 2012).

Recent reviews examining the neural circuitry implicated in processing of emotional stimuli for individuals with depressive disorders suggest support for a dual systems model emphasizing bottom-up and top-down processes. Automatic responding to emotional stimuli primarily draws upon amygdala and ventral and medial prefrontal cortex including subgenual ACC. In contrast, voluntary behavioral and attentional processing of emotional stimuli has been found to involve dorsal regions, including dorsal ACC and dorsal lateral PFC (Rive et al., 2013). Neuroimaging studies of adults with depression diagnoses suggest that effective connectivity from the subgenual ACC and amygdala is increased, with depressed individuals needing to deploy greater medial PFC activation to maintain automatic attentional control relative to their non-depressed counterparts. This hypothesis has been supported by findings indicating increased activity in dorsal medial PFC and dorsal ACC in depressed participants relative to healthy controls during tasks requiring automatic emotion regulation such as facial matching and Stroop-like tasks where emotional stimuli are embedded. In short, activation of neural circuitry underlying executive functions appears to be increased in a compensatory fashion in individuals with depression to redirect attention away from emotionally negative and distracting stimuli (Etkin & Schatzberg, 2011; Rive et al., 2013). This added demand on executive cognitive abilities may indicate that deficits in executive cognitive ability are secondary to increased demand on attention to emotional processing. Patterns of hypoactive function in lateral prefrontal areas across a number of studies examining depressed participants' performance on tasks involving voluntary cognitive control of negative emotions may indicate typical depletion of executive abilities in the face of repeated demands. Such findings are aligned with results suggesting the individuals with major depressive disorder have difficulty voluntarily stopping or inhibiting the processing of negative information (Gotlib & Joorman, 2010). Treatment studies using fMRI to examine the impact of pharmacological treatment using SSRIs such as paroxetine, sertraline and fluoxetine highlight the joint roles of amygdala, rostral ACC and the lateral PFC in emotion processing. In one recent study, decreases in amygdala activation as well as increased dorsal cortical activation (including increased rostral cingulate and DLPFC) were found as a function of antidepressant treatment, with evidence argued to support indirect pathways of influence (e.g., SSRI treatment leading to improved dorsal prefrontal control over dysregulated limbic activity; Ruhe et al., 2013).

Parallel to these findings, investigators focusing on HPA axis function among depressed individuals have highlighted corresponding patterns of disrupted neuroendocrine function that align well with our model of self-regulation. Specifically, depression has been found to be associated with higher cortisol and increased CRF activity. Importantly, melancholic depression characterized by hyperarousal of negative emotion, higher anxiety, and greater focus on the self is associated with a pattern of hyperfunction of the HPA axis (Struber, Struber & Roth, 2014)

THE EXPERIENTIAL CANALIZATION MODEL OF SELF-REGULATION IN THE STUDY OF EMOTIONAL DEVELOPMENT AND RISK FOR THE DEVELOPMENT OF PSYCHOPATHOLOGY

In previous sections, we have outlined a case for the multiple ways that chronic exposure to adversity disrupts self-regulation through both top-down and bottom-up processes. In the sections that follow, we focus more specifically on the bottom-up processes of emotion regulation, through which stressors impact higher order cognitive functions and increase risk for poor longer term mental health outcomes. In the next section, we build on the idea that this model of emotion regulation can be productively understood through the lens of experiential canalization, and can be characterized as the emergence of specific and well ordered forms and behaviors that represent a progressive narrowing of developmental paths taken and foreclosed.

Three domains of emotion regulation (ER) may be particularly relevant to the experiential canalization of psychopathology including (1) the individual's attention to emotional information, (2) the capacity to comprehend and categorize that emotional information, and (3) the individual's capacity to make sense of emotional information within the self, including subjectively experienced anxiety, fear, anger, and frustration. Following the basic principle that understanding of normal development must serve as the foundation for our understanding of psychopathology, we first outline a schematic or thumbnail representation of some of the basic neurobiological and developmental processes that underlie each of these three domains of ER (see Cicchetti, 1984, 2002; Werner, 1948). We then go on to review ways that these domains are shaped by adversity, drawing from a theoretical model of experiential

canalization to highlight the ways that children's emotion regulation is shaped by chronic exposure to environmental stressors.

Attention to Emotional Information

Attention represents the gate to engagement, the key, early step to detecting, processing, and optimally responding to emotionally salient stimuli (Petersen & Posner, 2012; Posner, 1994). As noted earlier, attention processes (to both emotionally negative and neutral stimuli) are understood to be composed of three key components (see Petersen & Posner, 2012; Posner & Petersen, 1990). These include a first alerting phase (i.e., the brain's effort to handle the when of the presentation of a stimulus through vigilance), and involve key cholinergic neurotransmitters ascending through the basal forebrain (Stormer et al., 2012). The second component involves attentional orienting, where the brain focuses on location (or the where of the stimulus), involving the deployment of the parietal cortex. Finally, the third component of attention is composed of the executive network, where the DLPF and dorsal ACC are recruited in distinguishing the target stimulus from multiple competing stimuli with the involvement of multiple neuromodulators including serotonin and dopamine (Desimone & Duncan, 1995; Stormer, et al, 2012).

Humans are clearly neurobiologically and behaviorally wired to attend to stimuli that have an emotional valence, with extensive laboratory studies demonstrating that adults and children orient to emotional stimuli more quickly than to non-emotional stimuli within a given visual array (LeDoux, Mogg, & Bradley, 1997; LoBue & DeLoache, 2008; Ohman et al., 2001). These findings have been offered as evidence for ways that human attention is evolutionarily tuned to the rapid detection of threatening stimuli. Similarly, emotional information captures attention making it harder for individuals to disengage from emotionally valenced stimuli than nonemotional stimuli (Steinmetz & Kensinger, 2013).

Research demonstrates these forms of attention bias through the use of several laboratory paradigms including visual search, where the individual has to locate targets with emotionally salient vs. emotionally neutral distractors, and the dot probe paradigm, where individual has to locate targets after presentation of paired neutral-neutral versus neutral-emotional stimuli. Using these paradigms, researchers highlight the ways that emotion and attention are bidirectionally linked: For example, individuals with mood disorders (e.g., high anxiety) consistently demonstrate increased attentional bias for emotionally negative stimuli (Bar-Haim et al 2007; Waters et al., 2011). These processes emerge in early infancy, are complex and extend over a relatively long time course, with cognitive theories of anxiety suggesting initially faster orientation to threat followed by later avoidance, or suppression of attention to threat in an effort to modulate anxious mood (Nakagawa & Sukigara, 2012). Faster initial orientation to threat suggests that individuals prone to high levels of anxiety are demonstrating differences in amygdala function, processing percepts differently than non-anxious controls at the preattentive stage, that is, early in the bottom-up model of attention and emotion processing (Debiec, Diax-Mataiz, Bush, Doyere, & LeDoux, 2010; Dolan & Vuilleumier, 2003; Mogg & Bradley, 1998). This body of research on individual differences in attention bias has also highlighted the roles of rostral ACC and the lateral PFC in postattentive phase of emotion processing, where highly anxious individuals show reduced functioning of the DLPFC and consequently, in managing and shifting attention across multiple competing, or conflicting cognitive demands relative to nonanxious controls (Bishop, 2009; Bishop, Duncan, & Lawrence, 2004: Pesoa, 2009; Rueda et al., 2004).

This level of complexity across multiple components of attention (and respective activation of multiple corresponding brain regions) is important to keep in mind when mapping the development of individual differences in attention to threat. As outlined earlier, emerging research suggests that individual differences in both early facilitation of attention and later difficulty managing and shifting attention may be powerfully shaped by chronic exposure to a range of environmental stressors. Given the key role of the multiple neuromodulators listed earlier, molecular genetic processes (involving multiple polymorphisms of several candidate genes such as COMT and CHRNA4) are also likely to be involved in driving individual differences in both the early and late phases of attention bias (Posner, Rothbart, Sheese & Voelker, 2012; Vuilleumier & Pourtois, 2007). In the following section, we review ways that environmental and genetic processes may work additively and interactively to support or constrain individual differences in attention to threat.

Past research on the link between trauma exposure and later symptomatology (across diverse conditions of war, community violence, and parental maltreatment) highlight the role of the environment in altering children's development of attention, with well-replicated evidence of higher levels of difficulty shifting and maintaining

attention on clinical measures (Husain, Allwood, & Bell, 2008). Functional neuroimaging research with adults with PTSD yields consistent evidence of heightened amygdala response to rapidly presented emotional stimuli, and correspondingly, behavioral hypervigilance and exaggerated startle response (Bruce et al, 2013; Shinn et al, 2007). These findings are indicative of alterations in the early preattentive period where the "rapid and automatic alerting mechanism for responding to nonconscious signals of fear" are altered by exposure to trauma (Bryant et al., 2008, p. 518). Importantly, several studies have also yielded evidence for increased connectivity between the amygdala and other brain regions associated with the assessment of emotional stimuli and difficulties with the redirection of attention, including left and ventral anterior cingulate and medial PFC, and for hyporesponsiveness in the ventral medial PFC (Bryant et al, 2008; Liddell, et al, 2005). In short, trauma may have negative sequalae in both heightening the system responsible for initial alerting to threat and in lowering capacity for disengagement (including shifting and executive processing) occurring in the late or phase of attention deployment. These findings regarding fear circuitry from the PTSD literature are helpful in demonstrating that it may be that disruptions in both early and late phases of attention processes are at work when trauma-exposed individuals manifest tremendous difficulty in downregulating fear, once it has been triggered (Bryant et al, 2008).

For example, some previous studies using behavioral and attentional paradigms (including dot-probe tasks) demonstrate that chronic exposure to both parents' and peers' anger and aggression tunes children's attention for heightened vigilance to emotionally negative stimuli (Pollak, Messner, Kistler & Cohen, 2009; Pollak, Vardi, Bechner, & Curtin, 2005). Functional neuroimaging research with adults who experienced childhood maltreatment has also found evidence for reduced medial PFC volume, relative to nonmaltreated controls (Van Harmelen et al, 2013). Emerging work on attention bias among young children who have experienced maltreatment relative to controls has replicated some of these findings.

Higher Order Cognitive Processing of Emotional Information

A second key component of emotional self-regulation is the extent to which children appraise stimuli as angering, upsetting, or fear-inducing, that is, children's capacity to cognitively control emotionally salient conditions through top-down cognitive processing (McRae, Ochsner, & Gross, 2011). The capacity to read others' emotions is thought to have species-wide benefit, allowing individual members of a group to communicate signals of fear, anger, threat, nurturance, and appetitive desire with conspecifics in ways that promote survival and reduce the risk of predation (Damasio, 2004). Children's appraisal of others' signals (including facial expressions, vocal tone and posture) as capable of communicating emotional information has been a key area of past research: Past work has focused both on children's discrete ability to label others' facial expressions (termed declarative emotion knowledge) and to individual differences in their tendency to attribute particular emotions (such as anger) to others' intent, termed emotion processing patterns (Schultz, Izard & Abe, 2005). Not surprisingly, children's ability to identify others' emotions relies heavily, but not exclusively on the attention processes described earlier. In addition, exposure to facial stimuli produces activation in the face-selective fusiform face area (FFA) of the fusiform gyrus (see Kawasaki et al., 2012) with concomitant orienting and attending to this specific type of emotional cue. Amygdala activation also plays a central role in cognitive processing of expressions of anger and fear, with studies of lesion to the amygdala demonstrating striking deficit in the ability to interpret emotion from others' facial expression and tone of voice (Adolphs, Tranel, Damasio & Damasio, 1995; LeDoux, 1996; Vuiellemier et al, 2004).

As children transition from infancy through middle childhood, they develop increasing skill in identifying and labeling others' emotions using appropriate emotion language. Children's also demonstrate increasingly strong tendencies to read sadness, anger, or fear into emotionally ambiguous social situations and into others' intentions as they transition through early and middle childhood (Ackerman, Izard & Schultz, 2000). Children's accurate perception of emotional information has consistently been associated with adaptive social responses to peers, for example, while inaccurate perceptions of others' emotions has been predictive of children's negative attributional biases regarding others as well as feeling of failure in social situations, social isolation and loneliness (Denham et al, 1990; Fine et al, 2003; Garner, Jones & Miner, 1994: Schultz et al., 2010). Difficulty or deficits in accurately labeling emotions in others as well as heightened tendencies to attribute anger in others has consistently been found to serve as a major stumbling block for some children as they struggle to make friends and attempt to navigate emotionally intense interactions in classrooms and on playgrounds (Arsenio, Cooper & Lover, 2000; Blair & Coles, 2000; Schultz, Izard, Ackerman & Youngstrom, 2001).

Individual differences in children's cognitive processing of emotional cues (both in terms of their declarative knowledge and their proneness to attributional bias) are clearly shaped by environment. Past correlational studies of family socialization and randomized control studies of emotions curricula have implicated adults' use of emotion language, the quality of adults' care, and broader emotional climate as key contributors in shaping children's ability to accurately perceive, encode, and label others' emotions (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011). Findings also clearly highlight the extent to which chronic exposure to violence within and outside the home is associated with deficits in children's cognitive processing of emotional information. Children exposed to higher levels of interparental conflict demonstrate compromised, less fully formed cognitive schema about emotions and relationships as a central feature of profiles of maladjustment (McCoy, Cummings, & Davies, 2009). Importantly, though children from high-conflict households show greater physiological arousal as well as greater behavioral distress, they perceive lower levels of angry affect when overhearing a simulated argument between adults than do children who live in low-conflict households (Cummings, Pellegrini, Notarius, & Cummings, 1989; El-Sheikh, 1994).

Consistent with the theoretical model of self-regulation in Figure 13.1 and using the lens of experiential canalization, we and others have argued that this disruption in children's perception of and response to others' emotion is undergirded by environmentally shaped neuroendocrine and neurocognitive processes: Higher exposure to the acute and chronic dimensions of threat associated with parental fighting, aggression, and violence may lead to alterations in the adrenocortical and neurocognitive response among conflict-exposed children (Blair & Raver, 2012; Davies, Sturge-Apple, & Cicchetti, 2012). Prior research suggests that, for children exposed to high levels of parental harshness and aggression, prolonged exposure to threat increases children's arousal to such a great extent that they are less able to make accurate attributions about their own and others' emotions (Kim & Cicchetti, 2010; Sullivan, Carmody & Lewis, 2009). These effects may be exacerbated by exposure to neighborhood stressors: Recent research suggests that low-income children's higher exposure to neighborhood violence is clearly associated with compromised ability to marshal attention at chronometrically slower, molar levels (as assessed by observer report) and with maladaptive patterns of attention to negative stimuli at the chronometrically faster, micro level (using neuropsychological assessments such as the dot probe) (McCoy, Raver, & Sharkey, in press; Sharkey et al., 2012). Importantly, violent crime exposure was found to be differentially related to the risk of manifesting hypervigilant versus avoidant patterns of attention depending on children's profiles of high versus low trait-based negative affectivity, illustrating the ways that these regulatory subsystems are complex, integrated, and recursive rather than independent (McCoy et al., in press; see also Solomon, O'Toole, Hong, & Dennis, 2014).

The Body as a Source of Emotional Information: Subjective Feelings of Negative Affect

Finally, children vary greatly in their struggles and successes with felt experiences of negative emotion, as indicated through large research literatures on self-reported negative affectivity (Ronan, Kendall & Rowe, 1994), negative affect regulation, self-reported state and trait anxiety, and subjective distress. The neurocognitive and affective substrata for children's emerging understanding of their own feeling states is remarkably complex, including somatosensory changes in striated musculature, and first- and second-order changes that range across several major brain regions including the amygdala, thalamic regions, and left prefrontal, as well as medial PFC and dACC regions (McKrae et al., 2011). Additional research focusing the somatic marker hypothesis underscores the role of the vmPFC in linking somatosensory information and feeling states, with individuals with lesion to that area unable to access emotionally relevant internal cues and also less able to predict the emotional consequences (whether positive or negative) of their actions (Bechara, 2004; Damasio et al., 1996). In other studies, higher levels of vmPFC have been associated with self-awareness, higher levels of processing of self-relevant emotion words, and rumination, supporting its role in individuals' ability to identify and think about their own internal states (termed interoceptive awareness; Struber et al., 2014).

Across all these literatures, the individual's conscious appraisal of his or her own affective state yields evidence that individuals can either perceive those emotions are well-managed versus overwhelming and out of control, with a sense of themselves as reasonably good at regulating emotion, or less so. Early in development, children may be less aware of their own emotional states, but by middle childhood, children can reliably report both on dispositional negative affectivity and on transient emotional states. Recent experimental evidence from studies with adults highlights ways emotional states can be internally generated through thoughts or internally evoked images, and that those emotional states are accompanied by

matching physiological responses (such as changes in eye blink startle) that support the veridicality of subjective report (Ray, McRae, Ochner, & Gross, 2010). High levels of dispositional negative affectivity have consistently been found to relate to higher levels of attention bias to threat, particularly when children have lower levels of behavioral self-control (Lonigan & Vasey, 2004).

Subjective experiences of distress (including feelings of sadness, fear, and worry) that are chronic, overwhelming, or debilitating represent hallmark symptoms of mood disorder, particularly when accompanied by the attentional and cognitive biases previously described. Bidirectional relationships between these three components of ER have been established at neuroanatomical and behavioral levels, with evidence that fear circuitry is self-reinforcing, becoming increasingly canalized over time. For children diagnosed with social phobia, for example, reported subjective experience of symptoms of physiological arousal such as blushing and elevated heart rate are not only more easily triggered and more acute than subjectively experienced by controls, but also accompanied by faulty attributional biases (e.g., that others can see their nervousness) and by heightened or excessive self-focused attention (Kramer et al., 2011). Those cognitive biases are accompanied by heightened autonomic and neuroendocrine reactivity, including disrupted patterns of sAA, HR and cortisol levels across both basal and stressor conditions (e.g., social evaluative threat tasks such as the Trier Social Stress Test) and across multiple pediatric samples (van Veen et al., 2008). Our own and others' work highlights the ways that bottom-up processes such as dysregulated feelings of self-reported trait anxiety can interfere with EF performance on standardized assessments such as Stroop and Hearts and Flowers tasks (Ursache & Raver, 2014). Additional research on the role of experienced anxiety, lower EF performance, and heightened attention to error suggests that as children get older, they not only perform less well on cognitively demanding tasks when experiencing high levels of anxiety, but their subjectively experienced difficulties with working memory and heightened attention to failure may magnify their experiences of negative emotions as overwhelming and spiraling out of control (Ramirez, Gunderson, Levine, & Beilock, 2013).

Exposure to chronic adversity has consistently been found to be predictive of earlier onset, steeper trajectories, and more acute symptomatology for a wide range of internalizing mood disorders including anxiety, depression, across multiple developmental periods from early toddlerhood through adolescence and early adulthood (Grant et al., 2003). Certainly, mood disorders such as depression and anxiety are understood to have multiple etiologies: There is a wealth of empirical emphasis for the direct and indirect pathways by which parents with genetic vulnerability to mood disorders may transmit that risk to their offspring. However, our model of experiential canalization provides a complementary neurobiologically and environmentally mediated mechanism by which conditions of high versus low adversity may substantially increase individuals' risk. That model is well aligned with developmental cascades models suggesting that cumulative exposure to high levels of poverty-related adversity is jointly predictive of profiles of externalizing behavior problems and high risk of comorbid internalizing problems from childhood through early adulthood (Herrenkohl et al., 20011; Jaffee et al., 2003; McCarty et al., 2009).

As outlined earlier, models of mood disorder and neurocognitive function have highlighted the extent to which disrupted or compromised limbic function and attention bias represent hallmarks of anxiety and depression and that those changes in neurocognitive function have been argued to reinforce individuals' dysphoria over time. Importantly, cognitive processing in the context of mood disorder has been understood as a two-way street. That is, a large number of observational and experimental studies in developmental and clinical areas of research highlight the importance of higher order cognitive processing, considered through the lenses of cognitive appraisal and coping, as a mechanism through which some individuals are able to ward off depression and anxiety and as a powerful approach to ameliorating elevated symptomatology (Lazarus & Folkman, 1984; Moos & Holahan, 2003).

Past work on rumination versus cognitive avoidance provides good examples of styles of cognitive appraisal (or coping) that have been identified as placing some individuals at greater risk for long-term trajectories of mental health difficulty relative to others. Individuals who ruminate extensively about situations and events as negative, unmanageable and uncontrollable and about themselves as less capable in handling those situations are at substantially greater risk of higher levels of depressive symptoms and more frequent bouts of depression over time, even after controlling for symptomatology at baseline (Lyubomirsky, Tucker, Caldwell, & Berg, 1999; Nolen-Hoeksema, 2000; 1999) Alternately, individuals struggling with high levels of distress and fear may resort to cognitive styles of coping that involve cognitive avoidance, characterized by high mental effort not to think about the problems, events, or situations that are understood as sources of worry or sadness. In contrast, individuals able to maintain shift and persist involving realistic appraisal of obstacles and

challenge with long-term positive outlook or confidence in long-term persistence or success in overcoming of those obstacles strategies of cognitive appraisal have been found to weather major stressors with lower vulnerability to health and mental health problems, than other individuals facing similar psychosocial challenges (Chen & Miller, 2012). Importantly, treatment involving shifts in cognitive appraisal serve as the foundation of much cognitive behavioral therapy (CBT) and have been found consistently in meta-analyses of randomized control trials to be effective in lowering the odds of mild and moderate depressive symptomatology in childhood adolescence, and adolescence (Harrington, Whittaker, Shoebridge, & Campbell, 1998; Jakobsen et al., 2012) as well as in reducing the risk of relapse after pharmacological treatment of depression (Paykel, 2007).

Recent work integrating interpersonal and psychobiological perspectives highlights the ways that multiple systems can interact to alter individuals' HPA axis reactivity and chances of long-term mental health problems in the face of chronic exposure to stress (Cacciopo et al., 2002; Gianaros & Hackman, 2013). Specifically, emerging work on the stress-buffering role of social support in both animal and human models suggests that social interactions suppress stress-responsive HPA reactivity through direct and indirect mechanisms. For example, the presence of socially supportive conspecific or romantic partner during stressful conditions such as the TSST has been associated with increased release of the neuropeptide oxytocin, which in turn has been found in both rat and human randomized controlled trials to significantly lower HPA axis activity in the face of experimentally induced stress (Heinrichs et al., 2009; Struber at al., 2014). Research in this area has been complicated by difficulty of measuring oxytocin peripherally: in several recent studies, positive tactile contact from a socially supportive partner has been found to substantially reduce cortisol levels and heart rate for adults during stressful lab procedures but not to reduce plasma levels of oxytocin (Ditzen et al., 2007). Additional work on the salutary effects of parents' provision of positive caregiving on lowering HPA reactivity through mediating mechanisms of oxytocin in children is promising and is reviewed now. Across this range of social interactions, theoretical and empirical perspectives have emphasized the need to consider both transitory and longer term consequences of positive provisioning of care: results yielded from longer term studies of individuals exposed to early trauma and prolonged periods of deprivation suggest the likelihood of inhibition of oxytocin receptor expression. In contrast, supportive caregiving during early periods in the context of adversity may facilitate long-term patterns of adaptive HPA axis response mediated through longer term changes in serotonin and oxytocin expression (Struber et al., 2014).

Theoretical and Methodological Challenges and Innovations

One strength of the model that we have outlined is that it underscores developmental plasticity and malleability, for good or for ill, rather than trait-like fixity in considering the dynamic attentional, cognitive, and neuroendocrine processes involved in making sense of one's emotional world. On the other hand, one grave implication of this model consistent with the developmental science principle of correlated constraint is that individuals undoubtedly contribute to the reinforcement or canalization of their own emotion regulatory trajectory by selecting, structuring and reappraising emotional information from social interaction and by subsequent patterns of approach versus withdrawal from those social interactions (Cicchetti, 2002). The implications of this theoretical shift are immense: Through this lens, for example, feedforward models of fear circuitry would need to be reexamined across both neurobiological and biobehavioral strata. How does the responsiveness of those early components of the alerting and orienting mechanism develop, over time, increasingly constrained by prior development and experience, as an anxious child, for example, increasingly opts out of new and potentially frightening social contexts? At the neuroendocrine level, we also know less about ways that individuals who experience higher levels of anxiety in socially ambiguous situations may effectively reduce opportunities to learn to entrain HPA axis regulation of high arousal by avoiding social engagement. In short, models of canalization underscore the extent to which processes of self-regulation are self-organizing. Yet we have only just begun to consider ways that those systems are interrelated, along multiple neurobiological, representational, and behavioral strata.

A major problem in research on self-regulation and psychological development in the area of emotions research is the failure to replicate across samples facing varying levels of environmental risk, varying types of stimuli, and varying age groups. For example, studies that have explored attention bias have often used stimuli that are of human faces, with depressed and anxious individuals more prone to attend to emotionally threatening stimuli (see for example, Waters et al, 2011 where children ages 9 to 12 and high though not clinical levels of anxiety showed clear attentional bias for angry versus neutral faces on

dot-probe, with stimulus duration ranging from 500 to 1250 ms). Yet other studies find that children with high levels of anxiety may be more prone to demonstrate avoidance of threat, rather than bias toward (or hypervigilance for) threatening stimuli. This may be because higher acuity in detecting negative stimuli may arise from multiple sources that are themselves nonlinear—exposure to moderate levels of conflict or threat, for example, may tune the attentional system to be more alert, more vigilant, and the PFC to be more actively mobilized to resolve conflicting system in order to promote the capacity to act. On the other hand, exposure to high levels of threat may lead the system to a pattern of blunted, avoidant, or hyporesponsive profile.

Second, the process of attention, interpretation, and somatosensory response to threat occurs over a time course that is rarely accounted for in extant emotion regulation research. Temporally early bottom-up attention processes in handling threatening, emotionally arousing information may be facilitated (as reflected in behavioral measures) for individuals chronically exposed to threat, while top-down, temporally late-breaking processes (such as memory, retrieval, and labeling of emotion terms) may be disrupted by high levels of stress and among individuals experiencing high threat. Those individuals exposed to very high levels of anxiety may show correspondingly lower performance on behavioral measures that tap complex processes involved in recognizing, identifying, and correctly naming facial emotions (Henckens, van Wingen, Joels, & Fernandez, 2012). Research in this area is still nascent: we are not yet able to carefully parse neurobiological, neuroendocrine, and behavioral responses across a microanalytic time course in ways that yield consistency in our findings.

Thirdly, with respect to developmental time course, the model of self-regulation indicates the need to identify and track processes that are occurring very early in development, at conception and over the first year, and to consider self-regulation intergenerationally. Emotion and attention in infancy have been studied extensively in their own right, but few studies, with the exception of the research on temperament of Rothbart, Posner, and colleagues (Posner & Rothbart, 2000) have studied relations between the constructs developmentally. As well, although the role of caregiving in early development has been the primary stock in trade of child development researchers, few programs of research have focused on the psychobiology of caregiving and the way processes of self-regulation in caregivers influences both the biological and experiential environment in which child development takes place.

THE ROLE OF EARLY CAREGIVING IN THE EXPERIENTIAL CANALIZATION MODEL OF SELF-REGULATION: IMPLICATIONS FOR RISK AND RESILIENCE IN DEVELOPMENTAL PSYCHOPATHOLOGY

In the foregoing sections we have outlined processes of self-regulation development as a function of multiple levels of influence, focusing primarily on the internal processes of the experiential canalization model of self-regulation. In the following sections we turn to external influences that are presumed to shape development through experiential input. As noted in the earlier sections, a primary shaper and canalizer early in development is thought to be stress hormones and a primary environmental influence on hormone levels is thought to be experience with caregivers. Information about the environment is transmitted to developing offspring, prenatally and postnatally through maternal experience and behavior. As such, in the experiential canalization model, parenting behavior is presumed to be a central if not the central mechanism through which information about the quality of the environment is communicated to the developing child. Notably, the psychobiological system is multigenerational and recursive. The primary caregiver is itself a self-regulating psychobiological system and caregiving a product of the caregiver's psychobiological makeup and developmental history. The model in Figure 13.1 applies as readily to the parent as to the offspring. Here, inheritance must be understood broadly—that what is passed on from parents to offspring is not only a biological inheritance or an environmental inheritance but an interactive psychobiological system, an interacting manifold of biology and experience (Gottlieb, 1997).

The Neuroendocrinology of Maternal Behavior

Given the psychobiological nature of parental behavior and influence (Corter & Fleming, 2002; Rosenblatt, 1994), the experiential canalization model provides one framework for understanding the intergenerational transmission of risk for the development of psychopathology. In the parent as in the offspring, stress hormones are a primary influence on maternal behavior with implications for child physiology and behavior. A number of key hormones are involved in the maternal response to infant stimuli including cortisol, oxytocin, dopamine, and endogenous opioids, which facilitate and regulate typical maternal behaviors (for review see Swain et al., 2011). In their review of the literature, Swain and colleagues (2011) used the example of

the maternal behavioral response to a baby cry to illustrate how multiple hormonal influences come online to facilitate maternal behavior in the course of a typical interaction between mother and child. In this example, dopamine and oxytocin are the first to engage in response to baby cry, and promote maternal action by focusing attention and decision making on the part of the mother. In response to infant suckling, oxytocin is involved in milk ejection during lactation. Subsequent to the initial response of dopamine and oxytocin, the HPA axis regulates maternal behavior in ways that vary as a function of life stressors, postpartum time, age, and parity status. Once resolution is reached, endogenous opioids promote relaxation, and in addition, reinforce maternal behaviors via reward circuitry. Importantly, each step in this behavioral and psychobiological cascade must be situated in context; each step is a point of inquiry and intervention.

The relation between the HPA axis and maternal thoughts and actions is complex, however, given that it varies as a function of the personal history of the mother, her parity status, and time since parturition (Barrett & Fleming, 2011). For instance, resting levels of cortisol measured within the first four postpartum days are positively associated with increases in affectionate behaviors in mothers (Fleming, Steiner, & Anderson, 1987) as well as with a mother's increased attraction to her infant's odors (Fleming, Steiner, & Corter, 1997). These findings suggest that maternal HPA axis activity during the first postpartum days may enhance the salience of infant cues and in turn increases sensitive caregiving by mothers (Fleming et al., 1997). The direction of association changes between cortisol levels and maternal behavior in the months after parturition, however. Specifically, heightened cortisol levels at 3 months postpartum are associated with negative mood and fatigue in middle-aged mothers (Krpan, Coombs, Zinga, Steiner, & Fleming, 2005), and cortisol reactivity at this time has been related to less synchronous or sensitive behaviors with infants (Thompson & Trevathan, 2008). Increases in basal cortisol levels at 6 months postpartum are associated with increases in negative and intrusive behaviors with infants (Mills-Koonce et al., 2009).

It is also critical to keep in mind the environmental and social origins of maternal physiological dysregulation and parenting behaviors. As an example, interparental avoidance in marital relationships is positively related to cortisol reactivity in mothers, which, in turn, is related to increases in psychologically controlling parenting behaviors and inconsistent discipline of children (Sturge-Apple, Davies, Cicchetti, & Cummings (2009). In addition, experiencing adversity in early life, including experiencing inconsistent care or maltreatment by past caregivers, is related to higher levels of diurnal cortisol in mothers as well as with decreases in maternal executive functions (Gonzalez, Jenkins, Steiner, & Fleming, 2012), both of which mediated the relation between early life adversity and maternal sensitivity in adult mothers. Thus, the context of physiological stress is an important component of the psychobiological relation between maternal physiology and behavior. It is clear that biological as well as experiential influences critically shape maternal behaviors that have powerful downstream implications for child development.

Development of the Caregiving System

Typical and atypical development of the caregiving system is mutually informative. The early parent–child relationship provides a foundation upon which child development proceeds, from early influences on emotion and attention and the stress response, with implications for gene expression, brain growth and development, and emerging higher order cognitive abilities (Blair & Raver, 2012). As described in a previous section, the canonical example of the experiential canalization model of development is found in the effect of maternal behavior in the rat on stress physiology and behavior in offspring (Francis, Diorio, Liu, & Meaney, 1999; Liu et al., 1997; Weaver et al., 2004). Cross-fostering studies highlight the psychobiological factors accounting for the intergenerational transmission of the stress response in rats. Specifically, the adult biological offspring of low licking and grooming (LG) and low arched back nursing (ABN) mothers who were fostered by high LG-ABN mothers show significantly reduced fear response to novelty and additionally, exhibit increased LG-ABN behaviors themselves compared with adult offspring from high LG-ABN mothers who were fostered by low LG-ABN mothers (Francis, Diorio, Liu, & Meaney, 1999). Thus, rearing experiences with caregivers in very early life contribute to the intergenerational transmission of both stress response and maternal behaviors later in adulthood. Indeed, this multilevel epigenetic process from maternal behavior down to the genetic level and back again to the behavioral, presents both a top-down and bottom-up process of the shaping of biology by experience—the central tenet of the experiential canalization model.

The example of cross fostering is very interesting in that it highlights the potential plasticity of the developing self-regulation system early in life. Alterations to experience can shape the developing system in ways that are likely to lead to a prototypically well-regulated profile or to a more reactive and less well regulated behavioral

profile that can predispose to psychopathology. An important point here, however, is the rapidity with which this developmental process unfolds. The influence of maternal behavior on the outcomes of adult offspring in the rat model unfolds over the first 8 postnatal days. This is a remarkably short period that is presumably specific to rats. The historical emphasis on early experience in child development, however, perhaps extending over the first year or more, is consistent with such a rapid effect. The presence of such an early occurring effect, however, does not preclude the possibility of later malleability. Indeed, in the developmental psychobiological model, earlier occurring processes shape later processes, propagating an essentially conservative nature of development, referred to in the principle of correlated constraint. Reorganization of the system is possible, however, and has been demonstrated in the LG-ABN rat model through environmental manipulations occurring in the immediate post-weaning period (Meaney, 2001). In the cross-fostering example, pups of low LG-ABN mothers reared by high LG-ABN mothers exhibited behavior similar to the biological offspring of the high LG-ABN mothers (Francis et al., 1999a). In another example, low LG-ABN mothers increased LG and ABN when their pups were briefly handled, an expected result, and these animals exhibited high LG-ABN themselves as mothers, providing evidence of the causal role of experience in shaping later behavior (Francis et al., 1999b).

While the effects of maternal behavior on development in the rat model have been shown to persist into adulthood, these effects have been shown to be functionally reversible. Specifically, Francis and colleagues (Francis, Diorio, Plotsky, & Meaney 2002) have shown that the effects of maternal separation on HPA-axis reactivity and behavioral responses to stress are attenuated in maternally separated rat offspring reared in enriched environments during the peripubertal period. The authors highlight, however, that this reversal in stress response physiology and behavioral response associated with enriched environments is not mediated by the reversal of underlying neural mechanisms (i.e., gene expression) but rather, that activity of brain areas including the PFC and hippocampus may play a role in compensating for earlier life stress (i.e., maternal separation). Similarly, Bredy, Humpartzoomian, Cain, and Meaney (2003) demonstrated that the effects of low maternal caregiving competence on hippocampally dependent learning and memory could be reversed at the behavioral level through environmental enrichment, but that the physiological function of the hippocampus was not altered in expected ways. Thus, the effects of environmental enrichment in functionally reversing the negative effects of maternal separation and low maternal caregiving competence occur on some levels of analysis but not others. This is consistent with the psychobiological perspective on the development of self-regulation, which not only highlights the considerable plasticity of the developing self-regulation systems at the neural and behavioral levels, but also the idea that these systems, in and of themselves, should not be considered at isolated levels of analysis, but rather, at multiple levels of analysis ranging from the genetic, to the neural and physiological, to the behavioral.

The Prenatal Period

Given the emphasis on malleability but also concerning the essentially conservative nature of development, it is important to consider how influences on the maternal psychobiological state may shape the developing psychobiological state of the offspring from conception onward. The prenatal environment influences both offspring embryological development as well as postnatal development through the influence of the HPA axis (Barbazanges, Piazza, Le Moal, & Maccari, 1996a; O'Donnell, O'Connor, & Glover, 2009). The fetal programming hypothesis suggests that during sensitive periods in utero, the placenta affects fetal development in ways that are adaptive for future environments, as it is a proximal indicator of the external environment. In the case of low-resource, stressful environments, the evolutionary significance of the fetus' interaction with proximal (placental) and distal (external) environments is that insults to the fetus may adaptively prepare offspring for potential harsh external environmental conditions. Research on maternal stress during the prenatal period in humans and non-human animals indicates effects on behavioral and physiological aspects of the development of the stress response in offspring with substantial implications for the development of psychopathology. One pivotal mechanism by which prenatal stress is passed on to offspring is via secretion of corticosterone from mother to fetus through the placenta. Indeed, blocking maternal secretion of corticosterone prenatally resulted in no difference between offspring of prenatally stressed and nonstressed mothers, suggesting a mechanism of stress transmission via corticosterone placental transfer (Barbazanges, Piazza, Le Moal, & Maccari, 1996b). Neurophysiologically,, high prenatal maternal stress is associated with decreased glucocorticoid receptor (GR) density in the hippocampus (Maccari et al., 2003), which may compromise negative feedback regulation of glucocorticoids (Sapolsky, Meaney, & McEwen, 1985). Behaviorally, prenatally stressed rats display abnormalities

in social behavior and dysregulation of the HPA axis and these outcomes are mediated by heightened levels of corticotrophin-releasing hormone (CRH) in the amygdala, reduced hippocampal GR density, and attenuated endogenous opioid GABA/BZ inhibition (Weinstock, 1997). Maternal stress in both the prenatal and early postnatal environment is associated with physiological and behavioral outcomes in rat offspring, and in both scenarios, the influences of biology and environment are intertwined in an irreducible way.

Research on the effects of maternal stress in the prenatal period in humans suggests processes similar to those seen in animal models. Buss and colleagues have shown that prenatal maternal anxiety specifically regarding pregnancy is related to both decreased gray matter density in the PFC (Buss, Davis, Muftuler, Head, & Sandman, 2010) as well as to diminished executive function abilities (Buss, Davis, Hobel, & Sandman, 2011) in child offspring at 6- to 9-year longitudinal follow-up. Maternal prenatal psychological distress and anxiety have been associated with infant temperament (Huizink, Robles de Medina, Pascale, Mulder, Visser, & Buitelaar, 2002) cognitive impairment (Mennes, Stiers, Lagae, & Van den Bergh, 2006), ADHD, anxiety, and externalizing problems in children (Van den Bergh & Marcoen, 2004) and with flattened diurnal cortisol patterns associated with depression in females (Van den Bergh, Van Calster, Smits, Van Huffel, & Lagae, 2007).

Motivational Model of Maternal Behavior

In addition to the mechanism of transmission associated with stress physiology and effects of glucocorticoids on the developing brain, the shaping of self-regulation development in offspring postnatally is of course predominantly shaped by caregiving behavior. In addition to passing on elevated stress levels and an HPA axis that may be less effective in regulating stress hormones within an optimal zone, caregivers under stress shape offspring behavior through caregiving behaviors that may provide limited support for the development of prototypically optimal self-regulation. Caregiving behavior is itself shaped by an underlying neurobiology that influences offspring development for good or for ill.

As reviewed by Numan (2006), animal models support a motivational model of maternal behavior, whereby the medial preoptic area (MPOA) of the hypothalamus and the neighboring ventral bed nucleus of the stria terminalis (vBST) regulate maternal behavior in the presence of infant stimuli by inhibiting competitive avoidance motivations and increasing approach–response motivations, via downstream projections inhibiting a competitive medial amygdala (MeA) to periaqueductal gray (PAG) circuit and activating dopaminergic mesolimbic circuitry involving the ventral tegmental area (VTA) and nucleus accumbens (NA), respectively (Numan, 2006).

Here, as with the experiential canalization model of self-regulation in children, hormones are the essential mechanisms through which the development of the maternal response is understood to be shaped. Maternal behavior in rats is exhibited directly after parturition (Numan, 2006) and in contrast virgin rats do not immediately display maternal behavior in the presence of pups (Fleming & Luebke, 1981; Fleming, Vaccarino, & Luebke, 1980) due to their lacking the necessary hormonal shift occurring in the late prepartum period. Thus, the experience of giving birth to offspring critically primes the mother for childrearing. The hormonal mix during the peripartum period includes a dramatic decrease in the hormone progesterone and simultaneous increase in estradiol and lactogen hormones, responsible for the regulation of maternal behavior (Numan, 2006; Numan & Insel, 2003). As evidence for this, injection of the hormones at levels similar to those found during the peripartum period induces maternal behavior in virgin rats, suggesting the integral role that neurohormones play in the transition to parenthood (Numan, 2006).

Similar to the above mechanisms of motivation and attachment in mothers, attachment and odor preferences on the part of offspring can be formed even in the instance of very low quality care and abuse. Specifically, Sullivan and colleagues have shown that infant rats learn preferences for maternal odor that are accompanied by a neurobiological mechanism in which the locus coeruleus is hyperfunctioning, sending large amounts of norepinephrine (NE) to the olfactory cortex to ensure that a preference for the odor of the mother is formed (Landers & Sullivan, 2012). For rats, this is a primary means by which attachment to the mother is formed. As a consequence of this neurobiological cascade, infant rats have a reduced ability to acquire learned aversions during this time and do not regularly learn aversions until post weaning age. At that age, corticosterone increases and begins regulating amygdala function, which is useful at an age that is characterized by life in and out of a nest. Notably, attachment is formed in infants regardless of the quality of the care received; even maltreated infants successfully form attachments. These findings are significant within the lens of experiential canalization, where early experiences shape expectations of future environments. That the process of attachment is robust enough to persist

even in contexts of pain or adversity—where instead of avoiding the mother, the infant remains in close proximity to, and learns from the mother—is consistent with what is known as the maternal provision model (Cameron et al., 2005). This neurobiological mechanism of attachment is therefore essential for learning in early life.

Animal and human models illustrate a critical multisystem psychobiological shift during the peripartum period in neuroendocrine and neural architecture that set the stage for the initiation of maternal behavior with consequences for offspring development. This maternal behavior is guided by the motivation to perceive infant stimuli and to provide necessary care. However, parenthood in humans is qualitatively more complex than in animal models. Research on the neural substrates of parenting in humans is beginning to expand upon what is already known about the transition to parenthood in animal models (Kim, Leckman, Mayes, Feldman, et al., 2010; Lambert & Kinsley, 2012; Swain, 2011). In humans, structural maternal brain changes occur over the postpartum period. Specifically, Kim and colleagues (2010) compared magnetic resonance images of brain volumes during the early postpartum (2–4 postpartum weeks) and in the later postpartum (3–4 postpartum months) and found increases in gray matter in prefrontal cortex (PFC), parietal lobes, and midbrain. Moreover, the authors show that increases in gray matter volumes in hypothalamus, substantia nigra, and amygdala were related to positive perceptions of infants (Kim et al., 2010). These neural and behavioral developments taking place over the first postpartum year in mothers are thus the result of a combination of neurobiological and experiential input, consistent with the psychobiological model.

Research highlights specific neural circuits involved in typically occurring maternal behavior in response to experience with implications for ways this circuitry might result in atypical maternal behavior (Champagne & Meaney, 2006; Jans & Woodside, 1990; Nephew & Bridges, 2011; Terkel & Rosenblatt, 1971). Gestational stress is associated with decreases in maternal licking and grooming behaviors in high LG-ABN dams, but not in low LG-ABN dams (Champagne & Meaney, 2006). Additionally, after a gestational stress condition, oxytocin receptor binding (OTR), which is typically increased in high LG-ABN dams, decreases to levels comparable to that of low LG-ABN dams (Champagne & Meaney, 2006). Additionally, thermal factors, access to resources, and social stressors disrupt maternal behaviors including nest building and time spent with pups and also affect the growth of dams and pups (Jans & Woodside, 1990; Nephew & Bridges, 2011; Terkel & Rosenblatt, 1971).

In humans, studies have begun to investigate the maternal brain response to infant cues such as pictures or baby cries (Lorberbaum et al., 2002; Swain, Lorberbaum, Kose, & Strathearn, 2007; Swain, 2011). The canalization process, through which maternal behavior and child behavior are reciprocal and mutually reinforcing, suggests that maternal sensitivity in perceiving infant stimuli will be shaped by the combined action of experience and biology. Using fMRI, the typical response to standard baby cry versus white noise is associated with activity in the medial thalamus, medial prefrontal cortex and right orbitofrontal cortices, hypothalamus, midbrain, dorsal and ventral striatum (Lorberbaum et al., 2002). These areas are broadly involved in key decision-making, planning, reward/punishment circuits, and are likely critically involved in the motivation circuitry defined earlier in rodent models (Numan, 2006).

Importantly, infants' neuroendocrine and behavioral response has been found to be altered dramatically by the presence or absence of supportive maternal caregiving. Just as mothers' olfactory sensitivity to infant odors likely increases provisioning of care, infants are sensitive to odors expressed from the nipple, with increased suckling following exposure to maternal odors, and with memory for odors regulated by oxytocin released in the infant's brain while suckling (Nagasawa et al., 2012). Theoretical and empirical traditions that highlight dyadic synchrony at behavioral levels have been extended to examine psychobiological attunement during the course of social interaction between caregivers and offspring (Feldman et al., 2010; Laurent, Ablow, & Measelle, 2012). Among a sample of 86 low-income mothers and their 18-month-old infants for example, increases in mothers' cortisol/sAA predicted increases in infants' cortisol/sAA across two different stressors (e.g., separation episode or LabTab fear/frustration tasks; Laurent et al., 2012).

It is important to note that evidence for attunement (i.e., a moderate to strong correlation between maternal and infant trajectories of cortisol) has been found for some but not all studies (note Hibel et al., 2009, with reported correlation of $r = .01$ versus Atkinson et al., 2012 with reported correlations in the $r = .40$ to .62 range). One reason for this variability in findings may be due to the moderating role of maternal sensitivity, with significantly higher values for cortisol and sAA attunement found among highly sensitive caregivers as relative to their less sensitive counterparts (Atkinson et al., 2013). Another source of difference across these studies may be the use of alternate stress paradigms to assess child and maternal reactivity. In exploring the possible role of stressor type and the extent of stability across contexts, Atkinson et al. (2013)

report greater intraindividual variability in child HPA axis activity across multiple stressor paradigms (separation and frustration) for children of more sensitive caregivers, while children of less sensitive caregivers demonstrated weaker and less variable responses to both stressors, over time. Building on these findings, Hibel and colleagues (in press) found in a predominantly low-income prospective longitudinal sample that mother–child adrenocortical attunement is disrupted in response to a child stress task and that both maternal sensitivity during free play and child emotional reactivity elicited during a stress task moderate the strength of attunement. Whereas reductions in attunement in response to the stress task were evidenced by dyads in which mothers engaged in low amounts of sensitivity, attunement in dyads of highly sensitive mothers was moderate and stable across the stress task. This finding provides evidence that maternal sensitivity may buffer the otherwise disruptive effects of stress on attunement.

LONGITUDINAL EVIDENCE IN SUPPORT OF THE EXPERIENTIAL CANALIZATION OF SELF-REGULATION AND RISK FOR THE DEVELOPMENT OF PSYCHOPATHOLOGY

Given the wide variety of influences and levels of analysis that self-regulation encompasses, it is not surprising that there are numerous research literatures related to the topic, particularly in adults (e.g., Vohs & Baumeister, 2011). We have focused on relevant literatures on the early development of emotion, attention, executive functions, and stress physiology, relying on correlational and experimental work, much in nonhuman animal models. We now turn to three prospective longitudinal examples that provide some empirical evidence in humans in support of the experiential canalization model. We conclude with examples from prevention research in which efforts to foster self-regulation development and prevent the development of psychopathology provide key tests of the theory of the experiential canalization of self-regulation development.

Longitudinal studies highlight the value of looking across levels of analysis and suggest the extent to which change in experience through typically occurring variation can alter developmental trajectories in specific ways. Our own work on the experiential canalization of self-regulation has been conducted through a project funded by the National Institute of Child Health and Human Development of the U.S. National Institutes of Health, known as the Family Life Project (FLP). Through the FLP, we have been following a population-based sample of 1,292 children and families recruited at birth. The sample is located in predominantly rural and low-income communities in the United States (in Northern Appalachia and the Southern Black Belt) and the participating children and families have been seen in home visits for data collection at approximately annual intervals between the ages of 7 and 60 months. Children have also been seen at school from prekindergarten through the second grade.

One component of the FLP is designed to assess the development of emotion, attention, and executive functions in early childhood. During home visits for data collection when children were 7, 15, and 24 months of age, data collectors implemented protocols to assess emotional reactivity and regulation in response to fear and frustration evoking challenges and collected saliva samples from the children before and after the emotion challenge procedures. The samples were later assayed for cortisol and alpha amylase in order to examine physiological reactions to stress. Cortisol, as noted above, is a glucocorticoid hormone and indicator of activity in the HPA axis. Alpha amylase is a surrogate marker of norepinephrine, and as such an indicator of the faster acting sympathetic adrenal system.

With these data, we first examined the idea that the quality of early experience would shape the development of stress response physiology in ways that are consistent with the experiential canalization model. Here we focused on the quality of parenting that children received as a proximal indicator of the quality of the environment. In one analysis (Blair et al., 2008), we found a relation between the mother's style of parenting and the infant's cortisol levels at 7 months of age. Here, we found that infants whose mothers supported and scaffolded their child's play, meaning that that they were neither too intrusive nor too detached, had lower levels of cortisol than infants whose primary caregivers exhibited less scaffolding and support for the child's play. Importantly, we also found that 7-month-old infants whose mothers displayed the positive parenting style were more likely to exhibit a cortisol response to the emotion challenges. Children of mothers with the more supportive parenting style exhibited a larger increase followed by a decrease in cortisol, indicating a flexible and prototypically healthy response to the stress of the emotion challenge. As well, the amount of increase and decrease was associated with the level of emotional reactivity observed behaviorally. The physiological and behavioral responses are presumed to be one in which the organism prepares itself to deal with the challenge of the emotion inducing contingency but then returns to baseline following this challenge. In contrast, children whose mothers did not show the sensitive pattern had higher initial cortisol levels and tended to exhibit either a flat or blunted

response to the emotion challenge despite high levels of emotional reactivity to the challenge.

Following the sample longitudinally, we found that at age 15 months, children receiving higher levels of positive parenting in infancy at age 7 months, maintained lower cortisol levels and were more likely to exhibit lower overall cortisol levels in response to the same emotion challenges implemented again at this later time point. These results demonstrated that typical aspects of the parenting that children receive, namely, positive scaffolding and active encouragement of children's play behavior, are shaping or canalizing the development of the stress response system as indicated by levels of cortisol.

Given expectations for relations between the regulation of cortisol and executive functioning, we next sought to chart the complete path in environmental disadvantage in the context of poverty from parenting to stress regulation to executive functions. In this analysis we examined whether the development of executive function abilities in the sample was consistent with the predictions of the experiential canalization model. That is, we examined executive function at age 3 years in relation to demographic characteristics associated with poverty (income, race, maternal education, crowding and safety in the home) as well as parenting behavior and baseline cortisol levels measured at 7, 15, and 24 months of age. Using covariance structure modeling, we found that the effects of poverty on executive function ability were mediated through both parenting and cortisol, over the child's first two years (Blair et al., 2011). Notably, in support of the experiential canalization model of self-regulation development, we found that the effects of poverty on cortisol levels, and by extension executive function abilities, were mediated through positive aspects of parenting behavior. Primary caregivers (in almost all cases the child's mother) living in poverty were less likely than their more affluent counterparts to exhibit the positive parenting style characterized by support for and scaffolding of their child's play. In turn, lower levels of the positive parenting style were associated with a higher level of cortisol, which was in turn inversely related to child executive function at age 3. Positive parenting was also directly related to executive function in children. These results indicated that in addition to directly affecting child executive function, sensitive parenting also influenced the development of children's executive function abilities through child cortisol.

In a subsequent analysis with the Family Life Project data, we examined further the relation between stress physiology and executive function and also between stress physiology and early academic abilities, such as knowledge and reasoning ability in mathematics as well as knowledge of letters, sounds and early reading ability. In the examination of stress physiology we expanded our analysis to include sAA as an indicator of activity in the sympathetic adrenal system. Consequently, we expected that baseline levels of cortisol and sAA might show an interactive pattern in relation to executive function. That is, lower cortisol levels but higher sAA levels, indicating an attentive and prepared orientation to experience might be a more optimal physiological state conducive to executive function. Conversely, simultaneously high or low levels of both cortisol and sAA might reflect an over or under aroused state. As expected, again using covariance structure analysis, we found that high levels of sAA and low levels of cortisol at each time point of measurement in infancy and early childhood, 7, 15, and 24 months of age, were associated with a higher level of executive function ability as measured by our test battery. Conversely, simultaneously high or low levels of these stress markers were associated with poor performance. There was also some indication that higher cortisol but lower sAA was also associated with a higher level of executive function than simultaneously low levels. Finally, we found that cortisol and sAA were also related to the indicator of academic ability but that this relation was fully mediated through executive function abilities (Berry et al., 2012).

In the realm of emotion recognition and emotion regulation, analyses of Family Life Project data suggest that higher levels of physical aggression between parents during the period from infancy through early childhood, chronic exposure to chaos in the household and income poverty, could each be empirically distinguished as additive and statistically significant contributors to 58-month-olds' ability to recognize, interpret, and modulate negative emotion (Raver, Blair, Garrett-Peters, and FLP Investigators, in press).

Although the model of experiential canalization and self-regulation development emphasizes development early in life, from conception onward, notable longitudinal examples of the combined action of biology and experience are also seen in young adolescent high-risk samples. Analyses from these samples indicate the ways that the environment of poverty shapes physiological processes with implications for physical and mental wellbeing. For example, in a rural poverty sample, elevated stress physiology as assessed by a cumulative index of allostatic load composed of overnight levels of catecholamines (dopamine, norepinephrine) and cortisol from urine and body mass index at ages 9 and 13 years was positively related to an index of psychosocial risk in poverty in

childhood and negatively related to a measure of working memory at age 17 years (Evans & Schamberg, 2009). Findings from this sample also indicated, however, the extent to which sensitive maternal behavior can influence development. At child age 13 years, it was shown that the relation between risk from poverty and allostatic load was moderated by maternal sensitivity. In adolescent children of mothers rated as sensitively responsive, no association between risk and allostatic load was observed. It was only among children of mothers low in sensitivity that the relation between cumulative risk and allostatic load was observed (Evans, Kim, Ting, Tesher, & Shannis, 2007).

Similar findings have been observed for an adolescent sample of African American youth in rural communities. Here, however, relations between risk factors associated with poverty and mental and physical health outcomes were moderated by genetic variation. Combinations of high life stress and specific genes associated with dopamine and serotonin function (e.g., DRD4, 5-HTTP) act to increase or decrease the likelihood that stress will lead to mental health problems (Simons et al., 2011). Several general findings of analyses from this sample are notable from the perspective of experiential canalization. One is that in the analysis of the moderation of life stress by DRD4 in the prediction of aggression, effects were mediated by individual's cognitive schemas and subjective experience of emotion (hostile attribution, anger). This provides some evidence for the shaping of psychological state through the combined action of biology and experience with implications for behavior and risk for psychopathology. This finding also suggests that alterations of cognitive schemas and emotional states might act as an effective intervention for the prevention of aggression and its attendant consequences and that effects would be greatest for those with greater genetic susceptibility. Indeed, in intervention trials with this sample, the investigators demonstrated such genetic moderation of intervention effects in evaluations of programs to reduce aggression and substance use by fostering positive parent-child interaction (Brody, Chen & Beach, 2013; Brody et al., 2013). Finally, also of relevance in this sample is the indication that genetic susceptibility can also affect resilience. That is, in the sample, despite high risk, relatively few individuals exhibited high levels of behavior and substance use problems, denoting a high level of resilience. Among the proportion of the sample exhibiting resilience, however, those with the short allele of the serotonin transporter gene (associated with lower serotonin transporter availability) also tended to exhibit elevated indicators of stress physiology (high allostatic load) and high levels of health problems (Brody, Yu, Chen, et al., 2013) despite healthy psychological functioning.

CONCLUSIONS AND IMPLICATIONS FOR FUTURE RESEARCH AND INTERVENTION

In the previous sections of this chapter, we have drawn upon several examples from human and animal models of self-regulation that underscore the idea that individuals develop though combined biological, maturational, experiential, behavioral and cultural strands that are fused in ontogeny. Biology is found in these examples to influence and be influenced by behavior through complex interactions and pathways that have only recently become clear. In some ways, the complex integration of biology, behavior, and interpersonal interaction implies constraints on the range of developmental pathways taken. Caregivers' provisioning for infants, and infants' subsequent development of self-regulation, is clearly shaped not only by the best of parents' intentions, but also by neuroendocrine processes that are breathtaking in the directness and precision of the mechanisms involved. Overall, however, we find across numerous examples that developmental paths are far more complex, circuitous, and open to environmental forces both for good and for ill than is generally assumed. That is, we have dramatically diverged from simpler arguments regarding whether nature or nurture has the upper hand in shaping development. Instead we find that exposure to multiple forms of experience shapes development through complex and conditional relations among variables at multiple levels of analysis. This complexity and conditionality signals four key conclusions.

First, we are only at the beginning of the path to multidisciplinary scientific discovery needed to understand human developmental processes. At various moments it is easy to become daunted by the forest of research literatures covering the neurobiological and behavioral mechanisms related to self-regulation, across animal, infant, child, and adult literatures emphasizing development in typical, at risk, and atypical populations. To find a way through the wilderness, we will need collaborative teams of scholars from disciplines as diverse as neuroscience, biological anthropology, epidemiology, and behavioral health research among many others, united under the conceptual framework of developmental science. We will need appropriate, population-based samples of research participants that can be followed longitudinally to appropriately model processes and trajectories as they

unfold. Much can be learned from such data sets, particularly when they include comprehensive biobehavioral and psychiatric epidemiological data on adolescent and adult outcomes. Population-based data sets with a rich array of data over the life course offer opportunities to test the role of self-regulation not only for adult risk of psychopathology but also for different trajectories of both biological and economic inheritance. For example, in the Dunedin Multidisciplinary Heath Study, a birth-cohort study, self-control before age 10 predicted not only a range of better health, economic, and demographic outcomes by age 32, but also whether participants were parenting their own children in one- versus two-person households, signaling tremendous dynamic complexity on both theoretical and empirical fronts (Moffitt et al., 2011). To match this focus on development will likely require idiographic methods that explicitly model processes within the individual as well as across individuals. In the absence of an idiographic approach, multifinality and equifinality can be described conceptually but are less likely to be convincingly demonstrated empirically.

Second, we conclude that our success in pursuing this ambitious intellectual course will in some ways be pinned to the clarity and precision of the key constructs in our models. To date, the term *stress* has been used widely and less precisely. The many disciplinary perspectives represented in this chapter will not be able to speak effectively to one another until environmentally linked terms such as stress, adversity, and neuropsychologically linked terms such as reactivity and executive attention are clearly provided and justified. Recent discussion by Odgers and Jaffee (2013) has highlighted this concern regarding the distinction between adversity and daily hassles, finding that daily hassles can actually serve to both mediate and moderate the role of adversity on child health outcomes. Here, a further implication of the approach is the need to focus on persons more so than on variables. A focus on the principles of development noted in the introduction makes clear that a given variable may take on different meanings depending on the configuration of variables with which it is embedded.

Third, we conclude that we must find new ways of leveraging experience; of using interventions designed to support mental health and well being as an experimental basis from which to draw strong causal inferences regarding developmental mechanisms outlined earlier. A central point of research in the tradition of developmental psychopathology concerns the way developmental theory and preventive intervention are mutually informative. Theory informs the development of efforts to reduce or prevent the occurrence of psychopathology in individuals at risk and in turn experimental evaluations of these preventive interventions serve as key tests of developmental theory (Cicchetti & Hinshaw, 2002). Just as pharmacological studies have manipulated doses of cortisol and oxytocin to yield evidence of neuroanatomical, behavioral, and cognitive mechanisms underlying risk for psychopathology, increased attention to the measurement of neuroanatomical, neuroendocrine, genetic, cognitive, and emotional processes in the design and evaluation of prevention trials can yield highly valuable information on processes of experiential canalization and the malleability of the multiple, interrelated processes involved.

There are relatively few extant examples of prevention trials that focus on the early development of self-regulation that provide insight into experiential canalization and processes of malleability and change in self-regulation development. In infancy and toddlerhood, prevention science research has recently expanded from targeting molar dimensions of parenting, more broadly, to improving specific caregiving practices that are theorized to scaffold early regulation of attention and emotion (see, e.g., Dozier et al., 2006; Fisher et al., 2007; Neville et al., 2013). These experimental tests build upon theoretical and empirical insights provided by Izard and collaborators over a decade ago (Izard et al., 2002), outlining the ways emotion theory can inform prevention efforts. The recent generation of prevention science studies targeting processes of self-regulation provides compelling evidence of biological mediating mechanisms that have profound interpersonal consequences. In one natural experiment, for example, foster mothers' peripheral oxytocin levels were found to become increasingly attuned, or related to ERP indicators of their brain activity in response to images of their own child versus other children over the first 2 months of caring for a foster child, providing fascinating evidence of experiential canalization processes involved in optimizing the provision of care (Bick, Dozier, Bernard, Simmons & Grazzo, 2010). There are also strong implications for the reduction of risk of psychopathology among both adults and children from this new generation of research: As another example, the Family Check-Up intervention yielded significant reductions in mothers' depressive symptoms along with reductions in very young children's risk of externalizing and emotional dysregulation problems (Shaw et al., 2009). In our own lab (as well as in projects recently launched by colleagues funded by the Administration for Children and Families' Buffering Toxic Stress Consortium) we increasingly capitalize on randomized control trials that target both maternal and child indicators of physiological, emotional, and cognitive regulation

to examine processes of self-regulation development and to test models of experiential canalization.

Experimental tests of the role of experience can extend to classroom contexts—one such example is a preschool-based intervention known as the Chicago School Readiness Project (CSRP). The CSRP is notable in that it focused on the early prevention of behavior problems in children by focusing on emotion regulation and did so in community-based educational settings for children in poverty, namely Head Start programs. Most notably for present purposes, it was developed within the developmental science framework, explicitly acknowledging connections among levels of analysis and the need to intervene across levels to bring about comprehensive behavior change (Raver et al., 2009, 2011). Recent results from CSRP analyses suggest that experimentally induced benefits to self-regulation gained in the context of classroom-based intervention can be undermined by later exposure to traumatic stressors such as unsafe school settings and neighborhoods with high levels of violent crime, (Sharkey et al., 2012; Raver, et al., 2013). Following children who were initially enrolled in early interventions like Family Check-Up or CSRP through early adulthood (using both biobehaviorally and psychologically anchored measures of self-regulation) will provide the empirical basis we need to test key models of experiential canalization, allowing us to use developmental theory to design preventive intervention and to use evaluation of the intervention to test developmental theory. Doing so will help to fill an important gap in research in early childhood in which knowledge of emotional development can play a central role in efforts to comprehensively foster child well-being and reduce early indicators for psychopathology.

A related example of the value of preventive intervention as a test of developmental theory, also in a classroom context, is found in a program based on emotions theory. The Promoting Alternative Thinking Skills (PATHS) program is a developmental science-informed approach to reducing behavior problems in young children. It does so by focusing on emotion knowledge and emotion regulation strategies with the understanding that promoting these abilities in children will be associated with benefits to executive functions. Evaluations of PATHS have shown that it is effective at reducing behavior problems and that change in executive function abilities is associated with program effects (Riggs, Greenberg, Kusche, & Pentz, 2006). Extension of the PATHS approach to other areas of behavior management and self-regulation provide further evidence of the efficacy of the approach. Altering the focus in PATHS on emotion regulation and impulse control to encompass healthy dietary choices, Riggs Sakuma, and Pentz, (2007) demonstrated changes in attitudes toward self-regulation and in choices relating to food and to physical activity.

Another example of the potential for change through experience in school-based settings is our evaluation of the educational approach known as Tools of the Mind with children in kindergarten. The Tools approach is explicitly designed to provide support for child self-regulation and the development of executive functions through structured child-directed, teacher-scaffolded activities (Bodrova & Leong, 2007). We found that children in schools randomly assigned to implement the approach had moderately higher levels of executive function abilities as well as mathematics and reading achievement (ES = .10). The effects were particularly large (ES = .30–.80), however, in high poverty schools and extended to measures of children's ability to control attention in the face of fear evoking stimuli in addition to reasoning and vocabulary ability (Blair & Raver, 2014). Notably, this demonstration of the effect of the Tools of the Mind approach followed two prior evaluations of the prekindergarten version of the curriculum, one of which demonstrated effects of the approach on children's executive function abilities (Diamond et al., 2007), and the second of which found no effects on any aspect of children's executive functioning or academic abilities (Wilson & Farran, 2012). Clearly, additional research is needed school-based approaches to the comprehensive promotion of self-regulation in school-based settings. In combination with the CSRP and the Tools of the Mind evaluation, longitudinal follow-ups of the Perry Preschool (Heckman et al., 2009) and Abecedarian (Campbell et al., 2014) programs, and findings from a recent meta-analysis of 213 school-based, universal social-emotional learning (SEL) programs involving 270,034 children indicating significant social-emotional and academic gains resulting from SEL (Durlak et al., 2011), provide clear empirical evidence of the potential to structure educational experiences for children in ways that comprehensively foster self-regulation development at multiple levels of analysis with the possibility of pronounced benefits into adulthood.

As illustrated by CSRP, Tools of the Mind, and classic early intervention studies, capitalizing on efficacy trials of preventive intervention extends our understanding of socioeconomic adversity's impact on self-regulation abilities. Many neuroscientists focusing on the recently established SES gradient in self-regulation may think that we can't experimentally manipulate poverty, but experts in policy analysis know that we can and we have

experimented with populations' experiences of material deprivation through anti-poverty programs. Were biological, neuropsychological and behavioral assays and assessments to be built into those and other experiments, we would gain additional purchase on ways that environments shape cognitions and mood states through both bottom-up and top-down processes, in ways that we can now speculate are plausible and have pieced-together empirical support. Moreover, attention to economic and demographic outcomes within efficacy trials of clinical intervention would allow us to test ways that those processes are bidirectional: Treatment of depression or other mood disorders would be expected to substantially shift not only individuals' executive functions but also their ability to navigate key life-course decisions in areas such as employment, housing, partnership, and risk taking. In short, we might learn not only about adversity's impact on self-regulation, but self-regulation's impact on exposure to adversity, over the long term.

There is also a host of what can be considered more proximal attempts to increase self-regulation and its consequences through interventions focusing on training working memory, modifying attention, and altering the ways individuals frame goals and intentions. Attempts to improve working memory through repeated practice reflect the top-down approach to self-regulation and represent the theory that strengthening executive control will lead to behavior change. Evaluations of this training, with children as well adults, indicate that it very clearly improves working memory abilities. Evidence to date that these improvements transfer or generalize to other aspects of behavior, however, has been limited (Melby-Lervag & Hulme, 2013; Shinaver et al., 2014). Notable examples of the effects of working memory training for children with ADHD indicate improvements in working memory tasks but limited evidence of improvements in ADHD symptoms (Klingberg et al., 2005; van Dongen-Boomsma et al., 2014). Similar to working memory training, efforts to modify attention bias to threatening, anxiety provoking, or highly appetitive, addictive stimuli indicate that the training is effective in altering the capture of attention by relevant stimuli. Effects on behavior from attention modification, however, are limited (Beard et al., 2012; Mogose et al., 2014). In contrast to limited effects on behavior from effective change at the attentional and working memory/executive cognitive levels, a relatively straightforward approach to changing problem behavior by mentally contrasting a desired goal state with one's current condition and developing a simple action plan to implement steps to attain the goal state, referred to as mental contrasting with implementation intentions, has demonstrated that it is effective at changing unwanted behavior (Stadler, Oettigen, & Gollwitzer, 2009) and improving academic performance (Duckworth, Kirby, Gollwitzer, & Oettigen, 2013).

In planning and executing preventive intervention experiments as tests of developmental theory, investigators can remain vigilant for the ways that individuals' responsiveness to treatment may vary as a function of genetic, cognitive, and interpersonal context. Put another way, interventions that have heretofore been understood to have relatively small average causal impact could be reexamined for large impacts in small but theoretically indicated subgroups. An interesting example concerns an analysis of the effect of working memory training on behavior among alcoholics in which problem drinkers were randomly assigned to receive working memory training or not (Houben et al., 2011). Results indicated that the training was associated with reduced alcohol intake over a 1 month period post-training for participants with strong automatic preferences for alcohol as indicated by an implicit attitudes task.

The foregoing brings us to our fourth and final conclusion; namely, the way in which the experiential canalization model of self-regulation development illustrates what is in many ways the most revolutionary of the central tenets of developmental science, namely the idea that behavior is the leading edge of development (Cairns, 1991). This phrase highlights the importance of a continued focus on experience, on behavior as a dynamic rather than fixed process that represents and can itself bring about change at multiple levels of analysis in a developmental system. Recognition of this central point can orient scientific inquiry in ways that are at once both familiar and new. On the one hand, it builds on well-established traditions of the study of behavior, particularly social behavior, and the potential of a host of techniques, practices, interventions, and programs to bring about behavior change. On the other hand, it challenges our understanding of the goals of these techniques, practices, interventions, and programs to move beyond the establishment of a fixed behavioral endpoint or outcome, to an understanding of process; of behavior as the representation of an organized state of relations among variables across levels of analysis, and also as a dynamic entity that can bring about change in that organized state. Comprehensive analysis of multiple influences on behavior at multiple levels over time is not merely a scientifically interesting if daunting endeavor, it is essential for understanding human development and preventing psychopathology.

INTRODUCTION

It has been roughly 20 years since Ross A. Thompson (1994) published a highly influential monograph outlining the challenges associated with defining emotion regulation and embedding the construct accurately in the broader matrix of knowledge about social behavior and cognition. This work synthesized and expanded on converging strands of research about a topic that had received a growing amount of attention in academic journals and books in the preceding years, including a widely cited special section of *Developmental Psychology* on development of emotion regulation that Kenneth A. Dodge edited in 1989. Around the same time, Gross and Muñoz (1995) clearly laid out various ways emotion regulation and dysregulation contribute to changes in mental health.

During the intervening decades since these works appeared, the phrase emotion regulation has become a central component in our definitions of most psychopathology (Dillon, Deveney, & Pizzagalli, 2011), and researchers have made great strides in clarifying the processes by which we modulate our emotional experiences across the life span in both adaptive and maladaptive ways (e.g., Tamir, 2011; Thompson, 2011). Not surprisingly, however, given that the term emotion regulation comprises a complex, nuanced, and dynamically interactive range of functions and concepts, questions remain regarding how it is best conceptualized and the ways it develops, evolves, and manifests across contexts (Aldao, 2013; Thompson & Goodman, 2010; Thompson, Lewis, & Calkins, 2008). Indeed, some researchers and theorists even debate its fundamental validity as a distinct entity that can stand independently from other facets of emotion (e.g., Gross & Feldman, 2011; Kappas, 2011).

Notably, although Thompson's (1994) framework emphasized processes involved in modulating emotions in general, recently burgeoning literatures also examine the biological and psychological processes involved in the regulation of specific emotions, including happiness (Quoidbach et al., 2010; Urry et al., 2012), sadness (e.g., Cassano & Zeman, 2010; Sheppes & Meiran, 2007), anger (e.g., Kim & Deater-Deckard, 2011; Novin et al., 2011), and anxiety/fear (e.g., Bowers, Choi, & Ressler, 2012; Cisler et al., 2010; Hartley & Phelps, 2010). These emotion types share multiple regulatory commonalities; indeed, findings regarding shared mechanisms have driven interest in transdiagnostic approaches to treating psychopathology (Aldao & Nolen-Hoeksema, 2010; Kring & Sloan, 2010). However, across the life span there also appear to be distinctive cognitive and neural patterns associated with the modulation of individual emotions (e.g., Amstadter, 2008; Kovacs, Joormann, & Gotlib, 2008), which provide

striking evidence of the complexity, flexibility, and nuanced functioning of our emotion regulation systems. Together, these patterns of overlapping and discrete functions serve to support a broad range of responses to emotional experience and expression.

Many recent reviews cogently summarize the literature on the umbrella construct of emotion regulation as it develops and changes across the life span (e.g., Denham, 2010; Jacob et al., 2011; Nolen-Hoeksema, 2012; Webb, Miles, & Sheeran, 2012). These works approach the topic from behavioral, cognitive, and psychophysiological perspectives and reflect in particular our growing understanding of the ways the brain mediates the experience and modulation of emotions. To extend and complement this body of research, the present chapter aims to describe and critically review the literature that focuses specifically on the regulation of anxiety from infancy through older adulthood.

We use the developmental psychopathology perspective, which emphasizes several core tenets, as a guiding framework for this chapter (Cicchetti & Cohen, 1995). Our review of the literature thus carries within it a number of implicit assumptions about the ways psychopathology emerges and evolves over the life span. First among these is the idea that multiple factors interact in a dynamic, transactional fashion to affect the ways a disorder might initially manifest, how it changes over time, and whether and how it resolves. Consistent with this idea, clinically significant anxiety can emerge as an endpoint of an array of developmental pathways, in accordance with the principle of equifinality (Ollendick & Hirshfeld-Becker, 2002). For example, varied combinations of genetic and environmental risk factors can precipitate the development of a particular anxiety disorder (McGrath et al., 2012). However, in keeping with the related principle of multifinality, none of those pathways is necessarily guaranteed to result in that condition, or, for that matter, in any anxiety disorder. Indeed a given etiological factor (e.g., genetic vulnerability) can produce any of several different effects depending on the system or context in which it operates. Findings that genetic characteristics, such as serotonin transporter polymorphisms, interact with stressful life events to differentially predict anxious symptoms (along with depressive and other symptom types) nicely illustrate this principle (Caspi et al., 2003; Petersen et al., 2012). Thus, the probability that an anxiety disorder will emerge at a given point in development varies depending on the evolving interplay among vulnerabilities and protective factors for any particular child, adolescent, or adult.

Based on the idea that an accurate understanding of dysfunction necessitates a comparable understanding of normal or successfully adaptive developmental paths, an additional core assumption of the developmental psychopathology perspective is that typical and atypical development must be studied in concert. This assumption is particularly salient to anxiety, which constitutes an integral, adaptive, and normative part of human existence throughout the life span (Barlow, 2002). Indeed, the absence of anxiety, a goal that clinically anxious adults in one qualitative study articulated with some regularity, has been aptly conceptualized as mythical normativity (Lloyd & Moreau, 2011).

It is only under certain circumstances that anxiety shifts from a normative to a dysfunctional response; considerable evidence suggests that convergence of salient biological and environmental factors leads to neural hypersensitivity that manifests behaviorally as hypervigilance and overresponsiveness to stimuli perceived as threats, or pathological anxiety (Rosen & Schulkin, 1998). Precisely how and why this transition occurs in some individuals, but not others, is a focus of considerable research attention; if we are to obtain accurate answers to these questions, it is critical that we comprehensively map the terrain that surrounds the transition.

An additional core tenet of the developmental psychopathology perspective informing this chapter is that the developmental context must be considered when evaluating whether or not a disorder is emerging or subsiding. Symptoms vary in their meaning and import at different points in development. A sizable proportion of children between the ages of 4 and 12 years, for example, report nighttime fears (i.e., realistic or unrealistic fears that something bad will happen during the night), with prevalence reaching its peak between seven and nine years (Muris et al., 2001). In contrast, such fears are less common among adolescents (Gordon et al., 2007). Nighttime fears thus appear more likely to be pathological, at least in terms of deviance from typical developmental patterns, at some points than at others. Similarly, whereas being separated from primary caregivers commonly provokes fear among infants and toddlers (Thompson & Limber, 1990), comparable separation-related distress is less typical among older children and adolescents (Compton, Nelson, & March, 2000). Its occurrence among older youths may thus indicate the presence of pathology.

Taking these tenets as a guiding structure, we aim in this chapter to examine the mechanisms and methods by which humans regulate anxiety over the course of the life span. In the first section, we define salient terms and concepts that are at the heart of our review. We clarify the models we rely on to describe emotion and anxiety regulation, and

we then offer a short overview of common manifestations of anxiety across development. In the second section, we shift focus to the regulation of anxiety and fear per se. In particular, we examine whether and how cognitive and neural mechanisms underlying the regulation of anxiety vary across development. The third section of this chapter turns to the contexts, both intrapersonal and interpersonal, that may facilitate or inhibit the use of different regulatory mechanisms and strategies among individuals experiencing acute or chronic anxiety across the life span.

DEFINITIONS OF TERMS

Emotion Regulation, Emotion, and Feelings

The human capacity to modulate emotional experience and expression in intentional ways has been a topic of scholarly interest for centuries. Physicians, philosophers, and psychologists have long acknowledged both the power of emotions to both elevate and disrupt human experience and the many ways people try variously to rein in or amplify these internal states. In a succinct review of influential ideas on these topics, Cicchetti, Ackerman, and Izard (1995) traced the path along which our understanding of emotion and emotional control has evolved from the time of Hippocrates and Aristotle to the late twentieth century. In particular, they highlighted two core themes that pervade thinking on these topics throughout history: first, that uncontrolled emotion is a key player in the development of psychopathology; and second, that reason is necessary to keep the emotions under control.

As early as the mid- to late 1800s and the early 1900s, while some continued to explore these themes by delving into the relationship between emotion and the broad constructs of reason, sensibility, and will (e.g., Bain, 1859; Jastrow, 1915; Moore, 1852), other researchers and theorists moved away from treating these constructs as unitary forces that one could willfully exercise to keep emotions in line. These scholars instead, or concomitantly, examined specific cognitive mechanisms that might participate in or facilitate the regulation of emotion. In his book on principles of mental physiology, for instance, the prominent British physiologist William B. Carpenter (1876) speculated about the fundamental role that attention plays in the regulatory process, noting that until our attention is drawn to our emotional reactions, we are unable to intentionally direct those reactions; indeed, we may not even be aware of whether and how they are changing. Motoric inhibition of emotional displays, if not experiences, also received mention in the literature (e.g., Bain, 1859), as did executive functions, such as cognitive or mental inhibition (e.g., Clouston & Folson, 1884).

Early in the twentieth century, references to emotional regulation or control also began to appear in the educational literature, reflecting a surging interest in expanding the role of schools in the processes of behavioral and characterological development, in concert with their ongoing efforts to encourage intellectual growth and achievement (Henry, 1917). Further, educators were acknowledging with increasing frequency the impact of emotional factors on academic performance, which appeared to heighten interest in helping children acquire self-regulatory skills (e.g., Arthur, 1922; Johnson, 1928). This theme recurred in the education and child-rearing literatures through the mid-twentieth century (e.g., Arlitt, 1938; Stendler, 1950), and it continued to translate more broadly, particularly to developmental psychology outlets, in the latter decades of the twentieth century.

By the late 1980s and early 1990's, the term *emotion regulation* appeared regularly in the general psychological and psychiatric literatures; recent searches of online databases (PsycINFO, PubMed) yield nearly 2,000 publications since 1980 that list it as a key search term or phrase, and thousands of additional articles and chapters reference the topic. In these many publications, emotion regulation has been used to label a diverse array of clinical and psychological phenomena, some very broad and others more narrow in scope. For example, as Grolnick, McMenamy, and Kurowski (2006) summarized, some definitions focus on general changes in emotions, which involve altering or maintaining patterns of emotional valence, intensity, or course in the context of interpersonal transactions or salient cultural norms (Campos, Mumme, Kermoian & Campos, 1994; Cole, Martin, & Dennis, 2004, Fox, 1994). Others, however, maintain that emotion regulation encompasses a broader set of processes; Campos, Frankel, and Camras (2004), for example, defined it as "the modification of any process in the system that generates emotion or its manifestation in behavior" (p. 380).

For the purposes of this chapter, we rely primarily on Thompson's (1994) definition of emotion regulation. More precisely, we use the term specifically to describe "processes responsible for monitoring, evaluating, and modifying emotional reactions . . . to accomplish one's goals" (pp. 27–28). Of note, our chosen definition identifies emotional reactions as the target of regulatory processes. These reactions are multifaceted and may manifest in one or more different ways, both within and out of awareness. Indeed, as Jacob and colleagues (2011) underscore,

emotion regulation involves an array of dynamic processes; while inhibition or suppression are the processes most often intuitively linked to emotion regulation, other regulatory processes, including exaggeration, substitution, avoidance, or neutralization of affective responses, warrant attention.

We consider affectively valenced states that one experiences subjectively and can describe reliably to be feelings, consistent with Damasio's writings (Damasio, 2001; Damasio et al., 2000). Feelings may or may not be associated with emotions, which we define as patterns of neural response (along with their broader physiological or information processing correlates) associated with the experience of rewards (any stimuli that animals or humans work to procure) or punishments (any stimuli that animals or humans make effort to avoid; Rolls, 1999). Changes in emotion are thus necessarily reflected in neurophysiological and, in many cases, information-processing measures; they can be, but do not have to be, reflected in measures of subjectively reported experience. As such, the relationship between feeling and emotion is unclear, and will remain so until a suitable theory of consciousness exists to define subjective feeling states in the same types of neuroscience-based terminology used currently to define emotions. Nevertheless, theorists and researchers have articulated ways the two may interact. For example, scholars who approach the topic from developmental, neuroscience, and translational perspectives contend that feelings act to influence emotional states, both by monitoring variations that occur at the level of emotions and by feeding information back to higher cognitive processes, which in turn modulate the ongoing stream of emotion (e.g., Damasio, 2000; Hoeksma, Oosterlaan, & Schipper, 2004; Panksepp, 1998; Scherer, 2000).

Carefully distinguishing feelings from emotions is important; although the terms are often used interchangeably in lay language, the psychological/psychiatric literatures specify subtle distinctions between the two and use them in slightly different contexts. In particular, feelings are at the core of many currently conceptualized psychiatric disorders included in the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual for Mental Disorders* (*DSM-5*; APA, 2013) in that subjectively reported changes in emotional states (e.g., depressed mood most of the day, nearly every day) or behaviors (e.g., distractibility) form the basis for a variety of diagnostic criteria. Objectively measured behaviors that are putatively associated with emotional states (e.g., pressured speech; avoidance) also constitute a handful of criteria. Notably, no current diagnostic criteria incorporate data from directly measured changes in brain states, although research under the auspices of the National Institute of Mental Health's Research Domain Criteria (RDoC) initiative aims to reorganize our understanding of psychopathology and its diagnostic classification according to a neuroscience-based framework (Insel & Wang, 2010; Morris & Cuthbert, 2012). This initiative, if successful, will facilitate the use of biomarkers in addition to or in place of phenomenological observations for diagnostic purposes; it already played an influential role in shaping the fifth edition of the *DSM* (Kupfer & Regier, 2011).

Until the literature better supports a biomarker-driven method for identifying and classifying psychopathology, however, a continued focus on feelings in our efforts to understand and distinguish among most psychiatric diagnoses will be necessary. This reliance on subjective data is problematic at a number of levels. First, correlations between subjective reports and performance on objective measures tapping the same domain are often relatively weak, even for cognitive and behavioral functions that observers can readily assess with high reliability (e.g., Burdick, Endick, & Goldberg, 2005; Gosling, John, Craik, & Robins, 1998; Svendsen et al., 2012). It thus remains unclear how well and how consistently self-reports regarding internal, affective states, which are currently hard to evaluate objectively, describe lived experience. Notably, some evidence suggests that even very young children are able to provide valid and meaningful information regarding their feelings, based on findings of convergence between 3- and 6-year-old youths' self-reports and objective coding of their facial expressions during affectively evocative tasks (Durbin, 2010). However, the magnitude of convergence between these measures was small to moderate across emotions, with self-report accounting for no more than 15% of the variance in objective coding scores.

Second, reliance on subjective reports of feelings in our conceptualizations of mental disorders introduces marked challenges into the conduct of translational work that integrates research across human and nonhuman species. Even though many mammalian species show evidence of consistencies and continuities in terms of experienced emotion (Davis & Whalen, 2001; LeDoux, 1994, 1998, 2000), it is difficult to measure the presence of feelings in nonhuman organisms. This difficulty, at least in part, reflects our almost exclusive reliance on verbal reports of feelings, which we cannot obtain from nonhuman species. It is further confounded by the lack of an accepted model of consciousness and subjective reports, which could support cross-species investigations of feelings. Panksepp (2011; 2012), however, argued that the current approach is unnecessarily limiting; instead, he contends that by

directly stimulating brain networks that have consistently been shown to mediate emotional behavior, it is possible to access at least some types of emotional experience without need for verbal report. His ideas suggest a path out of the current impasse, in which nonhuman species' lack of verbal language appears to prohibit insight into their mental and emotional processes. However, until empirical data point us toward a broadly accepted and widely used, reliable, and valid approach to accessing mental and emotional states in the absence of language, translational studies will continue to grapple with the interface between feelings and emotions, which remains imprecisely specified across species.

Our understanding of regulatory mechanisms is similarly complicated by the challenges inherent in identifying boundaries between emotions and feelings. Indeed, in light of our emphasis on the distinction between emotions and feelings, one could argue that in addition to attention to emotion regulation, a parallel focus on feeling regulation is warranted. However, despite the availability of cogent hypotheses about the dynamic interplay between feelings and emotions (e.g., Hoeksma et al., 2004), the term emotion regulation is broadly operationally defined, so that it encompasses the processes that serve to modulate both constructs. Thus, in the interest of simplicity and consistency with much of the literature that we review, and in recognition of the inextricable links between emotions and feelings, we have adopted a comparably broad and inclusive use of the term emotion regulation.

Fear and Anxiety

Just as we tend to conflate emotions and feelings in popular discourse, we also commonly treat fear and anxiety as indistinguishable. Notably, however, as far back as 45 BC, Cicero wrote about the divergence between *anxietas*, a state of general fearfulness, and *angor*, a passing state of fear provoked by a specific stimulus (Cicero, 1927). Consistent with Cicero's ideas, the scientific literature has come to recognize anxiety and fear as representing different constructs (e.g., Sylvers, Lilienfeld, & LaPrairie, 2011), and in this chapter, accordingly, we treat them distinctly. For our purposes, the term *anxiety* denotes a frequently enduring phenomenon that may arise in response to a range of nonspecific, overt, or covert stimuli that an individual perceives as representing potential threat (Dias, Banerjee, Goodman, & Ressler, 2013). The perception of possible impending threat is commonly accompanied by feelings of apprehension, as well as increased arousal and vigilance. The term fear, in contrast, represents a transient state that typically evokes defensive responses in the presence of specific overt stimuli and subsides when those stimuli are gone (Dias et al., 2013). Thus, whereas fear is tied to relatively clear, unambiguous threats, the dangers that give rise to anxiety are less clearly demarcated.

Such a conceptualization of anxiety and fear as distinct constructs finds support in empirical work on the structure of mental disorders. Krueger (1999) analyzed comorbidity patterns in a large epidemiological sample of adults and found that the best fitting factor structure included distinct, although highly correlated, first-order anxious-misery and fear factors that loaded on a higher order internalizing factor. This pattern of findings has been widely replicated in adult samples (e.g., Slade & Watson, 2006; Vollebergh et al., 2001; Watson, 2005). In a recent effort to extend Krueger's (1999) work to an adolescent and young adult sample, however, Beesdo-Baum and colleagues (2009) found a slightly different factor structure to yield the best fit. Like Krueger's (1999), their data were consistent with the presence of anxious-misery and fear first-order factors; notably, however, the correlation between the two factors was much weaker, and a model including the higher order internalizing factor yielded a weak fit. This structural variation raises questions about the developmental stability of anxiety and fear constructs and points to the need for more research in this area, ideally with developmentally sensitive methods that permit examination of within-subject changes over time.

Neurobiological studies in both nonhuman and human species also point to clear distinctions between anxiety and fear. As Sylvers and colleagues (2011) summarized, research on varied rodent species, as well as on nonhuman primates, converges to suggest that discrete neural structures play key roles in fear and anxiety. Whereas the lateral and central nuclei of the amygdala (LA and CeA) appear to be critical players in the acquisition of fear and the emergence and expression of fear-conditioned responses (Kalin, Shelton, & Davidson, 2004; Ledoux et al., 1988, 1990; Wilensky, Schafe, Kristensen, & Ledoux, 2006), additional regions, including the bed nucleus of the stria terminalis, the septum, and hippocampus may figure in the emergence of anxious responses (e.g., Degroot & Nomikos, 2005; Edinger & Frye, 2006; Gray & McNaughton, 2000).

Of note, despite their distinctions, anxiety and fear share a number of common features, which fuels the common tendency to treat them as interchangeable. Both, for example, can be categorized as either emotions or feeling states that humans experience when they encounter stimuli that they perceive as threatening or as capable of producing harm and that elicit avoidance. Although both

can manifest in atypical or dysfunctional ways, neither necessarily connotes a pathological state, as we discuss below in further detail in our overview of anxiety disorders. In addition, both anxiety and fear elicit a number of common physiological responses including autonomic arousal (Cook, Hawk, Davis, & Stevenson, 1991), as well as activation from a number of overlapping neural structures that include the amygdala and areas within the medial prefrontal cortex in human and nonhuman species (Blair, 2003).

Regulation of Fear and Anxiety

When applied to fear and anxiety, our definition of emotion regulation demands attention to two distinct, but related, processes. First, anxiety/fear regulation is initiated by stimuli and circumstances that elicit fearful or anxious reactions, due to their real or perceived capacity to harm the organism. Second, the individual enacts a range of behavioral, cognitive, and neural response that serve to monitor, evaluate, and modify the elicited fearful or anxious reactions that the stimulus elicits. The sequence as a whole thus necessitates a triggering stimulus or circumstance and a regulatory response to it. Taken together with the increasing tendency in the developmental and general psychopathology literatures to conceptualize anxiety disorders as centrally characterized by maladaptive emotion regulation (e.g., Cisler, Olatunji, Feldner, & Forsyth, 2010; Esbjørn, Bender, Reinholdt-Dunne, Munck, & Ollendick, 2012; Jacob, Thomassin, Morelen, & Suveg, 2011; Rodebaugh & Heimberg, 2008), our definition suggests that anxious pathology lies less in the circumstances that elicit emotion or the magnitude of an initial emotional reaction and more in the degree to which an individual can engage resources to regulate this reaction once it emerges.

Within the course of the regulatory process, however, there are also nuances that warrant attention. Davidson (1998) laid some of these out clearly in his description of a model of emotion regulation that emphasizes affective chronometry, referring to the time course of emotional responding. According to this model, it is important to view the processing of emotionally evocative stimuli in the context of their temporal dynamics rather than as a unitary block. In other words, the processes that are engaged as an affective reaction rises to its peak may differ from those engaged as the reaction subsides and disruption of processes during either period may contribute to the emergence of different forms of pathology. Further, the trajectory of the rise and fall of a response is likely to vary considerably both across individuals and across biological and cognitive systems within an individual. We thus risk inadequately characterizing a regulatory response if we fail to consider its temporal course along with its content. A range of such temporal features, including the continuity of a feeling or emotion from one moment to the next (Koval & Kuppens, 2012) and the process of transition within an emotional response (Filipowicz, Barsade, & Melwani, 2011), have received increasing research attention since Davidson's (1998) article first appeared.

From an affective chronometry perspective then, conceptual distinctions between emotional reactions and emotion regulation may be arbitrary. Instead, it may be more useful to consider the two constructs as representing conceptually unified, but temporally distinct phases within an individual's response to an emotional stimulus at behavioral, cognitive, and neural levels. Such a perspective gives rise to the possibility that some disorders may relate to perturbations that occur early in the course of a response, while others may relate to perturbations that are evident later during the processing of emotional stimuli. Davidson (1998) reviewed data, for example, that suggest that differences between anxiety and depression, which share many features and often emerge comorbidly (Angold & Costello, 1993; Brown, Campbell, Lehman, Grisham, & Mancill, 2001), may, in part, reflect variability in the functioning of neural regions that participate in regulatory processes (e.g., prefrontal cortices) that leads to differential influences on the dynamic unfolding of the emotion regulation sequence. For example, in a later publication focused explicitly on anxiety, Davidson (2002) underscored the important roles that ventromedial and orbital regions of the prefrontal cortex play in modulating the time course of responses in subcortical neural structures such as the amygdala, which converging data have shown to function atypically in the context of anxiety disorders.

Taken together, both content- and process-oriented perspectives provide a broad range of intersecting hypotheses about how abnormalities in either emotional reactions or emotion regulation, as they are measured in the laboratory, may relate to the emergence and maintenance of developmental psychopathologies, including anxiety disorders. Research over the past few decades has made advances in testing these hypotheses and we review, in subsequent sections of this chapter, the findings that are emerging within this growing literature and their interpretation through a developmental psychopathology lens. Many questions in this domain, however, remain unanswered and we attempt to point out gaps in the existing body of work on the regulation of anxiety that merit further attention, particularly in the context of anxiety that is severe or pervasive enough to qualify as pathological.

Pathological Anxiety

As a group, anxiety disorders represent the most severe and extreme manifestations of anxiety. These conditions are common throughout development, with recent lifetime prevalence estimates for any anxiety disorder in the United States appearing as high as 32.4% for adolescents to 33.7% for adults (Kessler, Petukhova, Sampson, Zaslavsky, & Wittchen, 2012). The same study also found twelve-month prevalence rates for individual anxiety disorders to be high in adolescent and adult populations, with, for example, up to 7.4% of individuals meeting criteria for social phobia and 12.1% meeting criteria for a specific phobia in a given year. Prevalence rates for 12 months among children under 12 also appear high; a review of epidemiological research using both *DSM-III-R* and *DSM-IV* criteria found 12-month estimates of the presence of any anxiety disorder to range from a low of 3.05% to a high of 20.2%, with a median of 4.02% (Cartwright-Hatton, McNicol, & Doubleday, 2006). Evidence also suggests that at least some anxiety disorders are stable over time; one study, for example, found 56.7% of adolescents and adults diagnosed with social anxiety disorder to continue to meet criteria 10 years later (Beesdo-Baum et al., 2012). Stability rates appear particularly high in individuals with comorbid anxiety and depressive disorders (Fichter, Quadflieg, Fischer, & Kohlboeck, 2010). Surprisingly, however, in light of their frequent occurrence and persistence, anxiety disorders received relatively little research attention until the past few decades, perhaps because they have historically been perceived as less severe than other forms of psychopathology.

Research since the late 1980s indicates decisively that perceptions of anxiety as minimally impairing and rarely associated with adverse outcomes are inaccurate. Anxiety disorders are associated with a variety of adverse outcomes, including development of other psychiatric problems such as major depression and suicidality (Fehm, Beesdo, Jacobi, & Fiedler, 2008; Fichter et al., 2010; Pine, Cohen, Gurley, Brook, & Ma, 1998). Indeed, most adults who suffer from a mood or anxiety disorder will have first developed signs of their illness, manifest as an anxiety disorder, during childhood or adolescence (e.g., Costello et al., 2002; Pine et al., 1998; Ramsawh, Weisberg, Dyck, Stout, & Keller, 2011).

Anxiety disorders are also costly to society in terms of both financial and social consequences. Medical costs and utilization rates associated with this diagnostic category are high (Berger et al., 2011; Martin & Leslie, 2003), especially when treatment is concordant with practice guidelines (Prins et al., 2011). School dropout rates are also elevated among adolescents who meet criteria for anxiety disorders (Leach & Butterworth, 2012), and affected adults have also been found to miss work more frequently and to show decreased output when they do attend work (Erickson et al., 2009; Revicki et al., 2012).

Finally, anxiety disorders are a source of impairment in multiple domains for children, particularly those who meet criteria for more than one diagnosis (Alfano, 2012; Klein & Pine, 2002; Langley, Bergman, McCracken, & Piacentini, 2004). Research has found evidence, for example, that sleep-related problems (Alfano, Ginsburg, Kingery, & Newman, 2007), interpersonal difficulties (Weeks, Coplan, & Kingsbury, 2009), and school absenteeism (Dube & Orpinas, 2009) are associated with the presence of anxiety, particularly when it manifests at clinically significant levels. In light of their negative impact on individuals across the course of development, it is critically important that we understand what the anxiety disorders are, how they emerge and evolve across the course of development, and how they converge with and diverge from normal manifestations of anxiety.

CLASSIFICATION OF ANXIETY DISORDERS ACROSS DEVELOPMENT

In May 2013, the American Psychiatric Association published the fifth edition of its *Diagnostic and Statistical Manual of Mental Disorders, 5th Edition* (*DSM-5*; American Psychiatric Association, 2013) with the aim of updating the diagnostic nosology based on changes in the research base since the fourth edition of the manual (*DSM-IV*; APA, 1994) was published in the mid-1990s and revised in 2000 (*DSM-IV-TR*; APA, 2000). The authors' intensive attention to the integration of novel research findings with solidly supported older data resulted in a number of changes to diagnostic criteria and, in some cases, disorder definitions (American Psychiatric Association, 2013). However, the magnitude of change in the anxiety disorders is relatively minimal, particularly when compared with the changes that occurred more than 30 years ago with the publication of *DSM-III* (APA, 1980), where anxiety classification was radically transformed. Given that the *DSM-5* was not yet published when this chapter was in preparation, the research data on anxiety disorders that we cite come from studies that used the nosology of the *DSM-IV* or earlier editions of the DSM. These editions recognized eight distinct anxiety disorders: separation anxiety disorder (SAD), social phobia, generalized anxiety disorder (GAD), specific phobia, posttraumatic stress disorder (PTSD), acute stress disorder (ASD), panic disorder/agoraphobia,

and obsessive-compulsive disorder (OCD), along with a less specific diagnosis, anxiety disorder not otherwise specified (NOS), for clinically significant conditions that did not fully meet criteria for other disorders.

With the transition to the fifth edition of the *DSM*, however, this grouping changed in two key ways. First, PTSD and ASD were moved to a separate section on trauma- and stressor-related disorders; this section also includes two forms of attachment disorder that were both classified in *DSM-IV* under the rubric of reactive attachment disorder (RAD). Second, OCD was shifted to a section centered on obsessive-compulsive and related disorders (*DSM-5*; APA, 2013). These changes reflect ample evidence, described below, that the longitudinal outcomes, comorbidities, familial aggregation patterns, and biological correlates of these conditions are distinct from those of other disorders traditionally considered to be anxiety disorders. In this chapter, accordingly, we focus only on conditions classified in the *DSM-5* as anxiety disorders; we further limit our focus to three that commonly aggregate and are often treated as a cluster (RUPP, 2003), especially in the developmental literature: SAD, social phobia/social anxiety disorder, and GAD. Notably, although social anxiety disorder and GAD were previously classified as anxiety disorders in *DSM-IV*, SAD was identified as a child-specific disorder along with such conditions as attention-deficit/hyperactivity disorder (ADHD). The section devoted exclusively to childhood disorders was eliminated from *DSM-5* due to evidence that it encompassed conditions that manifested in adults as well as youths and thus set artificial age-related boundaries. In place of a section devoted explicitly to children and adolescents, a developmentally influenced perspective helped shape the diagnostic criteria and considerations for all of the anxiety disorders. Nevertheless, SAD was placed in the anxiety disorders section for *DSM-5*, as opposed to the neurodevelopmental disorders, and readers were informed that it was suitable to apply the diagnosis of SAD to adults.

Although the importance of a developmental mindset is overtly recognized with the publication of *DSM-5*, developmental considerations have been important, if subtler, components of the DSM diagnostic process for the past two decades. With the *DSM-IV*, the American Psychiatric Association adopted a nosological convention in which identical diagnostic criteria were to be applied to individuals across the life span, in the absence of strong data that supported using a developmentally tailored approach. Thus, as noted already, in the *DSM-IV*, all anxiety disorders but one (SAD—which was conceptualized as occurring exclusively in childhood) were diagnosed using the same criteria for children, adolescents, and adults. In addition, although the GAD criterion items were identical for youths and adults, juveniles had to show fewer symptoms than adults to cross the threshold for the disorder. In the *DSM-5*, however, based on data suggesting that some elements of this developmental tailoring lacked empirical support, SAD is recognized as a condition that can manifest after the age of 18 (Marnane & Silove, 2013).

To meet criteria for any anxiety disorder, individuals must exhibit a specific set of symptoms; in the third and fourth editions of the DSM, they were also required to show signs of either functional impairment or significant distress. The latter requirement, commonly termed the impairment/distress criterion, was initially added to diagnoses that had first appeared in the *DSM-III* in 1980, with the aim of ensuring that individuals who experienced normal fluctuations in psychiatric symptoms were not inappropriately diagnosed with and treated for categorically distinct disorders. However, despite the intuitive appeal of this conceptual distinction, it has proved difficult to apply in practice. First, many core symptoms of anxiety disorders consist of variants of distress, which Rapee and colleagues (2012) define as "a personal and subjective sense of malaise and negativity" (p. 455). Second, it is simply easier to disentangle symptoms and the impairment associated with them in some conditions than in others (Rapee et al., 2012). For example, even highly anxious individuals can function adequately or even well in many domains (Keyes, 2005), unlike most individuals with some other forms of severe psychopathology, such as psychosis or dementia, particularly at advanced stages. Indeed, given the long-noted lack of specific functional impairment criteria for the anxiety disorders (e.g., Beidel, Silverman, & Hammond-Laurence, 1996), it is remarkably challenging to determine reliably where the line is between adequate and problematic adaptation to a given environment.

This challenge is compounded by the fact that diagnostic decisions about the presence or absence of anxiety disorders, especially those made regarding youths, must often be made against the background of normative developmental changes in behavior, cognition, and affect. As we noted earlier, some anxious thoughts, feelings, and behaviors are normal at different stages of development—fears of negative evaluation from others, for example, become increasingly common as children transition into adolescence (Vasey, Crnic, & Carter, 1994). Such fears, in contrast, are relatively unusual among three year olds (Spence, Rapee, McDonald, & Ingram, 2001); thus, the presence of negative evaluation fears might be considered normal in adolescents but atypical in young children.

Because of this narrow and constantly moving line between typical and atypical anxiety across the life span, as well as the fact that symptoms that lead to impairment at one age may not do so at others, the developmental psychopathology perspective's emphasis on considering normal and deviant processes in conjunction is particularly appropriate to the study of anxiety disorders.

In recognition of these and other related issues, the authors of the *DSM-5* considered removing the impairment/distress criterion from individual disorders, thus shifting from a view in which impairment/distress are integral features of different conditions to one in which they are consequences of psychopathology. Ultimately, however, they retained this criterion for most of the anxiety disorders, while electing to provide on the *DSM-5* Web site (http://www.psychiatry.org/practice/dsm/dsm5/online-assessment-measures#Disorder) dimensional disorder-specific scales that can be used to describe severity.

The subtlety of the distress/impairment threshold for anxiety disorders clearly poses problems for clinicians, who are charged with distinguishing between normal range and clinically significant conditions. It also creates issues in the epidemiological literature, in that it complicates the determination of population-level prevalence rates. This set of problems is particularly salient for anxiety-related conditions; indeed, studies that set different impairment thresholds tend to find dramatically different prevalence rates for anxiety disorders, for which many symptoms are internal and accessible only by self-report. In contrast, the threshold for impairment has a much smaller influence on rates for other psychiatric conditions, such as depression or conduct disorder, whose symptoms may be more readily observable to others (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Shaffer et al., 1996).

The challenges associated with differentiating normal from abnormal anxiety, in terms of both impairment and distress, reflect the limitations of our current approach to identifying and categorizing most psychopathology primarily via clinical evaluation (e.g., interview, self-report). Alternate, more objective approaches, such as assessments of physiology, genetics, or brain function have generated considerable excitement among researchers and enjoy some empirical support (e.g., Siegle et al., 2012). They have only been used to date clinically, however, for the diagnosis of mental disorders that result from underlying nonpsychiatric medical illnesses (e.g., genetic disorders such as Fragile X syndrome, disorders such as AIDS that can be associated with dementia). Thus until we can move beyond a reliance on clinical evaluation and incorporate a broader range of converging measures in our diagnostic decisions, consistent with the NIMH's RDoC initiative (Insel & Wang, 2010; Morris & Cuthbert, 2012), our definitions of most mental disorders must be regarded as preliminary.

Identification of reliable and effective biological predictors of mental illness may also contribute to the already active shift away from an exclusively categorical nosology for mental disorders and toward the incorporation of dimensional models that help more precisely capture the multifaceted and complex nature of most psychiatric illness (Morris & Cuthbert, 2012). Indeed, by clarifying the ways observable behaviors and neurobiological characteristics relate to the presence or absence of psychopathology, we may ultimately alter the criteria we use to distinguish health from disease broadly and normal from abnormal anxiety more specifically. Moreover, some psychiatric conditions, including certain anxiety disorders, may eventually be recognized as extremes on continua with normality, just as some forms of hypertension are thought to represent the extreme end of the blood pressure continuum. Indeed, efforts have been under way for several years to develop dimensional measures for use in diagnostic assessments for anxiety (e.g., LeBeau et al., 2012; Niles, Lebeau, Liao, Glenn, & Craske, 2012) disorders and many of these are now accessible on the *DSM-5* Web site (http://www.psychiatry.org/practice/dsm/dsm5/online-assessment-measures).

Evidence for Anxiety Disorder Specificity

The conditions classified as anxiety disorders, both historically and currently, are broadly related, in that each has anxiety of some sort as a core feature. Moreover, virtually all of the individual anxiety disorders have been linked in longitudinal studies to later onset of another anxiety disorder. However, these conditions do not form a neatly unified group; indeed, as noted earlier, in recognition of their marked distinctions, several (PTSD, acute stress disorder, OCD) were removed from the anxiety disorders cluster with the transition to the *DSM-5*. These decisions were based in part on five sets of standards that researchers have used to distinguish among the anxiety disorders; notably, relatively few data are available that use these criteria to validate specific anxiety disorders in children and adolescents and most of the research base is thus focused on adults.

First, both the *DSM-IV* and the *DSM-5* define anxiety-related conditions as distinct by setting forth different sets of diagnostic criteria for each disorder. These criterion sets identify symptoms that most frequently cluster in patients

TABLE 14.1 Social Anxiety Disorder, Generalized Anxiety Disorder, and Separation Anxiety Disorder: Changes From *DSM-IV-TR* to *DSM-5*

	DSM-IV-TR	*DSM-5*
Disorder name	Social phobia	Social anxiety disorder
Cardinal symptoms	Marked and persistent fear of one or more social or performance situations involving potential scrutiny or exposure to unfamiliar people.	Marked fear or anxiety about one or more social situations involving potential scrutiny.
Differences between Editions	Adults (but not children) must recognize that their fear of social situations is excessive or unreasonable. Recognized two forms of the disorder—isolated fear of public speaking versus anxiety in a range of social situations.	Recognition that fear is unreasonable or excessive is no longer required for individuals aged 18 years or older. Anxiety must be out of proportion to actual risks, after cultural contextual factors are taken into account. Most cases treated as generalized, with specifiers added to cases restricted to public speaking or involving selective mutism.
Disorder name	**Generalized anxiety disorder**	**Generalized anxiety disorder**
Cardinal symptoms	Excessive and hard-to-control anxiety and worry about a number of events or activities.	Excessive and hard-to-control anxiety and worry about a number of events or activities.
Differences between Editions	—	No substantive changes from *DSM-IV-TR*.
Disorder name	**Separation anxiety disorder**	**Separation anxiety disorder**
Cardinal symptoms	Developmentally inappropriate and excessive anxiety concerning separation from home or from attachment figures.	Developmentally inappropriate and excessive fear or anxiety concerning separation from those to whom an individual is attached.
Differences between Editions	Classified as a disorder usually first diagnosed in infancy, childhood, or adolescence. Onset before the age of 18. Symptoms last at least 4 weeks.	Classified as an anxiety disorder. No cutoff set for age of onset. Symptoms last at least 4 weeks in children and adolescents and, typically, 6 months or more in adults.

with one or another condition. Although there is considerable consistency in the diagnostic criteria that the *DSM-IV* and *DSM-5* use for the disorders on which this chapter focuses (SAD, social anxiety disorder, GAD), there have also been several changes, as summarized in Table 14.1.

The remaining four standards focus on characteristics that can vary across condition types. Thus, the second standard centers on clarifying distinctions in the specific longitudinal trajectories and associated pattern of comorbidities for the anxiety disorders, and the third takes into account variations in familial patterns of aggregation within families for different anxiety-related conditions and their comorbidities. The fourth standard shifts focus to the specific risk factors or perturbations in biological systems reflective of underlying pathophysiology that research has shown to relate to individual disorders. Treatment response is at the heart of the fifth standard, which has led to evidence that at least some adult anxiety disorders show differential patterns of improvement following specific psychotherapeutic or psychopharmacologic interventions.

OCD and PTSD

Within the *DSM-IV* anxiety disorders, the strongest evidence for specificity based on these five standards derives from studies of disorders that were moved, due to cumulating findings suggesting that they were better classified elsewhere, to new sections of the *DSM-5*. The case is particularly clear for OCD, which is characterized by recurrent, time-consuming, and impairing compulsions or obsessions. With respect to longitudinal trajectory and associated comorbidity, OCD exhibits relatively strong cross sectional and longitudinal associations with disorders of impulse control, including tic disorders and ADHD (Grados et al., 2001; Peterson, Pine, Cohen, & Brook, 2001). Similarly, OCD that occurs early in development predicts an increased risk for further OCD either later in adolescence or during adulthood (Peterson et al., 2001). Family-genetic studies show similar patterns of coaggregation, with associations among OCD, tics, and ADHD emerging frequently within families (Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995; Pauls, Leckman, Towbin, Zahner, & Cohen, 1986; Peterson et al., 2001) and work is also under way to identify gene variants associated with the condition (Grados, 2010). Such patterns of comorbidity are thought to reflect dysfunction in a common neural circuit encompassing the prefrontal cortex, striatum, and thalamus, forming so-called cortico-striato-thalamo-cortical (CSTC) loops (Saxena & Rauch, 2000).

Relatively consistent findings also differentiate PTSD and acute stress disorder (ASD) from other anxiety disorders (but see Zoellner, Rothbaum, & Feeny, 2011, for a dissenting view); in particular, both conditions stand out from most other DSM disorders, in that a specific causal factor, in the form of a frightening event or stressor, is explicitly tied to their onset. The pattern of associated symptoms and comorbidities is also distinctive in PTSD (e.g., Brett, 1997; Sullivan & Gorman, 2002), and a few studies show associations between PTSD in children and signs of stress-related psychopathology in their parents (Yehuda, Halligan, & Bierer, 2001; Yehuda, Halligan, & Grossman, 2001). A growing body of research provides evidence that PTSD is characterized in adults by a specific pattern of neural dysfunction, with excessive activation evident in the amygdala and hippocampus and underactivation apparent in medial prefrontal regions (see Patel, Spreng, Shin, & Girard, 2012 for a review). Less evidence exists to distinguish childhood PTSD from other childhood conditions at a neurobiological level, although some findings suggest that youths with PTSD show structural anomalies in a set of brain regions (corpus callosum, prefrontal cortical areas) that is distinct from areas documented as functioning atypically in adults (Jackowski, de Araújo, de Lacerda, Mari, & Kaufman, 2009). Trauma exposure itself, however, has been associated in a number of pediatric studies with a range of neurodevelopmental consequences, and further work is needed to disentangle these from sequelae or correlates of PTSD (Watts-English, Fortson, Gibler, Hooper, & DeBellis, 2006). Finally, optimal psychotherapeutic treatment of PTSD also differs from that for other anxiety disorders, in that it often involves a heavy focus on repeated exposure to traumatic events (Smith et al., 2013).

Evidence for the specificity of the three conditions on which we focus in this chapter—separation anxiety disorder, GAD, and social anxiety disorder—is weaker than for OCD and PTSD. Indeed, these three conditions are frequently, particularly in pediatric research, treated as a cluster, given their frequent comorbidity (RUPP, 2001). Nonetheless, for each of the three disorders, data suggest that at least some of the five standards are met, including distinct patterns of symptoms.

Separation Anxiety Disorder

Investigators have adopted conflicting conceptualizations of separation anxiety disorder (SAD) during the past few decades and only recently have they begun to recognize it as a condition that can manifest across the life span (Marnane & Silove, 2013). For many years, the prevailing view has held that this condition is closely related to panic disorder, as defined in the *DSM-IV*, and recent findings support a genetic link (Roberson-Nay, Eaves, Hettema, Kendler, & Silberg, 2012). Panic disorder is characterized by sudden, unexpected paroxysms of extreme anxiety or terror. While panic attacks can occur at any point during the life span, the experience of spontaneous, recurrent panic attacks rarely begins before adolescence. In severe cases, the disorder typically follows a developmental course in which isolated, spontaneous panic attacks begin during adolescence and are followed later in life by multiple, recurrent panic attacks that meet criteria for panic disorder (e.g., Pine, Cohen, Gurley, Brook, & Ma, 1998). Agoraphobia, or anxiety about being in places or circumstances from which escape would be difficult or embarrassing in the case of a panic attack, is a common ensuing complication.

The conceptualization of SAD as related to panic disorder arose largely from clinical data in adults with panic disorder, who report high rates of SAD during childhood (Bandelow et al., 2001; Silove, Manicavasagar, Curtis, & Blaszczynski, 1996). Such data are problematic, however, in that they are vulnerable to referral biases and retrospective distortions. In general, data from family and longitudinal studies provide some support for the view that SAD relates to panic disorder; however, the data are not unequivocal (Biederman et al., 2007; Pine et al., 1998; Roberson-Nay et al., 2010). The strongest support for the link between SAD and panic disorder comes from studies of respiratory function, where panic attacks and SAD have been tied to similar breathing perturbations (e.g., Atli, Bayin, & Alkin, 2012; Goodwin & Pine, 2002; Pine, Klein, et al., 2000).

Notably, however, high rates of SAD are also found in offspring of parents with major depression (Biederman et al., 2001), in individuals who have experienced traumatic stress (Goenjian et al., 1995; Pine & Cohen, 2002), and even in the context of streptococcal infection (Swedo et al., 1998). In light of these findings, as well as evidence that childhood SAD is a strong predictor not only of adult panic disorder, but also of adult depression (Lewinsohn, Holm-Denoma, Small, Seeley, & Joiner, 2008), there may be utility in alternate models that conceptualize SAD as a specific pattern of responses to general distress (Lipsitz et al., 1994).

Generalized Anxiety Disorder

GAD, which is characterized by a pattern of pervasive and recurrent worries about a range of topics, along with avoidance of emotional experience or processing, has also been conceptualized as a set of responses to real or anticipated distress (Newman & Llera, 2011). The diagnosis of GAD

has evolved since its initial appearance in the *DSM-III* (APA, 1980). In its first incarnation, the diagnosis was assigned only to adults who presented with a pattern of recurrent worries; children with similar symptoms were instead diagnosed with overanxious disorder (OAD). With the publication of *DSM-IV*, despite mixed evidence regarding the overlap of GAD and OAD (Beesdo-Baum et al., 2011), the GAD diagnosis subsumed overanxious disorder and age was eliminated as a defining diagnostic criterion, although lower symptom thresholds were still used for youths than for adults (Andrews et al., 2010). The *DSM-5* conceptualization of GAD, which emerged after substantive debate regarding multiple issues, including the relative merits of dropping some associated symptoms (Comer, Pincus, & Hofmann, 2012) and the most appropriate minimum duration of symptoms and appropriate symptom thresholds (Beesdo-Baum et al., 2011), continues to allow youths to display fewer symptoms than adults to cross the diagnostic threshold.

Of the conditions classified in *DSM-5* as anxiety disorders, GAD has generated perhaps the most debate, because it virtually always presents with another concurrent anxiety disorder (Klein & Pine, 2002; RUPP, 2001). Indeed, some have contended that GAD represents a complication of other anxiety disorders rather than an independent disorder in its own right (Klein & Pine, 2002). Further, GAD shows unusually tight links with major depressive disorder (MDD), in children as well as adults (Kendler, 2001; Pine et al., 1998; Silberg, Rutter, & Eaves, 2001), leading some prominent theorists to suggest that GAD be grouped conceptually with other distress disorders marked by high levels of negative affectivity, including MDD and PTSD (Watson, 2005).

Social Anxiety Disorder

In individuals with social phobia or social anxiety disorder, anxiety symptoms emerge in anticipation of embarrassment in social or performance situations. Although this construct was historically labeled social phobia, evidence that social anxiety disorder differs dramatically from specific phobias on several fronts (impairment, treatment-seeking behavior, longitudinal outcome, and familial aggregation; e.g., Fyer, 1998; Fyer, Mannuzza, Chapman, Martin, & Klein, 1995; Pine et al., 1998) led to a preference for a new label: social anxiety disorder.

Whereas *DSM-IV* recognized two forms of social anxiety disorder, one characterized by an isolated fear of public speaking and the other characterized by high levels of anxiety in a range of social situations, *DSM-5* treats most cases as generalized, with a specifier assigned to those cases that are restricted to public speaking fears. This change reflects considerable evidence that although individuals with exclusive performance/speaking fears share other socially anxious individuals' core concern about being negatively evaluated, they show distinctive etiological and treatment response profiles (Bögels et al., 2010).

Of note, prior to the publication of *DSM-IV*, children who showed severe avoidance of social situations could be diagnosed with avoidant disorder of childhood instead of social phobia/social anxiety disorder. In light of evidence, however, that the distinction between the two conditions was minimal (e.g., Francis, Last, & Strauss, 1992), the authors of the *DSM-IV* elected to fold avoidant disorder of childhood into the social anxiety disorder category, just as they decided that GAD would subsume overanxious disorder of childhood. This change not only eliminated age as a diagnostic criterion, but it also decreased redundancy among diagnoses, given that avoidant disorder appeared to be rare and to overlap considerably with social anxiety disorder.

Shared Characteristics Among the Anxiety Disorders

A large and growing body of evidence identifies distinctive symptom and familial aggregation patterns as well as markers of neurophysiological dysfunction, within individual anxiety diagnoses. As interpreted most recently by the *DSM-5*'s authors, this literature supports the view that anxiety disorders can be defined as a family of related, but discrete, conditions. However, although individual disorders clearly show specific profiles, there is also ample and comparably strong evidence of commonalities among at least some conditions. For example, common to virtually all of the anxiety disorders is a persistent tendency to experience any of a wide range of anxious symptoms. These can be somatic (e.g., racing heart, sweating, nausea, trembling), cognitive (e.g., worry, fear), or behavioral (e.g., avoidance, tearfulness).

These symptoms may occur discretely or in clusters; when four or more somatic or cognitive symptoms suddenly co-occur and rapidly peak in the context of intense fear, they constitute a panic attack. In individuals with panic disorder, another condition classified as an anxiety disorder (but not a focus of this chapter), panic attacks occur spontaneously and without apparent provocation. In this context, such attacks sometimes lead to agoraphobia, or a fear of experiencing panic symptoms or attacks in a public setting. However, in the presence of specific feared stressors, individuals with other anxiety disorders can also experience panic attacks. For example, individuals with

social anxiety disorder may experience panic when they must speak to a group or mingle at a party. Children with separation anxiety disorder may experience panic when leaving for school in the morning, and adults with the disorder may have such attacks while heading to work.

Worry also represents a core feature of most anxiety disorders for youths and adults alike (Borkovec, 1994; Fialko, Bolton, & Perrin, 2012). Conceptualized as hard-to-control repetitive thoughts or images about future events perceived as uncertain and likely negative, worry represents an effort to reduce the likelihood that those future events will occur (Borkovec, Robinson, Pruzinski, & DePree, 1983). As we discuss later in this chapter, it can function as a type of emotion regulation strategy, albeit one that is less adaptive than others.

Worry can be observed in children as young as preschoolers and it appears to become an increasingly central factor in anxiety disorders over the course of development. This pattern of repetitive thinking appears to emerge as a function of multiple processes—cognitive avoidance, proclivity to interpret problems as difficult to address, beliefs that the process of worry has value, and intolerance of uncertainty (Fialko, Bolton, & Perrin, 2012). Because the process of worry differs minimally across disorders, it is the content and precipitating environmental cues that serve as distinctive characteristics. In GAD, for example, worry and excessive anxiety develop about a variety of events or circumstances and can float from target to target. Objects of worry may also be circumscribed items or situations, as in SAD or social anxiety disorder.

Thus, although SAD, GAD, and social anxiety disorder each demonstrate distinctive profiles in numerous ways, they also share a number of core features. Further, because these three disorders commonly co-occur, particularly in childhood and adolescence, it is difficult to disentangle and study individual disorders in isolation. For these reasons, our review of the literature on mechanisms of anxiety regulation will focus largely on research that encompasses one or more of these three conditions. Recent findings from both developmental psychology and cognitive neuroscience studies of these disorders and of normal-range anxiety converge to provide an increasingly clear picture of the mechanisms of anxiety regulation, at behavioral, cognitive, and neural levels.

ANXIETY REGULATION

The relevance of the construct emotion regulation to our understanding of anxiety, in both clinical and normative manifestations, has been a topic of intense interest in the past several years, leading to the publication of numerous reviews and analytical papers. These put forth a number of ideas about how emotion regulation processes may figure in the onset and maintenance of anxiety disorders in childhood and adulthood (e.g., Cisler, Olatunji, Feldner, & Forsyth, 2010; Rodebaugh & Heimberg, 2008; Suveg et al., 2010). Models vary in the degree to which they emphasize cognitive versus neural versus behavioral processes, but most recognize the importance of all three to our management of anxiety. Further, theorists and researchers are acknowledging with increasing regularity the value of multilevel models for understanding the regulation of such constructs as anxiety; such models are designed to integrate knowledge regarding multiple constructs, processes, and modulatory factors, including genetics, neural function and structure, cognition, and context (e.g., Philippot et al., 2004). Finally, in recent years, more models of anxiety regulation have emerged that pay explicit attention to broad developmental processes and contexts and the ways they may figure in an individual's acquisition of skills for managing and responding to anxiety.

Cognitive-process-oriented models, such as Gross's widely cited (1998) process model of emotion regulation, emphasize the varied cognitive activities that people enact in the course of an emotional event with the aim of modulating their emotional responses. Gross distinguishes between antecedent-focused activities, which include selecting whether to enter given situations or contexts, modifying those situations, deploying attention toward or away from emotionally salient features, and changing one's appraisal of those features, and response-focused activities, which encompass attentional, evaluative, and behavioral processes that occur after an emotionally charged event has occurred. The adaptive value of these strategies varies—results of recent meta-analyses suggest that reappraisal strategies have the greatest impact on emotional responses or psychopathology, with weaker evidence available to support the use of attentionally centered strategies (e.g., distraction or concentration) or efforts to suppress or amplify emotions (Aldao, Nolen-Hoeksema, & Schweizer, 2010; Webb, Miles, & Sheeran, 2012). Notably, however, some strategies within the attentional deployment and response modulation categories appeared more effective than others, which may have obscured significant effects. Specifically, active distraction and control of emotional expression were more closely associated with successful regulation than were concentration or effort to control emotional experience (Webb et al., 2012).

With respect to anxiety in particular, findings regarding cognitive regulatory strategy use are consistent with those from studies focused on emotion regulation more broadly. Reappraisal appears to be an especially effective strategy for modulating anxiety, and youths and adults who report elevated or clinically significant anxiety show atypically weak skill at implementing this strategy and make infrequent use of it (Carthy, Horesh, Apter, Edge, & Gross, 2010; Carthy, Horesh, Apter, & Gross, 2010; Werner et al., 2011). Further, recent findings suggest that even when anxious adults engage in cognitive reappraisal, it may not have the impact on daily life experiences that it appears to have for nonanxious peers (Farmer & Kashdan, 2012).

The process model's focus on cognitive activities aimed at modulating emotion is complemented by other perspectives that aim more specifically to understand how such activities, along with behavioral actions, may be put into use in the context of anxiety. Rodebaugh and Heimberg (2008), for example, framed their model of anxiety regulation in terms of Carver and Scheier's (1998) self-regulatory theory, in which both approach-related or appetitive systems and defensive or avoidant systems engage to facilitate attainment of goals. According to Rodebaugh and Heimberg, anxiety disorders are marked by an excessive focus on ensuring safety and avoidance of negative outcomes, which engages the prevention system, as well as relatively weak activation of the promotion system, which mediates the pursuit of positive or desired goals. Thus, anxious individuals preferentially enact behaviors and thoughts that presumably help them avoid negative outcomes; in the example that Rodebaugh and Heimberg used, individuals with GAD engage in worry behaviors to avoid experiencing negative affect, leaving few resources available for instead initiating behaviors that might help them reach goals that would reduce the negative affect that they are avoiding.

Models also differ in their focus on anxiety versus fear. Anxiety-focused models (e.g., Rodebaugh & Heimberg, 2008) emphasize the ways emotion regulation may modulate the cognitive and neural correlates of the anxious state. Fear-focused models (e.g., Cisler et al., 2010), in contrast, consider the ways emotion regulation may modulate the process of fear conditioning and its outcomes. Each model type informs our understanding in distinctive ways, and both hold value for helping us to better understand the role that emotion regulation plays in the emergence and resolution of both anxiety and fear.

Cisler and colleagues' (2010) proposed model suggests that capacity for emotion regulation influences one's range of response to fear cues after the fear conditioning process is complete. These authors contend that, first, an individual's access to and facility with different emotion regulation strategies will affect the ways that an individual responds in the moment when facing a fear cue. These online responses, in turn, can either weaken or strengthen the learned fear association; in the latter instance, they would increase risk for onset of an anxiety disorder. For example, two people who have been conditioned to fear public speaking are likely to employ different regulation strategies when they find themselves standing in front of an audience and experience the conditioned fear response. One may flexibly employ adaptive regulation strategies such as reappraisal, thus increasing the likelihood that she will be able to proceed with her talk and thus to gain exposure to experiences likely to weaken the learned association. In contrast, the other might use a less adaptive strategy, such as suppression, which paradoxically heightens her fear in the moment and leads her to leave the podium. She thus avoids the experiences that might have decreased her fear and instead chooses an experiential path that maintains or amplifies it.

In the models discussed so far, developmental considerations are implicit, if incorporated at all. In recent years, however, additional models of the anxiety regulation process have been proposed that explicitly assume a central role for developmental processes. Suveg and colleagues (e.g., Suveg, Morelen, Brewer, & Thomassin, 2010), for example, have described the emotion dysregulation model of anxiety (EDMA), in which child temperament and family emotional environment interact to predict capacity for emotion regulation and risk for anxiety. According to this model, youths who exhibit high emotional reactivity, manifested as a behaviorally inhibited temperamental style, and who also inhabit a family whose emotional environment is weighted toward the expression of negative affect rather than positive affect, are at risk for developing a maladaptive emotion regulation style. Consequent failure to manage arousal in the context of anxiety-provoking stimuli, in turn, is predicted to maintain anxiety. This model, which focuses primarily on factors that may contribute to poor emotion regulation skills, complements other models, which place emphasis instead on the cognitive, neural, or behavioral processes implemented in efforts to upregulate or downregulate emotional reactions.

Another recent developmentally informed model of anxiety regulation is embedded in attachment theory and underscores the key role that early attachment experiences may play in determining the emergence of adaptive or maladaptive approaches to managing stress and, by extension, the development of anxiety disorders (Nolte, Guiney, Fonagy, Mayes, & Luyten, 2011). This model is notable

in that its authors have made great effort to integrate data across multiple levels of analysis, with attention to the putative roles of genetic, neural/physiological, behavioral, cognitive, and contextual variables. In brief, Nolte and colleagues (2011) propose that children who encounter an early life environment that is characterized by inconsistent or unpredictable caregiving, particularly if they are temperamentally vulnerable to hyperarousal, may develop a hyperactive response style for coping with stress. While this style is initially adaptive, it begins to become problematic as the child generalizes it to circumstances outside the initial attachment relationship, eventually consolidating a maladaptive style marked by avoidance of threat cues and consequent failure to develop realistic expectations and perceptions of the environment. Consistent with the developmental psychopathology perspective, this model also takes into account the probability that salient variables interact in different ways at different points in development, and thus that multiple anxiety-related outcomes are possible. Recent reviews of the literature suggest that many elements of this model enjoy considerable empirical support (Esbjørn et al., 2012; Jacob et al., 2011); clearly there is value in a perspective regarding anxiety regulation that incorporates attention to developmental factors.

Further integrating this kind of developmentally informed model, which takes a wide-angle view of the big picture, with more elemental models that revolve around the discrete cognitive and neural processes involved in regulating anxiety and fear is a logical next step in the literature. Such broadly integrative efforts will need to take into account emerging data regarding the viability of different strategies and processes at different points in the life span, as well as the neural structures and functions and cognitive skills and capacities that must be in place to support them. In the next sections of this chapter, we summarize recent findings regarding the cognitive and neural processes and structures that support and facilitate the regulation of anxiety. Where possible, we also examine ways individual differences may influence the paths along which these factors evolve from childhood through the life span.

Cognitive Mechanisms of Anxiety Regulation

Much of the research on cognitive mechanisms of anxiety regulation as they emerge and evolve across the life span has focused on strategies that are commonly characterized as explicit or consciously and intentionally implemented. As Amstadter (2008) summarized in a recent review, the use and effectiveness of two strategies, reappraisal and suppression, have been especially common targets of study in samples across much of the life span. As we briefly noted earlier in this chapter, reappraisal, or cognitively reframing an anxiety-provoking situation in ways that are calming and constructive, enjoys perhaps the most empirical support as a useful approach to regulating anxiety in youths and adults (Webb et al., 2012). It is also a strategy that anxious individuals from middle childhood to early adolescence and onward appear to implement less often and less effectively than their less-anxious peers (Carthy, Horesh, Apter, Edge, & Gross, 2010; Carthy, Horesh, Apter, & Gross, 2010; Farmer & Kashdan, 2012; Legerstee, Garnefski, Jellesma, Verhulst, & Utens, 2010; Werner et al., 2011; but see Decker et al., 2008, and Tan et al., 2012, for conflicting findings), at least in part because they doubt the utility of this approach (Sung et al., 2012). In light of these findings, it is not surprising that quick mastery of cognitive reappraisal in the context of CBT shows promise as a predictor of positive treatment outcomes for anxious adults (Moscovitch et al., 2012).

Effective implementation of cognitive reappraisal places demands on a number of cognitive systems, some of which mature slowly. For example, cognitive control, or the ability to intentionally use effort to manipulate attention, memory, and other mental functions, appears to be a critical foundation for successful reappraisal (e.g., Vanderhasselt, Baeken, Van Schuerbeek, Luypaert, & De Raedt, 2013). This capacity does not appear to be fully developed until adulthood (Kar, Vijay, & Mishra, 2013), which is not surprising given that its neural substrates show a long, slow, and complex developmental trajectory that can extend into an individual's mid-twenties (Raznahan et al., 2011). Further, some evidence suggests that as the brain ages, the neural underpinnings of cognitive control show waning efficiency, as reflected in increased difficulty implementing reappraisal strategies (Opitz, Rauch, Terry, & Urry, 2012). Thus developmental status is an important consideration in evaluations of whether an individual shows deficits or strengths in capacity for cognitive control.

Ability to control and direct attention in the context of emotion appears to be particularly important for cognitive reappraisal, which demands that an individual move flexibly from one set of perceptions and interpretations to another. Anxious adults, for example, even those who do not cross diagnostic thresholds for any disorders, appear to have more difficulty than their less-anxious peers in consistently implementing this skill, even when they show typical ability to redirect attention to nonemotional cues (Johnson, 2009). Similar patterns of difficulty controlling attention to emotional stimuli characterize youths with

anxiety, which suggests that even rudimentary or immature capacity for attentional control may be critical to effective regulation of anxious thoughts and feelings (White, Helfinstein, Reeb-Sutherland, Degnan, & Fox, 2009).

Numerous approaches to treating anxiety disorders have begun to incorporate explicit training in cognitive reappraisal as a core component. In particular, cognitive reappraisal's compatibility with traditional cognitive behavioral therapy (CBT) for anxiety, which integrates techniques and approaches from cognitive and behavioral perspectives and has been successfully implemented with anxious children, adolescents, and adults, has generated considerable interest among researchers and clinicians. Traditional CBT focuses on exposure to anxiety-provoking stimuli and challenges to maladaptive thinking patterns; while a large proportion of individuals with anxiety disorders respond well, a sizable number (up to 30 or 40% in some studies) do not (Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012). The merits of introducing cognitive reappraisal training to boost treatment effects, particularly in those who show weak responses to traditional CBT have received increasing attention, and some have even suggested making cognitive reappraisal and other emotion regulation techniques core elements of anxiety treatment for both adults (e.g., Mennin, 2006) and children (e.g., Hannesdottir & Ollendick, 2007). Although data are still emerging from studies that test the hypothesis that training in cognitive reappraisal and other adaptive emotion regulation techniques may augment treatment response among anxious individuals, findings to date are mixed and suggest that close attention to individual differences in patterns of response is warranted (Newman et al., 2011).

A second emotion regulation strategy that has received considerable attention in the context of research on anxiety is suppression of emotional experience or, more commonly, expression. Unlike cognitive reappraisal, suppression has been associated with a range of problematic consequences in anxious and healthy adults, including slowed reduction of negative emotion, decreased experience of positive affect and events, and, in some cases, heightened physiological arousal (Campbell-Sills et al., 2006; Farmer & Steger, 2006; Feldner, Zvolensky, Stickle, Bonn-Miller, & Leen-Feldner, 2006). In both adults and adolescent girls, use of suppression to regulate emotions has also been found to relate to a lack of emotional awareness (Eastabrook, Flynn, & Hollenstein, 2014; Gross & John, 2003).

A few studies have suggested that in both youths and adults, suppression is positively associated with the presence of anxiety, particularly social anxiety. For adolescent girls, for example, implementation of this emotion regulation strategy appears to mediate associations between limited emotional awareness and social anxiety (Eastabrook et al., 2014). Adults with social anxiety disorder, as well as those who endorse having avoidant attachment styles, which have been linked to a pattern of anxious and avoidant behavior, endorse more use of this strategy than do healthy controls, and avoidantly attached adults have been shown to evidence a distinctive neural profile when using suppression to regulate emotion (Vrtička, Bondolfi, Sander, & Vuilleumier, 2012; Werner et al., 2012).

Notably, in healthy youths, the use of suppression, which is more common among boys than girls, appears to decline with increasing age (Gullone, Hughes, King, & Tonge, 2010), which suggests that as complex cognitive skills emerge and mature, healthy individuals are likely to switch to the use of more adaptive strategies. John and Gross (2004) hypothesized that this normative developmental shift may also reflect the acquisition of life experience, which provides individuals with direct feedback about the pros and cons of using different emotion regulation strategies. Further, the rewards and negative consequences associated with the use of suppression may change across the life span, thus differentially reinforcing its use at different developmental stages.

Other emotion regulation strategies that are prominently associated with anxiety include worry and rumination, which constitute distinct, but related, patterns of repetitive negative thinking that an individual finds hard to control (McEvoy & Brans, 2013). Worry, which characterizes many anxiety disorders and serves as a core feature of GAD, is thought to function by helping individuals avoid negative affect. At least two ideas about how worry may facilitate emotional avoidance have received empirical support; first, it may constitute an effort to prevent or prepare for negative experiences, second, it may blunt bodily responses to stimuli that elicit fear. Thus, at both cognitive and physiological levels, worry prevents the processing that is critical for extinguishing anxious responses to perceived threats (Borkovec, 1994). Worry has also been conceptualized, on the basis of accumulating findings, as a means of maintaining a state of chronic distress in order to avoid having to shift from positive or neutral to negative emotional states in the face of negative events (Newman & Llera, 2011).

Tendencies to worry emerge early in life; however, although worries have been documented among preschoolers, they appear to increase in prevalence around the age of eight years (Vasey, Crnic, & Carter, 1994). The ability to worry depends on being able to anticipate future events

and to anticipate catastrophic outcomes, thus children are less likely to employ this as a primary regulatory strategy until these reasoning skills reach at least a rudimentary level of development. As early as elementary school, girls endorse more worrying than do boys (Silverman, LaGreca, & Wasserstein, 1995), and this pattern of sex difference appears to continue into adulthood (Zalta & Chambless, 2008).

Rumination, which differs from worry in that it focuses more heavily on past events than on the future and on content that is oriented toward issues of self-worth and loss rather than anticipated negative experiences, is also more common among women than among men (see Nolen-Hoeksema, 2012, for a review). Like worry, it also appears to account in part for sex differences in rates of anxiety symptoms and disorders from at least middle childhood onward (Bender et al., 2012; Zalta & Chambless, 2008; Zlomke & Hahn, 2010). As Nolen-Hoeksema (2012) pointed out, much less is known about the emotion regulation strategies that men, particularly anxious men, employ, than is known about women's preferred strategies. Further research is clearly needed across the life span to better characterize the male developmental trajectory for adaptive and maladaptive approaches to managing anxiety.

Research in both children and adults tends to find rumination to relate more strongly to depression than anxiety (McEvoy & Brans, 2013; Verstraeten, Bijttebier, Vasey, & Raes, 2011). Not surprisingly, however, given the high rates of comorbidity between anxious and depressive conditions, ruminative thinking also appears common in individuals identified as primarily anxious. Individuals with social anxiety, for example, frequently engage in postevent processing, which consists of repetitive reflection on negative aspects of a social interaction. Further, some evidence suggests that a ruminative response to anxiety may increase risk for depressive disorders and, conversely, rumination both in and outside of the context of depression may increase risk for anxiety (McLaughlin & Nolen-Hoeksema, 2011; Starr & Davila, 2012). These associations between rumination and psychopathology may stem, at least in part, from negative interpersonal correlates of rumination, such as excessive support or reassurance seeking (McLaughlin & Nolen-Hoeksema, 2012).

In adults with social anxiety, CBT appears to decrease tendencies for post-event processing or anxious rumination (Price & Anderson, 2011). Limited research has examined treatment effects on this emotion regulation strategy in youths; however, at least one influential theoretical model of child anxiety and its treatment explicitly identifies postevent attributions as a key element that warrants attention (Kendall, 2012). Further, CBT has been used successfully to target worry in children as young as 7 years of age (Suveg, Sood, Comer, & Kendall, 2009), which suggests that further efforts to modify repetitive negative thought patterns in youths are likely to yield positive results.

In addition to the anxiety regulation strategies outlined above, individuals may also use a range of other adaptive and maladaptive approaches to modulate their emotional state in the context of an anxiety-provoking circumstance. No one strategy is likely optimal in every situation; even those identified as typically maladaptive may sometimes be the best option an individual has available. Further, the range of accessible strategies is likely to vary across development, as will the contexts that demand their implementation; it is thus likely that strategies that are less effective at some developmental stages may hold more utility at others. In fact, rather than simply being skilled at a few adaptive regulation strategies, possession of a broad and flexible emotion regulation repertoire may serve as a stronger predictor of psychological health. In at least one study, individuals who reported using an array of regulatory strategies exhibited less internalizing psychopathology than did peers who endorsed a more limited range of strategies (Lougheed & Hellenstein, 2012).

A growing body of research also points to the value of mindfulness, or fostering awareness and acceptance of one's emotional experience, for regulating anxiety. Together with self-reported difficulties with emotion regulation, limited mindfulness predicts both anxiety symptoms and disorders in adults (Roemer et al., 2009). Treatment approaches that explicitly teach and encourage mindfulness have shown efficacy in reducing anxiety, along with its neural correlates, in adults (Goldin & Gross, 2010). Anxious children and adolescents, too, have been found to respond positively to mindfulness-based therapies in both open and randomized controlled treatment trials, and clinicians are incorporating mindfulness training into child treatment with increasing frequency (Semple & Burke, 2012). Notably, however, at least one study found the use of mindfulness or acceptance techniques to perpetuate, rather than mitigate negative affect in adults with GAD, which suggests that individual differences that predict a positive response to such approaches warrant further investigation (Aldao & Mennin, 2012).

Research into cognitive strategies for regulating emotion broadly and anxiety specifically has made great strides in the past few decades, with particularly notable advances made in understanding normative patterns of strategy

use across development. Integration of the cognitive, developmental, and clinical literatures has also yielded useful information about what strategies are most effective and whether and how such strategies, particularly cognitive reappraisal and mindfulness, can be efficiently incorporated into evidence-based treatment approaches. Perhaps the most striking developments in the knowledge base regarding anxiety regulation, however, come from translational work that spans neuroscience, clinical, and developmental domains. In the next section, we review recent research findings regarding the neural substrates of anxiety regulation as they evolve across the life span.

Neural Mechanisms of Anxiety Regulation

Research in neuroscience has made fundamental contributions to the conceptualization of the emotion regulation construct, broadly speaking. Moreover, due to cross-species conservation in brain-behavior relationships for fear and anxiety, neuroscience research in this area has provided a particularly influential perspective in shaping conceptualizations of both emotion and emotion regulation. This neuroscience perspective has clear advantages when it is assumed in attempts to understand emotion regulation in typically and atypically developing children and adolescents, as well as later in the life course; it also, however, holds several inherent disadvantages.

Because the brain is the ultimate arbiter of behavior and cognition, neuroscience research has the advantage of examining factors that may ultimately cause emotions and emotion regulation, providing a mechanistic understanding of the constructs. However, because considerable research in neuroscience is conducted using a cross-species approach, a certain degree of reduction is necessitated in the experimental approach if researchers are to maintain experimental control. The reductive aspects of neuroscience carry marked disadvantages for clinical application, in that findings from neuroscience-based research can be difficult to extrapolate to the complexities of the clinical scenario, particularly for children, where development adds additional complications and considerations. Again, research on anxiety has been at the forefront of attempts to integrate findings from neuroscience into current thinking about developmental psychopathology. Accordingly, research on the neuroscience of the regulation of normal and pathological anxiety is important not only to our understanding of anxiety per se, but also to our broader understanding of individual differences in other clinical domains and for emotion regulation more generally.

Consistent with the definitions that we outlined earlier in this chapter, the somewhat reductionist neuroscience perspective on emotion regulation considers emotion to constitute a brain state associated with stimuli, such as threat or rewards, that the organism will expend effort to approach or avoid. In this context, a threat is a dangerous stimulus, capable of harming the organism, which creates fear (the brain state created by an immediately present threat) or anxiety (the brain state created by a more distal or potential threat). For both sets of stimuli, the associated distinctive brain state can be identified in various species based on the organism's tendency to avoid the threatening stimulus. Of course, these definitions can be applied to both normal and abnormal forms of fear or anxiety, with the distinction hinging on the degree to which the brain state ultimately facilitates or hinders adaptation.

In the neuroscience perspective, emotion regulation refers to any attempt by the organism to alter or modulate this initial emotional response. For both fear and anxiety, regulation is viewed typically from this perspective as attempts to modulate levels of the emotion to facilitate ongoing adaptive behavior. In this context, normal emotion regulation can be differentiated from pathological regulation, based on the organism's ability to reduce the level of fear or anxiety that is expressed when signs of danger have dissipated. In some sense, this distinction between an emotion and the attempt to regulate it is arbitrary. This is because the attempt to regulate an emotion can begin virtually instantaneously with onset of the emotion. However, emotion and emotion regulation can be viewed as co-existing on a dimension. In this perspective, the term emotion refers most directly to the organism's immediate response, and the term emotion regulation becomes increasingly relevant in describing this response at later points in time. At these later points in time, regulation of emotion is expressed as the organism engages various cognitive and associated behavioral processes to alter the initial emotional reaction.

Considerable research has translated work in rodents and nonhuman primates to clinical contexts. Interest has focused particularly deeply on brain-imaging research examining the substrates of emotion regulation. This interest has emerged, at least in part, because such research extends to humans the considerable range of findings in other species regarding the brain substrates of emotion generation and the associated structures that regulate generated emotions. As is typical in many domains of brain imaging research, more studies of emotion regulation examine adults than children or adolescents. This state of affairs reflects the methodological and ethical

complexities of conducting brain imaging research in vulnerable individuals, especially children, who may find the scanning environment frightening and who may have difficulty monitoring and managing their own movement and distress (Bookheimer, 2000). These issues are particularly salient in studies focused on the experience of negative emotions, such as fear and anxiety, the induction of which may require the application of gentler stimuli than those that are used with adults (e.g., Pine, Fyer, et al., 2001). Nevertheless, after many years of successful application of imaging technology in research on adults, a growing brain imaging literature also has arisen that focuses on normal and abnormal child and adolescent development across multiple emotional and cognitive domains.

Over the past 10 years, imaging research on emotion regulation typically has adopted one of two experimental approaches, consistent with the dual-process framework that Gyurak and colleagues (2011) outlined. In one approach, the research participant is directly instructed to regulate any emotion that arises during a brain-imaging experiment. While regulatory acts could involve increases or decreases in either positive or negative emotions, the most consistent results have emerged in studies examining attempts to reduce fear, an observation that again follows from the cross-species conservation in brain-behavior relationships for this brain state. This first approach has been termed explicit emotion regulation, reflecting the fact that the research participant is explicitly told the goal of the experiment, which is to change an initial emotional response. Moreover, in some such experiments, the participants are directly taught methods for regulating their emotions. These methods vary across studies, but most research focuses on reappraisal, or changing the way in which one thinks about an emotionally charged situation or topic with the aim of increasing or decreasing its emotional impact. In other experiments, no instructions are provided regarding whether or how to employ particular regulatory strategies.

The other approach to emotion regulation does not provide any instructions to the participant regarding emotion; indeed, no reference is made to emotion at all. Rather, the participant is required to complete a neutral task, such as target identification or memory encoding. In this context, task-irrelevant emotional and neutral items are embedded, and emotion regulation is indexed based on the degree to which research participants can stay focused on and engaged in the neutral task when they are confronted by task-irrelevant emotional stimuli. Studies using this second approach are considered to be examining implicit emotion regulation, or regulatory processes that occur out of awareness.

A number of fMRI studies map the neural correlates of re-appraisal and other explicit emotion regulation strategies in healthy adults, with regulatory efforts focused on negative or positive emotions in general (e.g., McRae et al., 2012) or on anxiety in particular (e.g., Ball, Ramsawh, Campbell-Sills, Paulus, & Stein, 2012). This work in adults also has been extended to various anxiety states, including normal individual differences in healthy populations on anxiety rating scales and clinical diagnoses of social phobia or generalized anxiety disorder (Ball et al., 2012; Blair et al., 2012; Brühl et al., 2012). Moreover, studies of this type have examined differences in the neural correlates of emotion regulation between healthy adolescents and adults, and although fMRI studies of cognitive reappraisal in children are limited, researchers have successfully measured neural activity during reappraisal tasks using electroencephalographic (EEG) techniques in youths as young as 5 years (DeCicco, Solomon, & Dennis, 2012). The research base is thus growing and expanding in ways that will allow a more developmentally informed understanding of the neural substrates of emotion and anxiety regulation than was possible initially.

An additional factor renders a developmental approach to this area of study particularly challenging. Not only do researchers studying explicit emotion regulation face the general methodological and ethical issues inherent in neuroimaging work with youths, but they also must address one more specific set of complications. Because research participants are directed to attend to the study goals on each experimental trial, expectancies about what they should do can heavily influence their patterns of task responding. The relatively common use of self-report assessments of emotional change as the core measure of emotion regulation competency gives further weight to expectancies, and it remains unclear how tightly real life efforts to regulate emotion in the absence of instruction to do so or measurement of one's success map onto those produced during explicit emotion regulation tasks. In part because the effects of expectancy might vary among children, adolescents, and adults (Brenner, 2000), thus introducing a confound that is difficult to control for, relatively few studies compare the neural correlates of reappraisal in healthy adolescents and adults (but see McRae et al., 2012). None of these studies to date have made comparable comparisons across developmentally stratified groups with pathological forms of anxiety.

The most consistent findings from fMRI studies of explicit emotion regulation focus on the functioning of

areas within the association cortices, regions of the brain that are not directly involved in perception, motor execution, or even initial emotional responding, but instead support more integrative brain-based processes. Typically these areas operate in the context of brain networks known to support relatively complex forms of decision making, and include areas of the dorso-medial prefrontal cortex (PFC), the ventro-lateral PFC, and the dorsal parietal cortex. In healthy adults, these regions typically show enhanced activation during successful emotion regulation—both explicit and implicit, in tandem with reduced activation in brain regions such as the amygdala that are thought to support aspects of emotion reactions (e.g., Bush, Luu, & Posner, 2000; Somerville et al., 2013). Moreover, studies of adults with anxiety disorders, as well as those with temperamental or personality characteristics associated with anxiety generally find reduced activations in these parietal and PFC regions, suggesting that deficient emotion regulation in these individuals reflects an inability to engage regulatory neural structures (e.g., Ball et al., 2012; Vrtička et al., 2012).

Although the base of studies that take a developmental perspective to understanding the neural correlates of anxiety regulation is still growing, emerging evidence from comparisons of neural correlates of emotion regulation between healthy adolescents and adults suggests that the regions perturbed in adult anxiety disorders continue to mature through adolescence (e.g., McRae et al., 2012). Few studies have yet used neuroimaging to examine reappraisal in children prior to adolescence; one fMRI study, however, in which 5 to 10 year old children were asked to reappraise sad images, yielded evidence of bilateral activation in lateral and medial PFC regions, along with right-lateralized activity in the ACC and ventral lateral PFC (Levesque et al., 2004). Further, evidence from research that has measured evoked response potentials in preadolescent children during cognitive reappraisal of emotion also supports the hypothesis that the neural substrates of emotion and anxiety regulation are not yet functioning at an adult level (Dennis & Hajcak, 2009; DeCicco et al., 2012). Thus, maturation in these regions during development may explain why some forms of anxiety wane during adolescence.

Our understanding of the neural mechanisms of explicit anxiety regulation has become increasingly sophisticated in recent years, with a shift of focus from the activation of individual structures to the ways neural regions interact during an emotional event. This literature has yielded evidence that the degree to which prefrontal brain regions engage interactively and responsively with the amygdala is an important factor underlying variability in adult capacity to effectively down-regulate or decrease negative emotion. Lee and colleagues (2012) for example, recently found evidence that the PFC more effectively and efficiently modulates amygdala activity in adults who are more adept at using a reappraisal strategy than in those who show less skill at implementing this strategy.

Considerable fMRI research examines implicit emotion regulation in both healthy and anxious adults; this extensive database facilitates comparisons of the neural correlates of implicit and explicit forms of emotion regulation in such samples. Moreover, while relatively few studies examine developmental aspects of explicit emotion regulation (e.g., McRae et al., 2012), a more extensive database exists regarding implicit emotion regulation among children and adolescents. This body of research encompasses considerable work regarding the regulation of emotions in general, as well as the regulation of anxiety in particular. Research on implicit emotion regulation generally has relied on three different sets of processes, which can be characterized based on the neutral tasks that research participants complete. These tasks variously require participants to regulate emotion in the context of cognitive conflict, to orient attention, or to engage in stimulus-reinforcement learning.

In fMRI research on the brain response to conflict, participating individuals are presented with neutral stimuli that they are instructed to classify; for example, a subject may be asked to identify the direction in which an arrow is pointing or to label the gender of each model in a series of neutral faces. To make this classification more difficult, the neutral stimulus is surrounded with other, distracting stimuli, such as multiple task-irrelevant arrows pointing in opposite directions. The inclusion of task-irrelevant stimuli introduces cognitive conflict, in that the participant must stay focused on task-relevant stimuli and resist being derailed by the task-irrelevant distracters. Finally, to make the otherwise neutral task emotional, researchers embed features that connote threats and rewards in at least a subset of trials. For example, on neutral trials, a subject may be asked to perform difficult classifications of neutral faces, whereas on emotional trials, the subject must classify faces making emotional expressions. In these tasks, successful performance requires the subject to reduce responding to emotional stimuli in order to maintain task-relevant goals.

One particularly interesting example of such research examines the brain regions that implement both the monitoring and the control of cognitive conflict. Etkin and colleagues (2006) asked healthy adults undergoing fMRI scans to indicate the affect presented on fearful and happy faces; to introduce conflict, each face was overlaid with the word HAPPY or the word FEAR so that some face/word

combinations were congruent and others were incongruent. Their findings indicated that many of the brain regions involved in explicit emotion regulation, particularly prefrontal cortical areas and the anterior cingulate cortex (ACC), also play a role in conflict monitoring and control during performance of tasks that employ emotional stimuli. Further, taken together with the results of research focused on explicit processes, as well as those from additional studies that have found associations between state anxiety in healthy adults and patterns of function in prefrontal and ACC regions during cognitive conflict tasks (e.g., Bishop, Duncan, Brett, & Lawrence, 2004), these findings suggest that implicit and explicit forms of emotion regulation may draw on overlapping brain regions.

Moreover, the same group also implicates perturbed functions in these same regions in adults with GAD (Etkin et al., 2010; Etkin & Schatzberg, 2011). Using the same facial emotion conflict task, the authors of both studies found study participants with GAD to show difficulty engaging regulatory processes and their mediating neural structures that healthy individuals appear to activate spontaneously in the absence of explicit instruction. Blair and colleagues (2012) obtained strikingly similar findings in research directly comparing implicit and explicit forms of emotion regulation in patients with GAD and patients with social phobia. Notably, no significant differences in patterns of activation emerged between patient groups, suggesting that at least some shared neural substrates characterize the two disorders.

An important next step will be clarifying the neurochemistry of the anxiety regulation process as it is mediated in the PFC and other salient regions of the brain; studies that simultaneously probe neurochemical activity and neural function hold promise for advancing knowledge in this area. In one recent study, for example, Sripada and colleagues (2013) found evidence that by manipulating levels of allopregnalone, a neurosteroid that modulates the function of gamma-aminobutyric acid (GABA) type A receptors in healthy adults, they could enhance neural activity in the PFC and amygdala during an emotionally charged cognitive conflict task. When linked with the considerable data indicating that dysregulation of the GABA neurotransmitter system may play a key role in the development of anxiety (Kalueff & Nutt, 2007), these findings move us closer to understanding the anxiety regulation process as it plays out at multiple levels of analysis.

Because implicit emotion regulation tasks create different expectancies than explicit tasks, there has been interest in employing them in research that takes a developmental approach to understanding psychopathology, including anxiety. In healthy children as young as 9 years of age, evidence is emerging that suggests that prefrontal cortical activation, particularly dorsolateral regions, already differs between emotional and neutral task conditions (Lamm, White, McDermott, & Fox, 2012). Initial attempts to extend this work to individuals with or at risk for anxiety, however, have generated findings that are difficult to reconcile with the extensive research on normal and pathological emotion regulation, in the service of cognitive control. For example, two studies that have examined patterns of neural activation in adults or adolescents who were characterized during childhood as at high risk for anxiety due to a behaviorally inhibited (BI) temperamental style (Jarcho et al., 2013; McDermott et al., 2009), have yielded mixed findings. Whereas McDermott and colleagues (2009) found evidence that patterns of neural response to emotional cues presented within a conflict task moderated associations between childhood BI and adolescent anxiety disorders, Jarcho and colleagues' (2013) study of adults with and without a history of BI did not find brain activity patterns to function as either a moderator or a mediator in such associations (although BI history did predict atypical activation in prefrontal cortical regions).

Research on attention orienting, much like that on conflict, typically involves performance of a neutral task. However, participants tend to perform more quickly and accurately on orienting tasks than on cognitive conflict tasks, which suggests that the former are easier. In some orienting tasks, the participant is simply required to identify, as quickly as possible, the spatial locale of an easy-to-detect target. In others, participants might have to classify the target much as they might in cognitive conflict tasks; however, the classification is typically far easier due to the absence of explicitly conflicting cues. Orienting tasks present such stimuli in different contexts—some involving no other stimuli, others involving proximal neutral stimuli, and a third set involving proximal emotional stimuli. For example, in a hypothetical orienting task, a letter or symbol might serve as the target; in some trials it will appear alone (no other stimuli), in others it will appear with neutral faces (proximal neutral stimuli), and in still others it will appear with emotional faces (proximal emotional stimuli). In the context of this kind of task, emotion regulation is conceptualized as the capacity to rapidly orient across these different contexts at a consistent rate over time. Typically, orienting ability is quantified based on reaction time (difference scores are calculated for emotional vs. nonemotional trials), and various task arrays have been used.

The most frequently employed orienting paradigm in developmentally informed studies of normal and abnormal aspects of anxiety is the dot-probe task (e.g., Mogg & Bradley, 1998); numerous versions exist, which variously use emotional words, faces, and pictures as target stimuli. In healthy youths and adults, successful orienting to target cues in the context of the dot-probe task and other similar orienting tasks requires engagement of the ventro-lateral PFC, encompassing associated expanses of the anterior insular cortex (e.g., Monk et al., 2006) as well as parietal regions (Pourtois et al., 2006). Interestingly the ventro-lateral PFC region implicated in orienting processes overlaps with regions implicated in reappraisal (e.g., Campbell-Sills et al., 2011), which echoes evidence from conflict studies regarding parallels in neural correlates of explicit and implicit emotion regulation tasks.

The most consistent finding in studies of pathological anxiety, including trauma-related distress, is enhanced activation in this PFC region, which often correlates negatively with levels of anxiety (Fani et al., 2012; Monk et al., 2006). This pattern of results suggests that engagement of the ventro-lateral PFC facilitates maintenance of orienting, particularly in contexts where threats can disrupt it. Findings regarding both normal and abnormal variations in adolescent anxiety extend this framework to developmental psychopathology, representing a particularly broad application of the emotion regulatory framework.

The third area of fMRI research aimed at elucidating the neural correlates of implicit emotion regulation focuses on aspects of stimulus-reinforcement learning. Much as research on cognitive control and attention orienting does, studies of stimulus-reinforcement learning consider how responses to stimuli that initially are neutral change when those stimuli are linked to emotionally salient information. Of the three task types, those that involve stimulus-reinforcement learning place the fewest demands on research participants, whose learning can be assessed in the absence of any overt behavioral response.

The most basic form of stimulus-reinforcement learning examined in efforts to clarify the neural substrates of anxiety and its regulation focuses on fear conditioning (Dunsmoor & LaBar, 2013). In fear conditioning tasks, a neutral stimulus, such as a tone or a light, is paired with an aversive unconditioned stimulus (the UCS). Research with rodents, nonhuman primates, and adult humans typically uses electric shock, a highly potent stimulus, as the UCS; studies in children and adolescents, however, have relied for ethical and practical reasons on milder UCS, such as loud sounds or annoying air blasts (e.g., Monk et al., 2003; Pine et al., 2001). Following pairing of the neutral stimulus and UCS, the neutral stimulus acquires the capacity to evoke the same emotion as the UCS, in part because the participant learns to associate the two together. As a function of its newly acquired evocative capacity, the neutral stimulus is reclassified as a conditioned stimulus (CS+). In fMRI research, this initial form of learning is typically viewed as part of an emotional reaction that unfolds over time as the association between the UCS and the CS+ emerges, strengthens, and subsides.

In the context of most research on fear conditioning, emotion regulation is operationally defined in terms of changes that occur in this initial emotional reaction, following other experimental manipulations. Probably the most extensive body of research in this area considers changes in extinction, or the reduction or disappearance of a conditioned response. Extinction occurs when an organism repeatedly encounters a CS+ in the absence of the UCS, which appears to lead to a new learning process in which the CS+ is linked with safety, or the absence of threat (Bouton, 2004). This leads the organism to reappraise and reclassify the CS+ as an ambiguous stimulus, one that could evoke fear in one context, but not in others, including the UCS-free context in which the stimulus is currently encountered.

Many theories of anxiety, particularly those that emanate from the behaviorist tradition, emphasize the role of deficient extinction in sustaining individual differences in anxiety. Empirical data lend support to this notion; Lissek and colleagues (2005) found, in a meta-analysis of the fear conditioning literature, that not only does fear conditioning occur more rapidly in individuals with anxiety disorders, but extinction also occurs more slowly. Such impairment of extinction processes may reflect underlying genetic diatheses. Indeed, one study found that individuals with a particular genetic polymorphism (COMT met/met) that has been implicated in anxiety and other negative mood states were unable to extinguish conditioned responses at all (Lonsdorf et al., 2009). How these diatheses interact with experience and context to influence the developmental course of anxiety remains unclear; however, recent work takes a first step toward answering this question by suggesting that extinction failures may serve as a link between childhood anxiety (which is common but typically resolves) and the less common outcome of developing an adult anxiety disorder (Britton et al., 2011).

Some of the strongest support for these theories derives from research on the therapeutics of anxiety disorders, where CBT has emerged as one of the more effective treatments across the life span (Hofmann, Asnaani, Vonk, Sawyer, & Fang, 2012). CBT for anxiety holds as central aims the modification of maladaptive thinking and the reduction of avoidance or facilitation of extinction via

exposure to feared or anxiety-provoking stimuli. Along with training in cognitive reappraisal, as discussed earlier, exposure has proven to be one of the most important elements in successful CBT treatment of a range of anxiety disorders (Moscovitch, Anthony, & Swenson, 2009), and neuroscience research into the mechanisms that underlie the exposure-mediated extinction process is yielding clues regarding both how extinction works and how it can be best achieved in the context of CBT.

In healthy adults, fMRI research has demonstrated that the amygdala is a primary mediator of fear learning and that the medial prefrontal cortex and the dorsal ACC play key roles in implementing extinction via inhibition of amygdala activation (Quirk, Garcia, & Gonzales-Lima, 2006; Sehlmeyer et al., 2009). There is some evidence that the ability to extinguish conditioned threats is still maturing during adolescence (Pattwell et al., 2012), with decreased capacity for extinction learning relative to children and adults observed both in adolescent humans and adolescent mice. Although the neuroimaging literature on fear conditioning and extinction in youths is still too limited to permit definitive statements about neural mechanisms, presumably this developmental pattern maps onto the maturation of relevant brain regions, particularly the PFC. Notably, however, related studies have yielded evidence of developmental changes in the fear conditioning process, as well as its psychophysiological correlates from age 3 years onward (e.g., Gao, Raine, Venables, Dawson, & Mednick, 2010), which suggests that similar attention to neural correlates across development may be fruitful.

Clearly our knowledge about the neural correlates and substrates of anxiety regulation has grown exponentially in the past several years and as researchers continue to find new ways to bridge neuroscience, clinical, and developmental domains, this literature is likely to continue to expand at a rapid pace. One particularly exciting direction that this work is taking builds on ideas that Tucker (1989) articulated many years ago by considering the interpersonal contexts in which emotion and anxiety regulation processes unfold. In the final section of this chapter, we describe recent advances in understanding how contexts, intrapersonal and interpersonal, may reciprocally influence the neural and cognitive processes involved in anxiety regulation across development.

The Role of Context in Anxiety Regulation

As Aldao (2013) astutely pointed out in a recent article, understanding contextual influences on emotion regulation in individuals with psychopathology is especially important, given that an inflexible set of responses to environmental cues serves as a core characteristic of many disorders. Many of the cognitive and behavioral biases that are commonly observed among individuals with anxiety disorders constitute precisely this kind of response set, and it will thus be critical to clarify how both intrapersonal and extrapersonal features may reinforce or discourage their implementation. A broad range of such features is likely to be relevant, with different contextual factors weighing more heavily into the anxiety regulation process at different points in development.

In infancy and early childhood, for example, interpersonal interactions with parents constitute a large proportion of an individual's daily life, and thus those interactions will typically play a large role shaping in the individual's responses to emotional cues. A large literature examines the ways parent–child interactions facilitate or interfere with healthy emotion regulation (Scaramella & Leve, 2004), and increasingly sophisticated research takes into account parent and child characteristics and the interplay between them as predictors of child responses to distressing circumstances (e.g., Aktar, Majdandžić, de Vente, & Bögels, 2013). In adolescence, in contrast, an individual's peer group assumes increasing salience for both adaptive and maladaptive responses to emotional cues, and while family relationships remain important, their patterns of influence on regulatory processes evolve (Adrian et al., 2009; Larsen et al., 2012).

Studying how these interaction patterns figure in the development of regulatory strategies and capacities is complicated, particularly if one aims to gather data at multiple levels (e.g., neural, cognitive, and behavioral). A number of recent neuroimaging studies focused on adolescents have addressed this challenge by incorporating clever behavioral paradigms that involve real or perceived social interchanges that carry varied affective charges (see Pfeifer & Blakemore, 2012 for a brief overview). For example, tasks that lead participants to believe that they are being rejected by peers tend to elicit activity consistently in ventral prefrontal regions (e.g., Guyer et al., 2012; Masten et al., 2009) that map onto those engaged during implicit and explicit emotion and anxiety regulation tasks. Such findings suggest that the neural activity associated with decontextualized experimental tasks parallels that evoked by real-life (or close to real-life) experiences. Other studies have begun to experiment with real-time interaction with an actual person during fMRI scanning (e.g., Redcay et al., 2010), an approach that may prove particularly fruitful for studying the neural correlates of efforts to regulate social anxiety.

Just as studies of the enactment of anxiety regulation and its neural correlates in the context of ecologically valid interpersonal interactions are important, research that

focuses on the process of selecting a regulatory strategy in response to environmental cues will be useful. Very little work to date has examined neural activity while an individual chooses among available regulatory approaches—typically, either participants are instructed to use a particular strategy or they are permitted to accomplish the regulatory task in any way they prefer to do so. Research that presents individuals with a range of regulatory options and then tracks patterns of choice and their correlates (e.g., neural, psychophysiological) may help elucidate optimal points of intervention for individuals who tend to rely inflexibly on maladaptive strategies. At least one study has found evidence that the ability to flexibly implement different regulatory strategies predicts later psychological health in college students (Bonnano, Papa, Lalande, Westphal, & Coifman, 2004); clarifying intrapersonal and situational factors that facilitate such flexibility and how those factors may or may not vary across development will help us better understand ways to encourage and support adaptive coping with anxiety.

At an even broader level, examining anxiety regulation in comparable interactions across varied interpersonal contexts (e.g., family, friends, romantic partners, unfamiliar peers) may provide clues about the ways specific patterns of interaction and different levels of intimacy may modulate both the available and the selected strategies for regulating anxiety. Engaging with a trusted person, for example, might facilitate more flexible use of regulatory approaches than would interaction with a novel individual, with whom a more circumscribed set of reactions might feel safer. Sociological approaches to the study of emotion, which provide useful insights into how we might better take into account the background against which anxiety and its subsequent regulation occurs may help inform work exploring such questions (e.g., Barbalet, 2011).

Translational Implications of Research on Anxiety Regulation

As the research we have described in this chapter illustrates, work conducted from multiple perspectives, at varied levels of analysis (e.g., genetic, neural, behavioral), and with a broad range of measurement tools is converging to yield a rich picture of emotion and its regulation. Calls for translational studies that facilitate communication between basic and applied scientists who study emotion and its regulation have been increasing over the past decade, driven in part by NIMH initiatives aimed at supporting research that transforms our understanding of mental illness and its neurodevelopmental origins (see Austin, 2013; DelCarmen-Wiggins, 2008). Increasingly, researchers are responding to these calls by designing studies of emotion regulation that transcend a single-level-of-analysis approach and that target ways biological processes, viewed through varied lenses, both influence and are shaped by behavior and context (e.g., Oberle, Schonert-Reichl, Lawlor, & Thomson, 2012). In addition, the importance of translating basic-science-informed clinical knowledge into both effective and efficacious practices in the community is informing scholarship on emotion regulation (e.g., Ferrell, 2009).

Anxiety represents a domain of normal and abnormal behavior and psychology that is particularly ripe for such a translational perspective. This is because there is particularly marked cross-species conservation in research on anxiety, relative to other areas. Thus, the increasingly widespread implementation of translational and multilevel approaches to research on anxiety regulation holds numerous implications for both our understanding of anxiety and our efforts to intervene with and prevent its maladaptive manifestations. One key implication is that scientists and clinicians will need to engage with each other in creative ways to bridge the terminological and methodological divides that commonly impede their collaboration (Cicchetti & Toth, 2006). Multidisciplinary teams, as well as cross-site collaborations, are of growing importance in the study of anxiety and its regulation, as is research that looks for underlying biological commonalities among superficially distinct psychopathologies (e.g., Meyer-Lindenberg, Domes, Kirsch, & Heinrichs, 2011).

As a function of broader interactions among scientists and clinicians who bring multiple perspectives to the table, it is likely that diagnostic boundaries for the anxiety disorders will continue to shift and evolve. As this process unfolds, it will be essential for scholars to hold assumptions lightly and loosely, and to be prepared to revise or jettison long-favored conceptions of anxiety and its management in the face of new evidence about its biological correlates and the ways they interact with environmental contingencies to yield varied patterns of response. However, such research on nosology is likely to unfold relatively slowly, compared with research on novel therapeutics. In fact, translational research in this area already has begun to influence anxiety treatment (Pine et al., 2009; Pine & Fox, 2015).

CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE WORK

This chapter reviews the literature on the cognitive and neural mechanisms that allow humans to regulate anxiety

over the course of the life span. We provide an integrative perspective on research from clinical psychopathology, developmental psychology, and cognitive neuroscience, with the goal of illustrating the ways these related, but distinct, fields inform each other. Such translational engagement among researchers is critical if we are to identify optimal, personalized approaches to enhancing anxiety regulation repertoires, especially among those who are vulnerable to internalizing psychopathology broadly, and to anxiety disorders specifically. Clearly, this need has been widely recognized among anxiety researchers, who have devised a range of creative approaches to bridging relevant literatures that historically have operated in parallel. In reviewing their work, we find that several themes emerge, each of which suggests directions for future study.

First, although anxiety and its regulation across development have historically been understudied, the past decade has seen an explosion of research focused on this topic. The historical neglect of these topics reflects, in part, a clearly outdated belief that anxiety disorders constitute mild psychopathology. It is now widely acknowledged that anxiety, particularly if it emerges early in life, predicts a variety of negative outcomes, including major depressive disorder and suicide, as well as marked functional impairment across the life span. Further, researchers and clinicians typically recognize that enhancement and expansion of anxious individuals' emotion regulation repertoires has strikingly positive effects on their internal experience and their ability to perform effectively in social, academic, and occupational domains. This new clinical vision resonates with the availability of novel translational neuroscience methods and findings from basic neuroscience to raise particular interest in clinical applications of research on anxiety regulation.

To maintain the momentum of research on anxiety and its regulation, it will be critical that we produce studies that integrate a developmental psychopathology perspective with some of the elegant theoretical models of emotion and anxiety regulation that have been put forth in the past few decades. In particular, attention to developmental variation in patterns of affective chronometry (Davidson, 1998) as they manifest across different anxiety regulation strategies might help identify salient points for targeted intervention. Such work should, ideally, also gather data at multiple levels of analysis (e.g., genetic, neural, and cognitive), to facilitate generation of a more integrative and comprehensive picture of the anxiety regulation process.

In addition, continued effort to move beyond subjective reports of experience as the core markers of anxiety disorders and of the processes that become dysregulated in the context of these disorders is key to advancing the field. Consistent with the RDoC project (Insel & Wang, 2010), which aims to move the diagnostic process away from its reliance on difficult to quantify self-reports and toward the use of readily observable and measurable behavioral and biological data, researchers have begun to identify neural and psychophysiological correlates of both typical and atypical anxiety regulation processes. Extending this work to very young children is an important, if difficult, next step—notably, functional imaging studies have been completed that demonstrate atypical activation in emotion regulation circuitry in depressed preschoolers as young as 3 years of age (e.g., Gaffrey et al., 2011), but no published work has yet emerged to describe neural correlates of anxiety regulation in children this young.

Further, continuing a process that figured prominently in the most recent revision of the *DSM*, it is critical that we draw on novel clinical, genetic, and neuroscientific data to identify alternative classification schemes for anxiety. Given increasingly clear evidence that anxiety disorders represent the end result of complex interplay among many risk factors, it will be important to precisely describe the dynamic processes that can, under some circumstances, lead to a pathological outcome. If we can elucidate both the potential cascading effects of, for instance, genetic perturbations, that may interact with other genes or environmental factors to increase risk at neural and cognitive levels, we will be better poised to identify effective, precisely targeted interventions that can be implemented before an individual crosses the threshold into a full-blown clinical syndrome. Notably, such knowledge may also upend our current nosology for anxiety disorders and diagnostic boundaries may blur or disappear, possibly in different ways at different points in development. Already, research findings have led to the reclassification of OCD and PTSD; as the research base expands, further changes are likely.

Additionally, as Aldao (2013) clearly articulated with regard to emotion regulation research in general, there has not yet been enough research on anxiety regulation that fully considers the contexts in which strategies are learned and implemented. Integrative research that better characterizes the complex interplay among genetics, neurobiology, family environment, peer relations, and other influences is needed and is beginning to emerge in the literature. Research that combines genetic approaches with neuroimaging techniques, for example, has become increasingly common, and fMRI studies that are designed to maximize ecological validity are also appearing frequently in the literature.

Finally, further characterizing the elemental processes that constitute various explicit and implicit anxiety regulation processes in terms that are amenable to research in experimental psychology and neuroscience is likely to advance the field notably. To achieve this goal, it will be useful to move beyond broad constructs such as reappraisal by breaking them down into more fundamental cognitive and neural processes, each of which may have a distinct developmental trajectory. By defining salient constructs in language that bridges neuroscience, clinical, and developmental domains, we will be better poised to capitalize on the important findings emerging in each area and, ultimately, to develop novel, highly personalized, and rapidly effective treatments for anxiety and the regulatory impairments that maintain and perpetuate it.

INTRODUCTION

In this chapter, we present a new diathesis–stress model of the onset of psychopathology across the life span. We highlight the role of the brain in the diathesis–stress processes through the integration of two paradigm shifts in the fields of stress research and psychopathology, respectively: (1) the role of allostasis in stress research (Sterling & Eyer, 1988) and (2) new thinking about the role of the neural connections and networks in psychopathology (Menon, 2011). The brain is central to the concept of diathesis (e.g., Zuckerman, 1999) and, under allostasis, the brain is also central to the stress process (Ganzel, Morris, & Wethington, 2010; McEwen, 2007; Sterling, 2004; Sterling & Eyer, 1988). With the brain as a core feature of both sides of any diathesis–stress interaction, integration of these concepts is facilitated. This has two main benefits. First, bringing research on allostasis and large scale neural networks (connectomics[2]) together in the context of a diathesis–stress

We would like to thank Dr. Nathan Spreng of the Department of Human Development and the Human Neuroscience Institute at Cornell University for his expert advice on the dynamics of large-scale brain networks.

[1]Color versions of Figures 15.2, 15.8, 15.9, 15.12–15.14, 15.17, 15.21–15.24 are available at http://onlinelibrary.wiley.com/book/10.1002/9781119125556

[2]Connectomics is the study of the connectome, the functional and structural connections in the brain (e.g., Johansen-Berg, 2013). In this chapter, we focus on the large-scale connectomics of the human brain.

model enables us to identify stress-vulnerable brain processes that are likely to be implicated in the onset of psychopathology. We note that this effectively reframes the debate about whether the root cause of psychopathology is internal or external to the individual. Second, the central role of the brain in the diathesis–stress process mandates a consideration of the role of brain development; given evidence of a continually changing brain, we posit a developmental model of the onset of psychopathology. In this way, we advance understanding of the neural processes involved in the onset of mental illness and, in so doing, squarely embrace the core principles of developmental psychopathology.

We begin our discussion with a history of the diathesis–stress model in the study of psychopathology. Fifty years ago, clinicians regularly eschewed the role of physiological processes in the onset of psychopathology. More recently, though, the field of psychopathology has slowly come to embrace the joint roles of the internal (diathesis) and external (stress) in the onset of psychopathology. Questions now focus on the form of the diathesis–stress interaction and the processes by which they together produce psychopathology. Even so, it has been only recently that the tools of neuroimaging have allowed the neural processes underlying psychopathology to be explored in depth.

A key turning point in the history of stress research for this discussion is the introduction of the concept of allostasis. The value of the allostatic model is that it explicitly brings that which was considered external (stress) into the brain itself. Our discussion of allostasis builds on our prior work (Ganzel et al., 2010), which used an integrative human neuroscience approach (Cacioppo, Berntson, Sheridan, & McClintock, 2000) to develop theoretical models about the relationship between stress and both physical and mental health. Our own work has highlighted the brain's survival/salience circuitry and associated modulatory systems[3] as the neural front lines of allostasis, making this the specific neural circuitry that is likely to be most vulnerable to the accumulated wear and tear of allostatic load (the physiological cost of stress; Ganzel et al., 2010). This has allowed us to develop an allostatic model of the onset of psychopathology in response to current and prior stressors. Thus, under the concept of allostasis, stress and diathesis are intersecting processes that both take place in the brain.

[3]The neural systems underlying the central motivational "states of the brain" (Rosen & Schulkin, 1998, p. 326) formerly termed the core emotion systems of the brain in our work (Ganzel & Morris, 2011; Ganzel et al., 2010).

Because the brain is the central mediator of allostasis, and allostasis is key in our diathesis–stress model of psychopathology, we have also argued that brain *development* across the life span must play an essential role in the diathesis/stress process. To inform this discussion, we review the evidence for brain maturation and senescence across this life span. Doing so allows us to extend our model of diathesis–stress to include an explicit developmental component (Ganzel et al., 2010). As such, we explicitly examine how life span brain development intersects with developmental psychopathology (Cicchetti, 1993; Cicchetti & Posner, 2005) to inform diathesis–stress models of psychopathology across development.

To a diathesis–stress process taking place in the developing brain, we add a final level of complexity: the role of large-scale brain networks in psychopathology (Menon, 2011; Uhlhaas & Singer, 2012). Much of the prior work linking stress, psychopathology, and the brain has focused on individual regions of the brain thought to underlie the deficits in cognitive and affective functioning that characterize mental conditions, such as schizophrenia and depression. However, given the complexity of psychopathological disorders in their affective, cognitive, and behavioral presentations, it is perhaps not surprising that mapping of disorders onto local differences in brain regions has proved insufficient. Instead, current thinking suggests that neural *circuitry* might be critical here, i.e., it is *networks* of brain regions (and not just individual regions) that matter. Thus, building from a model in which stress can drive long-term structural and functional change in survival/salience-related brain regions (via allostasis; Ganzel et al., 2010), we highlight the role of stress sensitivity in large-scale neural networks in our development of a new diathesis–stress model of psychopathology.

In this work, we strongly espouse a number of key principles of the developmental psychopathology perspective (Cicchetti & Toth, 2009). First, we recognize that the study of normality and pathology are mutually informative, with normal development providing an understanding of the baseline processes on which there is deviation in the context of psychopathology. As such, our discussion of allostasis builds from a discussion of typical (nonpathological) neurophysiological responses to stress and our discussion of brain plasticity draws from what we know about typical (nonpathological) brain development. Second, as discussed previously, we develop a life span model of the diathesis/stress process, arguing for a model that maps brain development across age and stage of development with the development of psychopathology across this same period. Third, in keeping with the field's

focus on the interplay between the internal and the external, and the goal of reducing biological/environmental dualism, we highlight how external processes such as stressor exposure come to be instantiated in the brains of typical (nonpathological) individuals as neural processes and long-term changes in brain structure and function. This approach moves the entire diathesis/stress interaction into the brain. Finally, we draw on information from developmental neurobiology, from stress research in the social sciences and in neuroscience, and from new work on large-scale neural networks in psychopathology to bring cross-disciplinary perspectives to bear on the development of our diathesis–stress model.

DIATHESIS–STRESS MODELS OF THE ORIGINS OF PSYCHOPATHOLOGY

Diathesis Meets Stress

The classic diathesis–stress model was not born whole. Instead, it grew incrementally over time during the *sturm und drang* in psychiatry and clinical psychology that accompanied the decline of psychodynamics in the mid-twentieth century and the emergence of modern, more integrative perspectives on mental health. The 1972 inaugural volume of the *International Journal of Mental Health* provides a case in point. This was a special issue on the topic of genetics and mental disorders, which was a highly divisive topic at the time. A number of the authors in this volume describe the resistance of their clinical colleagues to a consideration of genetics in the origins of psychopathology. For example, the journal's editor, Martin Gittelman, wrote:

> . . . Bear in mind that one of the major theories of the etiology of mental illness is "parentogenesis," i.e., that family characteristics, interaction, milieu, etc., are largely responsible for mental illness, and that long-term hospitalization is therefore considered therapeutic since it removes the patient from the noxious influences of the family. However, if we can entertain the possibility that endogenous factors play an important role in severe mental illness, then one of the principal justifications for long-term hospitalization is made less tenable. . . . The implications for the organization of mental health services are obvious. (Gittleman, 1972, p. 4).

Other authors in this volume expressed parallel sentiments:

> Clinicians typically react negatively to genetic formulations on the ground that a genetic emphasis contradicts what we know about psychodynamics; that, as a corollary, it makes psychological intervention (e.g., psychotherapy, behavior modification, milieu therapy, vigorous combating of the hospitalization syndrome) theoretically incomprehensible or pragmatically useless; and, finally, that the overall result would be the development among professionals of a malignant therapeutic nihilism. (Meehl, 1972, P. 10)

This latter author, Meehl (1962, 1972, 1989), is credited with one of the one of the earliest diathesis[4]–stress models of the development of a mental disorder—in this case, a gene–environment model predicting the origins of schizophrenia (also see Gottesman & Shields, 1967; although they emphasized the polygenic nature of the diathesis more so than its interaction with environmental influence). Meehl's model included a dichotomous diathesis (Zuckerman, 1999), in that schizophrenia was portrayed as the result of a patient's dominant schizogene interacting with an inconsistent and aversive home environment generated by the unfortunate patient's battle-ax mother. This rearing condition was hypothesized to drive the cognitive slippage and soft neurological and psychometric signs that, over time, resulted in the symptoms and inappropriate behaviors associated with schizophrenia. The model broke new ground in that it explicitly embraced the role of biology in mental illness (a contentious point with many mental health professionals of the day) and the role of social and environmental factors in mental health (which was an equally sore point with much of the rest of medicine at that time: Engel, 1977). In an article in the journal *Science*, George Engel articulated the impasse at which the field of psychiatry found itself (Engel, 1977). Psychoanalysis and psychodynamics were still the dominant paradigms in psychiatry, but these approaches were increasingly criticized on a number of grounds (e.g., Delprato & McGlynn, 1985; Grunbaum, 1979, 1982). Psychiatry, as a field, was struggling with the claim that mental illness was a myth (i.e., that many mental disorders did not achieve the medical standard of being identifiable disease states because they had no basis in biological brain dysfunctions; see, e.g., Szasz, 1960). The psychosocial elements of human malfunction were deemed by some in the medical establishment to be the province of the theologian and the philosopher and needed to be disentangled from the organic elements of disease

[4]The concept of a diathesis has a lengthy history in medicine. The term is used in the present day to refer to a biological vulnerability to disorder that is either hereditary or acquired (Monroe & Simons, 1991), although in the more distant past it was also used to refer to the character of a disorder (e.g., hemorrhagic [yellow] fever versus pneumonia; Brown, 1813; LeConte, 1810).

(Engel, 1977; Szasz, 1960). In short, mental illness did not fit the medical model of the time, which emphasized the biological components of disease and eschewed the underbrush of psychosocial variables. But Engel cautioned psychiatrists against embracing the medical model of the 1970's, which he believed to be reductionistic, dogmatic, and irrationally supportive of mind-body dualism (1977). Other clinicians of the time shared this frustration, stating that "reductionism is particularly harmful when it neglects the impact of nonbiological circumstances upon biological processes" (Holman, 1976, p. 134).

In response to this debate, Engel (1977) proposed an inclusive *biopsychosocial medical model* of psychopathology that defied Western medicine's traditional separation of the mental from the somatic, which he argued had a practical basis in medieval Christian church politics and had thereafter devolved into unexamined sociocultural dogma (also see Rasmussen, 1975). Engel's biopsychosocial model included the patient as a biological individual in a social context with a history of early, past, and present life experiences (Engel, 1977). Engel's work was strongly informed by Ludwig von Bertalanffy's (1952) influential work on *general systems theory,* which stood in opposition to the reductionism that had become embedded in the dominant models of biology. Von Bertalanffy argued that the organism is better explained as a functionally interdependent whole rather than the sum of its independent biological parts. Under systems theory, the linkages among all levels of organization are revealed by holistic approaches to scientific inquiry. Following this lead, Engel included consideration of the doctor–patient relationship and the social context of the health care system into his ideas for a biopsychosocial model, thus articulating the interdependent levels of analysis within a patient–doctor system that ranged from biology to society.

The breadth of Engel's vision may have defeated the usefulness of his model, which failed to find practical application in research designs of the day (McCutcheon, 2006). Detractors argue that Engel can be credited with proposing the biopsychosocial model, but he failed to adequately specify its form (McLaren, 1998). Others have pointed out that science has only recently progressed to the point where the form of such a model could be specified, since explicit testing of the associations across a multilevel and interactive biopsychosocial system has been possible only with the recent development of new technologies supporting neuroimaging, genetics, and psychosocial measurement (McCutcheon, 2006) and the statistical modeling of multilevel and dynamic data in complex systems (e.g., Sporns & Chialvo, 2004).

Following Meehl's lead, Zuckerman (1999) is often credited with providing one of the first comprehensive discussions of the onset of psychopathological conditions deriving from two (not one) primary determinants—diathesis and stress. Zuckerman's models draw extensively on work by Meehl (1962), Gottesman and Shields (1967), and Monroe and Simons (1991), who made the case for an interactive diathesis–stress relationship in the onset of schizophrenia and depression, respectively. As with his predecessors, Zuckerman's framework makes it clear that a diathesis is a predisposition, and as such creates a vulnerability to stress, but that vulnerability alone is insufficient to result in expression of the disorder. Rather, psychopathology results from the combination of that predisposition (which he argued is an enduring trait of the individual) and the experience of an environmental stressor (which he argues are objective and external to the individual; Figure 15.1). Notably, for Zuckerman, the term diathesis refers to "genetic and biological factors in the nervous system" (Zuckerman, 1999, p. 7), a point that we will return to later.

Zuckerman's contributions to the diathesis–stress concept are extensive. His contributions expand the relevance of the diathesis–stress model to a broader set of psychopathological outcomes, and make explicit what constitutes stress, diathesis, and their relationship. In doing so, he highlights two aspects of Monroe and Simons's (1991) work that enlarged upon the conceptualization of the diathesis–stress relationship relative to prior formulations (e.g., by Meehl and others). First, he defines a fan-shaped interactive relationship between stress and diathesis in predicting the onset of disorder. While it might seem like only a small step forward from Meehl's (1962) dichotomous-diathesis–stress interactive model, Monroe and Simons (1991) and Zuckerman (1999) present a quasi-continuous model, in which a *diathesis-threshold*

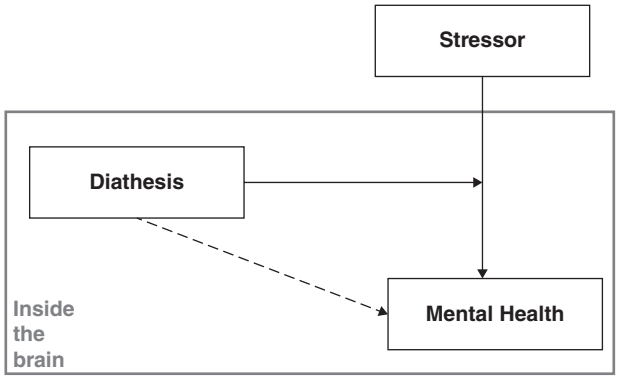

Figure 15.1 Traditional diathesis–stress model.

still exists (the level of the diathesis above which there is a positive relation between stress and disorder) but the strength of the positive relation now varies as a function of the level of the diathesis above this threshold. This is important because it allows for the conceptualization of a continuous diathesis, which was heretofore unacknowledged. Second, these models suggest that diathesis may predict the onset of stress. In this way, the experience of stress is not randomly distributed across persons, such that some (but indeed not all) stressors may be the result of the diathesis. For example, certain personality characteristics may elicit negative behavior from others, and these resulting negative interactions may be the daily stressors that, in interaction with the diathesis, cause the onset of disorder. In this way, the internal becomes external. As we discuss later, the newest models suggest the reverse may be true as well.

Importantly, Zuckerman (1999) also presents diathesis as having two components—the role of personality and the timing of stressor exposure (early in development versus at the onset of the disorder). In so doing, he argues for a dual-diathesis model—one aspect of which is mediated by personality and is the result of the effect of genes on the CNS, and a second aspect that has a biological basis in the nervous system that can originate from the environment. In other words, this second aspect of diathesis derives from the ongoing impact of the environment on the central nervous system (CNS). Such a conceptualization—in which environmental stressor exposure can become the basis of later vulnerability—is highly consistent with the model of stress and allostasis that we discuss later.

The mid- to late twentieth century saw a sweeping upsurge in interest in multilevel approaches that opposed one-sided accounts of biological versus psychosocial functioning (Belsky, 1997; Bronfenbrenner & Morris, 1998; Chrousos & Gold, 1992; Goldstein, 1995a, 1995b; Levine & Ursin, 1991; McEwen & Stellar, 1993; Sterling & Eyer, 1988; Walker & Diforio, 1997; Zuckerman, 1999). Indeed, the entire theory volume of the 2006 *Handbook of Developmental Psychology* is devoted to the implications of von Bertalanffy's (1952) general systems theory as applied to developmental science, which argues for mutually influencing and interactive processes across a multileveled system (Damon, Lerner, & Eisenberg, 2006). This increased consideration of multilevel and interactive perspectives has spanned biology, medicine, psychology, and sociology to foster diverse and comprehensive accounts of an organism's health and development.

Biological Sensitivity to Context

As the previous discussion makes clear, consideration of the multilevel and interactive perspectives inherent in diathesis–stress models of psychopathology is in fact quite young—having emerged over the last few decades from relatively one-sided views of the sources of psychopathology (environment-only versus biology-only). Yet these earliest accounts represent a relatively straightforward formulation of the interaction between diathesis and stress (Figure 15.2a.). As we discuss later, the last 5 years or so have seen a reconsideration of the *form* of that interaction. Gone are discussions of whether it is biology or environment that is the source of psychopathology. However, there is continued debate about precisely *how* stress and diathesis interact to jointly produce psychopathology, as well as about the mediating processes of that relationship.

In Belsky's *differential susceptibility theory* (Belsky, Bakermans-Kranenberg, & van IJzendoorn, 2007), genetic factors do not make children vulnerable; instead, such children are susceptible or *plastic* to environmental influences.

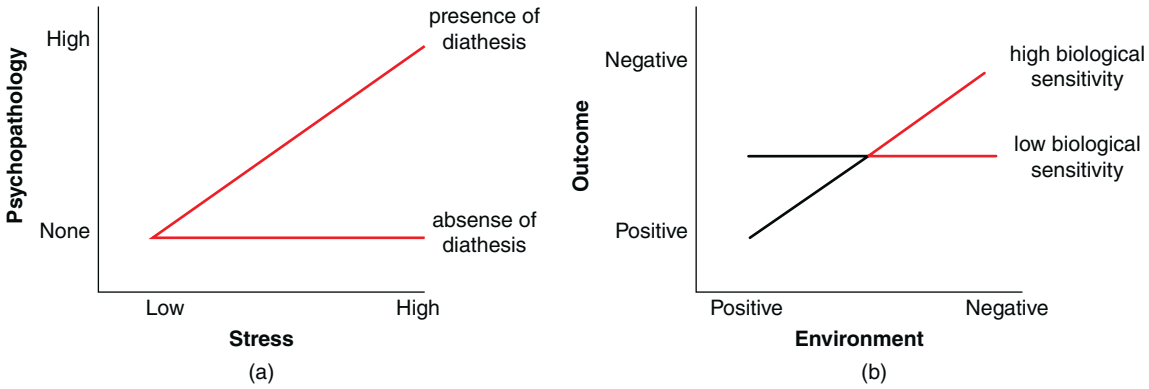

Figure 15.2 Diathesis–stress models. Traditional diathesis–stress model (a). Diathesis–stress model based on differential susceptibility theory/biological sensitivity to context (b). See footnote 1. *Source:* Adapted from Belsky et al. (2007).

As such, the same vulnerability factor that conferred risk in the context of poor environments confers intellectual or social-emotional benefits in positive environments. Statistically, this requires a crossover interaction (rather than a fan-shaped interaction), in which the slope for the susceptible group is different from zero and steeper than that for the nonsusceptible group (which is ideally zero; Figure 15.2b.). In this way, susceptible children are more strongly influenced by environmental influences, but how those children fare depends strongly on the valence of that environment's influences. Thus, the diathesis is less of a precondition or threat to psychopathology and more of a measure of plasticity. Belsky draws heavily on evolutionary theory to suggest that having children varying in susceptibility to different environmental contexts is advantageous because it creates heterogeneity within the population. He cites both experimental and nonexperimental evidence to suggest that some children previously considered vulnerable may actually be the most plastic and benefit the most from positive rearing conditions (Belsky et al., 2007).

Boyce and Ellis's (2005) *biological sensitivity to context* theory provides a rendition of the diathesis–stress interaction that seems empirically similar to Belsky's, but has critical conceptual distinctions. In Boyce and Ellis' formulation, stress reactivity has the potential for negative effects under conditions of adversity and positive effects under conditions of supportive environments. But unlike Belsky's formulation, these highly reactive phenotypes are *not* highly malleable, in that they are inflexible in the face of a variety of ecological conditions. Rather, they are highly responsive to both the threats and dangers in high stress environments, as well as to the social supports in highly supportive environments. It is this increased vigilance or awareness to environmental influence that results in their highly divergent outcomes across contexts.

If we are proposing to model the etiology of psychopathology (the dark side of adaptation), one might think there is little difference between diathesis–stress theories and their more optimistic cousins, differential susceptibility theory (e.g., Belsky et al., 2007) and biological sensitivity to context theory (Boyce & Ellis, 2005). For negative outcomes, all of these theories make precisely the same *statistical* prediction, that is, that an interaction between a preexisting vulnerability and a stressor will drive maladaptation (Roisman et al., 2012). However, these theories do differ with regard to the underlying process by which the interaction between diathesis and stress occurs, and the nature of what happens in high-quality environments.

The interactive nature of stress and diathesis is not the only contribution that Boyce and Ellis (2005) bring to this discussion. As they describe, these biological predispositions are partly the *result* of adaptations of stress-response systems to the environment (although genes and gene–environment interactions are also sources of such predispositions). In the context of low-stress environments, the high reactivity phenotype serves to support children in eking out the good in the environment, allowing them to benefit especially well. But, in the context of highly stressful environments, high reactivity serves to ready the individual to respond to stress, even if it has physiological costs. But to fully understand those physiological costs, we turn to a discussion of how the brain plays a role in this diathesis–stress model of psychopathology.

DIATHESIS AND STRESS IN THE BRAIN

In diathesis–stress models of psychopathology, the brain has consistently been portrayed in the literature as a key mediator of diatheses (e.g., Meehl, 1962; Zuckerman, 1999). Not so the stress process. Stressors are modeled as external (e.g., Zuckerman, 1999) and the stress process itself has largely been conceived as having bottom-up effects on the brain through homeostatic processes and hypothalamic-adrenal-pituitary (HPA) axis effects. We argue here that placement of the brain as the primary mediator of the stress process is potentially transformative for thinking on diathesis–stress models of psychopathology. To fully understand this work, we begin with a brief history of the stress process with attention to the inclusion over time of the role of the brain.

The Stress Concept

Cannon and Selye

Stress research shares common origins in the work of Walter Cannon (e.g., Cannon, 1932) and Hans Selye (e.g., Selye, 1956). In Cannon's conceptualization, the sympathetic-adrenal medullary system mobilizes the body's energy resources by increasing epinephrine (adrenaline), which in turn increases blood pressure, heart rate, and blood sugar, as well as hastening blood coagulation, clearing fatigue products from muscles, and decreasing digestion (Cannon, 1920). In Cannon's view, these processes occurred locally in the body, independent of central nervous system (CNS) control (and hence did not involve the brain). He used the term *homeostasis* to refer to the way this array of independent physiological systems works together to reestablish initial conditions when the system is perturbed (Cannon, 1932).

By the mid-twentieth century, Hans Selye demonstrated that an organism has an adaptive response to adversity that includes both Cannon's sympathetic (adrenaline-driven) responses plus the actions of hormones from the pituitary gland, which globally affect the major organs of the body in indirect but important ways (e.g., Selye, 1956). Selye proposed the existence of a generalized physiological syndrome that occurs in response to a great diversity of threats to the integrity of the organism (e.g., Selye, 1956). The syndrome included three stages of physiological response to stressor exposure, which he called the General Adaptation Syndrome or GAS (Selye, 1956). The first stage is the sequential actions of the hypothalamic-pituitary-adrenal (HPA) axis, including production of corticotropin releasing hormone (CRH), the resulting release of adrenocorticotropin releasing hormone (ACTH), and the production of glucocorticoids (cortisol, in humans) (*alarm stage*). In the second stage, overt symptoms of stress are often reduced or disappear. In the final (*exhaustion*) stage, physiological defenses are depleted and the organism will die if the stressor is not released. For Selye, stress was "that which stimulated the GAS response" (1956, p. 54).

Selye's claims for the scope of the application of the GAS were very broad and his work prompted thousands of articles across medicine, psychology, sociology, and biology (Goldstein, 1995b; Mason, 1975). However, while expanding the concept of homeostasis (Bernard, 1878; Cannon, 1932), his work retained many of the omissions inherent in Cannon's original conceptualization, including inattention to the significance of psychological state, anticipation, coping, life history, and environmental context beyond the specific stressor (Burchfield, Woods, & Elich, 1980; Mason, 1975; Toates, 1995). Moreover, Selye wrote of a hypothetical neural or endocrine common mediator that lies between application of the noxious stressor and the GAS response (1950, p. 105). This unknown common mediator would serve to receive and integrate local inputs and then transmit generalized messages to all parts of the body to activate the GAS response, including facilitating changes in regulatory (i.e., homeostatic) set points during the stage of resistance (e.g., Selye, 1950, 1956). Selye never identified this critical common mediator.

Work following Selye balked at these gaps with increasing intensity. For example, in psychosocial research, it was noted the measurement of the *valence* or the level of *threat* posed by a given stressor often improved the amount of variance explained in the outcomes (Brown & Harris, 1978; Dohrenwend, Ashkenasy, Krasnoff, & Dohrenwend, 1978; Holmes & Rahe, 1967; Pearlin & Schooler, 1978; Wheaton, 1999). Changes in stressor *context* over time also made significant independent contributions to the outcomes of stress models (e.g., Baltes & Baltes, 1990; Furstenberg, Brooks-Gunn, & Morgan, 1987**;** Hobfoll, Johnson, Ennis, & Jackson, 2003; Holahan, Moos, Holahan, & Cronkite, 1999; Lazarus, 1993; 1999; Masten et al., 1988; Rutter, 1979; Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987), as did individual differences in cognitive and emotional response (e.g., anticipation, appraisal, coping, learning, and other types of information processing: Foa & Kozak, 1986; Holahan, Moos, Holahan, & Cronkite, 1999; Ironson et al., 2000; Lazarus, 1991; Siegal & Allan, 1998; Sterling & Eyer, 1988; Stone, 1995; Toates, 1995; Tolin & Foa, 2002; Wheaton, 1985). Taken together, this body of work has stretched the psychosocial requirements for models of the stress process well beyond the classical homeostatic perspective or the GAS.

Similarly, within biomedical research, evidence of the influence of cognitive and affective processing on the stress process was also prompting reconsideration of classical homeostasis and Selye's GAS (Mason, 1971, 1975; Pacák & Palkovits, 2001; Schulkin, 2004). For example, Mason (1971, 1975) documented substantial variation in elements of the GAS response as a function of the stressor context, the individual's history, and the individual's perception of the noxiousness of the stressor, thus raising questions about the specificity of the "nonspecific" GAS response (also see Pacák & Palkovits, 2001). "The knowledge that the psyche is superimposed upon the humoral machinery for endocrine regulation drastically complicates our whole view . . . " (Mason, 1975, p. 177). Thus, the biomedical stream of stress research also found itself in need of a model that included appraisal, cognition, and affective (or emotional) state as primary elements of the stress process (Frankenhaeuser, 1980; Moore-Ede, 1986; Weinberg & Levine, 1979).

The Brain Enters the Stress Process

This work set the stage for Sterling and Eyer (1988) to propose the concept of *allostasis*, which holds that the central nervous system (CNS) exerts executive control over all physiological regulatory responses to environmental demand in the alert, intact organism (see Figure 15.3). CNS control of the stress response, in turn, allows the regulatory set points of the organism to vary in response to environmental demand (McEwen & Wingfield, 2003; Sterling & Eyer, 1988). This placed the CNS in general, and the brain in particular, squarely in the role of Selye's common mediator between environmental demand and physiological response (1950).

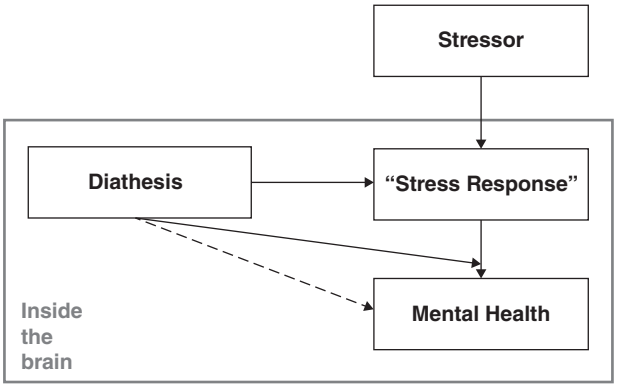

Figure 15.3 Bringing stress into the brain. The most basic diathesis–stress model of response to a current stressor is presented as a traditional psychosocial *stressor → stress response → distress* model of the stress process; with the exception that the processes are represented as occurring within the brain (the solid gray line represents operations that occur within the brain, within which all processes are biological).

This work went largely unnoticed at the time of its publication. Three years later, Levine and Ursin (1991) proposed that the sensory input from all types of stressors is gated through the brain before affecting any other physiological regulatory response, and that this input is modified by expectation and evaluation. They argued that this is true even for stressors that do not appear overtly psychological, such as cold exposure and tissue damage, because novelty, expectation, and efforts to avoid noxious stimuli will all activate brain responses (Levine & Ursin, 1991). Soon after, Chrousos and Gold (1992) and Goldstein (1995a, 1995b) independently proposed a model in which homeostasis resets itself in response to stress exposure, and Goldstein (1995b) argued that "distress invariably resets homeostasis." P. 41. Thus, by the end of the twentieth century, it was clear that homeostasis required revision to account for the influences of environment and the CNS on physiological regulation.

None of these proposed modifications of homeostatic theory addressed the accumulating consequences of physiological accommodation to environmental challenge over the life span. This prompted McEwen and Stellar (1993) to introduce the concept of *allostatic load*, which they defined as the physiological cost of making long-term adaptive shifts across a broad range of systems to match internal functioning to environmental demand. With the inclusion of allostatic load as a key element of the theory, allostasis became the most comprehensive account of regulatory accommodation to environmental demands and accumulated physiological cost over time. The adaptation and dissemination of allostatic theory by McEwen and an expanding cohort of colleagues is lending allostasis the status of "a new conceptual framework" (Schulkin, Gold, & McEwen, 1998, p. 220) for the study of stress (e.g., McEwen, 1998, 2000, 2001, 2003; McEwen & Seeman, 2003; McEwen & Stellar, 1993; McEwen & Wingfield, 2003; Schulkin, 2004; Schulkin, McEwen, & Gold, 1994; Singer, Ryff, & Seeman, 2004).

The concept of allostasis provides us with a new approach to specifying the mechanisms of the diathesis–stress model of mental disorder. In particular, it suggests a need to update the classic diathesis–stress model to include the role of the brain in the stress process. In the following sections, we will argue that the process by which diathesis and stress result in psychopathology occur through the central mechanisms of allostasis. A key consequence of model is that diathesis is no longer static, but is dynamically changing over time. Articulating this process requires that we briefly specify these mechanisms.

Allostasis Situates the Brain in Diathesis–Stress Models

Allostasis and Response to a Current Stressor

In prior work, we used the theory of allostasis as the foundation for a model of the ongoing stress process (Ganzel et al., 2010). The most basic model of allostatic accommodation to a current stressor (Figure 15.4) is presented as a classic psychosocial *stressor → stress response → distress* model of the stress process. In this model, the stress response allows the resetting of homeostatic set points during the process of reestablishing physiological equilibrium during and after stressor exposure (i.e., allostasis). From the previous discussion (Figure 15.3), recall that the brain is the central mediator of allostasis (e.g., McEwen, 2007; Sterling, 2004; Sterling & Eyer, 1988).

Allostatic response and adaptation to a current stressor can be viewed as a two-stage process, wherein a brain-based *central allostasis* has executive control over *peripheral allostasis* in stress-responsive physiological systems external to the central nervous system (which in turn have critical feedback on the brain: for a full discussion, see Ganzel et al., 2010). These effects include, but are not limited to, production of stress hormones and catecholamines, inhibition of the reproductive system; and alterations of metabolism, cardiovascular activity, and gastrointestinal and immune system function (Davis, Walker, & Lee, 1997; Heinrichs, Menzaghi, Pich, Britton, & Koob, 1995; Maier & Watkins, 1998; Stratakis & Chrousos, 1995). These processes feed back on the brain via interoceptive, hormonal, catecholamine, and immune signals (Damasio, 2003; Davidson, Maxwell, & Shackman, 2004; Sapolsky,

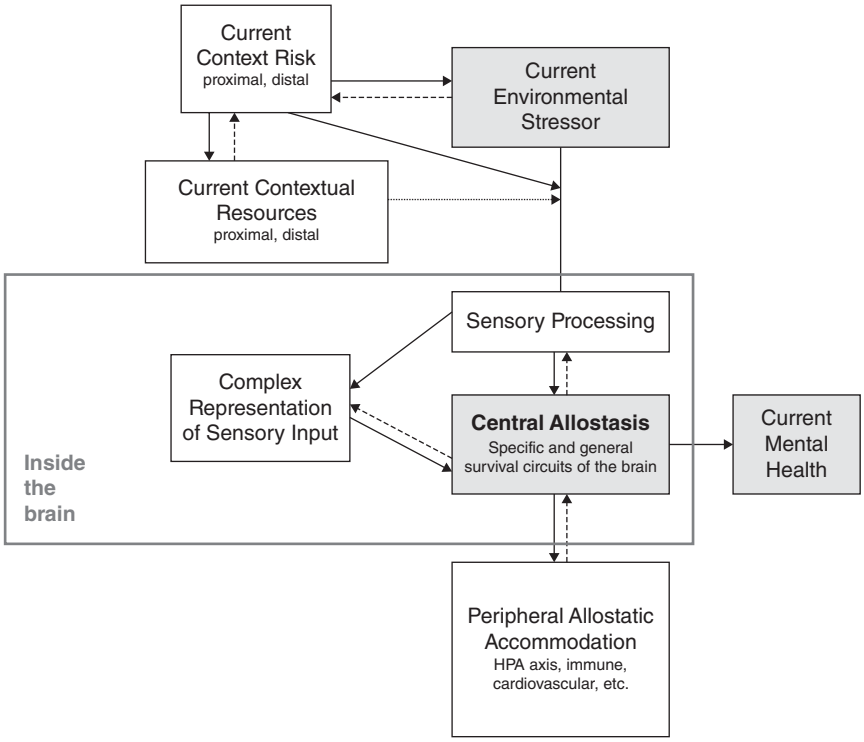

Figure 15.4 An allostatic model of response to a current stressor. Here, the brain is shown as a dynamically adapting interface between ecological challenge (in context) and the biological self. This model shows the role of central and peripheral allostasis in predicting mental health. Dotted lines indicate active feedback. Interaction would be expected between allostatic load and major pathways of allostatic accommodation (not shown). The role of genes is not shown here. *Source:* Adapted from B. L. Ganzel, P. A. Morris, & E. Wethington, Allostasis and the human brain: Integrating models of stress from the social and life sciences, *Psychological Review, 117*(1), 134, 2010.

1998) and create iterative sequelae of physiological and psychological effects over time in response to the trigger stimulus, as discussed later. This central-peripheral distinction allows us to specify the neural mechanisms underlying the moment-to-moment physiological response to a current stressor.

Genes serve as an additional source of input to these processes (Figure 15.5). As with a classical diathesis–stress model, there is a role for both biological and social/environmental processes. But stress gets under the skin and into the brain/body system, so our model posits that diathesis is not biological and stress is not external—but rather both are deeply embedded within convergent neural processes.

Previously, we highlighted the brain's *survival circuitry* (LeDoux, 2012) and its closely linked domain-general modulatory processes[5] as the neural front lines of allostasis, and we reviewed the evidence that these brain regions are particularly vulnerable to the accumulated wear and tear of allostatic load (Ganzel et al., 2010). There are multiple, overlapping survival circuits in the brain, each of which detects a particular class of trigger stimulus (e.g., defense–avoidance, reward, energy and nutritional maintenance, fluid balance, thermoregulation) and then integrates relevant sensory and motor information to drive adaptive response behavior (LeDoux, 2012). The triggers for each survival circuit are *salient*, either because they have intrinsic biological value (stimulating stereotypical approach or avoidance behaviors) or because they have learned, personal value (for discussions, see LeDoux, 2012). These specific survival circuits, together with a general-purpose modulatory system, form an interconnected network that serves to represent salient stimuli and produce and regulate behavioral response. This extended (specific + general) survival network constitutes the central motivational states of the brain (Rosen & Schulkin, 1998) that underlie human behavioral adaptation to the environment (also see core affect: Barrett, Mesquita, Ochsner, & Gross, 2007; Bechara, Damasio, Damasio, & Anderson, 1994; Damasio, 1999; LeDoux, 2012). We have argued that

[5]Termed the core emotion systems of the brain in our prior work (Ganzel & Morris, 2011; Ganzel et al., 2010). Also see discussion on this topic by LeDoux (2012) and Barrett and Satpute (2013).

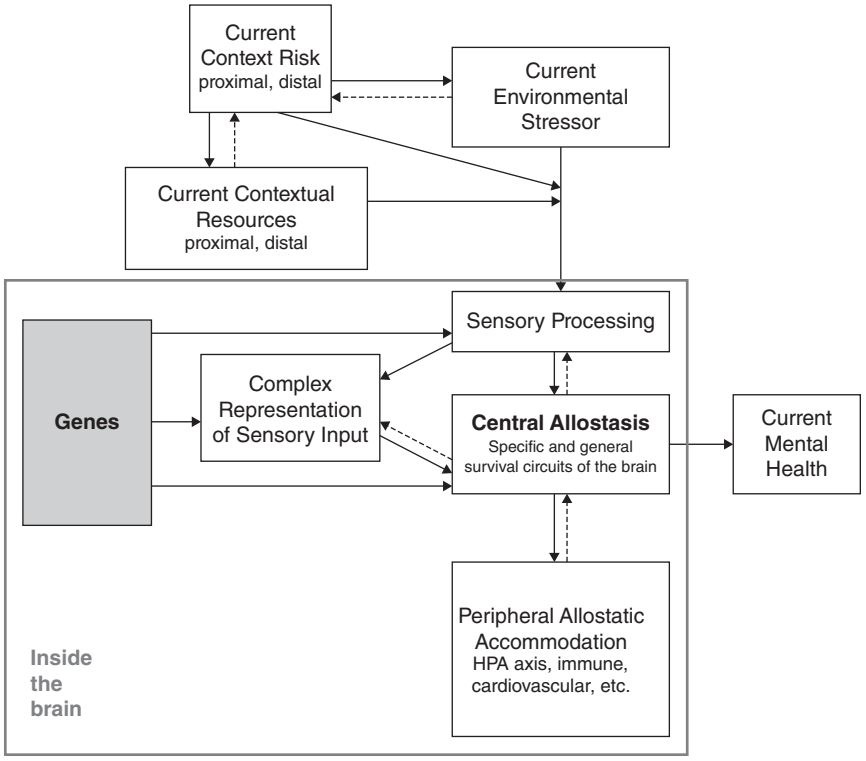

Figure 15.5 The direct effect of genes on central allostasis. Here, we emphasize the main effect of original genetic compliment on central allostasis, but we note that genes are also likely to serve as a moderator of associations within central and peripheral allostasis. We also anticipate an effect of genes on input to the model—that is, on current contextual risk, current contextual resources, and the current stressor itself.

this extended survival circuitry is also the main organizing factor in allostasis (i.e., in the translation of stressor exposure into a behavioral or physiological stress response) and thereafter into stress-related changes in mental health (Ganzel et al., 2010). Variously called the limbic system (but see LeDoux, 1996, pp. 98–102) or the emotional brain (but see Barrett & Satpute, 2013), this extended survival system is at the heart of the diathesis–stress model.

We will focus on the *defense circuit* (LeDoux, 2012) as our exemplar of a specific survival circuit. The defense circuit detects and responds to threat; it includes the amygdala and periamygdaloid regions, hippocampus, thalamus, hypothalamus, midbrain periaqueductal gray, and the basal forebrain/brainstem nuclei that underlie stress-related neurotransmitter production, all which work together to process threatening stimuli and facilitate behavioral response (e.g., Armony & LeDoux, 1997; Davis et al., 1997; LeDoux, 1996; Phan, Wager, Taylor, & Liberzon, 2002; Phelps, 2004, 2006). Other key survival circuits exist. Notable among these is the reward circuitry of the brain, within which the ventral striatum plays a key role. The amygdala and ventral striatum are highly connected with one another and with the anterior insula, with which they share many functional similarities.

The more domain-general modulatory regions (e.g., insula, anterior cingulate cortex, orbitofrontal cortex) integrate information from multiple survival circuits with interoceptive information and prior experience to provide threat evaluation or response modulation (e.g., Bremner & Vermetten, 2001; Kaufman & Charney, 2001; Sanchez, Ladd, & Plotsky, 2001) (also see supporting human neuroimaging data : e.g., Dolcos, LaBar, & Cabeza, 2004; H. Kim et al., 2004; Urry et al., 2006; Wager, Phan, Liberzon, & Taylor, 2003). The high level of structural and functional connectivity between these brain regions and the rest of the cortex allows this extended defense circuitry to recruit and integrate a wide range of the brain's computational resources to process threatening or stressful stimuli (Pessoa, 2008; Stephan et al., 2000). Such stimuli effectively engage attention, inhibit other activities (Choi & Brown, 2003; Gray, 1987; Petrovich, Setlow, Holland, & Gallagher, 2002), and are prioritized in the competition for processing resources in the brain (e.g., Anderson, 2005; Ohman, Flykt, & Esteves, 2001; Vuilleumier, Armony, Driver, & Dolan,

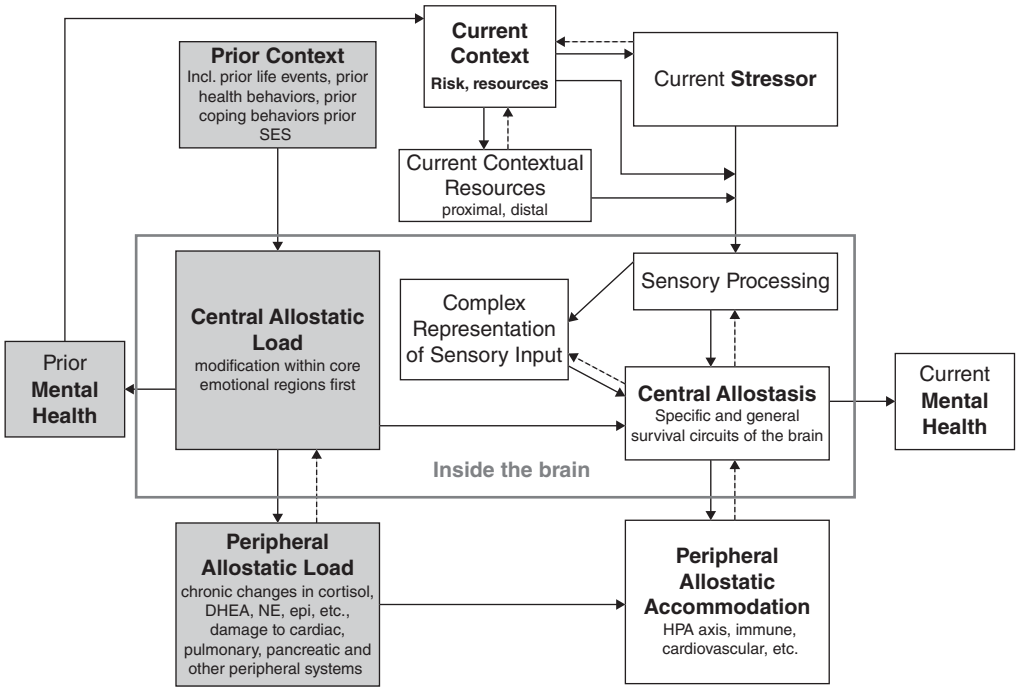

Figure 15.6 Including allostatic load in the model. The allostatic model, including the role of central and peripheral allostatic load in the response to a current stressor. Interaction would be expected between allostatic load and major pathways in central allostatic accommodation (not shown). The role of genes is not shown here. *Source:* Adapted from B. L. Ganzel, P. A. Morris, & E. Wethington, Allostasis and the human brain: Integrating models of stress from the social and life sciences, *Psychological Review, 117*(1), 134, 2010.

2001). This provides salient (in our exemplar, threatening) stimuli with a privileged status[6] in the brain (Davidson et al., 2004; LeDoux, 2012) and underscores the critical role that the survival circuits play in allostasis.

Allostasis Across Time: Allostatic Load

The expanded version of this model (Figure 15.6) shows the accumulation of physiological wear and tear in the form of allostatic load (McEwen & Stellar, 1993). Under chronic and repeated exposure to stressors, the short-term gains of allostatic accommodation are reduced and associated physiological adaptations may become entrenched and automatic (e.g., chronic high blood pressure: Sterling & Eyer, 1988). In this figure, previous stressors have also contributed to the need for allostatic accommodation, which, over time, has accumulated in the form of allostatic load. Acquisition of load, in turn, affects the individual's ability to respond to a current stressor. In this way, the body carries with it the long-term results of prior experiences into its current responses to a stressful event (Geronimus, Hicken, Keene, & Bound, 2006).

The relationship between stressor exposure and adaptive physiological outcomes takes the form of an inverted U-shaped curve (e.g., McEwen & Lasley, 2002). With mild stressors, the accumulation of load that results from ongoing allostatic accommodation is likely to be negligible—well within the elastic limit of human resilience described by Cannon (1932) in his engineering model of stress. In the adaptive portion of the U-shaped curve, the benefits of allostatic accommodation outweigh the costs. Moderate amounts of stress (good stress or eustress: Lazarus, 1966; Selye, 1974) may be associated, for example, with enhanced neurogenesis (e.g., Kirby et al., 2013; Rhodes et al., 2003), improved brain metabolism and enhancements of neuronal architecture (e.g., Kempermann, Kuhn, & Gage, 1998; Sirevaag & Greenough, 1988), improved executive function (Colcombe et al., 2003), and improved immune system function (Sapolsky, Romero, & Munck, 2000). For example, moderate amounts of exercise are associated with increased cortical plasticity and improved executive function, even in adults (Colcombe et al., 2003). However, allostatic load will increase over time when allostatic accommodation to a

[6]We note that this privileged status is vulnerable to high attentional load and strongly competing sensory input (e.g., Pessoa, Japee, Sturman, & Ungerleider, 2006; Pessoa, McKenna, Gutierrez, & Ungerleider, 2002).

stressor is sustained, when it is repeated, or when it is large (McEwen, 1998, 2000; McEwen & Stellar, 1993). Studies of peripheral allostatic load using a composite index of biological risk factors (e.g., cortisol, norepinepherine, epinephrine, glycosated hemoglobin, systolic and diastolic blood pressure, cholesterol, waist-to-hip ratio) suggest that load is accumulated according to stress dosage, such that increased stressor exposure is associated with increased load (e.g., Brody et al., 2013; Evans, Kim, Ting, Tesher, & Shannis, 2007; Glover, Stuber, & Poland, 2006). In addition, different types of stressors are likely to accumulate allostatic load somewhat differently, and accommodation to some types of stressors may be more costly than others (Alleva & Santucci, 2001; Pacák & Palkovits, 2001).

The tipping-point in the inverted U-shaped curve is the point at which a healthy challenge becomes a progressively unhealthy stressor. Healthy exercise, for example, can segue to being worked to death. Within the body, there is a point at which stressor exposure begins to compromise immunity, neurogenesis, dendritic growth in the hippocampus, and the host of other negative physiological consequences of increasing stressor exposure (for a review of these, see Ganzel et al., 2010). In terms of the present model, this is the point at which the process of allostatic accommodation begins to generate deleterious amounts of allostatic load. Under chronic, repeated, or severe stress, the short-term gains of allostatic accommodation dwindle, while its physiological adaptations become entrenched and automatic (fixed automatisms, see: Sterling & Eyer, 1988) and the long-term physiological costs of that sustained accommodation continue to accumulate. Under extreme stress, this process may happen very quickly.

Fast or slow, continuing accrual of load-related symptoms will be physiologically overwhelming and ultimately lethal, as described in Selye's general adaptation syndrome (GAS; Selye, 1950, 1956). On the way to the deadly end of stage three of the GAS, it is increasingly likely that the individual will experience physiological and/or psychological failure to compensate for intolerable levels of stressor exposure (e.g., Seeman et al., 2004; Seeman, McEwen, Rowe, & Singer, 2001; Seeman, Singer, Rowe, Horwitz, & McEwen, 1997). That individual's diathesis will determine when decompensation is reached, and how, but no one is exempt. Vulnerable individuals simply reach decompensation earlier and perhaps in a nonstandard way.

Allostasis Across the Life Span and Generations: Epigenetics

Finally, recent work suggests that continuity in load and its associated physiological consequences may reflect intergenerational contributions of environmental experience through *epigenesis,* or environmental effects on gene expression (Moffitt, Caspi, & Rutter, 2006). What is important for this discussion is that stress in the environment may result in changes in DNA expression that can have implications for an individual's physiology and mental health throughout that individual's own life span and for subsequent generations (Harper, 2005). As such, environmental conditions present in one generation are remembered in the behavioral and physical responses of the subsequent generation even after the precipitating environmental conditions have ended (see Harper, 2005, for a discussion). Some of the most compelling empirical evidence driving this theory comes from studies of rodents in Meaney's lab (Champagne, 2010; for reviews, see Diorio & Meaney, 2007; e.g., Francis, Diorio, Liu, & Meaney, 1999; Weaver et al., 2004). This work demonstrates that rat pups who experienced low levels of maternal care during the first week of lactation go on to show more fear of novelty as adults and increased HPA-axis reactivity to stressors, relative to pups who experienced higher levels of care from their mothers.

In this example, DNA methylation patterns appear to be the key mediating mechanism (Weaver et al., 2004). That is, alterations in the methylation of a glucocorticoid receptor gene affect the hippocampus' ability to regulate glucocorticoid negative feedback on the HPA axis, producing a lasting increase in HPA-axis response in offspring who received lower levels of maternal care (Weaver et al., 2004). This is an example of epigenetics serving as the mechanism through which environmental conditions produce central allostatic accommodation to environmental challenge (for a discussion, see Ganzel & Morris, 2011). This environmentally-mediated epigenetic alteration in hippocampal function carries forward in the life of the rat pup as allostatic load. These changes appear to have long-lasting implications to future generations (Champagne, 2010). Notably, parallel processes may take place among humans, as demonstrated by evidence that severe food shortages during pregnancy have similar lasting effects on later health of the child (physical growth; Susser & Stein, 1994). In this way, epigenetics serves as a key process by which early experiences may carry forward to bring lasting modifications in the individuals' response to stressors at later points in development and in future generations. These discoveries require diathesis–stress models of psychopathology to reflect past history of adversity. Future models might benefit from including past history of the parent generation, as well (for a first foray, see Ganzel et al., 2010).

THE CASE FOR A CONSTANTLY CHANGING BRAIN

In a prior theory paper (Ganzel & Morris, 2011), we presented a set of models that were a first step toward a more developmentally informed understanding of allostasis and stress-related health outcomes. In that work, we touched on how stress-sensitive periods may manifest as windows of plasticity, on one hand, and as windows of vulnerability on the other. Our aim in the present chapter is to expand on this previous work by applying it to diathesis–stress models of the origins of psychopathology.

To best do so, we will first provide an overview of early brain development. As with other complex systems, brain development is observable across multiple levels of analysis. So to lay the groundwork for our allostatic diathesis–stress model, we weave together information from multiple levels of analysis, from molecules to genes to large-scale neural networks. Activity across these levels of analysis can be observed across a wide range of time spans (milliseconds to years) using multiple methods of measurement. Electroencephalography (EEG) measures millisecond changes in voltage from the scalp that directly indicate electrical current flow in neurons. Magnetic resonance imaging (MRI) gives a static measure of tissue densities in the brain, thus providing a spatially detailed map of brain structure that we discuss here as gray matter and white matter. Diffusion tensor imaging (DTI) allows the mapping of white matter fiber tracts and their integrity. Functional MRI provides a dynamic (although indirect and somewhat slowed) measure of brain activity—usually in response to a stimulus or task (fMRI) but also in the resting state (RSFC). These are all techniques that can be used to study the brains of living people; we will also refer to findings from studies of dead brains (e.g., immunohistochemistry of autopsy tissue), which provide very detailed information about brain structure that cannot be obtained from living humans. Our goal here is to provide relevant snapshots of brain development at these several levels of analysis to illustrate our point that the brain undergoes constant nonlinear change across the life span. We then develop our allostatic diathesis–stress model within this framework.

We will begin with a focus on the relatively early-maturing processes that underlie increasing *functional specificity* within local (several cubic millimeters) ensembles of neurons or *nodes*. We follow with a discussion of the slower-growing white matter tracts that link these nodes into mature *functionally integrative* large-scale *neural networks* that span the entire brain (Hagmann et al., 2010; Honey et al., 2009; Stevens, 2009; van den Heuvel, Mandl, Kahn, Pol, & Hilleke, 2009). The vastly enlarged capabilities of the mature human brain are thought to be supported by synchronous neural activity within these complex large-scale networks (e.g., Fair et al., 2007; Fries, 2005) and there is increasing evidence that dysfunction within these networks plays a prominent role in psychopathology (Menon, 2011; Uhlhaas & Singer, 2012). The emergence and senescence of these nodes and networks across the life span creates a constantly changing neural landscape within which diathesis and stress intersect to predict mental health. This sets the stage for the subsequent section, in which we integrate this information into new diathesis–stress models.

Early Human Neurodevelopment

The central nervous system (CNS) begins to form during the first few months of fetal development in humans (the first few weeks of gestation in rodents; Rice & Barone, 2000). The neural plate is formed first via neural induction, then a further series of inductive processes leads to the expression of different developmental programs within distinct subregions of the new neural plate. These dictate the formation of the major subdivisions of the CNS and the early progenitors of its major structures (e.g., Rakic, 1995; Rubenstein, 2009). Subsequently, region-specific early precursor cells proliferate outward following radial glial processes. In the process, they undergo differentiation, axogenesis, synaptogenesis, pruning, and myelination as they form the mature neural circuits that underlie normal physiological function and complex behavior (Caviness & Takahashi, 1995; Oda & Huttenlocher, 1974; for a comprehensive review, see Rubenstein & Rakic, 2013).

The wiring of the human nervous system is accomplished through the construction and sculpting of connections that foster information exchange among multiple cell types (e.g., Courchesne, Chisum, & Townsend, 1994). The two primary cell types within the brain are neurons and neuroglia (glia). In neuroimaging terms, neurons make up the gray matter of the brain, which is composed of neuronal cell bodies, dendrites, and short axons, while neuroglia (oligodendrocytes in particular) make up the white matter of the brain, the most visible element of which is the pale-colored myelination on long neural axons that connect regions of gray matter (e.g., Wonders & Anderson, 2006). In the period between the third prenatal trimester and the third year of life in humans, a period of heightened apoptosis (programmed cell death) eliminates about half of previously generated neurons (e.g., Davies, 2013; Lossi & Merighi, 2003). In the mature brain, the ratio of

neurons to glia varies by brain region. For example, the adult human cerebral cortex has approximately four times more glia than neurons, while the cerebellum has four times more neurons than glia (Pelvig, Pakkenberg, Stark, & Pakkenberg, 2008).

Neurons have long been considered the core components of the nervous system, and the mechanisms that guide neuronal maturation and senescence are well studied (e.g., Rubenstein & Rakic, 2013). Until relatively recently, however, neuroglia have been thought to play passive structural or housekeeping roles in the brain (e.g., myelination, ionic homeostasis, metabolic support of neighboring neurons and glia: Kurth & Huber, 2012; Parpura & Verkhratsky, 2012; Wang & Bordey, 2008). It has become clear, however, that different classes of neuroglia variously (1) interact with neurons to allow signal transfer at synapses, (2) play a critical role in brain development (for a review, see Wang & Bordey, 2008), (3) function as neural stem cells (e.g., Cameron, Woolley, McEwen, & Gould, 1993; Doetsch, Caillé, Lim, García-Verdugo, & Alvarez-Buylla, 1999) and as precursor cells for other types of glia (e.g., Alvarez-Buylla & Kriegstein, 2013). There is also preliminary evidence that glia (e.g., oligodendrocyte precursor cells) may use neurotransmitters to signal to other glia to allow ongoing plasticity in white matter structure and thus promote ongoing plasticity in the functional capabilities of neural networks (Alvarez-Buylla & Kriegstein, 2013). The fact that both neurons and glia play unique and critical functions in the brain argues for the consideration of both in a developmentally informed diathesis–stress process.

Early Functional Specialization of Local Neural Networks: Focus on Gray Matter

Early Cortical Development via Proliferation and Pruning

In humans, much of the basic adult form of the brain (overall size, weight, cortical folding, and rudimentary functional specialization) is in place by early to middle childhood (Armstrong, Schleicher, Omran, Curtis, & Zilles, 1995; Giedd et al., 1999). During this time, local brain areas begin to develop varying levels of specialization, i.e., they learn to process specific types of information in specific ways. Refinement of functional specificity in local information processing involves the formation and experience-dependent remodeling of synapses. This process is largely complete by young adulthood. This early phase of adaptive organization/re-organization is instantiated in developmental changes in gray matter thickness, which are measurable using magnetic resonance imaging (MRI: e.g., Good et al., 2001). Cortical (gray matter) thickness rises and falls across the life span; it is greatest around 10 years of age in girls and around 12 years of age in boys (e.g., Giedd, 2004; Sowell et al., 2003; Westlye et al., 2010b). Different brain regions vary as to when they reach maximum thickness. In general, the human brain develops from posterior to anterior and from the medial regions out to the lateral portions of the brain. For example, the occipital pole (the primary visual processing area at the very back of the brain) is one of the first brain regions to reach its maximum gray matter thickness (at about age 7.5 years; e.g., Shaw & Gross, 2008), while the superior and lateral prefrontal regions are among the last to reach their maximum thickness at ages 10–12 (between 10 and 12 years of age: Giedd, 2004; Shaw & Gross, 2008). Maximum thickness does not, however, define the maximum *adult* cognitive capacity that is yet to come.

In humans, neural synaptogenesis and the expression of synaptic genes in the prefrontal cortex begin to rise steeply before birth; this continues until the fifth postnatal year, after which rates increase more slowly until about age 10 (Liu et al., 2012). Increased synaptogenesis is associated with enhanced cortical plasticity and roughly coincides with increasing gray matter thickness and increases in cognitive capacity (McArdle, Ferrer-Caja, Hamagami, & Woodcock, 2002). This early proliferation of synapses is countered by bouts of accelerated synaptic pruning, the first of which occurs in early childhood and the second of which occurs during later adolescence (Gogtay et al., 2004; Rakic, Bourgeois, & Goldman-Rakic, 1994). During pruning, the neurons themselves are preserved but any neural connections (synapses and dendrites) that have not undergone experience-dependent strengthening are eliminated, leaving a more efficient circuit, as well as room in the skull for continuing myelination (for a discussion, see Paus, Keshavan, & Geidd, 2008). Pruning is argued to streamline the neural circuitry of the brain to *do best what it has been doing,* and it thus defines a period when experience may profoundly shape brain structure and function (i.e., the spontaneous or evoked activity of a neural system specifies its long-term connectivity: e.g., Changeaux & Danchin, 1976; Huttenlocher & Dabholkar, 1997).

The effects of synaptic pruning during adolescence are profound (see Figure 15.7). Postmortem studies allow direct count of synapse density. Such studies of humans and macaques have found a 50 to 55% decrease in the number of synapses across the entire cortex between late childhood and early adulthood (Good et al., 2001; Huttenlocher & Dabholkar, 1997; Rakic, Ayoub, Breunig, & Dominguez, 2009). These findings are reflected in MRI research, which has identified a 40% thinning in cortical

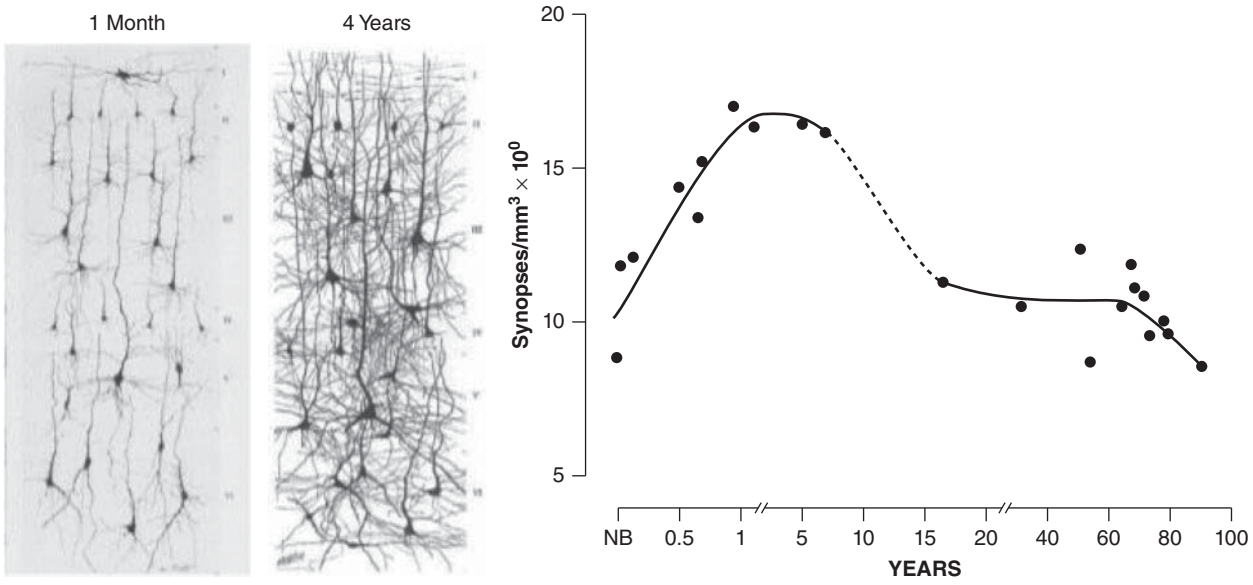

Figure 15.7 Pruning in multiple waves. These figures illustrate the acceleration of neuronal synaptogenesis and dendritic arborization in early childhood, followed by a rapid decline (via pruning) during adolescence (note expansion of time scale in early years). This These waves of synaptic pruning are associated with brain maturation and improved cognition. Another decline in synapse number and cortical thickness occurs late in life and is associated with brain senescence and impaired cognition. *Source:* Adapted from I. Feinberg & I. G. Campbell, Sleep EEG changes during adolescence: An index of fundamental brain reorganization, *Brain and Cognition, 72*(1), 59, 2009.

gray matter during adolescence (Shaw & Gross, 2008; Sowell et al., 2003). This cortical thinning is a marker of brain maturation and is associated with enhanced cognitive ability. It is considered to be a distinctly different process from the cortical thinning in the latter half of the life span, which is associated with the atrophy of large neurons, loss of neuropil (mostly dendritic arbors and synapses), and white matter degeneration (Bertoni-Freddari et al., 2002; Terry, DeTeresa, & Hansen, 1987; Westlye et al., 2010b).

As with cortical thickening and synaptic proliferation, synaptic pruning and cortical thinning/maturation proceed from posterior to anterior and from medial regions out to the lateral portions of the brain. Thus, the occipital pole (shown in black in Figure 15.8) is one of the first brain regions to mature, while the prefrontal and lateral temporal regions are among the last (shown in lighter shades in Figure 15.8; Giedd, 2004; Westlye et al., 2010b). Regional differences in the development of brain structure can be mapped onto maturational differences in brain function, leading to the progressive maturation of cognitive and perceptual capabilities. For example, the early maturation of the primary visual cortex (occipital pole) can be demonstrated through the early emergence of visual acuity (Teller, 1981). Complex motor skills mature later, during adolescence, and executive skills (associated with anterior and lateral PFC function) are not fully developed

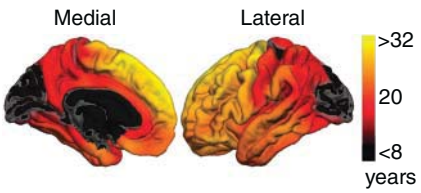

Figure 15.8 The developmental timing of gray matter maturity varies by brain region. Posterior regions develop earlier than prefrontal regions. Superior and lateral prefrontal regions develop last. Areas in black reach maturity prior to 8 years of age. See footnote 1. *Source:* Adapted from L. T. Westlye, K. B. Walhovd, A. M. Dale, A. Bjørnerud, P. D. Due-Tønnessen, A. Engvig, . . . A. M. Fjell, Differentiating maturational and aging-related changes of the cerebral cortex by use of thickness and signal intensity, *NeuroImage, 52*(1), 175, 2010.

until well into early adulthood (e.g., Kurth et al., 2012), along with dramatic increases in information processing capacity and speed (Demetriou, Christou, & Spanoudis, 2002; Luna & Sweeney, 2004).

Each brain region has a different developmental trajectory, so that the aggregate of these trajectories at any given age will demonstrate different patterns of local maturation. During adolescence, for example, the striatal regions (heavily implicated in reward-related behavior) mature earlier than the superior and lateral prefrontal regions that underlie complex cognition and planning (e.g., Galvan et al., 2006). The maximum imbalance in the maturity

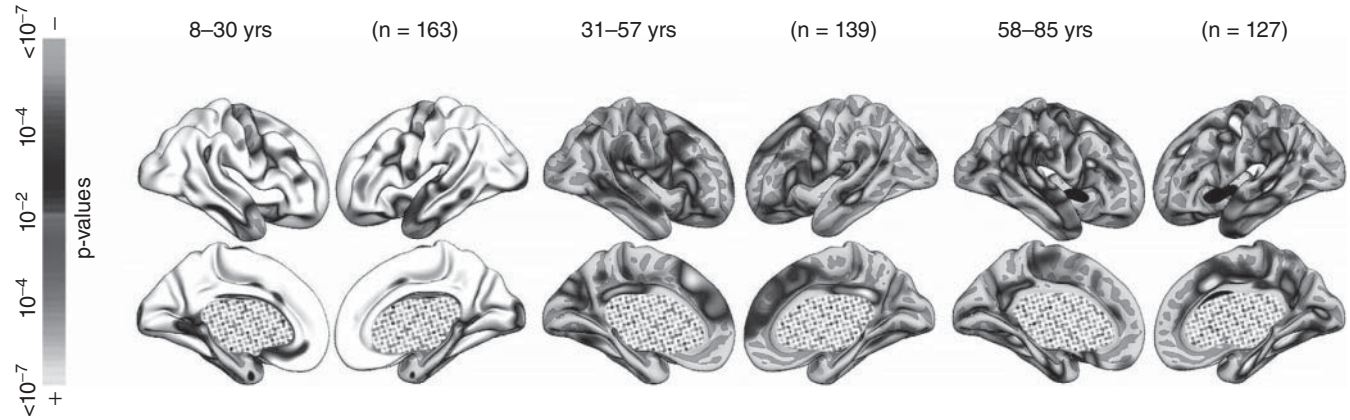

Figure 15.9 Change in cortical thickness with increasing age. See text for a discussion of the global cortical thinning associated with brain maturation in childhood and youth and the distinctly different pattern of cortical atrophy in aging. Also note the small regions of cortical thickening in anterior insula and dorsal cingulate in the aging brain, which will be relevant to our discussion of large-scale neural networks in subsequent sections of this chapter. See footnote 1. *Source:* Adapted from L. T. Westlye, K. B. Walhovd, A. M. Dale, A. Bjørnerud, P. D. Due-Tønnessen, A. Engvig, . . . A. M. Fjell, Differentiating maturational and aging-related changes of the cerebral cortex by use of thickness and signal intensity, *NeuroImage, 52*(1), Figure 4, 2010.

of these systems occurs during adolescence, and evidence suggests that this underlies at least some of the increase in risk-taking behavior observed during this developmental period (Casey, Jones, & Hare, 2008; Steinberg, 2008).

Cortical Development in Maturity

The post-adolescent brain continues to experience widespread reductions in gray matter volume that accelerate during old age. MRI data from cross sections of the total span of adulthood from early to very late in life (18 to 90 years) indicate that this involves a monotonic decrease in gray matter volume across most of the brain (Figure 15.9; Alexander et al., 2006; Giorgio et al., 2010; Good et al., 2001; Grieve, Clark, Williams, Peduto, & Gordon, 2005; Taki et al., 2004). Neuroimaging findings regarding declines in total gray matter volume (in vivo) are paralleled by stereological findings (postmortem) of significant decreases across the life span in neuronal size and total number of neurons (approximately 10% decrease between the ages of 20 and 90 years: (Pelvig et al., 2008).

Compared to the profound maturation-related decreases in cortical thickness observed in earlier development, gray matter thinning associated with cortical senescence may be considered moderate (Westlye et al., 2010a). As previously noted, however, cortical thinning in maturity and old age is considered to be atrophy and it is associated with accelerating declines in cognitive function and increasing frequency of aging-related mental disorders. Recent research supports the view that this version of cortical thinning starts during middle age in both the posterior portions of the brain (cuneus and lateral occipital cortex) simultaneous with thinning in the anterior regions (superior PFC, dorsal anterior cingulate, and lateral OFC; Michielse et al., 2010; Westlye et al., 2010b). With increasing age, thinning extends down from the cuneus to the inferior parietal lobes and the posterior cingulate and fusiform gyri and from the superior PFC to the lateral PFC, temporal gyri, and entorhinal cortices (Figure 15.9; e.g., Westlye et al., 2010b). Thus, the overall picture of gray matter change in middle and old age is one of ongoing atrophy.

There has, however, also been mixed evidence that the midline brain structures, including amygdala, hippocampus, thalamus, entorhinal cortex, insula, and (sometimes) the cingulate gyrus, are exceptions to this rule of ongoing atrophy, at least during midlife (Giorgio et al., 2010; Good et al., 2001; Grieve et al., 2005; Kennedy et al., 2009; Westlye et al., 2010b). When researchers took a closer look at regional variation in gray matter volume between the ages of 20 and 50 years, they were presented with a much more varied picture of gray matter change (Figure 15.10; Terribilli et al., 2011). This group found robust support for the preservation, and even expansion, of medial temporal structures in middle age, including amygdala, extended amygdala, hippocampus, entorhinal cortex, and nearby structures (Terribilli et al., 2011). This is notable, as these areas are particularly vulnerable to tissue loss associated with a wide range of common biological and environmental insults, including depression, anxiety, cardiovascular disease, diabetes, stress, and hardship (Anan et al., 2010; Butterworth, Cherbuin, Sachdev, & Anstey, 2012; Frodl et al., 2002; Ganzel, Kim, Glover, & Temple, 2008; Gianaros et al., 2008; Gianaros, Jennings, et al., 2007; McEwen, 2007; Rauramaa et al., 2011). Nevertheless, there appears to be a significant increase

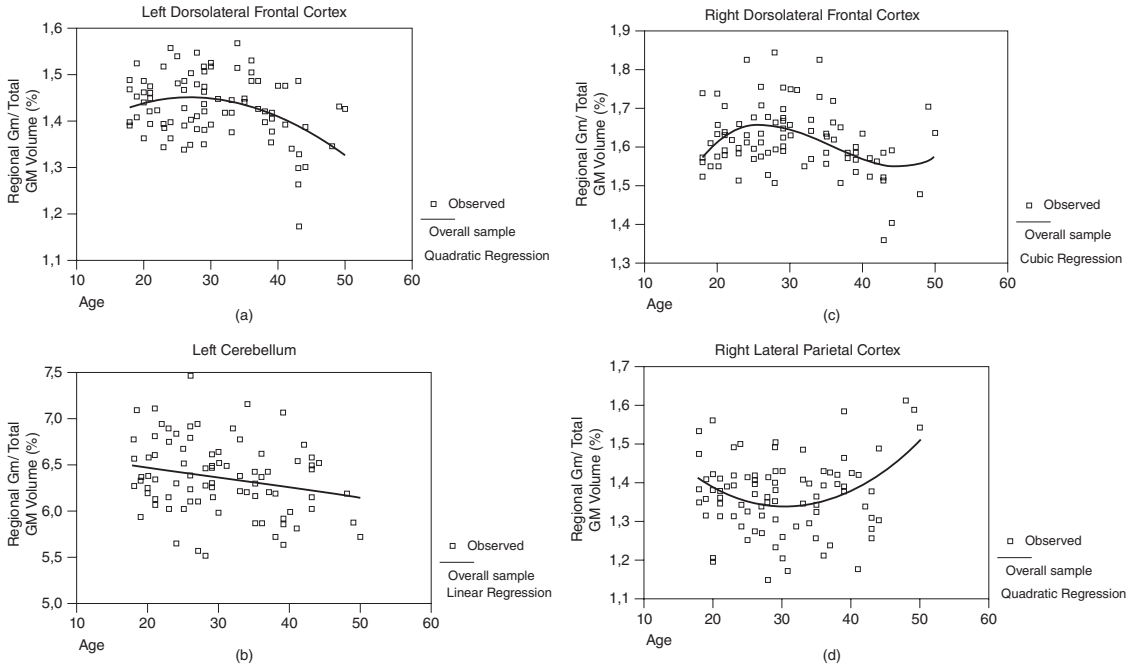

Figure 15.10 There is significant regional variation in gray matter volume across mature adulthood. *Source:* Adapted from D. Terribilli, M. S. Schaufelberger, F. L. S. Duran, M. V. Zanetti, P. K. Curiati, P. R. Menezes, . . . G. F. Busatto, Age-related gray matter volume changes in the brain during non-elderly adulthood, *Neurobiology of Aging, 32*(2), 2011.

in gray matter volume in medial temporal regions over the decades of midlife. This is consistent with findings of preserved structural integrity of amygdala in healthy aging (Good et al., 2001; Grieve et al., 2005; Rubinow & Juraska, 2009; Soininen et al., 1994), although preserved *functional* integrity of amygdala in old age is still debated (e.g., Mather et al., 2004; St Jacques, Dolcos, & Cabeza, 2010). Overall, this work suggests that there is significant decade by decade regional variation in gray matter development and senescence throughout midlife and into old age.

Glial Contributions to Local Connectivity

Neuroglia (especially myelinating oligodendrocytes) are best known for their support of long-range connectivity in the brain, as we discuss in detail later. However, glia also play a role in optimizing *local* synaptic connectivity and signaling between neurons. Astrocytes, in particular, figure prominently in this function by promoting neuron survival, synaptogenesis, and synaptic activity. Astrocytes line nearly all the capillary walls in the brain, which gives them a central role in the blood–brain barrier, as well as enabling them to couple local blood flow to neuronal activity (note that this provides the signal detected in functional magnetic resonance imaging, e.g., Raichle, 2001; Rossi, 2006). This placement allows astrocytes to absorb glucose, the primary energy source for both neurons and glia, and redistribute it to feed the cells of the brain (Rajkowska & Miguel-Hidalgo, 2007; Wang & Bordey, 2008). Astrocytes also regulate the availability of extracellular glutamate in the brain, thus providing critical protection to both neurons and glia, which are otherwise vulnerable to excitotoxic damage (e.g., Barres, 2008; Nedergaard & Verkhratsky, 2012; Rajkowska & Miguel-Hidalgo, 2007). In addition, astrocytes produce growth factors, such as ciliary neurotrophic factor (CNTF), brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), which serve a wide range of functions in the brain, including neuronal protection and support of neuronal maturation (Vaca & Wendt, 1992; Wang & Bordey, 2008). Glial growth factors also facilitate local connectivity in the brain by robustly promoting synaptogenesis and synaptic activity (Rudge et al., 1992; Seil, Eckenstein, & Reier, 1992).

Although they are electrically silent, astrocytes have been observed to play an active role in modulating neuronal synaptic transmission during development and across the life span (e.g., Araque, Parpura, Sanzgiri, & Haydon, 1999; Sun et al., 2013). Astrocytes partner with presynaptic and postsynaptic neurons to create a tripartite synapse (Araque et al., 1999) that acts in concert to regulate local availability of neurotransmitters (thus giving astrocytes a role in the therapeutic effects of antidepressants; e.g., Bal, Figueras, Vilaro, Sunol, & Artigas, 1997; Rajkowska & Miguel-Hidalgo, 2007). Early in development, astrocytes are also excitable in the sense that they can integrate multiple incoming signals into a single calcium (Ca^{2+}) signal/wave that modulates the activity of surrounding neurons, glia, and blood vessels (e.g., Hoogland et al., 2009; Schummers, Yu, & Sur, 2008). New research suggests that this form of gliotransmission shuts down quite early in brain development, after which there is a shift to more synapse-specific signaling (Sun et al., 2013). Thus, neuron-glia crosstalk via calcium waves is thought to support the enhanced synchronous neuronal activity observed in very early development, which in turn is hypothesized to support the establishment of large-scale neural circuits (e.g., Grotsch & Reichenbach, 2013). Subsequent developmental suppression of calcium wave gliotransmission is argued to increase functional specificity in local neural networks and thus supports mature information processing (Grotsch & Reichenbach, 2013). Notably, calcium wave gliotransmission can be reinstated by brain injury or in response to certain brain pathologies, even later in development (Grotsch & Reichenbach, 2013; Nedergaard & Verkhratsky, 2012). It is an open question whether psychological trauma also reinstates calcium wave gliotransmission and we suggest this as a topic for future research.

Global Changes in Local Connectivity: Evidence from Deep Sleep

Astrocytes also regulate slow wave activity during non-rapid eye movement (NREM) sleep (Frank, 2012; Postkanzer & Yuste, 2011), which is measured using EEG. Neurons are bi-stable in that they oscillate between "up" and "down" states[7] (Beltramo et al., 2013; Kurth & Huber, 2012; Steriade, 2006). During NREM sleep (deep sleep), this synchronized slow wave activity propagates smoothly through the cortex and is thought to play a critical role in memory consolidation and brain homeostasis. By resetting learning-related increases in synaptic weight (the strength of the connection between nodes of a synapse) to a constant baseline, long-term potentiation (LTP) function is optimized upon waking, while memory remains preserved (Tononi & Cirelli, 2003, 2006, 2012). Since neuronal LTP

[7]The "up" state of a neuron is characterized by a sustained elevation of the resting membrane potential, at the peak of which occur action potentials (neuronal firing). The "down" state is characterized by neuronal silence and cessation of signal input into the network (Beltramo et al., 2013).

is one of the fundamental cellular mechanisms of memory and learning, this synaptic resetting is a crucial for cognition and ongoing neural plasticity across the life span (Frank, 2010, 2013; Kurth & Huber, 2012). A previously noted, glia (especially astrocytes) release molecules that regulate synaptic transmission and neuronal excitability, and these in turn mediate sleep and also brain function during sleep (Fellin et al., 2009; Frank, 2012; Halassa et al., 2009). We will return to the importance of glia in local connectivity and neuronal function when we discuss theories about the role of astrocytes in stress-related changes in brain function and psychopathology across the life span.

EEG measurement of slow wave activity during NREM sleep is also valuable as a noninvasive biomarker of brain development. Slow wave activity during NREM sleep is characterized by low frequency (1.0–4.5 Hz), high amplitude (>75 μV) EEG waves that represent oscillating membrane potentials of cortical neurons that are synchronized in local networks. During NREM sleep, there is a marked loss of effective connectivity across the brain's large-scale neural networks that does not occur during waking or in other sleep stages (Tononi & Cirelli, 2009). Thus, EEG slow wave activity during NREM sleep is related in a systematic manner to moment-to-moment changes in *local* synaptic strength among cortical neurons (Huber et al., 2013; Vyazovskiy, Cirelli, Pfister-Genskow, Faraguna, & Tononi, 2008).[8] In other words, regional variation in slow wave activity provides a direct measure of the synaptic strength within local cortical networks (e.g., Steriade, Timofeev, & Grenier, 2001; Timofeev, Grenier, & Steriade, 2001; Vyazovskiy et al., 2009). Looking across the entire brain, NREM EEG slow wave activity serves as a biomarker of *global* changes in *local* synaptic maturity in the developing brain (Kurth & Huber, 2012).

Use of this biomarker in cross sectional and longitudinal studies has shown that there is a profound reorganization of the architecture of sleep during adolescence (Feinberg & Campbell, 2009; Kurth & Huber, 2012). Between the ages of 12 and 16, there is a steep (65%) and permanent drop in the amplitude of EEG recordings of slow wave activity (Campbell & Feinberg, 2009; Puligheddu et al., 2005). This drop in slow wave amplitude coincides with a strong developmental decline in overall energy metabolism in the brain (glucose utilization) as measured via positron emission tomography (Chugani, 1998). Slow wave activity and synapse number/strength are linked, per the earlier discussion, as are metabolism and synapse density (Attwell & Laughlin, 2001), so these changes are thought to be driven by that second wave of synaptic pruning that occurs in adolescence (Feinberg & Campbell, 2009). Taken together (see Figure 15.11), these observations demonstrate the scope of the fundamental reorganization of the structure, metabolism, and electrophysiology of the brain during childhood and adolescence, which in turn is linked with robust long-term increases in cognitive capability (McArdle et al., 2002).

Notably, there is some evidence that the steep adolescent decline in slow wave activity is specifically linked to puberty, rather than age (Campbell & Feinberg, 2009; Ringli & Huber, 2011). The magnitude of slow wave activity during NREM sleep is highest immediately before the onset of puberty, then drops across adolescence and stabilizes during middle adulthood (Campbell & Feinberg, 2009). These data are correlational and cannot speak to the question of whether changes in slow wave activity are caused by the neuroendocrine events of puberty and further research will be needed to determine whether these phenomena are physiologically linked. Nevertheless, these associations do raise the question of whether related maturational changes in the developing brain (e.g., changes in local synaptic connectivity or the second wave of synaptic pruning) are linked to pubertal timing rather than increasing age.

Local Connectivity Across the Life Span

As discussed previously, slow wave EEG activity during NREM sleep is a biomarker for local synaptic network maturity. Thus, the posterior-to-anterior pattern of gray matter maturation shown in Figure 15.8 is reflected in the topography of slow wave activity. This point was demonstrated in a cross sectional study of children and youth that found a steady shift in the location of maximum slow wave activity from the occipital lobe to the prefrontal cortex between the ages of two and 19 years (Kurth et al., 2010). In this study, regional slow wave maturation during childhood and adolescence preceded regional gray matter maturation, which in turn preceded region-specific increases in cognitive capacity (Figure 15.12b) (Kurth et al., 2010). EEG slow wave activity and the BOLD signal (the signal measured using fMRI) are coupled, so that the robust developmental decrease in the amplitude of spontaneous EEG slow wave signals is paralleled by a steep decrease in the absolute amplitude of the fMRI signal (Lüchinger, Michels, Martin, & Brandeis, 2012; Uhlhaas

[8] Regional variation in NREM EEG slow wave (delta-band) activity reflects regional variation in spontaneous neural activity, as measured by single cell recordings of rate and synchronicity of firing, and the slope of the local field potentials evoked by electrical stimuli (Huber et al., 2013; Vyazovskiy et al., 2008).

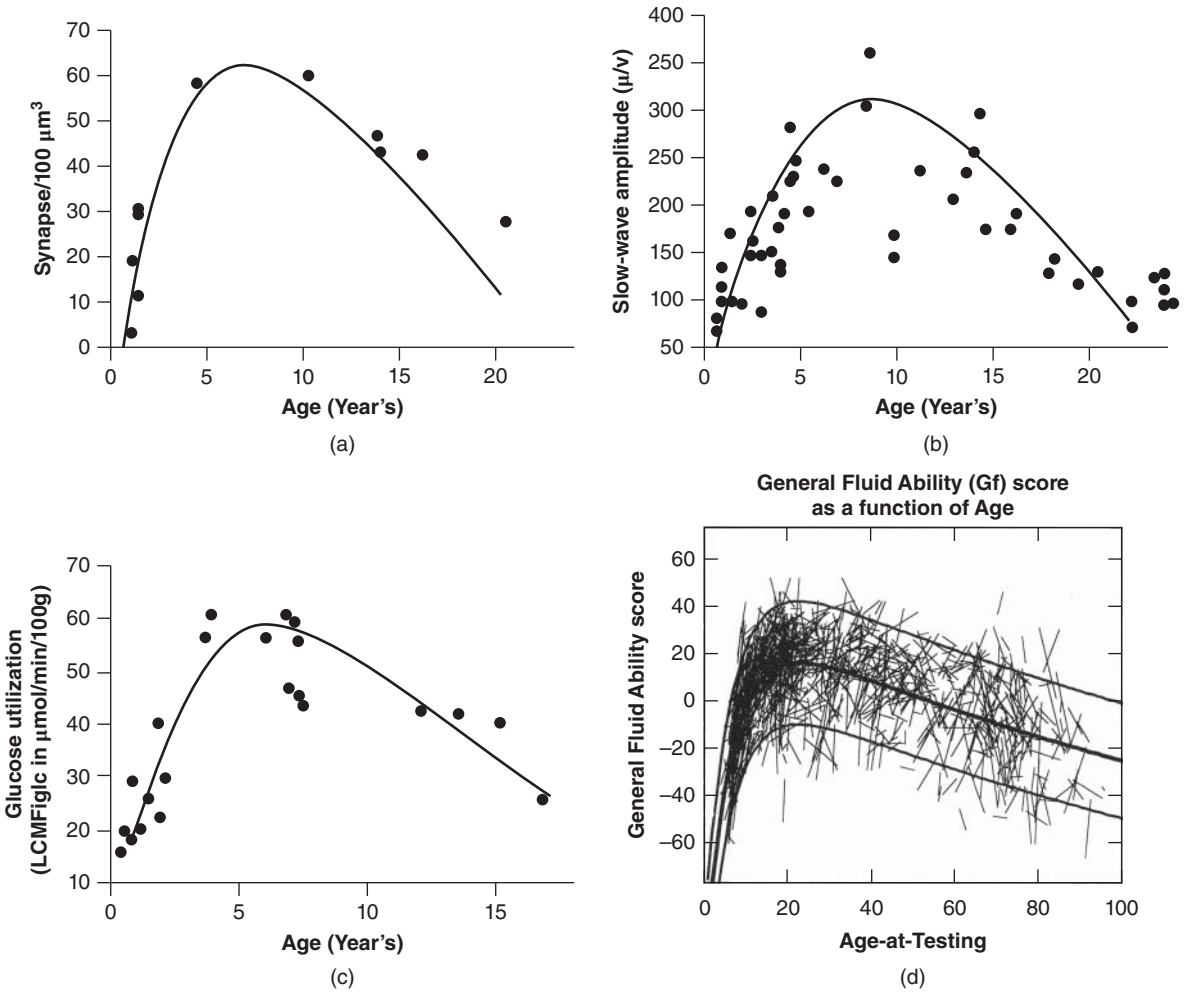

Figure 15.11 Parallel developmental trajectories of (a) synapse density (postmortem tissue), (b) slow wave amplitude (EEG), (c) energy consumption in terms of glucose utilization (adapted from Kurth & Huber, 2012), and (d) the trajectory of human intellectual abilities over development. *Source:* Adapted from J. J. McArdle, E. Ferrer-Caja, F. Hamagami, & R. W. Woodcock, Comparative longitudinal structural analyses of the growth and decline of multiple intellectual abilities over the life span, *Developmental Psychology, 38*(1), 133, 2002.

et al., 2009). Note that the maximum amplitude of the EEG slow wave is reduced by a factor of six between the ages of 8 and 17 years, reflecting the overall decrease in total number of synapses and mean brain metabolism over this time (the peak signal is shown in red numbers, upper right, in Figure 15.12a; see also Figure 15.11).

During adulthood, the peak amplitude of slow wave activity during NREM sleep stays focused in the medial prefrontal cortex (mPFC), which remains a major generator of EEG slow waves until this process is disrupted by tissue degeneration in mPFC in late aging (Murphy et al., 2009). As discussed already, the mPFC is one of the first brain regions to show gray matter atrophy with aging (Raz, 2000; Westlye et al., 2010b). This atrophy is inversely correlated with age-related impairment in memory (i.e., more atrophy predicts less memory), and recent research has demonstrated that age-related decreases in slow wave sleep statistically mediate this association (Mander et al., 2013). It is relevant here that the transfer of hippocampal memory to long-term storage in the neocortex is thought to occur during slow wave NREM sleep (e.g., Fogel et al., 2012; Mander et al., 2013). Together, these data support a model in which progressive age-related atrophy of the mPFC damages the EEG slow wave generator in the adult mPFC and thus disrupts healthy slow wave activity (Mander et al., 2013). This, in turn, interferes with memory consolidation to the neorcortex, resulting in impaired long-term memory (Mander et al., 2013).

In Sum

We have described early-maturing processes that underlie increasing segregation of the cortex into functionally

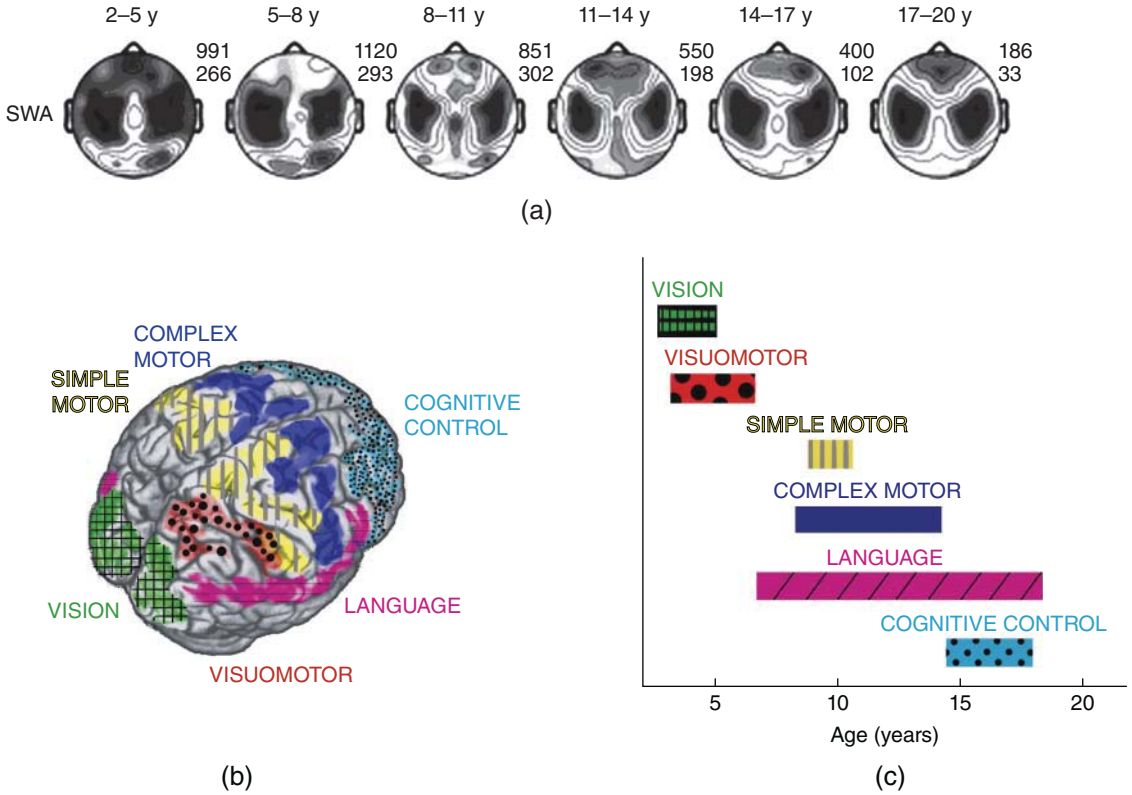

Figure 15.12 Linking local and global brain maturation with cognitive development. (a) The maximum amplitude of the EEG slow wave during NREM sleep moves from posterior to anterior brain regions, reflecting regional change in synaptic maturation (see text). Global gray matter maturation (b) and cognitive development (c) follow these maturational changes in slow wave activity. See footnote 1. Sources: Adapted from (a) S. Kurth, M. Ringli, A. Geiger, M. LeBourgeois, O. G. Jenni, & R. Huber, Mapping of cortical activity in the first two decades of life: A high-density sleep electroencephalogram study, *Journal of Neuroscience, 30*(40), -13214, 2010; and (b,c) S. Kurth, M. Ringli, M. LeBourgeouis, A. Geiger, A. Buchmann, O. G. Jenni, & R. specialized subregions, i.e., functional specificity in local networks of neurons and glia. Maturation within these local networks peaks and then undergoes age-related deterioration, with strong evidence for significant regional variation in these processes. These data are consistent with a model of coherent and continuous regional variation in cortical structure and function across the life span. We next turn to evidence for changes in functional integration in the human brain across the life span.

Late-Maturing Structural and Functional Integration: Focus on White Matter

Over the course of brain development, functionally specialized local networks (nodes) of neurons and glia become anatomically connected by later-developing subcortical white matter tracts (e.g., Dosenbach et al., 2010; Engel, 1977). This allows synchronous co-activation of nodes that are linked together into functionally integrative large-scale assemblies of neurons (Hagmann et al., 2010; Honey et al., 2009; M. C. Stevens, 2009; van den Heuvel et al., 2009).

Age-related change in the volume and integrity of white matter tracts reflects the maturation and (in old age) the breakdown of myelin, a fatty insulation around axonal processes that is produced by oligodendrocytes (Giedd, 2004; Westlye et al., 2010b). Myelination speeds up the transmission of information between neurons up to 100 times relative to an unmyelinated state (Giedd, 2004; Westlye et al., 2010b). Developmental expansion of white matter volume may also include increases in the cross sectional diameters of neuronal axons that traverse long distances in the brain, but verification of this point will rely on the development of new imaging technology. Specific white matter tracts continue to show developmental increases in volume and integrity through age 30 (e.g., Sowell et al., 2003; Westlye et al., 2010a). Maturation of these tracts is associated with increased ability for complex cognition, which is likely to be a consequence of increased efficiency

in large-scale neural networks (e.g., Sridharan, Levitin, & Menon, 2008; Uddin, Supekar, Ryali, & Menon, 2011). For example, the latest-maturing of these tracts include the uncinate fasciculus and the dorsal and hippocampal cingulum bundles, which connect the survival circuitry of the brain to regions of the prefrontal cortex that underlie planning, executive function, and behavioral inhibition (Hasan et al., 2009; Lebel, Walker, Leemans, Phillips, & Beaulieu, 2008; Westlye et al., 2010a). Increasing myelination in these tracts is thought to underlie emotion regulation and mature decision-making, and possibly mature episodic memory (Levine et al., 1998; E. A. Olson et al., 2009; Schmahmann, Smith, Eichler, & Filley, 2008). Reduced integrity in these tracts is associated with trait anxiety, harm avoidance, and memory problems (M. J. Kim & Whalen, 2009; Levine et al., 1998; Westlye, Bjornebekk, Grydeland, Fjell, & Walhovd, 2011), as well as a wide range of mental disorders, including generalized anxiety disorder (Tromp et al., 2012), social anxiety disorder (e.g., Phan et al., 2009), bipolar disorder (e.g., Wang et al., 2009), and schizophrenia (e.g., Mandl et al., 2013). Focal damage to the right uncinate fasciculus results in failure of retrieval of episodic autobiographical memory (retrograde amnesia) and impacts autonoetic awareness (the awareness or *feeling* of oneself as an individual existing continuously through time; Levine et al., 1998; Tulving, 1985). Damage to similar pathways on the left side of the brain affects episodic encoding and semantic retrieval, thus impacting noetic awareness/generalized knowledge of the world (Levine et al., 1998; Tulving, 1985).

Although specific white matter tracts mature around age 30, overall white matter volume does not peak until around 50 years of age, after which there is a decline in white matter integrity that accelerates toward the end of life (>70 years: Giedd et al., 2006; Westlye et al., 2010b; see Figure 15.13). For example, the average total length of myelinated fibers (axons) in the brain of a 20-year-old male has been estimated to be approximately 176,000 km or 109,361 miles, and the total length of myelinated fiber in the brain of a 20-year-old female has been estimated to be 149,000 km or 92,584 miles (Marner, Nyengaard, Tang, & Pakkenberg, 2003). By 80 years of age, males have only about 97,200 km (60,397 miles) of myelinated fiber in their brains and females have approximately 82,000 km (50,952 miles). Age-related loss of oligodendrocytes underlies this observed 45% decrease in the length of myelinated fibers, which represent a significant loss in the efficiency of intercellular information transfer in the aging human brain (Marner et al., 2003). As with gray matter, the rate of white matter loss varies by brain region (Hasan et al., 2009; Lebel et al., 2008; Westlye et al., 2010a), which supports the concept of regional variation in brain development and senescence across the life span (a constantly changing brain).

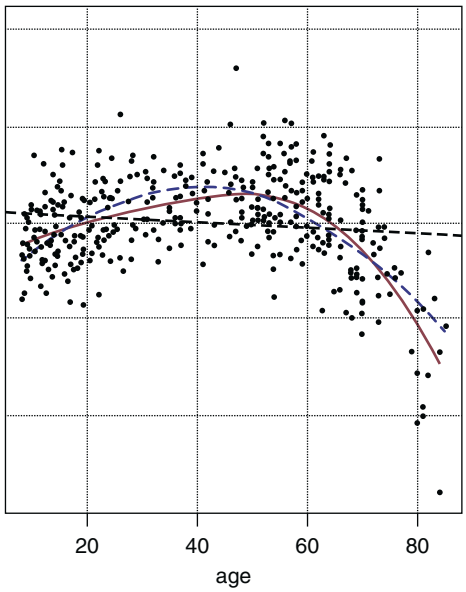

Figure 15.13 The longitudinal trajectory of human white matter development peaks at approximately 50 years of age. See footnote 1. *Source:* Adapted from Westlye, L. T., K. B. Walhovd, A. M. Dale, A. Bjørnerud, P. D. Due-Tønnessen, A. Engvig, . . . A. M. Fjell, Life-span changes of the human brain white matter: Diffusion tensor imaging (DTI) and volumetry, *Cerebral Cortex, 20*(9), 2060, 2010.

Developing Long-Range Connectivity in the Human Brain

Evidence suggests that brain maturation involves a shift from bottom-up neural processing in posterior regions to top-down controlled cognition (e.g., Fair et al., 2007; also see Figure 15.12). Mature cognition involves not only the local development of frontotemporal regions, but also increasingly robust interregional communications in broad neural networks that can extend from the prefrontal cortex to the parietal lobes and the cerebellum (e.g., Dosenbach et al., 2010; Fair et al., 2008; Fair et al., 2007; Rubia, 2012). Once mature electrical and chemical communications are established across each large-scale neural network, then coordinated activity is made possible through the oscillatory properties of neurons (e.g., Bechara, Damasio, Damasio, & Lee, 1999; Convit, Wolf, Tarshish, & de Leon, 2002). As the brain matures, populations of neurons are increasingly able to fire rhythmically and in synchrony, creating oscillating networks that link neural activity across multiple spatial and temporal levels of analysis (Barrett et al., 2007; Dosenbach et al., 2010; Engel, 1977). In this way, the firing of a single neuron in a local network may

be linked to oscillatory activity in vast neural assemblies that span the brain (Convit et al., 2002; Uhlhaas & Singer, 2012). Moreover, oscillatory activity may show partial coherence at high and low frequencies in different cortical layers of the same brain region, thus allowing the generation of complex, flexible, and swiftly changing patterns of neural activity (Uhlhaas & Singer, 2012). Synchronous neural rhythms shape brain states and underlie healthy brain functioning (e.g., Fries, 2005), and disrupted patterns of synchronization have been increasingly associated with a very wide range of psychopathologies (e.g., Kempermann et al., 1998; Uhlhaas & Singer, 2012).

In humans, these functional connections between spatially remote regions of the brain are inferred from correlations in the timing of neurophysiological signals from those areas (e.g., Friston, Frith, & Frackowiak, 1993; Friston, Frith, Liddle, & Frackowiak, 1993). Early human functional connectivity studies examined regional coupling in glucose metabolism using positron emission tomography (e.g., Clark, Kessler, Buchsbaum, Margolin, & Holcomb, 1984; Raichle, 2001). Today, connectivity in large-scale neural networks is more often studied as temporal correlations in the amplitude of blood oxygen level-dependent (BOLD) signal acquired while a study participant completes tasks in the MRI scanner (functional connectivity or fc-MRI) or as the amplitude of low-frequency (< .08 Hz) fluctuations in fMRI studies that do not involve tasks (resting state functional connectivity or RSFC; e.g., Whitfield-Gabrieli & Ford, 2012). Notably, there is accumulating evidence that functional connectivity in the human brain reflects anatomical connectivity (especially white matter connectivity; e.g., Greicius, Supekar, Menon, & Dougherty, 2009; Honey et al., 2009; Koch, Norris, & Hund-Georgiadis, 2002), so that an understanding of anatomical brain development and senescence can inform an understanding of functional neural connectivity across the life span.

The Canonical Large-Scale Neural Networks. In the present discussion, we will focus on three core neurocognitive networks—the default mode network (DMN), the salience network (SN), and the central executive network (CEN), described herein (Figure 15.14). Neural activity in these networks is, with a few exceptions, non-overlapping (e.g., Fox et al., 2005; Yeo et al., 2011). By flexibly coupling or competing with each other, these three networks frame the brain's intrinsic functional architecture and are thought to play a critical role in the emergence of complex cognition during development (e.g., Sridharan et al., 2008; Uddin et al., 2011). Likewise, decreases in the efficiency of long-distance interneuronal communication in old age signify decline in the integrity of these networks (e.g., Mander et al., 2013; Rajkowska & Miguel-Hidalgo, 2007; Ringli & Huber, 2011). Moreover, there is a growing body of evidence suggesting that dysfunction within these canonical networks plays a prominent role in the onset and continuation of psychopathology, which is of high interest to us as we build our allostatic diathesis–stress model.

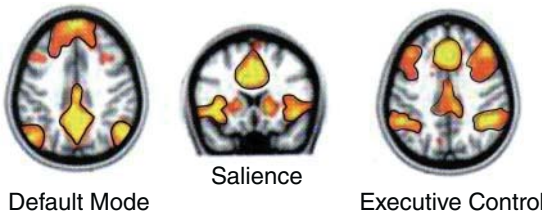

Figure 15.14 Functional MRI shows fluctuating patterns of intrinsic activity in the canonical resting state networks of the brain: the default mode network, the salience network, and the executive control network, also called the central executive network (CEN). See footnote 1. *Source:* Adapted from Whitfield-Gabrieli, S., & Ford, J. M. (2012). Default Mode Network Activity and Connectivity in Psychopathology. *Annual Review of Clinical Psychology, 8*(1), 62. doi: doi:10.1146/annurev-clinpsy-032511-143049

The Default Mode Network (DMN). In the resting state (i.e., when there is no experimental stimulus and the mind is free to do nothing), synchronous regional activity is observed within a distributed neural network that includes the medial prefrontal cortex, the posterior cingulate cortex and adjacent regions, with additional nodes in the posterior inferior parietal lobules (Binder et al., 1999; Fox et al., 2005; Greicius, Srivastava, Reiss, & Menon, 2004; Greicius, Krasnow, Reiss, & Menon, 2003; McKiernan, D'Angelo, Kaufman, & Binder, 2006; Raichle, 2001) and in the superior and inferior frontal gyri, and the medial and lateral temporal lobes (Buckner, Andrews-Hanna, & Schacter, 2008; Spreng, Sepulcre, Turner, Stevens, & Schacter, 2013). This network is referred to as the *DMN* (Raichle, 2001). It was initially characterized as having more activity in the aforementioned regions while the brain was at rest rather than when the brain is engaged in generating task-specific behavior (for reviews, see Mazoyer et al., 2001; Whitfield-Gabrieli & Ford, 2012). In this view, DMN activation was thought to reflect the internal, intrinsic consideration of one's own experience (thoughts, feelings, memories, goals, and mental time traveling, as opposed to a focus on extrinsic stimuli or goal-oriented activity; Gusnard & Raichle, 2001; Kelley et al., 2002; Northoff & Bermpohl, 2004; Whitfield-Gabrieli et al., 2010). More recent thinking places the DMN in a more dynamic role

in which it actively interacts with elements of the CEN to direct or inhibit self-generated thought (Andrews-Hannah, Smallwood, & Spreng, in press; Spreng, 2012). Activity and connectivity in this network have been associated with tasks that involve planning for or thinking about the future, memory retrieval, reasoning about moral dilemmas, theory of mind, self-reflection (reviewed in Andrews-Hannah et al., in press), as well as social cognition (Spunt & Lieberman, 2013), monitoring of the surrounding environment (Gusnard & Raichle, 2001), and the integration of cognition and emotion (Greicius et al., 2003).

The default mode network was among the first large-scale neural networks to be discovered (Greicius et al., 2003). Further functional connectivity studies have isolated multiple stable neural networks that appear to be fundamental to the organization of information processing in the human brain. These networks consist of local brain regions (nodes) in which fMRI responses are coupled in time, such that they activate in synchrony. These networks are said to demonstrate *intrinsic connectivity*, in that they show strong spontaneous temporal and spatial coupling during tasks (Smith et al., 2009) and at rest (typically detected using independent components analysis [ICA]; e.g., Seeley et al., 2007). At least a dozen highly structured functional networks have been identified in the human brain and each appears to serve a more-or-less distinct function (e.g., vision, language, spatial attention; Menon, 2011; Yeo et al., 2011) and demonstrate network activity in response to a more or less distinct set of tasks. Some of these networks consist of only a few nodes, while others span the entire brain and include multiple subnetworks (e.g., Buckner et al., 2008; Corbetta & Schulman, 2002; Dosenbach et al., 2010; Fox & Raichle, 2007; Fox et al., 2005; Mander et al., 2013; Niendam et al., 2012; Raichle, 2001; Seeley et al., 2007; Sporns, Chialvo, Kaiser, & Hilgetag, 2004; Spreng & Schacter, 2012; van den Heuval & Hulshoff-Pol, 2010; Vincent, Kahn, Snyder, Raichle, & Buckner, 2008). In general, these networks are nonhierarchical (no one node dominates activity in the system), however the large-scale networks tend to converge on association areas in prefrontal and parietal cortex that are likely to be the most recently evolved and also the latest to mature (Yeo et al., 2011).

The intrinsic neural networks of the human brain are observed to have efficient small-world properties, a term describing a complex network that has (1) a high degree of local connectedness, so that the nodes form tight clusters or cliques and (2) short path lengths between nodes and clusters (Sporns & Zwi, 2004; van den Heuval & Hulshoff-Pol, 2010; Watts & Strogatz, 1998). A growing body of evidence suggests that network properties (e.g., the strength of the correlation between nodes; the average path length between nodes) predicts individual differences in cognitive function (e.g., Kelly, Uddin, Biswal, Castellanos, & Milham, 2008; Seeley et al., 2007; van den Heuvel et al., 2009) and that learning and experience can shape spontaneous activity within these networks (Berkes, Orba'n, Lengyel, & Fiser, 2011; Kurikawa & Kaneko, 2013; Lewis, Baldassarre, Committeri, Romani, & Corbetta, 2009; W. D. Stevens, Buckner, & Schacter, 2010; Tambini, Ketz, & Davachi, 2010). Together, these findings suggest that intrinsic functional connectivity within large-scale neural networks encodes information relevant to behavior, as well as enjoying some level of experience-dependent plasticity (also see Stevens & Spreng, 2014). However, the strong link between functional and structural connectivity in the brain, noted previously, also suggests that activity within these networks is strongly canalized by anatomy (e.g., Greicius et al., 2009; Honey et al., 2009; Koch et al., 2002) and thus by anatomical development and senescence.

The Central Executive Network (CEN). The intrinsic CEN is active in situations requiring information maintenance and manipulation in the service of goal-directed behavior (e.g., J. R. Anderson, Fincham, Qin, & Stocco, 2008; Koechlin & Summerfield, 2007; Miller & Cohen, 2001; Seeley et al., 2007; Spreng et al., 2013). The anchoring nodes in this network are the dorsolateral PFC (DLPFC) and lateral posterior parietal cortex (PPC), with multiple additional nodes making up this large neural network (e.g., Habas et al., 2009; Seeley et al., 2007; Tomasi & Volkow, 2011). Some researchers divide this system into two functionally distinct subnetworks, a *dorsal attention network* (including dorsolateral PFC, dorsal anterior cingulate cortex [dACC], superior parietal lobule, and superior occipital gyrus with additional nodes in the inferior precentral sulcus, frontal eye fields, and middle temporal motion complex; Corbetta & Schulman, 2002; Fox et al., 2005; Seeley et al., 2007; Spreng et al., 2013) and a *frontoparietal control network* (bilateral anterior insula, dACC, lateral PFC, medial superior PFC, anterior inferior parietal lobule, and [sometimes] precuneus, dorsal striatum, and ventrolateral thalamus; Spreng & Schacter, 2012; Spreng, Stevens, Chamberlain, Gilmore, & Schacter, 2010; Tomasi & Volkow, 2011; Vincent et al., 2008). Although the default network and the dorsal attention network share very few connections, the frontoparietal control network is highly connected with both, which puts it in position to mediate information flow between the default network and the dorsal attention network

(Spreng et al., 2013). For this reason, the frontoparietal control network has been characterized as the gatekeeper of goal-directed cognition (Spreng et al., 2013). A subset of this network (anterior insula [AI]/dorsal ACC) plays a critical role in maintaining goal-directed cognition across time (set maintenance activity; e.g., Dosenbach, Fair, Cohen, Schlagger, & Petersen, 2008; Dosenbach et al., 2007; Dosenbach et al., 2006; Touroutoglou, Hollenbeck, Dickerson, & Barrett, 2012). The right side of the anterior insula/dorsal ACC subnetwork is also argued to play a critical and causal role in switching between the default mode network and the central executive network (Sridharan et al., 2008). Together, these data suggest that executive control of network switching lies within a frontoparietal control network, within which the right anterior insula and dorsal ACC appear to play a pivotal role in linking networks, as discussed later.

The Salience Network. The anterior insula and dorsal ACC are also core elements in a third intrinsic neural network, the salience network. Evidence from animal and human models suggests that the anterior insula plays a prominent role in monitoring and subjective evaluation of salient (survival-related) information from outside and inside the body, regardless of whether the precipitating stimulus is cognitive, affective, or homeostatic (e.g., Borsook, Edwards, Elman, Becerra, & Levine, 2013; Downar, Mikulis, & Davis, 2003; Seeley et al., 2007; Uddin et al., 2011). The dorsal ACC has been implicated in response modulation in sensory cortex, motor cortex (e.g., motor planning), and association cortex (e.g., executive function), as well as in both physical and social pain detection (Bush, Luu, & Posner, 2000; Eisenberger, Lieberman, & Williams, 2003; Kempermann et al., 1998). The anterior insula/dorsal ACC subnetwork shows heightened activity in situations of uncertainty, pain, empathy for pain, social pain/rejection, metabolic stress, temperature variation, and hunger (Buchel, Morris, Dolan, & Friston, 1998; Craig, 2003, 2008; Critchley, 2004; Critchley et al., 2003; Critchley, Weins, Rotshtein, Ohman, & Dolan, 2004; Downar, Crawley, Mikulis, & Davis, 2002; Downar et al., 2003; Eisenberger et al., 2003; Rainville, Duncan, Price, Carrier, & Bushnell, 1997; Seeley et al., 2007; Singer et al., 2004; Taylor, Seminowicz, & Davis, 2009; Touroutoglou et al., 2012). This subnetwork is also responsive to positive stimuli, such as pleasant touch and seeing the faces of loved ones or friends (Bartels & Zeki, 2004; Craig, 2003). Critically, the anterior insula/dorsal ACC subnetwork (particularly on the right side of the brain) is argued to mediate between *all three* canonical large-scale neural networks (Kempermann et al., 1998), thus serving as a critical hub for internetwork neural switching. In this model, the anterior insula/dorsal ACC hub detects salient events and then switches attention and processing resources among the salience network, the central executive control network, and the default mode to access memory resources at all levels, plan goal-directed action, and modulate autonomic response (Kempermann et al., 1998).

Membership of additional nodes in the salience network varies somewhat across studies but typically include rostral medial PFC (Brodmann area [BA] 10) and the presupplementary motor area (preSMA), and sometimes include dorsolateral PFC, dorsal or ventral basal ganglia, hippocampus, dorsomedial thalamus, and the temporal poles (e.g., Hill, Patel, et al., 2010; Seeley et al., 2007; Sridharan et al., 2008; Thomason, Hamilton, & Gotlib, 2011; Tomasi & Volkow, 2011). As with the CEN, the salience network can be divided into two somewhat expanded co-networks (Touroutoglou et al., 2012). Meta-analytic studies show that *dorsal* anterior insula is more engaged in tasks including attention and goal-related behavior, whereas the *ventral* anterior insula is more likely to be engaged in tasks involving affect and emotion (Kurth et al., 2010; Wager & Barrett, 2004). Consistent with this, dorsal anterior insula coactivates with more dorsal brain regions (e.g., dmPFC, dACC, superior parietal lobule, inferior parietal lobule, and superior temporal cortex, lateral occipital cortex, and dorsal striatum), whereas ventral anterior insula coactivates with more ventral regions (e.g., subgenual and perigenual ACC and associated mPFC, lateral OFC, PCC, ventral striatum, and basal forebrain; Taylor et al., 2009; Touroutoglou et al., 2012). This subdivision is compatible with earlier evidence that there are separable ventral and dorsal streams for attentional and affective processing that are integrated in the anterior cingulate (Dolcos & McCarthy, 2006; Yamasaki, LaBar, & McCarthy, 2002).

A Life Span View of Neural Networks

Establishing Neural Networks in Human Development

Coherent patterns of electrical activity are detectable in the human neocortex very early in development (Kilb, Kirischuk, & Luhmann, 2011; Rakic et al., 2009 for a discussion of these phenomena in animal models). These reflect spontaneous activity in emerging large-scale and local neural networks that, in turn, shape normal brain development across multiple systems (Kilb et al., 2011). Disturbances in these early patterns of activity can disrupt cortical development across a broad cross section of

neurophysiology, from neurogenesis (Bonetti & Surace, 2010) and apoptosis (Golbs, Nimmervoll, Sun, Sava, & Luhmann, 2011), to neuronal migration (De Lima, Gieseler, & Voigt, 2009; Heck et al., 2007; Komuro & Rakic, 1996) and the formation of large-scale neural networks (e.g., early vision and somatosensory networks; Catalano & Shatz, 1998; Galli & Maffei, 1988; Iwasato et al., 2000; Weliky, 2000; Weliky & Katz, 1999). Although accurate neural network formation is understood to be crucial to adaptive functioning of the central nervous system, study of the developing architecture of functional connectivity in very young humans has faced serious technological challenges.

Despite these challenges, resting state fMRI investigation of the development of neural networks in healthy fetuses has recently been conducted in the second and third trimester of pregnancy (Geronimus et al., 2006). These are, to date, the earliest data on the development of spontaneous synchronized neural activity in the human brain. In this study, fetal resting state fMRI data showed relatively constrained (anatomically proximal) neural networks with limited unilateral and cross-hemispheric connectivity that increased in strength with increasing fetal age (also see Power, Fair, Schlaggar, & Petersen, 2010, for a discussion of anatomically proximal neural networks in early brain development; Thomason et al., 2013). Increasing cross-hemispheric functional connectivity with increasing gestational age had been previously observed in very premature infants (Glover, 2006). However, prematurity itself is an insult, rendering these results more difficult to interpret. Relative to full-term controls, term-equivalent premature infants show reduced thalamocortical connectivity and no connectivity between medial PFC and posterior cingulate, which is suggestive of disruption in the precursors of mature large-scale neural network activity (Brody et al., 2013; Glover, 2006; Glover et al., 2006). Nevertheless, resting state fMRI studies of premature infants support the premise that anatomically limited neural networks emerge during the third trimester of pregnancy (Brody et al., 2013; Glover, 2006; Glover et al., 2006; Seeman et al., 2004) and this position is strengthened by the parallel findings in neurotypical fetal samples, discussed earlier (Geronimus et al., 2006). A number of forms of psychopathology include abnormalities in functional connectivity that are thought to have prenatal origins (e.g., autism, schizophrenia; Beltramo et al., 2013; Bluhm et al., 2007; Seeman et al., 2001; Seeman et al., 1997), so that better understanding of neural network development in utero may provide early biomarkers of these disorders.

Human functional neural networks show efficient small world properties, as previously discussed. These properties are established by at least middle childhood (Fair et al., 2008) and are maintained across the life span, despite dynamic development and senescence of the functional architecture of the brain through childhood and maturity, and into old age (Dosenbach et al., 2010; Engel, 1977; Markham et al., 2005; Tononi & Cirelli, 2012). There are systematic properties of developmental change in these functional neural networks.[9] In children, nodes appear more likely to cluster as a function of anatomical proximity[10], whereas in adults, nodes are more likely to cluster by their functional roles (e.g., Carstensen, Gross, & Fung, 1997; Dosenbach et al., 2010; Engel, 1977; Markham et al., 2005). This results in a profound reorganization of the overall network structure between the prenatal period and adolescence, but the efficiency and modularity of these complex networks has been assessed to remain remarkably similar across development (Engel, 1977; Markham et al., 2005; Tononi & Cirelli, 2003).

Across infancy and childhood, local circuit development is accompanied by dramatic increases in synapse density, EEG slow wave amplitude, and energy consumption in the brain, as discussed before. Across adolescence, there is a drop in synapse density, EEG/MEG slow wave amplitude, BOLD signal amplitude, and energy consumption that is nearly as profound. Gray matter is pruned. White matter expands. There is a parallel increase in variability and complexity in brain activity, accompanied by improved neural network efficiency, cognitive ability and task performance (see Garrett, McIntosh, & Grady, 2011 for the distinction between variability and complexity in moment-to-moment change in fMRI or EEG signals; McIntosh, Kovacevic, & Itier, 2008; Nakagawa, Jirsa, Spiegler, McIntosh, & Deco,

[9]There is a recent report of movement-related imaging artifacts that reduce the likelihood of detecting long-distance functional connections relative to short-distance connections during resting state fMRI (Tononi & Cirelli, 2003). Clinical samples, children, and older adults are more likely to move during neuroimaging, relative to young adults (Tononi & Cirelli, 2003). The impact of these artifacts on age-related and clinical RSFC MRI findings is still being assessed (e.g., Buckner, Krienen & Yeo, 2013).

[10]There is ongoing debate whether the constrained, anatomically proximal neural networks observed in early development should be studied as immature, fragmentary versions of adult cognitive networks or whether they should be viewed as intact, adaptive functional networks that are qualitatively different from mature networks (Engel, 1977; Markham et al., 2005). The latter would require a more global sampling approach during assessment of functional network properties (Markham et al., 2005).

2013; Uhlhaas & Singer, 2011). Increased whole-brain functional integration of neuronal processing is associated with decreases in the amount of information processing in anatomically local neuronal assemblies (as discussed previously, also see M. C. Stevens, 2009; Vakorin, Lippé, & McIntosh, 2011; Vogel, Power, Petersen, & Schlaggar, 2010). Interestingly, the hub architecture of the brain remains relatively stable across development, but connectivity between these hubs increases (Hwang, Hallquist, & Luna, 2012). In particular, the right anterior insula/dorsal ACC subsystem assumes increasing centrality as an integrative multinetwork hub (e.g., Carstensen et al., 1997; Fair et al., 2007; Markham et al., 2005), which is demonstrated in the late development of the right uncinate fasciculus, the white matter tract that links the dACC with the anterior insula (Uddin et al., 2011).

Large-Scale Neural Networks in an Aging Brain

Maturity brings a putative peak in neural signal variability/complexity and cognitive performance, which then decline with increasing rapidity with advancing age (Fellin et al., 2009; Frank, 2010, 2013; Halassa et al., 2009; Uchino, Birmingham, & Berg, 2010). There is emerging evidence that this is accompanied by decreases in functional neural network connectivity and cognitive function, particularly in the default network at rest (Mander et al., 2013; Rajkowska & Miguel-Hidalgo, 2007; Ringli & Huber, 2011) and during task performance (affected nodes vary; e.g., Ringli & Huber, 2011; Sambataro et al., 2010). These data are supported by evidence for a corresponding aging-related reorganization of large-scale network patterns within brain *structure*, as represented by cortical thickness measurements (assessed via MRI; Chen, He, Rosa-Neto, Gong, & Evans, 2011; He, Chen, & Evans, 2007; Niendam et al., 2012; Tononi & Cirelli, 2012; Zhu et al., 2012).[11] In these studies, both young and old cohorts showed a modular network-like organization of brain structure that corresponded topographically with the standard functional networks previously discussed (e.g., default, executive control, sensorimotor). In normal aging, however, structural networks showed lower efficiency (Zhu et al., 2012) and reduced connectivity within and across structural modules that overlapped with the default network and the executive control network (Chen et al., 2011). These aging-related differences in structural networks were accompanied by the escalating breakdown white matter structural integrity and gray matter atrophy previously discussed in normal aging. As with children and younger adults, small-world network organization was observed to be maintained in the aging brain, despite the evident reorganization of neural networks (Niendam et al., 2012; Tononi & Cirelli, 2012).

[11]The mechanisms through which neuronal activity is systematically translated into regional differences in cortical thickness or volume are not yet clear, but this question will arise in other contexts in the next section, and we will discuss it there.

In Sum

Healthy brain development involves a shift from early functional segregation of activity (local node development) to integration of mature nodes into large-scale functional neural networks that have efficient small-world properties (distributed processing in a complex system). Mature local circuits (nodes) make the most efficient contribution to large-scale neural networks, so that local maturation precedes establishment of mature large-scale neural networks. These processes are linked because the maturation of local PFC circuitry dramatically increases the territory into which large-scale neural networks can expand. During the period in which these extensive neural networks are being established, there is likely to be considerable instability in the global system.

In prior work (Ganzel & Morris, 2011), we provided evidence that each brain region has a unique developmental trajectory. Given the data presented already, we argue that this point is valid across the life span, so that close examination of the brain at any age will reveal different local patterns of maturation and senescence. We conclude here that human brain is constantly changing. In the next section, we apply this concept to our allostatic diathesis–stress model. In doing so, we discuss how both development and strong experience (good or bad) may open windows of instability in allostasis over time, which may create vulnerability to insult—but also opportunity for intervention.

ALLOSTASIS IN A CONSTANTLY CHANGING BRAIN

In this section, we will present models of stress, diathesis, and mental health that explicitly include the concept of a constantly changing brain that we presented in the previous section. There, we argued that brain undergoes continuous age-related change in structure and function across the life span—and that the trajectories of this change vary systematically by brain region. This regional variation occurs in the context of global changes in white matter development and functional network connectivity. In this section, we apply this concept to the diathesis–stress

model. If the brain is the central mediator of allostasis, then we argue that there is ongoing age-related change within the neural circuitry that underlies central allostasis, i.e., within the neural mechanisms of the stress process itself. Allostasis, allostatic load, and stress outcomes—including psychopathology—would thus be expected to vary with the developmental/life span timing of the target stressor. We review evidence in support of this hypothesis and then expand our allostatic diathesis–stress models to incorporate this information.

The focus of this discussion is the occurrence *of sensitive periods,* a term that describes a restricted time span when the effects of experience or insult are particularly strong (e.g., early childhood, adolescence, transitions in developmental stage; Knudsen, 2004). The centrality of the brain in allostasis makes it necessary to consider stress-sensitive periods in neurodevelopment and neurosenescence. However, it is not yet clear how a concept of stress-sensitive periods applies to the allostatic model. Strong implicit models in current developmental stress research include the view that only early-life stressors have long term effects, particularly in the absence of psychopathology (for a discussion, see Ganzel & Morris, 2011). But the ongoing processes of allostasis necessarily generate central and peripheral allostatic load—so what does this mean for a life span allostatic model? Is allostasis then restricted to sensitive periods in youth? We have written about the need for explicit attention to developmental stage in thinking about the allostatic process and the physiological cost of stress (Ganzel & Morris, 2011). We expand on that discussion here.

The processes of development and senescence uniquely constrain physiological response, creating periods or windows of varying sensitivity to experience. The source of these windows is multiply determined (e.g., Levine, 2000; Mead, Beauchaine, & Shannon, 2010). It has been argued that such windows arise because of system instabilities that are either inherent in development or that come about in response to experience (Knudsen, 2004). These have been likened to a temporary broadening of the stability landscape within a neural system that would otherwise be more heavily constrained and protected by innate programming, and thus less subject to change (Knudsen, 2004). Our focus is on those system instabilities that result in changes in the stress response itself, i.e., within the mechanisms of central allostasis. These, in turn, will drive changes in all downstream elements of the allostatic model, including alterations in allostatic load and current mental health. *These* will alter future contexts, future stressors, and future ability to engage allostasis, and—ultimately—future mental health.

In discussing long-term effects of stress on central allostasis, we will focus on the canonical large-scale neural networks discussed earlier. We will take a moment to make a clarification here about the salience network and related survival circuitry, which we have discussed as separate entities up until now. In the next sections, we will typically refer to survival and salience circuitry as a single coherent network. This is for parsimony, and also because these networks are rarely distinguished in discussions of neuroimaging findings for practical reasons. We have seen that activity in the salience network can be studied during rest—a stimulus is not required. In contrast, study of activity in a given survival circuit requires exposing the study subject to the appropriate circuit-specific trigger stimulus (e.g., Bachis, Cruz, Nosheny, & Mocchetti, 2008; Ganzel et al., 2008; Kang et al., 2012; LeDoux, 2012; Phan et al., 2004; Phan et al., 2002). Critically, however, survival circuitry and the salience network unite during the detection and evaluation of salient/survival-related information, and in the planning and execution of adaptive response.[12] Thus, for brevity, we will refer to the survival/salience network when we discuss co-activation of the salience network and LeDoux's (2012) defense circuit in imaging studies incorporating threat-related stressors.

Windows of Vulnerability; Windows of Opportunity

Stress Sensitivity in the Developing Brain

Here we examine some of the processes of development and senescence that create periods/windows of differences in sensitivity to stress or insult. For example, the typically developing brain is vulnerable to perturbation during neural and glial cell development (Knudsen, 2004). Stress-related disturbance or outright insults that occur during periods of rapid developmental are more likely

[12]Barrett (2013) argued that the salience network serves to orient and mobilize the brain's resources in response to generic (domain-general) innate or learned stimuli that have metabolic or homeostatic relevance. This domain-general salience network could be hypothesized to serve as the critical interface between LeDoux's (2012) survival circuits and the rest of the brain's neuronal architecture. As previously noted, however, there continues to be a lack of clarity as to whether the amygdala, ventral striatum, and closely related regions belong in the salience network proper or as inputs to the salience network. We propose that the salience network (both ventral and dorsal components) serves as a general-purpose neural modulator of the survival circuits described in an earlier section.

to disrupt brain structure and function than are system challenges that occur at any other time (Rice & Barone Jr., 2000). There are multiple points during brain development where these system instabilities may arise. At birth, the human brain has approximately 100 billion neurons. These neurons develop from early precursor cells and proliferate outward following radial glial processes, undergoing differentiation, axogenesis, synaptogenesis, pruning, and mylenation in the process of forming the mature neural circuits that underlie normal physiological function and complex behavior (Caviness & Takahashi, 1995; Oda & Huttenlocher, 1974). A window of stressor-sensitivity arises because perturbations or insults to the brain are exacerbated during rapid cell development, compared to perturbations/insults that occur before or after a developmental spurt (Rice & Barone Jr., 2000).

The increased plasticity that occurs during a period of sensitivity is likely to produce adaptive accommodation under typical conditions (e.g., normal maternal care; Diorio & Meaney, 2007). Conversely, accommodations made under atypical conditions are more likely to be adaptive in the short term, but maladaptive in the long term (for discussions, see Ganzel et al., 2010; McEwen & Lasley, 2002). Extreme, negative experiences constitute "failure of the average expectable environment" (Cicchetti & Valentino, 2006, p. 129). The additional plasticity inherent in development can heighten stress-related vulnerability, resulting in atypical physiological development and negative long-term health outcomes in stressed children and youth. Examples include the documented long-term physiological responses to neglect or prolonged early separation (Levine, 2000; Spinelli et al., 2009; Tottenham et al., 2010; Vazquez et al., 2006), early maltreatment (Andersen et al., 2008; De Bellis, Baum, Birmaher, Keshavan, & Ryan, 1999), or high levels of chaos in early rearing environments (Coplan et al., 2001; Evans et al., 2007; Taylor, Eisenberger, Saxbe, Lehman, & Leiberman, 2006).

We begin our discussion of stress-sensitive periods in early childhood. We focus on early childhood because it provides a case in point, allowing us to demonstrate by example the presence of stress-sensitive periods in development. In fact, the primacy of early experience is perhaps the defining concept of developmental stress research; most developmental models of stress in the social and life sciences include heightened stress-sensitivity to early experience with varying levels of exclusivity (e.g., Diorio & Meaney, 2007; Loman & Gunnar, 2010; Lupien, McEwen, Gunnar, & Heim, 2009; McEwen, 1987). Following the discussion of early life stress, we expand to include a life span perspective.

Animal Models of Early Stress-Sensitive Periods

Perinatal Sensitivity to Environment

There is clear evidence in rodent models for sensitive periods in the stress response during the perinatal period (for reviews, see Chapillion, Patin, Roy, Vincent, & Caston, 2002; Cottrell & Seckl, 2009; Matthews, 2002). The best-studied of these is a window of sensitivity in the first 8 days of a rat pup's postnatal life, in which the maturing stress response of the rat pup is hyporeactive, with low basal levels of glucocorticoids[13] and low levels of glucocorticoid response to stimulation (termed the *stress hyporeactive period*; De Kloet, Rosenfeld, Van Eekelen, Sutanto, & Levine, 1988). During this period, gradients in level of maternal care (e.g., licking, grooming, and arched-back nursing [LGABN] of pups) are observed to cause changes in offspring stress physiology and behavior that extend into adulthood (for reviews, see Diorio & Meaney, 2007; Levine, 2000). For example, rat pups that receive high levels of LGABN from their mothers during the first postnatal week grow up to show lower hypothalamic-pituitary-adrenal (HPA) axis response and less fear of novelty as adults, relative to adult pups of low LGABN mothers (Admon et al., 2009; D. Liu et al., 1997). If the mother is separated from her pups for too long (12 to 24 hours), her caregiving becomes disrupted and LGABN decreases. Notably, these effects can be eliminated by direct pharmacological downregulation of hippocampal glucocorticoid receptor levels in the offspring (Meaney, Aitken, Viau, Sharma, & Sarrieau, 1989), indicating a mediating role for glucocorticoid receptor activity in the association between maternal care and offspring stress response. Although low-LGABN mothers are more fearful and have more reactive HPA axis responses (and the converse is true for high- LGABN mothers), the distinct biobehavioral traits of their pups are not a function of genomic inheritance. When the offspring of low-LGABN

[13]Glucocorticoids are one of the primary products of the hypothalamic-pituitary-adrenal (HPA) axis. The HPA axis starts in the brain, where an area of the hypothalamus (the paraventricular nucleus) responds to perceived adversity and produces corticotropin releasing hormone (CRH). This, in turn, activates the anterior pituitary to produce adrenocorticotropin releasing hormone (ACTH), which stimulates the adrenal cortex to produce corticosteroids, including glucocorticoids (in humans, the primary glucocorticoid is cortisol). Corticosteroids, in turn, act broadly and relatively slowly to mobilize the body's energy resources (for a discussion, see Loman & Gunnar, 2010).

mothers are fostered by high-LGABN mothers, they are less fearful as adults and show lower HPA response—the opposite is true when pups of high-LGABN mothers are fostered by low-LGABN dams (Francis et al., 1999). Together, these data provide compelling evidence that, in rodents, early maternal care within a narrow developmental window is responsible for organizing lasting differences in the offspring's stress response.

In this system, epigenetics underlies the long-term effects of maternal care on the stress response. For these rat pups, the DNA methylation patterns of the exon 1_7 glucocorticoid receptor promotor are affected by maternal care. These stable alterations in the methylation of this glucocorticoid receptor gene affect the hippocampus' ability to regulate glucocorticoid negative feedback on the HPA axis. This produces the aforementioned increases in HPA-axis response in pups who experience low-LGABN maternal care (Weaver et al., 2004). Notably, severe food shortages during pregnancy (only) have been shown to have similar lasting effects on later health (physical growth; Susser & Stein, 1994), suggesting that parallel processes may take place among humans. In this way, epigenetics is one process by which early experiences carry forward to bring lasting modifications in the individuals' response to stressors at later points in development.

Early Stress Sensitivity in Humans

Research has repeatedly demonstrated that the neural correlates of prior stress and trauma look qualitatively different in human children, relative to those observed in adults. In adults with or without PTSD, exposure to psychological trauma is associated with characteristic dysregulation in the survival/salience network, including increased amygdala response to threat-related stimuli, relative to non-trauma-exposed adults (Ganzel, Casey, Glover, Voss, & Temple, 2007; Ganzel et al., 2008; Rauch et al., 2000; Sharot, Martorella, Delgado, & Phelps, 2007; Williams et al., 2006). Stress-related amygdala hyperactivity is frequently accompanied by either decreased (e.g., PTSD) or increased (e.g., resilience) signal in dorsal anterior cingulate cortex, medial PFC, or inferior frontal areas, along with regional decreases in gray matter volume in amygdala, anterior insula, anterior hippocampus, and medial PFC (Blair et al., 2013; Ganzel et al., 2008; Rauch, Shin, & Wright, 2003; Rauch et al., 2000; Shin et al., 2001, 2004; Williams et al., 2006; Yamasue et al., 2003).

In contrast, stress and trauma exposure in children appear to have qualitatively different sequelae; they are more likely to be associated with global differences in brain structure and function, including smaller intracranial volumes and larger ventricles, relative to nontrauma-exposed children (De Bellis et al., 1999; De Bellis et al., 2002). Other sequelae of stress and trauma in children include variable amygdala reactivity (Taylor et al., 2006; Tottenham et al., 2011) and regional volumetric decreases in ventral PFC, right temporal lobe, corpus callosum and cerebellum—but not in amygdala or insula (Carrion, Weems, Richert, Hoffman, & Reiss, 2010; De Bellis & Kuchibhatla, 2006; De Bellis et al., 1999, 2002; Seckfort et al., 2008). Very early social stress (maternal separation in institutionalized infants) is associated with increased amygdala volume, even in the absence of pediatric anxiety (Tottenham et al., 2010). Together, these data suggest that developmental timing influences the acquisition of allostatic load (a.k.a. the neural embedding of stress and trauma).

Early-Only Allostasis

An early-only allostatic model effectively captures these critical elements of developmental timing in stress process (Figure 15.15). Indeed, early-only models are implicit in much of stress research in the social and life sciences. While few stress researchers explicitly adhere to exclusive critical-period models, we note that much of developmental stress research focuses on early-life stressor exposure to the exclusion of studying age-related modulation of the stress-response at other points in the life span (although see Andersen & Teicher, 2008; Lupien et al., 2009).

There is robust evidence for developmental modulation of stress processing early in life. As previously discussed, adverse care (e.g., abuse or neglect) occurring in early childhood is likely to be damaging because this early period is a time of rapid development in the neural systems underlying the processing of salient stimuli (e.g., Tottenham & Sheridan, 2009). A compounding factor is the heightened social dependency of the younger child, which may make such experiences more overwhelming (Cicchetti, Rogosch, Gunnar, & Toth, 2010). For example, maternal stress and child cortisol levels during early childhood—but not later childhood—have been observed to predict externalizing symptoms in adolescent girls (Burghy et al., 2012). This association was mediated by disrupted amygdala-ventromedial PFC connectivity during adolescence, which suggests that connectivity between these brain regions is a potential key player in the mechanisms associating early cortisol levels with later symptoms (Baron & Kenny, 1986). Similarly, human infants who spend more time in orphanage care (an unfortunate natural experiment in maternal separation) are more likely to show neural differences and behavioral problems as older

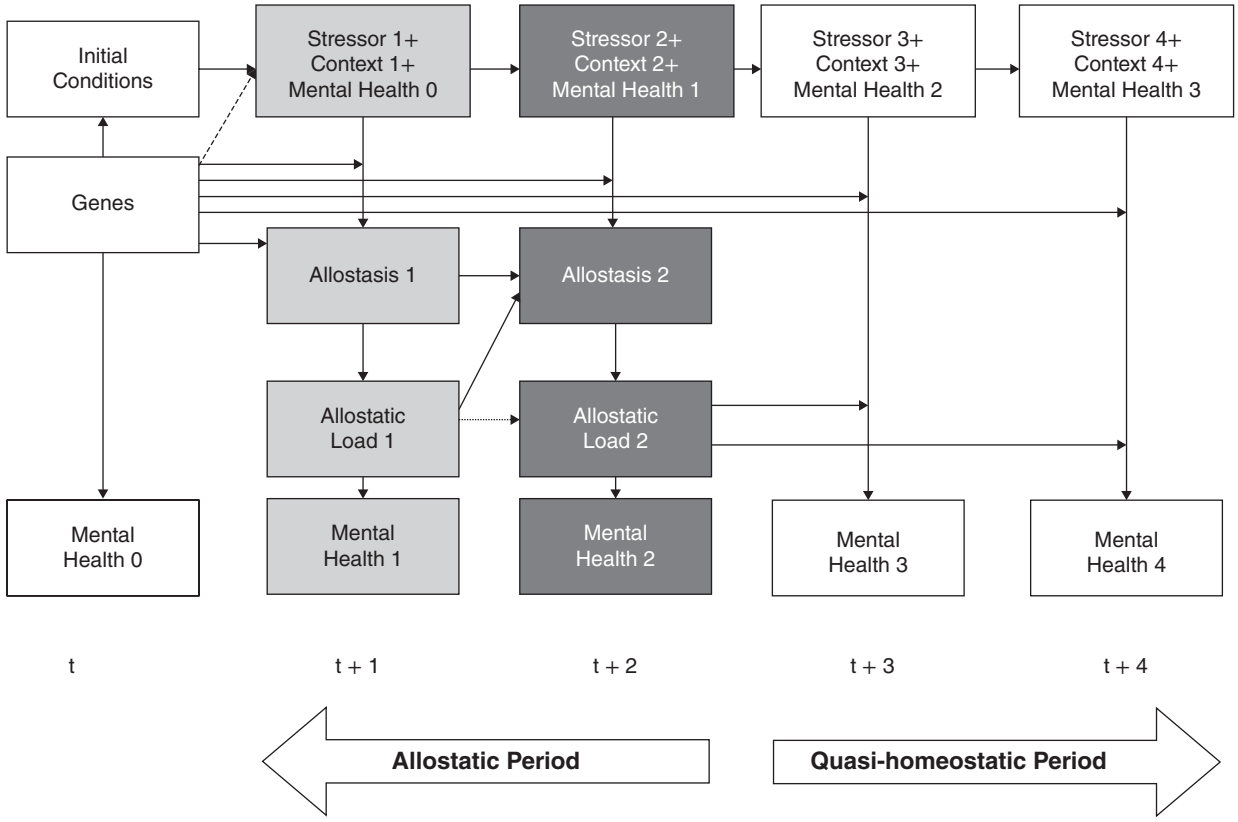

Figure 15.15 An early-only allostatic diathesis–stress model. This model illustrates strong tacit assumptions about early stress-sensitivity that are currently held in the field. In this conceptualization, allostasis is an early-life phenomenon that is active during a circumscribed allostatic period and not thereafter. The different shades of gray indicate developmental differences in central allostasis during this allostatic period (e.g., early childhood versus adolescence). Homeostasis or quasi-homeostasis best describes physiological response to a current stressor after this early period of allostatic flexibility. In this model, early diathesis is a dynamic construct that includes initial genetic loading plus early accumulation of allostatic load, which influence the biological stress response throughout the life span. *Source:* Modified from B. L. Ganzel & P. A. Morris, Allostasis and the developing human brain: Explicit consideration of implicit models, *Development and Psychopathology, 23*(4), 955, 2011.

children, relative to children who were adopted earlier in life (Gunnar et al., 2007; Rutter, 1998; Tottenham et al., 2010). For example, children between the ages of 5 and 12 years who were adopted after 15 months of age were observed to have larger amygdala volume, increased anxiety, and impaired emotion regulation, relative to children who were adopted earlier in life (Tottenham et al., 2010). This said, our intent here is not to argue for or against early stress-sensitive periods in development (as we have discussed, such periods clearly exist). Rather, we wish to expand the concept of developmental variation in stress sensitivity to include the life span.

Stress Sensitivity in Adolescence

Stress and trauma during sensitive periods can drive neural circuits into alternate patterns of connectivity and these new patterns can become entrenched if adverse conditions continue (Knudsen, 2004). Moreover, pruning during later developmental periods may uncover vulnerabilities that were acquired due to atypical earlier development (Williamson & Allman, 2011) and this may result in the later emergence of psychopathology. Happily, there is also evidence that strong, genetically preferred circuit configurations can be reestablished as a stable alternative to the atypical pattern, even after the end of the sensitive period (e.g., Brainard & Knudsen, 1998). The brain is organized in multiple parallel pathways of information processing, making it less likely that irrevocable change in a given circuit will lead to irrevocable change in complex behavior. In addition, even irrevocable change within one circuit may be compensated by changes in other circuits that may have later windows of sensitivity (Knudsen, 2004).

Differential Sensitivity to Intervention

We return to the example of the first postnatal days of a rat pup's life, and the long-term effects of maternal care on the pup's stress response. There is evidence that many of the deficits associated with poor early care can be reversed by providing the pups of low-LGABN mothers with enriched environments during the adolescent period (postnatal days 22 to 70; Bredy, Grant, Champagne, & Meaney, 2003; Bredy, Zhang, Grant, Diorio, & Meaney, 2004). In these studies, environmental enrichment consisted of increased social interaction with peers in a living environment with interconnected tunnel systems and many novel toys (versus standard solo laboratory caging with no toys). This environmental enrichment reversed the impact of low-LGABN maternal care on learning and memory and on the encoding of glutamate receptor genes that contribute to hippocampal-dependent learning. These effects were observed only for environmental enrichment during adolescence—enrichment applied before or after adolescence appeared to have no effect. Moreover, enrichment was only effective for the pups of low-LGABN mothers; it had no impact on the physiology or behavior of pups of high-LGABN mothers (Bredy et al., 2004).

In animal models, adolescent environmental enrichment also attenuates many of the neural and behavioral consequences of prenatal stress (Koo et al., 2003), postnatal extended maternal separation (Lu et al., 2003), and early lead exposure (Heim, Newport, Mletzko, Miller, & Nemeroff, 2008), all of which have different long-term outcomes relative to the consequences of adverse maternal care. Champagne (2010) emphasizes that ongoing plasticity is possible in later life stages through changes in the epigenome. Her work shows that pharmacological treatments can reverse the effects of both positive and negative maternal care, including methylation of hippocampal GR and the behavioral response to stress (Weaver et al., 2004). These findings have clear relevance to our model, in showing how epigenetic process later in development may overlay earlier epigenetic effects, thus modifying the carry-forward of allostatic load. This is an example of how past experience and current context can create iterative modifications of the stress response itself, with long-term consequences for behavior and mental health.

Stress and Human Adolescence

Figure 15.16 provides examples of the developmental time course of brain areas and processes that are likely to play a role in stress-sensitivity and central allostasis from the prenatal period through to young adulthood. From this, we can see that there are likely to be continuing effects of development on the stress response through to the end of adolescence. For example, development in the frontal cortex is region-specific, such that maturation starts in the motor area (just forward of the central sulcus) and the frontal pole (the front-most part of the prefrontal cortex [PFC]) and ends with maturation of the dorsolateral prefrontal cortex (DLPFC) in late adolescence or early adulthood (Gogtay et al., 2004). Stress processing often recruits these brain areas, as previously discussed. This point provides further evidence that the stress process itself can be expected to vary continuously as these brain regions mature in connectivity and efficiency.

Developmental trajectories also vary across key nodes of the survival/salience network, and the amygdala provides a case in point. Total amygdala volume increases rapidly in early childhood and then maintains a relatively steady volume across adolescence and early adulthood (Papagni et al., 2011). However, *functional connectivity* between the amygdala and the rest of the brain continues to undergo robust change from early childhood into adulthood (Convit et al., 2001; Tottenham et al., 2010; Wright, Dickerson, Feczko, Negeira, & Williams, 2007). For example, children show positive connectivity between amygdala and medial PFC, but adolescents and young adults show *negative* amygdala-mPFC functional connectivity that strengthens with increasing age (Convit et al., 2001). Relative to preadolescent children, adults also show much stronger and more segregated functional connectivity between key nuclei of the amygdala (basolateral and centromedial) and network nodes in the cortex and subcortex (Figure 15.17; Qin, Young, Supekar, Uddin, & Menon, 2012). Amygdala *response* also varies systematically with development (Thomason et al., 2011). For example, the adolescent amygdala is more reactive to standardized emotional stimuli (e.g., negative emotional faces) than are the amygdalae of younger children or adults (Hare et al., 2008).

In early adolescence, the salience network appears relatively mature, with resting-state synchronous activity in anterior insula/dorsal ACC, and also inferior parietal lobe, precuneus, and anterior cerebellum (Thomason et al., 2011). In this developmental period, increased hypothalamic-pituitary-adrenal (HPA) axis reactivity has been associated with greater temporal coupling of the salience network with subgenual ACC and other midline PFC regions during resting state imaging (Thomason et al., 2011). It is not yet clear whether this stress-related coupling is specific to young adolescents or how it may influence

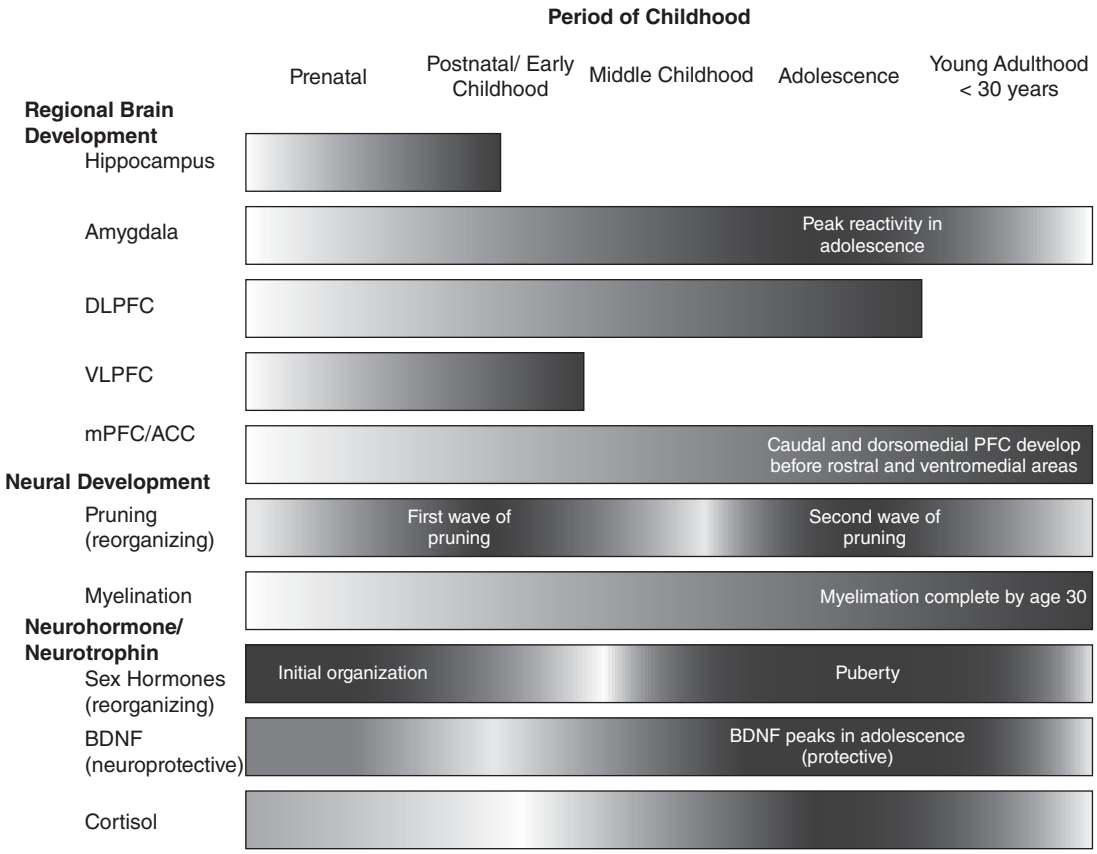

Figure 15.16 Some contributors to early variation in stress sensitivity in the human brain. Darker areas indicate periods in which developmental timing is likely to increase the impact of experience on specific brain regions, processes (pruning or myelination), or neurohormone/neurotrophin systems. In cases where there is limited information from middle childhood (ages 5 to 9 years), we have interpolated smoothly between values from infancy and adolescence. DLPFC—dorsolateral prefrontal cortex, VLPFC—ventrolateral prefrontal cortex, mPFC—medial prefrontal cortex, ACC—anterior cingulate cortex, BDNF—brain-derived neurotrophic factor. *Source:* From B. L. Ganzel & P. A. Morris, Allostasis and the developing human brain: Explicit consideration of implicit models, *Development and Psychopathology, 23*(4), 955, 2011.

the adolescent's future social-emotional adaptation or psychopathology.

Global Changes Within the Adolescent Brain

In addition to the regional variations in brain development that continue through adolescence, discussed earlier, there are also multiple global alterations in brain function that occur during adolescence. We previously discussed the massive and permanent elimination of synapses that occurs during the second wave of pruning, accompanied by an abrupt downward shift in brain energy metabolism. We also reviewed the precipitous drop in the amplitude of slow wave EEG activity during NREM sleep that occurs during adolescence, which is accompanied by the migration of the peak amplitude of the slow wave EEG activity from brain's posterior to the frontmost parts of the prefrontal cortex. We noted that, because of the putative role of NREM slow wave activity in the optimization of learning and memory, this may play an important role in cognitive development.

During adolescent development, there is also a global shift in *neuromodulatory tone*, i.e., in the balance of *excitation and inhibition* (E/I) in neural circuits (Bavelier, Levi, Li, Dan, & Hensch, 2010; Hensch & Bilimoria, 2012). This follows from the fact that a major neurotransmitter, gamma-aminobutyric acid (GABA), switches from being excitatory in early development to being the main inhibitory neurotransmitter in the adult brain (Ben-Ari, Gaiarsa, Tyzio, & Khazipov, 2007; Li & Xu, 2008; Wang & Kriegstein, 2009). During the years of adolescence, this reorganization of inhibitory and excitatory neurotransmission prompts a massive reorganization of neural networks, including a short period of wholesale destabilization of network synchrony in late adolescence (15 to 17 years of age; Uhlhaas et al., 2009). E/I balance also has a regulatory

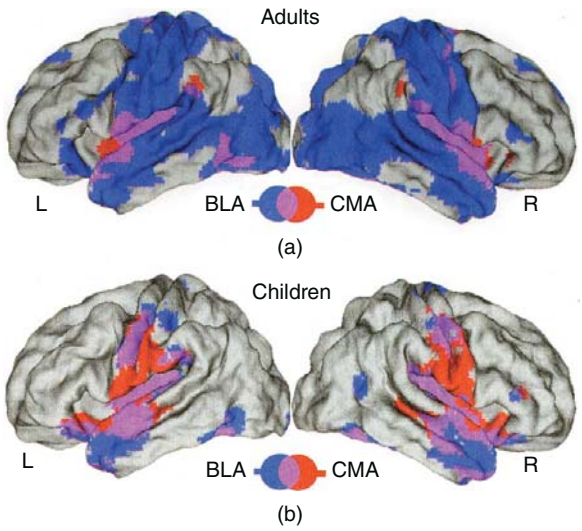

Figure 15.17 Immature integration and segregation of survival/salience network in children versus adults. The basolateral amygdala (BLA) is critical for the perception and evaluation of salient stimuli, whereas the centromedial amygdala (CMA) controls fear-related behavior. Intrinsic connectivity analyses show that (a) adults have strong segregation of the brain areas networked with the BLA and the CMA. Conversely, children (b) show relatively weak and undifferentiated functional connectivity of BLA and CMA. This is proposed to underlie immature evaluation and regulation of response to salient stimuli. See footnote 1. *Source:* Adapted from S. Qin, C. B. Young, K. Supekar, L. Q. Uddin, & V. Menon, Immature integration and segregation of emotion-related brain circuitry in young children, *Proceedings of the National Academy of Sciences of the United States of America, 109*(20), 7943, 2012.

role in the timing of sensitive/critical periods and developmental changes in neuroplasticity (e.g., Bavelier et al., 2010). For example, manipulation of GABA production (and hence the E/I balance) in the brain will alter the timing of onset of developmental critical periods or abolish them entirely (e.g., Di Cristo et al., 2007; Fagiolini & Hensch, 2000; also see Huang et al., 1999; Sugiyama et al., 2008). In short, E/I balance is fundamental to local and global brain development and plasticity, and to the organization of the canonical large-scale neural networks in the mature cortex (Bavelier et al., 2010; Hensch & Bilimoria, 2012; Uhlhaas & Singer, 2012). To our knowledge, the impact of stress- or trauma-related disruptions to this system during adolescence remains unexplored.

Implications for Psychopathology

We have argued here for a constantly changing brain so that a stressor experienced within one developmental time period is likely to have a different effect on long-term physiology and mental health than a stressor experienced later or earlier (Ganzel & Morris, 2011). There is emerging evidence for this type of developmental specificity in the neural embedding of stress. This is illustrated in an MRI study of young women who were similar in age at time of imaging, but who had experienced child sexual abuse (CSA) during different developmental periods (Andersen et al., 2008). Compared with women without a history of CSA, women who were abused between 3 and 5 years of age had the greatest reductions in hippocampal volume, relative to nonabused women and the other women with CSA. Women with CSA between 11 and 13 years of age also had significantly smaller hippocampal volumes, but the effect was not as strong as among the women with preschool CSA. By contrast, CSA between the ages of 9 and 10 was associated with reduced size of the front-most portion of the corpus callosum (the white matter conveying information between the two hemispheres of the brain) and CSA between the ages of 14 and 16 was associated with reduced volume of the prefrontal cortex. If replicated, these data suggest that there are different long-term effects of repeated childhood sexual abuse (CSA) on brain structure depending on when the abuse occurred (Andersen et al., 2008).

The mental health of the young women with CSA also varied as a function of the developmental timing of their abuse. Current symptoms of depression were associated with CSA during early childhood (preschool years) and current symptoms of posttraumatic stress disorder (PTSD) were associated with abuse between the ages of 9 and 10 (for a discussion, see Andersen & Teicher, 2008). There is a substantial body of research that examines the impact of early stress on the brain or mental health, or both. It is becoming clear, however, that there is further need to articulate the role of developmental timing in studies of the long-term effects of stress on brain, behavior, and mental health.

Stress-Related Neural Plasticity and/or Damage in Adults

Despite a general focus on early life stress in the literature, there is accumulating evidence for stress- or trauma-related functional and structural change in local brain regions in mature humans and other animals (Ansell, Rando, Tuit, Guarnaccia, & Sinha, 2012; Cerqueira, Mailliet, Almeida, Jay, & Sousa, 2007; Ganzel, Casey, et al., 2007; Ganzel et al., 2008; Gianaros, Horenstein, et al., 2007; Gianaros, Jennings, et al., 2007; McEwen, 2005; Mitra et al., 2005; Vyas, Mitra, Rao, & Chattarji, 2002). We briefly review this evidence here. In presenting data from humans, we will focus on research involving stress- or trauma-exposed adults who do not have PTSD or another mental disorder

(i.e., nonclinical or resilient adults). Acknowledging the neural embedding of stress in the nonclinical/resilient adult brain is a crucial step in constructing an allostatic diathesis–stress model. As previously discussed (Ganzel et al., 2010), the concept of allostasis fails unless it applies to everyone, regardless of current mental health and developmental stage. We review evidence for long-term effects of stress in the nonclinical/resilient adult brain. With this as a foundation, we will incorporate the intertwining roles of diathesis and life span development into our allostatic diathesis–stress model.

Evidence for Allostatic Load in the Adult Brain: Animal Models

Research with healthy adult animals has provided important evidence for long-term stress-related changes in neuronal architecture and activity in the adult brain. This research has largely focused on regions of interest, with particular focus on amygdala, hippocampus, and prefrontal cortex. For example, adult rodents exposed to a relatively intense single-event stressor will show increases in amygdala spine density (Mitra et al., 2005) and persistent amygdala hyperexcitabilty, which renders the amygdala and related structures more easily activated later (Adamec, Blundell, & Burton, 2005; Maier & Watkins, 1998; Rosen & Schulkin, 1998; Vyas, Pillai, & Chattarji, 2004). This is accompanied by blocked long-term potentiation within the hippocampus and in the pathway between the amygdala and the medial PFC (e.g., Maroun & Richter-Levin, 2003). Subsequent amygdala hyperreactivity does not require the original triggering stimulus (it can be stimulated by mild, ambiguous, or contextual stressors) and is accompanied by heightened anxiety-like behavior (Adamec et al., 2005; Mitra et al., 2005; Olson et al., 2011; Rosen & Schulkin, 1998). Research suggests that this may be driven by plasticity or pathology within the noradrenergic system, which is responsible for norepinepherine (NE) production in the brain (Olson et al., 2011). These stress-related alterations in amygdala, hippocampus, and medial PFC function, structure, and connectivity are arguably biomarkers of allostatic load.

Chronic or repeated stress intensifies the effects of acute stress (Rao, Suvrathan, Miller, McEwen, & Chattarji, 2009). Chronically stressed adult rodents develop long-term increases in dendritic arborization and spine density in pyramidal neurons in amygdala, this neuronal remodeling is associated with persistent increases in amygdala excitability and heightened anxiety-like behavior (Cui, Sakamoto, Higashi, & Kawata, 2008; Hill et al., 2012; Vyas, Jadhav, & Chattarji, 2006; Vyas et al., 2002). Recent work suggests that endocannabinoids play a critical role in these processes (e.g., Finn, 2010; Hill et al., 2012; Hill, McLaughlin, et al., 2010). Endocannabinoids are endogenous lipid-based neuromodulators that are involved in pain, hunger, mood, and memory, although they are probably best known for underlying the psychoactive effects of cannabis. Endocannabinoid receptors are expressed in amygdala, hippocampus, ventral striatum, medial PFC, and hypothalamus (at the head of the HPA axis) (Hill, Patel, et al., 2010). In these regions, endocannabinoids serve to regulate inhibitory (GABA) and excitatory (glutamate) neurotransmitter release to vary synaptic strength (Freund, Katona, & Piomelli, 2003). Chronic stress (but not acute stress) alters the availability of endocannabinoids in amygdala and this has been demonstrated to underlie the stress-related remodeling of amygdalar neuronal architecture, as well as stress-related changes in anxiety-like behavior (Hill et al., 2012; Hill, McLaughlin, et al., 2010) and habituation of the HPA axis under chronic stress (Hill, McLaughlin, et al., 2010). Endocannabinoids also interact with glucocorticoids (e.g., cortisol) to underlie many of the effects of chronic stress on memory, including increasing emotional memory consolidation in amygdala (Campolongo et al., 2009) and interfering with contextual memory retrieval in hippocampus (Atsak et al., 2012). While it is clear that the endocannabinoid system is emerging as a key player in the rodent stress response, it remains an open question whether identical processes occur in humans and how they may vary across the life span.

In parallel with stress-related expansion of dendritic architecture in amygdala, chronic stress has also been linked to gray matter loss in the prefrontal cortex and hippocampus in adult rodents (e.g., Bremner et al., 1995; Cerqueira et al., 2005; Gurvits et al., 1996; Sapolsky, 1985; Sapolsky, Krew, & McEwen, 1986; Uno, Tarara, Else, Suleman, & Sapolsky, 1989), and these are often accompanied by cognitive deficits (Cerqueira et al., 2007; Cerqueira et al., 2005). A similar pattern of effects is observed in humans. Stress-related alterations in gray matter volume have been argued to consist of synapse regression (Bennett, 2011). There is experimental support for this, as recent research has found that chronic stress or depression in humans and rodents increases the transcription factor GATA1 in the PFC, which in turn is responsible for reducing expression of several genes that regulate synaptic integrity (Kang et al., 2012). Increases in GATA1 in the PFC of rodents reduce spine density and dendritic complexity in PFC pyramidal neurons *and* cause depression-like behaviors (Kang et al., 2012). Notably,

stress-related increases in GATA1 expression are reversed by administration of antidepressants in rodents, but the same effect is not achieved in humans.

Stress-related changes are observed in other neural processes that are likely to affect global or regional brain structure or function. For example, chronic stress is observed to kill approximately 5% of the neurons in the rodent cortex (Bachis et al., 2008) and to decrease proliferation of glia by 35% in the rodent anterior cingulate, motor cortex, and hippocampus (Banasr et al., 2007). Chronic stress also decreases hippocampal neurogenesis (Gould, McEwen, Tanapat, Galea, & Fuchs, 1997) and generates chronic alterations in the neurohormones and neurotransmitters that have regulatory roles in the brain (Albeck et al., 1997). Some of these effects are reversible with rest, e.g., decreased neurogenesis (Gould et al., 1997), decreased medial PFC function (Liston, McEwen, & Casey, 2009) and hippocampal atrophy (Vyas et al., 2002). This may reflect a heartening elasticity in at least some components of adult central allostasis and suggests that at least some elements of allostatic load can be undone.

Evidence for Allostatic Load in the Adult Human Brain

Parallel findings arise in human neuroimaging studies of long-term correlates of prior trauma exposure (natural disaster, terrorist attacks, domestic violence) in the nonclinical/resilient adult brain. In these studies, trauma exposure in adulthood predicts persistent increases in amygdala reactivity—not only to trauma reminders (Admon et al., 2009; Sharot et al., 2007) but also to standardized affective stimuli (fearful versus calm faces)—even years after exposure to the target trauma (Ganzel, Casey, et al., 2007; Ganzel et al., 2008). A study by our group examined the effects of a naturally occurring disaster on affective processing of cues of threat (Ganzel, Casey, et al., 2007; see Figure 15.18). Specifically, we used fMRI to assess the impact of trauma exposure (proximity to the World Trade Center disaster on September 11, 2001) on amygdala function in 22 nonclinical adults. More than three years after the terrorist attacks, we found that amygdala activity in response to viewing fearful faces compared to calm ones was higher in people who were within 1.5 miles of the World Trade Center disaster, relative to those who were living more than 200 miles away that day (all were living in the New York metropolitan area at time of imaging). This effect was statistically driven by time since worst trauma in lifetime and intensity of worst trauma, as indicated by reported symptoms at time of trauma. These data are consistent with a model of heightened amygdala reactivity following psychological trauma exposure in nonclinical adults, with slow recovery (potentially on the order of decades).

There is also evidence for trauma-related alterations in emotional cognition in trauma-exposed nonclinical adults, compared with adults with PTSD and also with non-trauma-exposed controls (Blair et al., 2013; New et al., 2009). Relative to both other groups, resilient adults are observed to have unique increases in PFC activity during effortful emotion regulation (New et al., 2009) and in response to an emotional Stroop task (Blair et al., 2013; Qiu et al., 2010). This is argued to be trauma-related neural plasticity that fosters resilience in these adults, allowing them to employ increased top-down control during the processing of emotional stimuli (Blair et al., 2013; New et al., 2009).

Stress and trauma are also implicated in differences in brain *structure* in nonclinical adult humans. In the 9/11-exposed adults discussed previously, we observed broad 9/11-related reductions in gray matter volume that included amygdala, anterior insula, anterior hippocampus, dorsal ACC, and medial PFC, during imaging done approximately three years after 9/11/01 (Ganzel et al., 2008). This finding has been replicated in other samples by other groups (e.g., Ansell et al., 2012, although this study did not include amygdala as a region of interest). Our group has replicated the finding of stress-related reductions in amygdala gray matter volume in another sample, this time of nonclinical young adults with varied histories of trauma exposure (Monohan, McConnell, Salo, Sellers, Wong, & Ganzel, in preparation). In this sample, adults with more traumas in lifetime were observed to have decreased gray matter volume in amygdala. Interestingly, within the same sample, younger age the time of their first trauma was associated with decreases in gray matter volume in the subgenual cingulate (Brodmann area 25), whereas more recent trauma exposure was linked with decreases in gray matter volume in right insula (Monohan et al., in preparation). From prior literature, the association between early trauma exposure and decreased gray matter volume in subgenual cingulate (area 25) is consistent with the intersecting roles of early trauma and Brodmann area 25 in depression (e.g., Heim et al., 2008; Lozano et al., 2012; Mayberg et al., 2005). In addition, a robust association between trauma recency and smaller right insula has been replicated in another study (Ansell et al., 2012), with the additional finding of decreased gray matter volume through the rostral and ventral midline of the PFC (Ansell et al., 2012; Papagni et al., 2011). To our knowledge, this study is the first time that both findings have been identified in the same sample of nonclinical

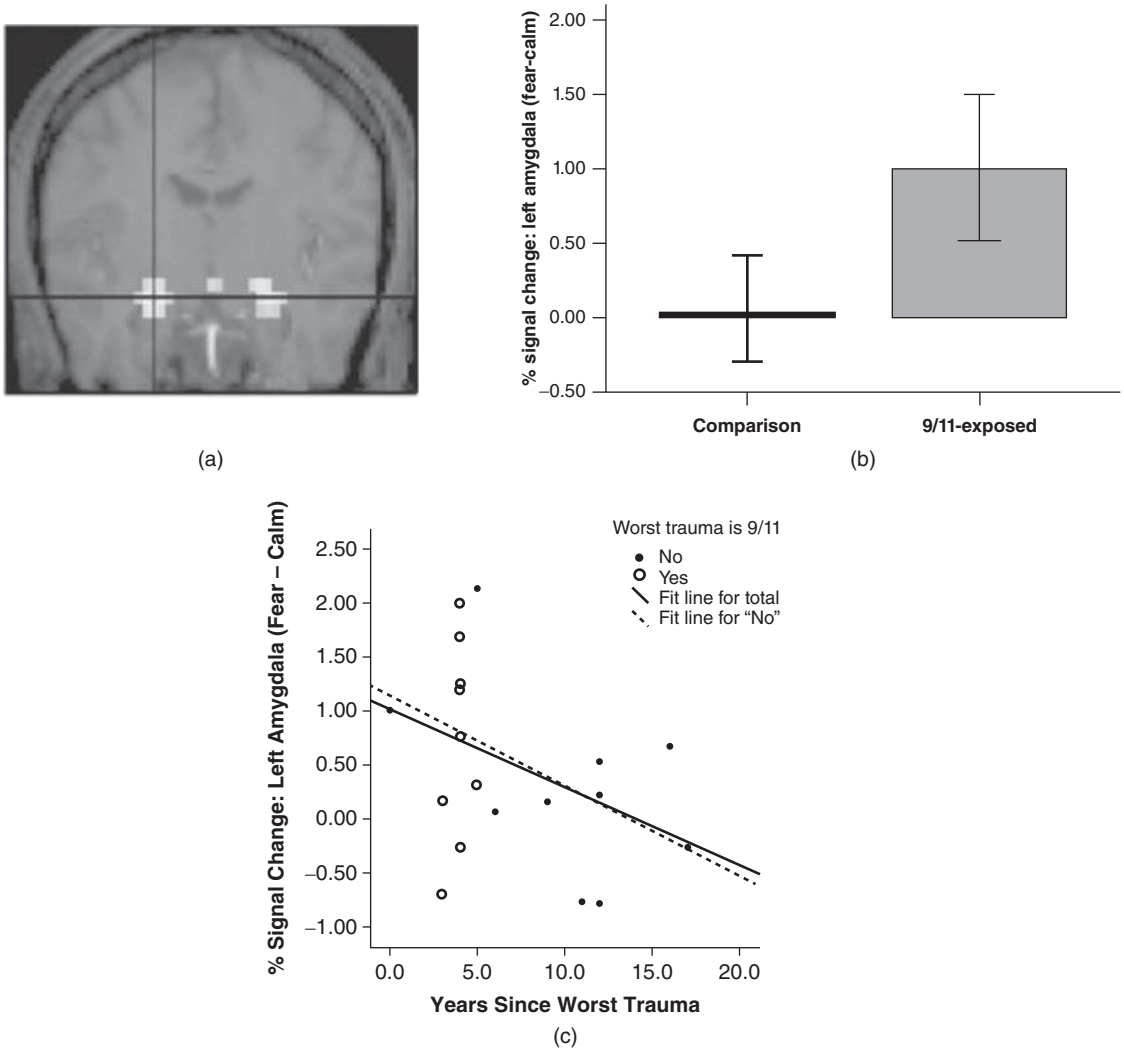

Figure 15.18 Slow amygdala recovery after trauma exposure in nonclinical adults. (a) Fearful versus calm faces elicited greater amygdala activity in the group that was near the World Trade Center disaster relative to the comparison group that was living more than 200 miles away at the time of the attacks. (b) Region of interest analysis showed signal in amygdala in response to fearful versus calm faces was higher in the 9/11-exposed group. (c) Partial plots for the whole group show mean signal change in left amygdala (fearful versus calm faces) versus years since worst trauma in lifetime, controlling for age. Data for those endorsing non-9/11 traumas as worst traumas are shown for comparison. *Source:* From B. L. Ganzel, B. J. Casey, G. Glover, H. U. Voss, & E. Temple, The aftermath of September 11th: Effect of intensity and recency of trauma on outcome, *Emotion, 7*(2), 231, 2007.

adults, thus lending weight to our life span perspective on the neural embedding of stress.

The observations of smaller amygdala volumes in nonclinical trauma-exposed adults appears counter to the animal data on chronic stress or even acute stress, discussed previously. If stress-related gray matter loss is driven primarily by synapse regression (Bennett, 2011), i.e., the retraction of dendritic arborization and synaptic boutons, then stress-related *increases* in amygdalar dendritic arborization and synaptogenesis should logically be associated with increases in amygdala volume. This is indeed observed in children with a history of postnatal stress (maternal separation combined with orphanage care), who show amygdala hyperactivity to standardized emotional stimuli (Tottenham et al., 2011) and larger amygdala volumes (Tottenham et al., 2010), both of which are associated with impairments in emotion regulation. As we discuss later, this effect is also observed in adults who are experiencing their first episode of depression. The mechanisms through which neuronal activity is systematically translated into regional differences in cortical thickness or gray matter volume are not yet clear, but this question will arise in other contexts in the next section and we will address it there.

Evidence for Allostatic Load in the Aging Brain

Age-related variation in neural stress sensitivity does not stop in adulthood, even into old age. Structure and functional response of amygdala, for example, continues to change systematically throughout the life span. In aging rodents, for example, the total number of neurons in the basolateral nucleus of the amygdala remains stable but the number of glia increases, along with increases in dendritic arborization (Rubinow, Drogos, & Juraska, 2009; Rubinow & Juraska, 2009). This is suggestive of ongoing plasticity in the aged amygdala, which is consistent with evidence for spared amygdala function in older humans (Denburg, Buchanan, Tranel, & Adolphs, 2003; Mather et al., 2004; Wright et al., 2007). In contrast, the aged hippocampus and medial PFC show notable shrinkage and loss of dendritic material in rodents and humans (Convit et al., 2001; Markham & Juraska, 2002; Markham et al., 2005; Raz, Rodrigue, & Haacke, 2007) and this is accompanied by significant functional decline (Driscoll & Sutherland, 2005; Resnick, Lamar, & Driscoll, 2007).

Older adults show increased sensitivity to stress relative to young adults, as demonstrated by increased stress-related cardiovascular and immune system dysregulation (e.g., Ong, Rothstein, & Uchino, 2012; Uchino et al., 2010). Along with heightened stress-vulnerability, older adult humans show a strong goal-directed decrease in attention to negative stimuli (a *positivity bias*), which is believed to be motivated by an increased interest in preserving positive emotionality and well-being (e.g., Carstensen et al., 1997; Fischer et al., 2005; Gross et al., 1997; Mather et al., 2004; Mather & Carstensen, 2003; St Jacques et al., 2010; Tessitore et al., 2005; Urry et al., 2006). Despite this positivity bias, increased stress sensitivity in older adults combines with increased exposure to stressors (a normal hazard of aging) to predict age-related declines in health (e.g., Cohen & Williamson, 1991; Kiecolt-Glaser & Glaser, 2001). This synergy of sensitivity and exposure is exacerbated by contextual factors, such as increased loneliness (Cole et al., 2007; Ong et al., 2012). There is also emerging evidence that prior trauma exposure carries unique risks for older adults. Older adults with a history of trauma exposure in adulthood have a higher likelihood of dementia than older adults with no trauma history (Burri, Maercker, Krammer, & Simmen-Janevska, 2013; Tsolaki et al., 2010; Yaffe et al., 2010). Notably, older adults with a history of childhood trauma do not appear to share this increased risk of dementia (e.g., Burri et al., 2013; Ravona-Springer, Beeri, & Goldbourt, 2011), but they are more at risk for geriatric depression (Kuhlman, Maercker, Bachem, Simmen, & Burri, 2013). Thus, the developmental timing of stress and trauma continues to be an important modulating factor in the diathesis–stress process, even into old age.

Incorporating Modulated Allostasis Into Diathesis–Stress Models

The Implications of a Constantly Changing Brain

The brain is the central executor of allostasis. Thus, we expect there to be multiple points across the life span in which the mechanisms of allostasis are uniquely constrained or expanded, or qualitatively changed by the processes of development or senescence. These changes may be temporary (a window) or long-term (a stage). Allostatic accommodation to a stressor that occurs during such a time period will generate a different pattern of physiological wear and tear (allostatic load) compared to a stressor that occurs before this window opened or this stage began. The large and small physiological insults that make up the new allostatic load from this stressor will be unique to this stressor and to this age/developmental period, with distinctive long-term consequences for mental health.

We integrate this concept of modulated allostasis into our diatheses-stress model (Figure 15.19). The tones and shading in each column of the model represent differences in the physiological processes of allostasis at different ages/developmental periods in the life span. These age-related differences in stress-sensitivity are expected to arise out of normal development and then senescence within the survival/salience network, the stress-sensitive peripheral systems, and the processes of plasticity themselves. As previously discussed, allostatic load is accumulating to a greater or lesser degree across the life span.[14] Thus, in this model, diathesis is *dynamic*; it is the sum of an individual's initial genetic compliment and accumulated (central and peripheral) allostatic load at any given point in time.

In Sum

We have argued that brain development is contiguous with brain senescence. Together, they constitute age-related change in the brain that is continuous and

[14]Note regarding *acquired* resilience and cognitive reserve, which may be described as antiload; see McEwen's (2002) argument regarding exercise and dietary interventions. Social interventions, too, must be instantiated in neurophysiology to influence future health and behavior (see Ganzel et al., 2010, for discussion of resilience and antiload).

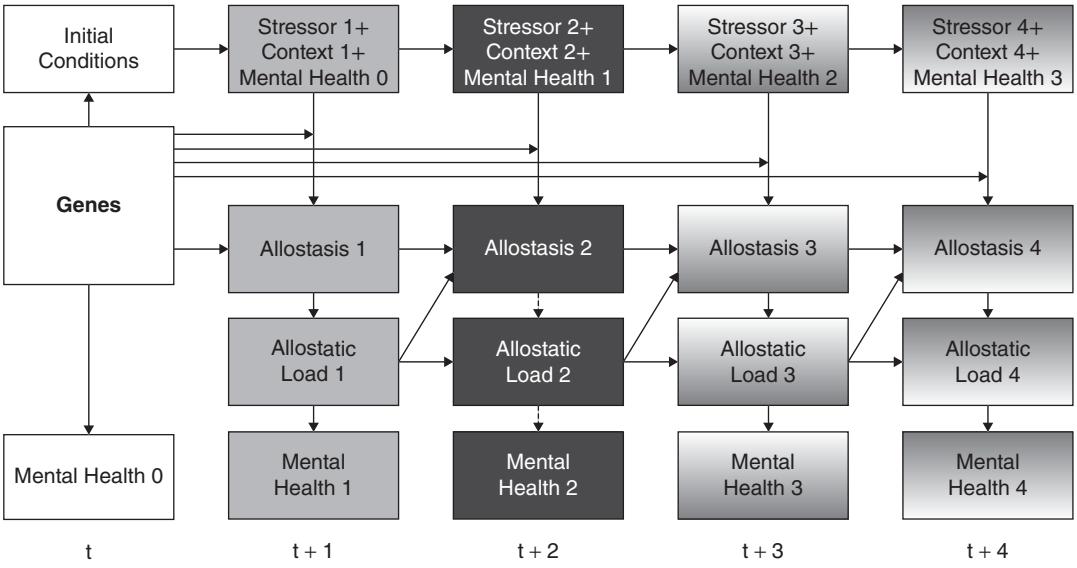

Figure 15.19 Life span diathesis–stress model with modulated allostasis. In this model, diathesis is a dynamic construct that includes initial genetic loading plus lifelong accumulation of allostatic load. Allostasis and allostatic load are shown varying as a function of changing stress sensitivity across the life span. The different shading at each time period in the model represents qualitative or quantitative differences in the physiological processes of allostasis and acquisition of load that arise as the result of these variations. Figure 15.19 shows the relative timing of some of these modulatory physiological processes. Note that mental health at one time period (t) becomes part of the context of any subsequent stressor. This is our most general allostatic diathesis–stress model. *Source:* Adapted from B. L. Ganzel & P. A. Morris, Allostasis and the developing human brain: Explicit consideration of implicit models, *Development and Psychopathology, 23*(4), 955, 2011.

multidimensional, varying across time, (brain) space, and neurobiological level of analysis. Focusing on the central role of the brain in allostasis, we have discussed evidence that the neural mechanisms of the stress process (i.e., of central allostasis) also develop and senesce as part of the phenomenon of the constantly changing brain. If the central mechanisms of allostasis are constantly changing, then the nature of allostatic load (the wear and tear due to ongoing allostasis) is also expected to vary continuously across the life span. We have reviewed the early evidence for this, along with generating unique downstream effects on mental health outcomes. These health outcomes are thus the product of each individual's diathesis (genes + prior allostatic load), stressor exposure, and the developmental timing of that stressor exposure.

Example: A Diathesis–Stress Model of Depression

There have been relatively few attempts to make a multilevel model of the onset and progression of psychopathology from a life course perspective. One illustrative example has been offered by Rajkowska and Miguel-Hidalgo (2007), who addressed the progression of the neurobiology of depression from onset through to old age. In this section, we will discuss this model in the context of our prior argument concerning the constantly changing human brain. To do so, we have adapted Rajkowska and Miguel-Hidalgo's hypothesized scheme of glial cell/neuronal pathology in depression into the format of our life span diathesis–stress model (Figure 15.20). The result is an explicit example of an allostatic diathesis–stress model of psychopathology onset and progression across the life span. To wrap up this subsection, we will then explore some of the ways in which this allostatic diathesis–stress model of depression might be used in hypothesis generation.

In the Rajkowska/Miguel-Hidalgo (R-MH) model, initial diathesis (genetic vulnerability) combines with stressor exposure (Stressor One) to generate stress-related increases in glucocorticoids (e.g., cortisol) and stress-related decreases in neurotrophic factors (supporting neuronal growth and survival) and angiogenic factors (regulating growth in the vascular system; Rajkowska & Miguel-Hidalgo, 2007). Figure 15.19 characterized these as key elements of allostasis (Allostasis One), the moment-to-moment response to a current stressor at depression onset ($t + 1$). Allostasis generates allostatic load (Ganzel et al., 2010), which in the R-MH model includes glucocorticoid-related inhibition of oligodendrocyte and

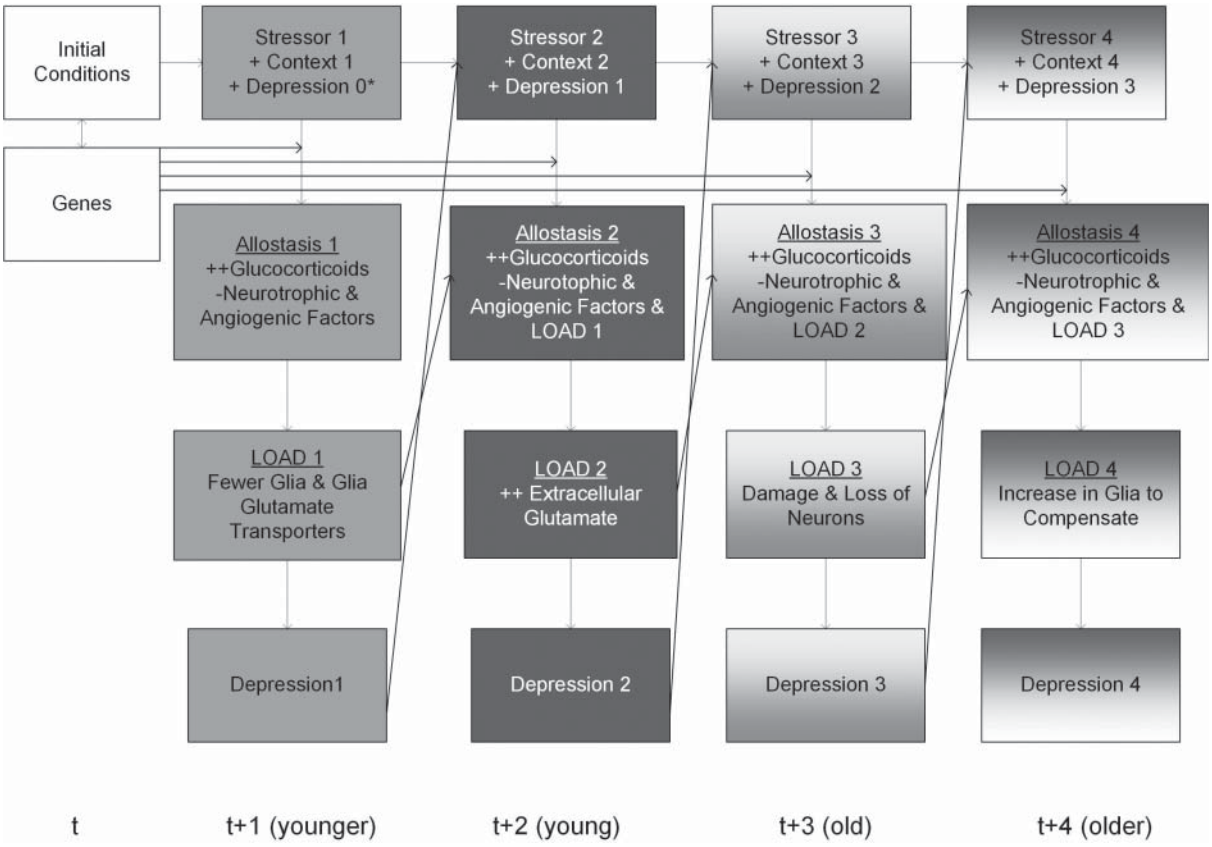

Figure 15.20 Allostatic diathesis–stress model of depression. Interactions between stressor exposure and diathesis (genetic compliment + depression-related cell pathology) drive variation in the underlying mechanisms of depression over the life span (modeled here as younger, young, old, older). *Source:* Adapted from G. Rajkowska & J. J. Miguel-Hidalgo, Gliogenesis and glial pathology in depression, *CNS & Neurological Disorders Drug Targets, 6*(3), 219, 2007.

astrocyte proliferation (Load One). This view is supported by postmortem studies of glial cell density, which show strong decreases in astrocyte density in anterior cingulate, amygdala, hippocampus, and dorsolateral PFC in younger depressed adults (see review by Sanacora & Banasr, 2013). Depression-related pathology of oligodendrocytes (reviewed by Edgar & Sibille, 2012) and microglia (reviewed by Beumer et al., 2012) has been well established, although the R-MH model highlights the role of astroglia. In particular, astrocytes are a crucial regulator of glutamate availability. One astrocyte will serve as the sole regulator of glutamate removal for a large number of synapses, so that "the failure of a single astrocyte could impair glutamate removal at thousands of synapses" (Sanacora & Banasr, 2013, p. 1175). In the R-MH model, stress-related depletion of astrocytes is expected to impair glutamate regulation, which would manifest as increased glutamate in the synaptic cleft. Thus, the carryover of allostatic load from time $t + 1$ to time $t + 2$ includes glial pathology and an associated dysregulation of glutamate uptake and release.

This latter point is critical to the R-HM model, as excessive glutamate exposure causes neuronal damage and death due to excitotoxicity (reviewed by Rajkowska & Miguel-Hidalgo, 2007). At time $t + 2$ in Figure 15.20, the individual is still in the earlier stages of depression. She experiences Stressor Two, but now she is carrying a diathesis that consists of her initial genetic vulnerability plus the acquired allostatic load from her encounter with Stressor One. Her mechanisms of central allostasis will now be trying to operate in a brain that has fewer glia and more extracellular glutamate (Allostasis Two). This is likely to hinder allostasis, resulting in a unique additional burden of allostatic load (Load Two), including fewer glia and an increasing burden of extracellular glutamate. Notably, however, this progression of stress-related glial loss and glutamatergic escalation appears to be limited. Rajkowska and colleagues (Si, Miguel-Hidalgo, O'Dwyer,

Stockmeier, & Rajkowska, 2004) have observed that younger individuals with major depression show minor neuronal pathology but prominent glial pathology (particularly pathology of astroglia). In Figure 15.20, this is represented by our allostatic R-HM model at time periods ($t + 1$) and ($t + 2$). On the other hand, older individuals (>60 years) with major depression show an increase in astroglia, combined with a notable reduction in pyramidal neurons. Because of this, Rajkowska and Miguel-Hidalgo (2007) proposed that many years of stress-related elevation in extracellular glutamate does substantial neuronal damage in aging depressives (Load Three). This exemplifies the life span development of load and an individual's diathesis (genes + load). To explain the age-related increase in glia, Rajkowska and Miguel-Hidalgo invoked the well-established tendency for glial cells to proliferate in response to neuronal damage—in this case, damage due to glutamate excitotoxicity (2007). We note that this model requires repeated stressor exposure (e.g., Stressor Four) to drive the ongoing, changing burden of allostatic load (e.g., Load Four). However, exposure to stress and trauma is relatively common in the general population (Copeland, Keeler, Angold, & Costello, 2007; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995) and psychopathology itself can serve as a stressor (e.g., Bruce, 1998).

Hypothesis Generation

Here, we depart from our reconceptualization of Rajkowska and Miguel-Hidalgo's (2007) glial model of depression to explore some of the ways this model—and our own overall approach to diathesis–stress modeling—might be used in hypothesis generation. For example, earlier we noted that astrocytes regulate non–rapid eye movement (NREM) sleep, as well as modulating sleep need, sleep intensity, and EEG slow waves, i.e., the slow neuronal oscillations that occur during NREM sleep (Fellin et al., 2009; Halassa et al., 2009). If stress-related astrocyte pathology is integral to depression, then these properties of NREM sleep should also be dysregulated in depression. There is a growing body of evidence for this. Dysregulated sleep is a core symptom of depression and there is a recent research focus on the interplay between astrocyte function, sleep (esp. NREM sleep), and depression in humans and in animal models (e.g., Cao et al., 2013; Duric et al., 2010; Florian, Vecsey, Halassa, Haydon, & Abel, 2011; Hines, Schmitt, Hines, Moss, & Haydon, 2013). Also from earlier, recall that EEG slow-wave activity during NREM sleep is argued to play a crucial role in synaptic homeostasis by downscaling LTP-related increases in synaptic weight, thus preserving memory and optimizing learning (e.g., Tononi & Cirelli, 2006). We would therefore expect that learning and memory would be impaired in depressives in direct relationship to their degree of astrocyte pathology and compromised LTP-related synaptic homeostasis. While astrocytes are observed to modulate cognitive declines associated with sleep loss (e.g., Halassa et al., 2009), to our knowledge, Tononi & Cirelli's (2003, 2006, 2012) synaptic homeostasis hypothesis has not been explored as a possible mechanism associating astrocyte pathology and the cognitive impairments observed in depression.

The R-MH model of cellular pathology in depression (Figure 15.20) embraces a life span perspective. Specifically, this model predicts pathological increases in the density of astrocytes and a parallel decrease in pyramidal neurons in key brain areas in aging depressives. It follows from the earlier discussion that we would expect to see progressive changes in NREM sleep biology, sleep-related symptoms, and cognitive deficits as depressed individuals grow old. Similarly, if age-related variation in glial and neuronal density is driven by stressor exposure, then we would expect people who have experienced more stress and trauma in lifetime to show an earlier transition to the aged scheme of depression neurobiology (more glia, fewer neurons), relative to depressed individuals with less lifetime stressor exposure. We leave these questions to future research.

In exploring this example, we do not suggest that astrocyte pathology is the only important factor in diathesis–stress models of depression. Our goal has been to demonstrate a specific use of our diathesis–stress model for hypothesis generation, as well as to emphasize that life span development is likely to underlie at least some of the observed heterogeneity in the neurobiology of psychopathology. We next turn to broader questions raised by our allostatic diathesis–stress model.

TRIPLE NETWORK ALLOSTASIS AND PSYCHOPATHOLOGY

In this section, we incorporate current research on the large-scale organization of the human brain into our allostatic model of response to a current stressor (Figure 15.4). This effort incorporates a neural network approach to psychopathology into our allostatic model of the stress process, discussed in detail in Sections Two and Four. Incorporated into a diathesis–stress framework, this approach serves as the basis for hypotheses about allostatic load within the large-scale neural networks the brain, and

its role in the onset and maintenance of psychopathology. We review emerging evidence for these effects and segue to directions for future research.

Dysfunctional Large-Scale Neural Networks in Psychopathology

A Paradigm Shift in Psychopathology Research

The intrinsic neuronal signaling within the human brain has been compared to the dark energy of the universe (Zhang & Raichle, 2010). New astrophysical evidence suggests that dark energy makes up approximately 68% of the mass energy of the universe, so this recently acknowledged (and largely hidden) component of the universe in fact constitutes *most* of the universe (Ade et al., 2013). This discovery is paralleled by recent findings in human neuroscience that less than 5% of the brain's resources are devoted to processing external stimuli—thus leaving the vast majority of the brain's energy budget devoted to previously uncharted intrinsic activity within brain systems (Raichle & Mintun, 2006). Exploration of this intrinsic activity has resulted in a functional network model of the neural function that is based on stable large-scale networks of synchronized neuronal activity. This model constitutes a paradigm shift in systems neuroscience (Sylvester et al., 2012), with a consequent paradigm shift under way now in clinical neuroscience and neuropsychiatric research (Menon, 2011; Sylvester et al., 2012; Uhlhaas & Singer, 2012).

Neuroimaging studies of psychopathology are increasingly focused on dysfunctions within large-scale neural networks. These dysfunctions can occur via damage to the nodes of a functional network, to the connections ("edges") between nodes, or to a combination of these. For example, changes in the excitation inhibition balance (Figure 15.21) at the local or node level can disrupt the synchronized neuronal activity in adjacent nodes. Thus, damage to a node can propagate to other nodes to which it is linked in a functional network (Carter, Shulman, & Corbetta, 2012; Ewers, Sperling, Klunk, Weiner, & Hampel, 2011). This may also lead to compensatory changes in other parts of the network (e.g., strengthening connectivity between between other nodes; Crofts et al., 2011). Even if the nodes of a network are healthy, network function is compromised if the connections between nodes are damaged. This can happen, for example, through age-related degeneration of white matter integrity. Damage to axonal myelin results in increased signal degradation between nodes and this, in turn, is associated with disruptions in neuronal synchrony (e.g., Mander et al., 2013; Rajkowska & Miguel-Hidalgo, 2007; Ringli & Huber, 2011). Aberrations in nodes or edges can derive from initial genetic loading or they can be acquired through experience, insult, or disease at any point in the life span. Analysis of abnormalities in functional neural networks provides a common quantitative framework for a novel synthesis of findings in psychopathology research, as well as highlighting fruitful directions for clinical research. This, in turn, has been productive in providing new insights into the neural underpinnings of schizophrenia, autism, anxiety disorders, and a wide range of other major forms of psychopathology, as we discuss later.

A Triple Network Model of Psychopathology

There is a groundswell of new research suggesting that some, if not all, psychopathologies are associated with more or less unique abnormalities in the functional connectivity of large-scale neural networks (for reviews, see Menon, 2011; Seeley, Crawford, Zhou, Miller, & Greicius, 2009; Uhlhaas & Singer, 2012; Zhang & Raichle, 2010). This suggests the alluring prospect that functional connectivity MRI (fcMRI) may be diagnostic at some point in the future. Meanwhile, research in fcMRI is driving new theorizing about neuropsychiatric disorders as pathologies of networks rather than brain regions. We will focus our discussion on an integrative model of large-scale neural network dysfunction in psychopathology, the *triple network model* (Menon, 2011). The core elements of this model are the three canonical neurocognitive networks discussed in **Section Three**—the default mode network (DMN), the salience network (SN), and the central executive network (CEN). As discussed, these three networks serve as the framework of the brain's intrinsic functional architecture, and there is growing consensus that disturbance in the function or organization of these three networks are fundamental to many neuropsychiatric disorders (e.g., Menon, 2011; Seeley et al., 2009; Uhlhaas & Singer, 2012).

Menon (2011) placed the salience network in general—and the right anterior insula in particular—at the core of triple network theory. As such, the salience network has a pivotal role in the onset of affective and cognitive dysfunction. In support of this hypothesis, he points to a robust pattern of structural or functional abnormalities in bilateral or right insula in schizophrenia (Glahn et al., 2008; Palaniyappan & Liddle, 2012; Palaniyappan, Mallikarjun, Joseph, White, & Liddle, 2011; Sommer et al., 2008; White, Joseph, Francis, & Liddle, 2010), bipolar disorder (Bora, Fornito, Yücel, & Pantelis, 2010), frontotemporal dementia (Seeley et al., 2006; Zhou et al., 2010), addiction (Naqvi & Bechara, 2009; Scott & Hiroi, 2011), anxiety

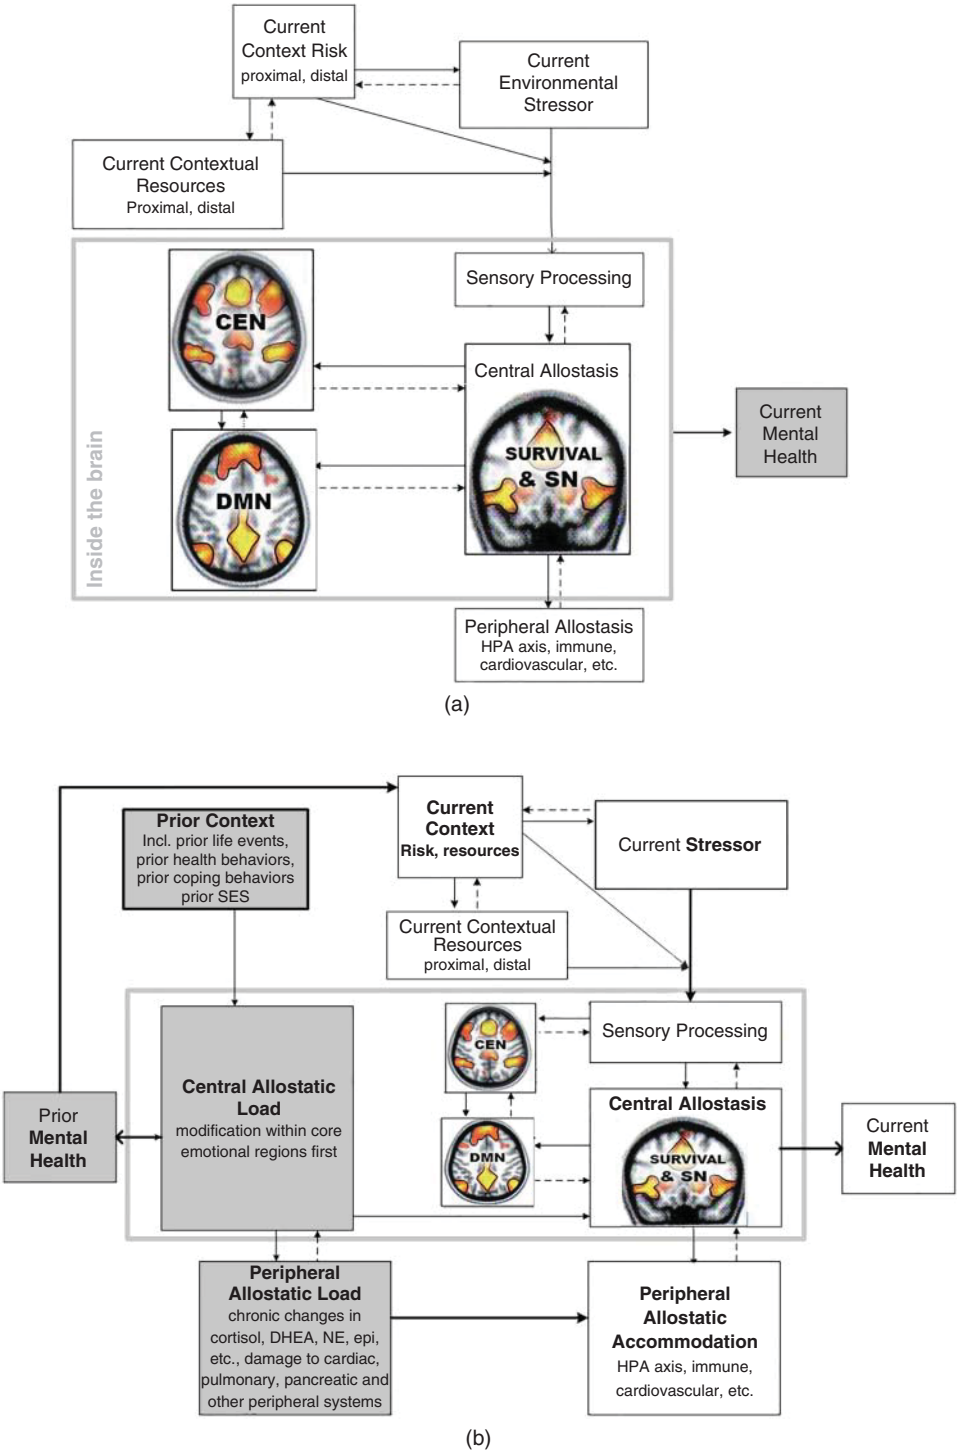

Figure 15.21 Triple network allostasis, including (a) the role of the canonical large-scale neural networks in the response to a current stressor and (b) the role of prior experience and prior allostatic load. Interaction would be expected between allostatic load and major pathways in central allostasis (not shown). DMN = default mode network; CEN = central executive network; SN = salience network; Survival = survival circuits (LeDoux, 2012). See footnote 1. *Source:* Adapted from B. L. Ganzel, P. A. Morris, & E. Wethington, Allostasis and the human brain: Integrating models of stress from the social and life sciences, *Psychological Review, 117*(1), 134, 2010; V. Menon, Large-scale brain networks and psychopathology: A unifying triple network model, *Trends in Cognitive Sciences, 15*(10), 483–506, 2011.

(Etkin, Prater, Schatzberg, Menon, & Greicius, 2009), autism (Allman, Watson, Tetreault, & Hakeem, 2005; Santos et al., 2011), and pathological pain processing (e.g., chronic migraine; Hadjikhani et al., 2013; irritable bowel syndrome; Hong et al., 2013).

Menon's (2011) proposal is based on the role of the anterior insula and the rest of the salience network in (1) detecting salient stimuli and (2) recruiting the central executive network or the default network to generate adaptive behavioral response, as discussed earlier. In his triple network model, abnormal salience detection of external stimuli or internal mental events is a core feature of psychopathology. In anxiety disorders, for example, overactive salience detection may result in misattribution of salience to relatively neutral or minor events. Atypical salience mapping could also stimulate atypical engagement of activity in the other canonical neurocognitive networks, including attention and executive control via the CEN or self-referential processing via the DMN (e.g., autobiographical memory; assignment of personal value to a stimulus). In depressed individuals, atypical salience control signals may prompt pathological rumination through hyperactivation of the default network (Berman et al., 2011; Menon, 2011; Sheline et al., 2009). In individuals with addictions, salience may be incorrectly mapped, resulting in heightened salience of drug-related cues and decreased CEN-based cognitive control of response to these cues. There is now evidence for this model of addiction through lesion studies (Naqvi & Bechara, 2009, 2010; Naqvi, Rudrauf, Damasio, & Bechara, 2007) and functional connectivity studies (Cisler et al., 2013), which have identified a crucial and unique role for the right insula in addiction.

Salience mapping may also play a key role in psychotic disorders. In schizophrenia, bilateral anterior insula volume is reduced relative to healthy controls, and these volume reductions are correlated with increasing symptoms of psychosis (Palaniyappan et al., 2011). Node-level dysfunction within the anterior insula may result in impaired connectivity within the salience network itself, and this may produce hallmark symptoms of schizophrenia. For example, disruptions in the synchrony between anterior insula and the dorsal ACC/presupplementary motor area (preSMA) could disregulate motor planning and motor execution, resulting in the psychomotor poverty or motor overflow associated with schizophrenia (Menon, 2011). Atypical activation of anterior insula is also associated with auditory verbal hallucinations, suggesting that abnormal processing of salience plays a role in these symptoms. It has been suggested that salience network dysfunction in schizophrenia underlies both the positive and negative symptoms of this disorder through disrupted recruitment of the DMN and the CEN, which together engender hallucinations and delusions and deficits in information processing (Palaniyappan et al., 2011).

In the triple network model, abnormal salience detection may have reverberating consequences not only within the salience network, but within either or both of the other canonical networks as well (Menon, 2011). Depending on diatheses and life experience, these downstream effects in other networks may be larger than the initial deficit in salience processing. Moreover, the small-world structure of each network will uniquely constrain the manifestation of these effects. In this way, the distinctive constellations of symptoms associated with particular neuropsychiatric disorders may arise out of characteristic perturbations/malfunctions within the functional architecture of the brain.

While there is some disagreement regarding whether the amygdala and ventral striatum are core elements of individual survival circuits or if they belong to the general-purpose salience network, Menon (2011) included them in the salience network (which we are calling the survival/salience network for clarity).[15] Menon contended that these nodes are particularly relevant to psychopathology. Amygdala dysfunction plays a consistent role in anxiety disorders (e.g., Etkin & Wager, 2007) and shows atypical function or structure in a number of other psychiatric disorders, while ventral striatum function is clearly aberrant in addiction and schizophrenia, among others (e.g., Barch & Dowd, 2010; R. W. Morris et al., 2011; Volkow, Wang,

[15]Recall from earlier that the amygdala and ventral striatum are key elements of two major survival circuits (LeDoux, 2012) associated with defense/avoidance and reward/approach, respectively. We also previously noted that the literature has been ambiguous about distinguishing the survival circuitry from the salience network. The distinction between these circuits depends on the type of study paradigm used. As discussed previously, activity in the salience network can be studied at rest but co-activation of survival circuitry is sporadic and highly variable. Reliable activation of any given survival circuit requires exposure to an appropriate circuit-specific trigger stimulus (e.g., Bachis et al., 2008; Ganzel et al., 2008; Kang et al., 2012; LeDoux, 2012; Phan et al., 2004; Phan et al., 2002). In experimental paradigms that do include these trigger stimuli, there will be activation of relevant survival circuitry in addition to the salience network. For clarity, then, we have elected to use the term *survival/salience network* in discussing co-activation of the salience network and one or more of the survival circuits in salience processing. Under stress, there will activation of this combined network.

Fowler, Tomasi, & Telang, 2011). As previously discussed, the amygdala and ventral striatum are highly connected with one another and with the anterior insula, with which they share many functional similarities. For example, Pessoa and Adolphs (2010) argued that the function of the amygdala in many cortical networks is primarily modulatory, in that it processes the biological value of stimuli (including ambiguity, salience, unpredictability) and serves to allocate and prioritize processing resources to generate adaptive behavior. If this sounds similar to the functions described for the anterior insula, discussed previously, it should be noted that studies of nonhuman primates indicate that the insula and amygdala are tightly linked, as well as being physiologically adjacent. The amygdala consists of multiple separate nuclei, and the insula has reciprocal connections with nearly all of them (Mufson, Mesulam, & Pandya, 1981), which helps to explain why the two structures appear functionally similar. Like the anterior insula, the amygdala is highly interconnected with much of the cortex, particularly medial and orbital PFC, but also much of the rest of the PFC. Studies from macaques indicate that amygdala inputs are able to reach approximately 90% of the PFC after a single connection (Averbeck & Seo, 2008) and that the amygdala constitutes a core brain area in terms of global brain connectivity (Modha & Singh, 2010). As previously discussed, however, the differing circumstances under which the insula, amygdala, and ventral striatum are functionally connected suggest that these three brain regions each play very different roles in the onset and maintenance of psychopathology.

As previously noted, functional connectivity between anterior insula and the rest of the salience network is observable all of the time, even at rest. On the other hand, the amygdala and ventral striatum and their respective survival circuits join robustly with the salience network only upon exposure to an appropriate circuit-specific trigger stimulus (e.g., Bachis et al., 2008; Ganzel et al., 2008; Kang et al., 2012; LeDoux, 2012; Phan et al., 2002, 2004). Menon (2011) argued for the unique integrative role of the right anterior insula in linking interoceptive/homeostatic information with the central processing of salient/survival related stimuli, including its command role in switching between the default and central executive networks. For this reason, the right anterior insula is the fulcrum, the pivot point, of the triple network model.

Triple Network Allostasis: A Novel Diathesis–Stress Model

Menon's (2011) triple network model of psychopathology provides a valuable heuristic for conceptualizing the process by which dysfunction within the large-scale neural networks of the brain predicts mental disorder. We incorporate this approach in developing an allostatic diathesis–stress model that takes the large-scale functional architecture of the brain into account. We refer to the resulting model as *triple network allostasis,* the core components of which are the canonical large-scale neural networks discussed earlier. This is an expansion of Menon's (2011) approach to include current contextual risk and resources, prior experience, life span development, peripheral stress physiology, and a dynamic diathesis into a working model that predicts mental state, psychopathology onset, and future mental health.

Triple Network Allostasis

Previously, we argued for the core affective[16] systems of the brain as the central mediator of allostasis (Ganzel & Morris, 2011; Ganzel et al., 2010). This followed from a growing body of evidence indicating that these regions are the main organizing factor in the translation of environmental stimulus into behavioral or physiological response (e.g., LeDoux, 1996; Ohman & Mineka, 2001; Rosen & Schulkin, 1998). In light of recent research on large-scale neural networks, we update this prior model by placing the survival/salience network in this key mediating role. As with Menon's (2011) triple network model, this proposal is based on the role of the survival/salience network in detecting the biological significance of external stimuli or internal events. The salience network is positioned to integrate information from the survival circuits (Cameron et al., 1993) with interoceptive information (e.g., Damasio, 2003; Rakic, 2009) to facilitate threat evaluation, selection of motor and homeostatic response, as well as response modulation (Touroutoglou et al., 2012). Moreover, the ability of the anterior insula/dorsal ACC hub to switch among canonical networks (Kempermann et al., 1998) provides flexible access to autobiographical memory, prospection, and semantic memory via the default network, and to executive control and goal-directed planning via the central executive network. Thus, the survival/salience network is the most current and precise representation of an organizing force linking salient stimuli with behavioral and physiological outcome. As such, the survival/salience network necessarily constitutes the primary regulator of allostasis, to which all other physiological and behavioral allostatic accommodation is secondary.

[16]Previously referred to as the "core emotional regions of the brain" (Ganzel & Morris, 2011; Ganzel et al., 2010).

It follows from this that the survival/salience network will be the first and primary site to show evidence of long-term wear and tear (central allostatic load) as a part of the cost of physiological accommodation to environmental demand. Accrual of allostatic load in the brain will, in turn, have consequences for peripheral physiology, psychosocial adaptation, and mental health. Identification of the specific neural circuitry that is most likely to undergo long-term change or outright damage from ongoing allostasis will allow better understanding of the physiological and behavioral consequences of environmental adversity. This will, in turn, allow more precision in intervention strategies to aid populations at risk.

The survival/salience network is a subset of synchronized nodes within the core affective systems of the brain, as those systems are currently delineated (Barrett & Satpute, 2013; Lindquist & Barrett, 2012), so that this update does not change the fundamental relationships within our prior model (Figure 15.4). In arguing that the survival/salience network is the central mediator of allostasis, we gain greater specificity in our understanding of the mechanisms of allostasis. We also acquire new and broader perspectives on the neural underpinnings of diathesis–stress processes in psychopathology. This model replaces our previous schematic of the organization of information flow and influence during moment-to-moment allostasis. Compared with the life span models discussed previously (e.g., Figure 15.19), triple network allostasis as depicted in Figure 15.21 represents a moment in the ongoing stress process—one point in time in which the salience of a current stressor is being computed, and processing resources are being mobilized in response. In a world with perfect graphic representation, progressive developmental variations of triple network allostasis would be incorporated as individual columns of a life span model like that we discussed in the previous section (e.g., Figure 15.19). With mental health as our outcome of interest, this becomes a novel articulation of the classic diathesis–stress model.

Peripheral Allostasis and Allostatic Load

In triple network allostasis, the salience network is the central mediator of allostasis, so that this neural network would be expected to accrue allostatic load at a faster pace than surrounding tissue (Ganzel et al., 2010). Said differently, the function and structure of the salience network is likely to be critically influenced by individual differences in life experience, which would, in turn, drive differences in accumulated central and peripheral allostatic load. This is an emerging area of stress research; to our knowledge, there are no studies that link prior life stress with canonical network integrity and autonomic, endocrine, or immune function in nonclinical humans (although see Eisenberger, Taylor, Gable, Hilmert, & Lieberman, 2007; Ganzel, Kim, Altemus, Voss, & Temple, 2007; Gianaros, Marsland, Sheu, Erickson, & Verstynen, 2012). Yet from our allostatic model, we would predict that individual differences in central allostatic load influence almost all peripheral allostatic regulatory functions (McEwen, 2004), and we would expect this to be a key predictor of long-term health and mortality. It may also be a key predictor of emotion, feelings, and sense of self, as it has been argued that these fundamentally derive from interoceptive information conveyed up from the physiological periphery, through the spinal cord and the thalamus, to the anterior insula—which then disseminates this information to the functional networks of the brain (e.g., Damasio, 1999; Damasio & Carvalho, 2013). This is the substance of the iterative feedback loop depicted in Figure 15.21a between central and peripheral allostasis. In this perspective, the irate boss is seen with the eye, perceived in the brain, felt in the gut, and acted upon using integrated brain/body input. Under allostasis, the physiological mechanisms underlying perception and feeling in this model are subject to central and peripheral allostatic load respectively (Figure 15.21b).

Stress Vulnerability Within the Functional Architecture of the Brain

We previously reviewed evidence for selective stress-related damage or long-term change in individual nodes of the survival/salience network and the default mode network in nonclinical adults and juvenile humans and animals. In this section, we focus on the impact of stress on large-scale neural network function and structure in nonclinical adults, with some reflection on the role of development.

In the Laboratory

In the laboratory, healthy/nonclinical adults show robust reconfiguration of salience network activity during exposure to highly aversive cinematographic stimuli (Hermans et al., 2011). When viewing aversive stimuli relative to neutral ones, study subjects' functional connectivity robustly increased in anterior insula, dorsal ACC, amygdala, ventral striatum, ventromedial PFC, and other regions associated with the survival/salience network. Increased synchronized activity within this network was correlated with heightened cortisol and alpha amylase production, as well as with increases in negative affect (Hermans et al., 2011; also see van Marle, Hermans, Qin, & Fernández, 2010). Interestingly, pharmacological manipulation during

exposure to these aversive stimulus showed that these effects were mediated by stress-related production of norepinephrine, but not cortisol. Norepinephrine (NE) neurons project from the locus coeruleus to salience-related brain regions, and firing in these projections varies to support focal attention during mild arousal, and hypervigilance and distraction during extreme arousal (Arnsten, 2009; Corbetta, Patel, & Shulman, 2008; Valentino & Van Bockstaele, 2008). This is consistent with a model of norepinephrine function as the means through which neural network activity—particularly salience network activity—is quickly co-opted in response to a stimulus and then reorganized to support adaptive response (Bouret & Sara, 2005; also see Olson et al., 2011). Also in the laboratory, a similar network reconfiguration favoring salience processing has been observed in response to sustained deep-tissue pain in humans (J. Kim et al., 2013). Moreover, there is evidence in animal models that exposure to uncontrollable stressors can produce generalized sensitization of NE-producing neurons, so that future stressors of different types will drive exaggerated production of NE and behavioral disturbance (for the potential roles of serotonin and BDNF, see Anisman, Merali, & Hayley, 2008; Olson et al., 2011). This suggests one mechanism through which stressor exposure may generate allostatic load (sensitization of NE-producing neurons) that in turn influences future stress reactivity.

Laboratory stressors also impact resting state functional connectivity within the default mode network (e.g., Vaisvaser et al., 2013; Veer et al., 2011). In one study, nonclinical adults exposed to a social stress test showed immediate, but transient, increases in resting state functional connectivity between the posterior cingulate cortex (PCC) and medial PFC, inferior parietal lobule, caudate, and thalamus, along with decreased connectivity between the PCC and bilateral posterior insula and lingual gyrus (Vaisvaser et al., 2013). Immediate post-test increases in amygdala-hippocampus functional connectivity were also observed. Among the regions of interest selected for this study, only the stress-related alterations in amygdala-hippocampal connectivity persisted for more than 90 minutes after the stress test. Self-reports of increased subjective stress during testing were related only to increases in amygdala-hippocampal connectivity, and not to alterations within the default network (Vaisvaser et al., 2013). In a RSFC study employing a similar social stress test but different regions of interest, persistent (>90 minutes) increases in functional connectivity were observed between amygdala and medial PFC, and between amygdala and PCC/retrosplenial cortex/precuneus (Veer et al., 2011). This latter finding is consistent with research identifying a direct ascending anatomical projection between the basal nucleus of the amygdala and the retrosplenial cortex in the macaque brain (Buckwalter, Schumann, & Van Hoesen, 2008). Direct reciprocal anatomical connections between amygdala and medial PFC have been previously established (e.g., Ghashghaei, Hilgetag, & Barbas, 2007).

Brain development will also play a key role in the interplay between the survival/salience network and the default network during stress. This, in turn, has implications for the accrual of allostatic load and the developmental timing of the emergence of psychopathology. For example, there is a full developmental reversal in functional connectivity between the amygdala (of the survival/salience network) and the medial PFC (of the default network) (Gee et al., 2013). Children younger than ten years of age demonstrate positive connectivity between amygdala and medial PFC during a laboratory stressor, such as viewing fearful faces; However, there is a linear decrease in the valence of this connectivity between the ages of 10 and 22, and amygdala-medial PFC connectivity in nonclinical young adults is robustly negative (Gee et al., 2013). Change in the valence of this association has been shown to mediate the decreases in separation anxiety that normally occur with increasing age, and this is argued to follow from increasing top-down control of amygdala reactivity by the maturing medial PFC (Gee et al., 2013). We note that this is yet another profound alteration in brain function that occurs between 10 and 20 years of age, along with the reversal of the global excitatory/inhibitory (E/I) balance of the brain, the winnowing of synapse density during the massive second wave of pruning, and the abrupt downward shift in brain energy metabolism and amplitude of slow wave EEG activity during NREM sleep that accompanies the migration of the peak amplitude from the back to the front of the brain (and which may underlie the optimization of learning and memory). While these considerable changes are all complex outcomes of brain maturation, their interrelationship is only loosely understood and their impact on the diathesis–stress process is, as yet, unclear.

In the Wild

There are very few ecologically valid studies of the impact of stress/trauma on functional neural connectivity in nonclinical human adults. Of the studies that do exist, most highlight aberrant connectivity within regions of interest in the default network. Exceptions do exist, though. One such study examined resting state functional connectivity in nonclinical adults with recent exposure to the great Sichuan earthquake of 2008 (Lui et al., 2009). Relative to a

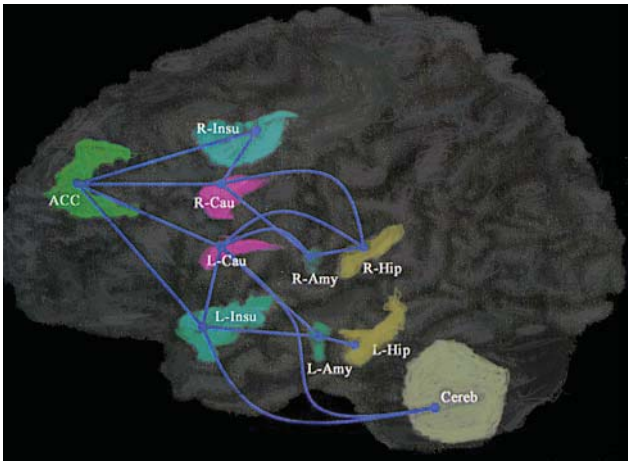

Figure 15.22 Survival/salience network disruption after the great Sichuan earthquake of 2008. In earthquake survivors, decreased functional connectivity was observed in salience-related circuitry (light-colored lines). Increased regional activity at the nodes of the salience circuit was correlated with increased distress (more symptoms of anxiety and depression). See footnote 1. *Source:* From S. Lui, X. Huang, L. Chen, H. Tang, T. Zhang, X. Li, . . . A. Mechelli, High-field MRI reveals an acute impact on brain function in survivors of the magnitude 8.0 earthquake in China. *Proceedings of the National Academy of Sciences of the United States of America, 106*(36), 15412–15417, 2009.

control group scanned prior to the earthquake, nonclinical adult earthquake survivors showed strong evidence of disrupted survival/salience network activity. Specifically, survivors showed decreased global resting state functional connectivity across bilateral insula, ACC, amygdala, hippocampus, striatum, and cerebellum (see Figure 15.22). Global decreases in functional connectivity across the salience network were accompanied by local increases in the amplitude of low frequency [synchronized] activity at nodes of the salience network, including insula, amygdala, hippocampus, and striatum. In the survivor group, this increased regional activity correlated with increased distress (more symptoms of anxiety and depression; Lui et al., 2009). This research provides convergent behavioral and neuroimaging evidence for stress-related change in the salience network in nonclinical adults. (We note that this convergence of findings helps to support the study's conclusions in the face of recent statistical concerns about group comparisons in resting state studies; e.g., Tononi & Cirelli, 2003.)

Functional connectivity studies of nonclinical adults who have experienced early life stress/trauma are also rare. One recent effort, however, used a graph analysis approach to examine the impact of early life stress on an emotion processing/emotion regulation network, which included bilateral insula, amygdala, hippocampus, and striatum, and PFC (Cisler et al., 2012). This was a rare three-group study that included women with a history of early life stress *and* a history of psychopathology (depression-susceptible individuals), women with early life stress *and no* psychopathology (resilient individuals), and a control group without histories of early life stress or psychopathology. Overall, this study found that more severe early life stress was associated with fewer connections between nodes, and fewer hubs. Interestingly, one of the network traits that best differentiated the three groups was the hub-like nature (the *betweenness centrality*) of left amygdala connectivity. Women in the nonclinical/resilient group had amygdalae that were less hub-like than controls, whereas women in the susceptible group had amygdalae that were more hub-like than controls. Increased centrality of the amygdala in information processing may lead to more affectively biased processing in susceptible women with early life stress (Cisler et al., 2013) and a greater vulnerability to affective disorders over time. If so, then a question for future research concerns the social, contextual, or biological factors that may moderate the hub-like qualities of the amygdala in children and adults who have experienced early life stress. This, in turn, may pave the way for more effective interventions.

Reverberating Effects

The survival/salience network is the neural front-line responder in initiating and supporting adaptive behavioral response to environmental challenge and (as argued here) the central mediator of allostasis (Ganzel et al., 2010). Earlier, we reviewed some of the early evidence that suggests this network is selectively vulnerable to stress, and that this influences its ability to respond to future stressors (allostatic load). We hypothesize that this stress-related damage or plasticity in the survival/salience network will drive disruptions in the other two canonical networks over time. For example, we have noted that the amygdala is extensively connected with other brain regions, serving as a connector hub that links other hubs (Pessoa, 2008). This provides ample means for the salience network, via the amygdala, to influence nodes in other networks. For example, the amygdala has direct ascending connections to the PCC and the mPFC, as previously discussed. These are the primary nodes of the default network, so that stress-related amygdala hyperactivity has a direct means of influencing default network function. Default activity is anticorrelated with activity in the dorsal attention network (which makes up half of the CEN), suggesting that stress-related disruption in one may well propagate to the

other via the amygdala. Most tellingly, the anterior insula and the dACC are included in the frontoparietal control network (which makes up the other half of the CEN), so that stress-related change in the salience network *equals* stress-related change in these key nodes of the CEN. Thus, we argue that stressor exposure can impact neural network function on a global scale, in a manner that (following our models) can be expected to be deeply influenced by individual diathesis.

Central allostasis drives peripheral allostasis (Ganzel et al., 2010). Stress-related disruptions in central allostasis can therefore be expected to drive disruptions in the stress response in physiological systems peripheral to the CNS. It is difficult to overstate the scope of these responses. Stress-related activation of both the HPA axis and the sympathetic nervous system produces glucocorticoids (cortisol, in humans) and catecholamines (e.g., epinepherine and norepinepherine; e.g., Feldman, Conforti, Itzik, & Weidenfeld, 1995; Pacák & Palkovits, 2001; Schulkin, 2003). These have profound preparative and modulating effects throughout the body, creating extensive short- and long-term stress-related alterations in peripheral physiology (e.g., McEwen, 2004, 2007; Sapolsky et al., 2000). These, in turn, feed back on brain function and structure via multiple pathways, including interoceptive input to the salience network (e.g., Critchley et al., 2004; Farb, Segal, & Anderson, 2013) and the effects of cortisol on hippocampal function and structure (McEwen, 2004, 2007; Pruessner et al., 2008). Individual differences will modulate this feedback, providing yet another avenue through which diathesis may influence the long-term impact of stress on brain and behavior.

Triple Network Allostasis in Context

The individual is embedded in a multilevel dynamical system that includes a current context, which influences the relationship between the current stressor and sensory processing, allostasis, and, ultimately, mental health (Figure 15.21). Consistent with our interest in specifying the multiple ecological levels of influence on mental health outcomes, we draw from psychosocial stress research to conceptualize the special conditions of contextual risk in this model. We also draw from dynamic systems theories in modeling the context of stress as an important source of input into physiological allostasis. Dynamic systems theory helps us understand the structure of context, how context interacts with other ecological and individual levels, and how contextual effects may play out across time. First, as shown in Figure 15.21, we conceptualize contextual risk as including both proximal and distal risk factors. While not shown on the figure for the purpose of efficiency, we do consider them as nested and interacting influences on the stress process. The direct arrow from current context to environmental stressor reflects the recognition that low-resourced environments are likely to result in higher levels of stressor exposure (Brooks-Gunn, Duncan, & Aber, 1997; Earls & Buka, 2000; Shonkoff & Phillips, 2000). In some cases, there is feedback (as indicated by the reverse arrow) from stressor to the current social or physical context. This accounts for the selection of individuals into environments, as well as the constraint on opportunities that stressors create in the choice of such contexts. Given the interactive nature of this system, we posit that prior and current risk will moderate, or shape, the effects of environmental stressors on sensory processing, as well as on the canonical large-scale neural networks and downstream peripheral physiology. In other words, the meaning of the stressor to the individual interacts with information about the physical and social context in which the individual is embedded (e.g., Hobfoll, 2001) to drive perception of the emotional intensity of the stressor and the resulting behavioral response. In short, the individual (mind, brain, peripheral physiology, and behavior) is highly influenced by extraindividual context.

Moderators of Triple Network Allostasis

Triple network allostasis also suggests approaches for predicting important moderators of the stress process. If the brain is the central mediator of allostasis, the biological capacities and organization of the brain can help to determine the properties of a stressor that are likely to influence mental and physical health outcomes in the allostatic model. For example, a stressor must have sufficient *magnitude* to activate the emotional circuitry of the brain or the stress response will not be invoked by the organism; conversely, stressors that are of a magnitude sufficient to overwhelm the mechanisms of allostatic accommodation will produce greater allostatic load. A stressor's *duration* or *chronicity* is also likely to modify the allostatic response; a stressor of sufficient persistence to exhaust (or render toxic) the biological processes of accommodation can produce profound effects on allostatic load, as previously discussed. We have also noted the expanding evidence that stressors of different *types* may be processed differently within the emotional circuitry of the brain, as, for example, with the neural processing of social pain versus physical threat (for reviews, see Alleva & Santucci, 2001; Dedovic, Duchesne, Andrews, Engert, & Pruessner, 2009; Depue

& Morrone-Strupinsky, 2005; Eisenberger & Lieberman, 2004; Lieberman, 2007). Likewise, there is evidence that the *developmental timing* of stressor exposure can moderate central allostasis (e.g., Liu et al., 1997; Susser & Stein, 1994). We have reviewed evidence here that significant amounts of central and peripheral allostatic load may be acquired in adulthood; thus, when long-term biological effects of stressor exposure are observed in children, it remains to be determined what is different about the mechanisms of allostasis and allostatic load in early human development and how the long-term health consequences of allostatic load acquired in childhood may be distinct from the consequences of load acquired in adulthood. This special role of developmental timing in allostasis may derive from the development of knowledge of emotion (Tottenham, Leon, & Casey, 2006), from differences in maturation time across the emotional circuitry of the brain (Casey, Getz, & Galvan, 2008), from a biological stress-sensitive period (analogous to the well-established stress sensitivity in the first ten days of a rat pup's life; e.g., Levine, 2001; Liu et al., 1997), or a combination of these. It remains for future research to distinguish the impact of all of these potential moderators of triple network allostasis.

Distinction between the differing impact of developmental timing and stressor type is of particular importance for studies of the consequences of early stressor exposure. The most frequently studied stressors of childhood involve separation from (or conflict with) the primary attachment figure (e.g., parental loss, neglect, rejection, or conflict). These are stressors that fit the description of social pain. As previously discussed, there is evidence for qualitative physiological differences in the neural processing of physical threat relative to that of social pain, regardless of age at time of stressor exposure (e.g., Dedovic et al., 2009; Eisenberger & Lieberman, 2004). If the processing of social pain and physical threat are biologically distinguishable within the core emotional systems of the brain, then the allostatic model would predict that central and peripheral allostatic load accrues in distinguishable physiological systems for each type of stressor. This, in turn, should lead to different long-term health outcomes for each type of stressor (there is preliminary evidence for this, e.g., Post, Leverich, Xing, & Weiss, 2001). If stressor type indeed moderates the stress process in a way that is independent of developmental timing, it will be important to include stressor type as a separate variable in models of early stress. Furthermore, the effects of stressors of different types may change across the course of development, so that developmental timing and stressor type interact with one another (a three-way interaction).

Together, these considerations point to the need for attention to likely moderators of triple network allostasis in studies of stress, as well as highlighting opportunities for new research. These may include, for example, further research into differences over time in the physiological processes underlying central and peripheral allostasis and allostatic load in response to stressors of different intensity, chronicity, type, and developmental timing, which in turn would be expected to drive multifinality in outcomes associated with long-term health and behavior. Longitudinal studies of amygdala responsiveness over time in samples of different ages and with different types and levels of stressor exposure would shed light on these points. Such work would also clarify the time frames for the development of stress-related alteration in brain structure and function, and their possible reversal. This is precisely the kind of work that can be built from the model we present.

FUTURE DIRECTIONS

Triple Network Allostasis as a Dynamic System

When we undertook this theoretical work (Ganzel et al., 2010), we aimed to model a dynamic bioecological system that fully penetrates physiology (gets under the skin). In doing so, we followed Bronfenbrenner and Morris (1998) in requiring this model to include "the joint, interactive, mutually reinforcing effects" of person, proximal process, context, and time (Bronfenbrenner & Morris, 1998, p. 996).

We also incorporated many of the principles of dynamic systems theories (Bronfenbrenner & Morris, 1998, 2006; Ford & Lerner, 1992; Sameroff & Chandler, 1975; Thelen & Smith, 1998; Waddington, 1957) that are integral to a multilevel approach to understanding behavior and development (Cacioppo & Berntson, 1992). For example, two principles of dynamic systems theories helped us to consider the relations between the levels of a multilevel system. The first is the principle of multiple nested and interacting levels, which states that the person is embedded in an ecological system that represents the influences of more distal systems through the most proximal system (e.g., a current stressor, as modified by contextual resources and risks). Individual behavior is moderated, or shaped, by the context in which that individual is embedded (interaction across systems). The second of these principles is the transactional relationships between levels of the system, which states that the relations between individuals and their environment, or between proximal and distal contexts, are transactional instead of unidirectional. That is, causality

Allman, *The human illnesses: Neuropsychiatric disorders and the nature of the human brain*. New York, NY: Oxford University Press, 2011. Color plate 3.1 (page 116)]

works in both directions (e.g., as in modulated allostasis; Figures 15.23 and 15.24).

Three more principles of dynamic systems helped us to consider how life span development plays out across time. The first, multifinality and equifinality, indicates that there are many paths to a single outcome and a single pathway can lead to a diverse set of outcomes. The second, attractor states constrain possible pathways, suggests that development proceeds on a small number of trajectories and is subject to a small number of possible influences, with biological and ecological constraints that limit possible outcomes. The third, continuous and discontinuous change, posits that change can occur through continuous developmental processes as well as through large changes (e.g., threshold effects).

These concepts have provided structure for our application of life span developmental neuroscience to the allostatic models we have presented here. These concepts may also be used in future research to aid in hypothesis generation about the form and nature of model outcomes. Integration of life span development and triple network allostasis into a diathesis–stress model suggests several avenues for future research, along with a number of predictions.

Is Triple Network Allostasis Universal?

Within a developmental psychopathology perspective, the study of normality and pathology are understood to be mutually informative. Nonetheless, study of the long-term effects of environmental and social stressors on the nonclinical human brain is still a newly emerging

topic of investigation in human neuroscience. The nonclinical human brain is of critical interest to these questions because this is where the basic mechanisms of allostasis will be the least confounded with disease processes. If allostatic load is to be a general mechanism underlying the "long-term carry forward of stress and adversity" (Rutter, 1996, p. 37), it must also have significant consequences for nonclinical adults and children, i.e., if allostasis is to be a useful replacement of classical homeostasis, it must apply to everyone (Ganzel & Morris, 2011; Ganzel et al., 2010). In preceding sections, we have reviewed evidence for the accrual of central allostatic load from stressors that occur in nonclinical humans both earlier and later in development. This is a pivotal concept in defining our model of the stress process because it suggests that allostasis and costs of allostatic load are not confined to a special clinical population or a particular developmental sensitive period.

Nevertheless, studies linking neural networks and long-term effects of prior stress have typically focused on clinical populations or early childhood. In addition, few studies link life stress and large-scale neural network integrity/function with measures of socioemotional adaptation/mental health in nonclinical humans. Still fewer studies blend these factors with a developmental component (although see Thomason et al., 2013; Thomason et al., 2011) and none, to our knowledge, include a broader life span perspective. However, our life span model of modulated allostasis (Figure 15.19) combined with the novel triple network approach to allostasis presented here (Figure 15.21), leads us to predict that the salience/survival network will be the first brain areas to show evidence of long-term plasticity or wear and tear as a consequence of accumulating stressor exposure, and that this will be the case for all populations. Via the salience network, individual differences in central allostatic load can be expected to robustly influence the other canonical neural networks in an age-dependent manner across the life span and in all populations, regardless of clinical status. Happily, these predictions are testable and results will lead to important refinements of the model.

We also argued here for inclusion of central and peripheral allostatic load in an individual's diathesis, thus rendering diathesis to be a dynamic force arising out of the confluence of an individual's initial genetic loading and their ongoing life experience. This allowed us to propose an allostatic diathesis–stress model that has triple network allostasis at its core. In this model, past and current stressor exposure interacts with a constantly changing diathesis to predict psychopathology onset, with robust implications for future mental health. As previously, we predict that this model is applicable regardless of an individual's age or current clinical status, and earnestly hope that this work prompts expansion of the research on stress, neural networks, and mental health beyond the circumscribed study of clinical populations or childhood stressors.

Can Triple Network Allostasis Serve as an Organizing Concept?

Next, we call attention to the considerable overlap between the salience network (Figure 15.22a; Seeley et al., 2007) and the brain areas that have key brain-body regulatory functions (Figure 15.22b; Lane & Wager, 2009). Identification of remarkable commonalities in the brain mechanisms that regulate the human autonomic, endocrine, and immune systems has been an exciting step forward in brain–body medicine (e.g., Gianaros & Sheu, 2009; Ohira et al., 2010; Urry, van Reekum, Johnstone, & Davidson, 2009; Wager et al., 2009). The neural loci of these brain–body interfaces fall along an axis that starts at the superior medial PFC and descends along the midline of the PFC and down into the brainstem. Thus, these neural brain–body regulatory mechanisms share significant common ground with the survival/salience network. Moreover, both the salience network and the brain–body "medial PFC-brainstem axis" (Lane & Wager, 2009, p. 1136) overlap with brain areas showing evidence of long- and short-term stress-related change in humans (Figure 22c; e.g., Ganzel et al., 2008; Gianaros, Horenstein, et al., 2007; Gianaros, Jennings, et al., 2007; Liston et al., 2009) and animals (Cerqueira et al., 2005; Vyas et al., 2002). While this three-way overlap is highly consistent with our theoretical models, there is relatively little research that examines the linkage between central and peripheral allostasis in the context of large-scale neural networks. We commend this topic to future research.

In the context of a constantly changing brain and our life span model of modulated allostasis (Figure 15.19), we argue that *all* allostatic functions will be influenced by life span development, i.e., they would be expected to vary with age. In triple network allostasis, central allostasis (as initiated and directed by the survival/salience network) is hypothesized to drive short-term stress-related alterations in autonomic, endocrine, and immune function, and peripheral/visceral physiology (peripheral allostasis), which are modified by prior accumulations of peripheral allostatic load (Ganzel et al., 2010). This somatic/visceral response feeds back via the insula to influence salience network function and the experience of emotion (Damasio & Carvalho, 2013) or affect (Figure 15.23d; Lindquist,

Wager, Kober, Bliss-Moreau, & Barrett, 2012). In the context of a constantly and systematically changing brain, age- and stress-related change in central allostasis can be expected to reverberate through this feedback loop to generate age- and stress-related change in the peripheral stress response (and in the quality and quantity of peripheral allostatic load), with subsequent feedback effects on the salience/survival network itself. Thus, this model predicts that there will be age-related change in the experience of salience, and indeed of affect. As a corollary to this, we would predict that life stress interacts with age to impact the experiences of salience and affect, and the activities of emotional cognition (e.g., emotion regulation, emotional decision making; Burri et al., 2013; Marsh, Nagengast, & Morin, 2012; Tsolaki et al., 2010).

Ongoing work in psychology, psychiatry, and human neuroscience tie together many of these themes in pairs (stress and emotional cognition; stress and development; development and functional neural networks; neural networks and psychopathology, neural networks and affect). The models presented here suggest novel combinations of these factors for future investigation, as well as the additional need for deployment of these factors as statistical controls.

Is Triple Network Allostasis Only Human?

We have argued that the triple network model of allostasis is common to all humans, regardless of age or clinical status. We have also suggested ways in which this model may serve as an organizing concept to unite theories of stress and diathesis–stress with brain–body medicine and research on emotion. In this section, we present the suggestion that this organizing concept may apply uniquely to humans and perhaps some of the higher primates and other big-brained species. This is not for grandiosity, but rather to outline possibilities—including possible limitations—for future research. The pivotal role of the salience network in our allostatic triple network model raises some broad questions about the nature and origins of psychopathology. We note that this point has implications for how appropriate traditional animal models are for studying some major mental disorders.

Von Economo Neurons

As discussed previously, the right anterior insula/dorsal ACC subnetwork is a hub of information traffic within the salience network and it is argued to play a unique and pivotal role in switching between all three canonical neural networks (Kempermann et al., 1998). It is therefore notable that the right anterior insula and ACC are the two primary locations of a unique type of neuron—the *von Economo neuron* or *spindle* neuron (Maroun & Richter-Levin, 2003; Vyas et al., 2004; Williamson & Allman, 2011). These large projection neurons have one apical axon and one primary dendrite, giving them a spindle shape (Olson et al., 2011). The von Economo neurons appear to be exclusive to the brains of humans, other great apes, elephants, and cetaceans, leading to the hypothesis that they are an adaptation necessary for the rapid flow of communication within large brains (e.g., Cui et al., 2008; Evrard, Forro, & Logothetis, 2012; Stimpson et al., 2011).

Concentrations of von Economo neurons are lateralized in the human brain, with populations being denser on the right side of the brain than the left. These neurons are also highly localized, occurring almost exclusively in layer five of anterior insula and anterior cingulate, with much smaller concentrations recently observed in human dorsolateral PFC (Hill et al., 2012; Vyas et al., 2006; see Figure 15.24). In keeping with their large and streamlined structure, von Economo neurons provide rapid relay of simple signals from anterior insula and dACC to target regions that, in animal models, include PFC, orbitofrontal cortex, temporal cortex, and subcortical survival systems (Hill et al., 2012). A recent resting state functional connectivity study has observed that von Economo-containing regions in the human brain activate in synchrony with individual nodes in the salience network, the dorsal attention network, the sensorimotor network, and portions of the default mode network (Hill, McLaughlin, et al., 2010) suggesting that von Economo neurons may project to nodes in each of these networks (also see Fischer et al., 2005). Thus, the network switching capabilities of the right anterior insula/dorsal ACC subnetwork may be, at least in part, due to the unique properties of von Economo neurons (Sridharan et al., 2008).

Von Economo Neurons Across the Life Span

In humans, von Economo neurons begin to appear by the thirty-fifth week of gestation; at birth, the density of these neurons is approximately 15% of the eventual total (Hill et al., 2012). The full complement and typical rightward anatomical distribution of this neuronal population is reached by the age of four years (Cui et al., 2008; Tsolaki et al., 2010). It is argued that this developmental timing renders von Economo neurons vulnerable to disruption during the third trimester of pregnancy, and in the perinatal and early postnatal period (Hill et al., 2012). Moreover, the immunocytochemistry of these neurons suggests that they play a role in social bonding (expression

of the vasopressin 1a receptor), reward under uncertainty (dopamine D3 receptor expression), monitoring of visceral response and possible amplification of threat-related signals (unique serotonin 2b receptor expression within the human CNS), and cognition (robust expression of DISC1, the primary product of the disrupted in schizophrenia [DISC] gene; Allman et al., 2011; Allman et al., 2005). Due to their unique cytochemistry and distinctive phylogeny, von Economo neurons have been proposed to play a role in human capabilities, such as rapid intuitive decision making in complex sociocultural contexts (Chick & Reyna, 2012; Cui et al., 2008; Williamson & Allman, 2011). Abnormal development of von Economo neurons is therefore hypothesized to underlie multiple neurodevelopmental disorders in which aberrant social conduct or emotion regulation are diagnostic features, including autism (e.g., Campolongo et al., 2009; Freund et al., 2003), and schizophrenia (e.g., Cui et al., 2008; Tsolaki et al., 2010).

Less is known about age-related change past midlife in von Economo neurons, except in the context of Alzheimer's disease and behavioral variant frontotemporal dementia (bvFTD; Tsolaki et al., 2010). In Alzheimer's disease, there appears to be a relative sparing of von Economo neurons, whereas bvFTD is characterized by a profound and specific early loss of these neurons (66 to 75% of the expected total; Cui et al., 2008; Fischer et al., 2005; Gross et al., 1997; Tessitore et al., 2005). The degree of selective degeneration of von Economo neurons in bvFTD is correlated with decreases in behavioral and functional indicators of empathy, self-control, and social awareness (e.g., Gross et al., 1997). This, in turn, is hypothesized to result from a catastrophic failure to integrate visceral-autonomic, social-affective, and cognitive cues as the anterior insula/dorsal ACC network hub degenerates (Gross et al., 1997; Tsolaki et al., 2010).

Allostatic Load and von Economo Neurons

This suggests questions for future research. As we reviewed previously, recent trauma exposure appears to selectively reduce gray matter volume in the anterior insula and ACC (Blair et al., 2013; Ganzel et al., 2008; Monohan et al., in preparation) suggesting that von Economo neurons may be uniquely vulnerable to life stress.[17] However, when traumas are farther in the past, the neural functional and structural correlates of trauma exposure vary more widely (Andersen et al., 2008; Blair et al., 2013; Monohan et al., in preparation). These data are consistent with the hypothesis that von Economo neurons are at or near the initial locus of impact of stress and trauma in the human brain, and that stress-related disruption subsequently propagates through the salience network, the default and central executive network, and the systems of peripheral allostasis. Developmental stage and individual differences in diathetic vulnerability would determine the direction and extent of the propagation of stress-related change in neural networks or nodes over time. Under this hypothesis, von Economo neurons would play a pivotal role in triple network allostasis and the onset of psychopathology. If so, further research into the stress-vulnerability of von Economo neurons may shed new light on the mechanisms of allostasis and allostatic load, and the origins of psychopathology. Investigation of possible age- and sex-specific effects in stress vulnerability of these neurons would then also be fruitful in this regard.

[17]This does not necessarily mean that they are a target of glucocorticoids, although they may be.

CONCLUSION

Diathesis–stress models of the origins of psychopathology have been a major organizing framework in mental health research and practice for the past half-century (e.g., Meehl, 1962). At their inception, these models were open to criticism on the grounds that they lacked specificity (McLaren, 1998) and considered stress and diathesis as a distinct (even if interacting) processes. However, such models have benefitted greatly from the development of new scientific tools that allow specification and measurement of processes that span levels of analysis from genes and brains, to cognition and behavior, and to broader contextual influences. Simultaneously, this work has benefited from disparate lines of inquiry into the origins of psychopathology and the sequelae of stressful experiences that spans the fields of biology, medicine, social neuroscience, and psychology. Together, these allow us to build a developmentally informed diathesis–stress model of psychopathology onset that reflects the individual's past history of adversity and that strongly draws on the core tenets of a developmental psychopathology perspective (e.g., Cicchetti & Toth, 2009).

We stand on the shoulders of three major contributions to the study of stress and psychopathology in the development of our new model.

First, the last two decades has seen a paradigm shift in thinking about how humans respond physiologically to stress. As a major revision of the classical theory of homeostasis, allostasis identifies the brain as the executor and central mediator of ongoing system-wide adjustment to meet environmental challenge (Sterling & Eyer, 1988).

Two points are critical from this work: (1) the brain's survival/salience network becomes the primary, physiological targets of stress, bringing stress well into the brain (and not merely as an external force influencing cognition or behavior); and (2) stress has long-term physiological costs in the form of allostatic load that affect later responses to stress, allowing stress to become a diathesis of sorts for the next stressful experience.

Second, we build on new research on the constantly changing brain, citing evidence for brain development and senescence across the life span. The central premise of our thesis is as follows: if the brain is the central mediator of a stress/diathesis-psychopathology relationship, and the brain is not static but represents a constantly changing neural landscape across the life span, then the stress/diathesis-psychopathology process itself must vary across development as well. That is, variations in stressor timing across the life span must have very different implications for brain processes if the neural circuitry of the salience network that is serving as the front lines of stress is changing as well (said another way, stressors at different ages may have different neural sequelae). And if the central mediators of allostasis are changing, then the accretion of allostatic load must be changing as well (i.e., stressors at different ages would have different effects on the development of this form of diathesis). With differential physiological consequences both for the sequelae of stress and the development of diathesis to future stress, it is not hard to see why psychopathological outcomes may also differ across the life course. This thinking has implications for a number of findings, including why the effects of stress and trauma might vary for children and adults; why a critical period approach to stress during early life might be insufficient; and why there are effects of trauma exposure in adulthood even in nonclinical/low risk individuals, to name a few. Making this argument allows us to build a theory of modulated allostasis, in which both the stress process and the diathesis (in part due to load from prior periods) contribute to different psychopathological outcomes, across developmental time from the prenatal period to older adulthood. In this way, diathesis–stress becomes a *developmental* model.

Third, Menon's (2011) triple network model of psychopathology is enormously useful addition to our diathesis–stress model. With this addition, deficits in the functional *connectivity* of neural networks (rather than specific brain regions alone) are key predictors of psychopathology. For example, while the right anterior insula in the salience network is key in the emergence of psychopathology, Menon adds the reasons why—for example, that the insula is critical in the recruitment of the executive network and the default network in generating adaptive behavioral responses. As a result, downstream effects on other networks may be even larger than those in the initial deficits in the salience network. In prior work, we argued that the core affective systems of the brain were central to the translation of stress into physiological and then behavioral response. Menon allows us to improve the neural specificity of this model—that it is synchronized *nodes* in the affective core system (i.e., the survival/salience network)—that produces allostatic responses in the context of stress, and results in the deficits in processing of information that results in deficits in mental health. The resulting model is termed triple network allostasis and represents our new proposed diathesis–stress model of psychopathology.

Having built a new diathesis–stress model of psychopathology onset, the question now arises: can it be used to better design intervention approaches aimed at reducing psychopathology? Indeed, a key principle of a developmental psychopathology perspective is its commitment to translation (Cichetti & Toth, 2009), and a central benefit of identifying the neural underpinnings of the stress–psychopathology relation is to support the development of more effective interventions for individuals at risk (Ganzel & Morris, 2011). However, research in this area is only in its infancy. The question is whether population-scalable, cost-effective, social and behavioral interventions can be developed that target the large-scale neural networks as key mediators of the diathesis/stress-psychopathology relationship. While research on brain architecture has strongly informed pharmacological treatment strategies, it has less often been utilized to inform social and behavioral interventions.

The hope here is that if we were to design and effectively implement promising social and behavioral interventions targeted at relevant brain processes, they would drive longer lasting changes in psychopathological outcomes. But the challenge is that we do not yet have a body of research to draw on about the physiological effects of community-based interventions. A number of research teams are forerunners in this research in their inclusion of physiological assessments in intervention efforts (e.g., Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008; Fisher, Stoolmiller, Gunnar, & Burraston, 2007). However, we are a far cry from being certain about which interventions are most likely to mitigate the risks of psychopathology because of their effects on neural networks. That is the next frontier for this area of research—translating

neuroscience from the lab and the clinic into the community, thus fully realizing the translational commitment of the developmental psychopathology perspective.

One promising, but still nascent, area of intervention includes mindfulness-based interventions. Mindfulness interventions are aimed at altering the experience of the stress process for the individual by addressing the individual's response to stressors, which should, in turn, result in alterations in the underlying stress–response system. Mindfulness-based interventions have been most often implemented with adults, and have shown some successes with moderate effect sizes (although more methodologically rigorous work is warranted; Baer, 2003; Grossman, Niemann, Schmidt, & Walach, 2004). Another approach to these interventions aims at improving the regulatory capacity of youth exposed to stress and risk. These use mindfulness-based training to focus attention and awareness and reducing rumination that can contribute to the physiological and psychological costs of stress as we have described here. The first work using these approaches for children and adolescents has demonstrated that these interventions are feasible to implement and are well received, but efficacy evidence is only now emerging (Burke, 2010; Mendelson et al., 2010). Further work in this area is currently under way (Greenberg & Harris, 2012) and is needed to determine if this approach can effectively build resilience in children exposed to stress and trauma by reducing the physiological and psychological costs of stress.

In contrast to the relatively new work on mindfulness-based strategies, social-emotional learning programs in schools have a much longer history and these sometimes also target the self-regulatory capacity of children and youth at risk. As such, these programs *may* have implications for building the social-emotional skills that underlie successful coping in the context of stress. As we have discussed, the brain's survival/salience network underlies the processing of salient (survival-related) information and serves as the central mediator of allostatic accommodation to environmental demand (Menon, 2011). We have argued that these systems of the brain underlie the translation of a stressor into a behavioral or physiological response, and are thus key to the onset of mental disorder. Then it stands to reason that interventions that target these same systems might be important in the prevention of such disorders. An extensive meta-analysis of over 200 social-emotional learning programs studied in the context of experimental and quasi-experimental studies shows moderate effect sizes on outcomes like emotional distress and conduct problems that may be the precursors to psychopathology (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011). But because these studies rarely if ever include physiological assessments, it is not at all clear if such interventions support the theory we have proposed here, or whether they effectively support children's development through other neural mechanisms.

While not typically considered as interventions aimed at psychopathology per se, a number of policy experiments have been conducted that are intended to directly reduce stressors in the external environment by targeting the contextual precipitators of that stress process. Some of the most well-studied of these are employment-based antipoverty programs, that directly target family income (Morris, Duncan, Huston, Crosby, & Bos, 2001; Morris, Gennetian, & Duncan, 2005). These programs provide low-income families with resources either from within or outside the welfare system. They typically tie that increased income to work by providing monthly cash or in-kind supplements to earnings, or by allowing welfare-recipient parents to keep more of their welfare benefits when they transition from welfare into employment. A relatively large and promising research base shows that these programs (known as Conditional Cash Transfers, or CCTs; Fiszbein, Schady, & Ferreira, 2009) can effectively raise income of families in ways that should reduce stressor exposure (Bloom & Michalopoulos, 2001; Morris et al., 2001). These condition cash assistance on parents' participation in some program or institution (historically, school or health visits). Indeed, findings demonstrate that CCTs might be especially good at encouraging participation in services and institutions that might benefit high-risk individuals, even while the increased resources going to families might reduce that risk exposure in the first place. In this way, CCTs could be effectively paired with supply side services to boost the emotional skills of high-risk children (e.g., mindful meditation or social-emotional learning programs). At the same time, they support key demand side adjustments (parents' and children's take-up of those services, which can be notoriously low for voluntary programs). These programs have the added benefit of simultaneously reducing family stress through a key contextual target—increasing income. Future work should certainly explore these opportunities to reduce the risk for psychopathology, although rarely do large-scale randomized trials include the careful measurement of physiological processes that would enable us to move forward in this line of work.

As we have discussed elsewhere (Ganzel & Morris, 2011), we strongly support the inclusion of physiological measurement in community intervention studies that hold promise for reducing psychopathology. Measuring change

in neural processes and in concomitant mental health outcomes in randomized control trials can dramatically advance our understanding of the sensitivity of systems to induced environmental change (Cicchetti & Gunnar, 2008), as well as providing us with information to refine and expand our theoretical models. And by offering such interventions to children at differing periods of development, such research can also tell us about points in development in which the system is plastic and open to change from intervention. Notably, however, caution is in order: interventions may be limited in their contribution to the understanding of risk and resilience if the neural processes deriving from *positive* events are not merely the mirror image of those precipitated by *negative* events. Indeed, it is even possible that the windows of sensitivity to *stress* of physiological processes and mental health outcomes do not always coincide with windows of sensitivity to the *positive* aspects of intervention. In effect, it is not clear whether developmental periods are plastic or merely vulnerable. Or if the neural effects of *positive* contextual change (intervention) are the same as the effects of *negative* contextual change (stress). If they are not, then learning about periods of plasticity to intervention may not tell us all we need to know about periods of sensitivity to stress. They certainly will tell us about one side of plasticity (the sensitivity of neural systems to positive inputs) but may leave us still wondering about the other. That said, such research can still provide sorely needed information about how to best reduce the risk of psychopathology.

In this paper, we draw from research across the disciplines of biology, medicine, neuroscience, and psychology to present a new diathesis–stress framework for the development of psychopathology across the life span. The field is at a pivotal moment—new work is coming on line rapidly, dramatically increasing our understanding of neural processes in ways we could not have imagined a decade ago. It is imperative that we use this new information to develop a cross-disciplinary life span perspective on the emergence of psychopathology—one that highlights our deepening understanding of the neural processes underlying the stress/diathesis process. And, perhaps most importantly, it is critical that this information be used for the design of interventions that can most effectively mitigate the negative effects of psychopathology. In doing so, we will fully realize the commitment of a developmental psychopathology perspective (Cichetti & Toth, 2009) in leveraging the interdisciplinary-informed study of normality and psychopathology across the life span to more fully inform effective intervention at scale for those who are most at risk.

INTRODUCTION

The human adult neocortex contains approximately 20 billion neurons, each connected to about 1,000 other neurons, resulting in networks involving trillions of connections. For the most part, these neurons have already been created and travelled to their correct positions by the time of full-term birth. They will, however, continue to differentiate and refine their patterns of connection over a prolonged period stretching into late adolescence. Relating changes in the developing brain to the remarkable changes in motor, perceptual, and cognitive abilities during the first decade or two of human life is the main focus of the field of *developmental cognitive neuroscience*. This includes normal development of brain–behavior relationships as well as how factors such as brain injury, neurodevelopmental disorder, or atypical environments affect these relationships.

While developmental cognitive neuroscience is still a relatively young field, several general perspectives have emerged that often frame the kinds of research questions asked and how results are interpreted. In this chapter we will outline three perspectives on human functional brain development: (1) a maturational viewpoint; (2) skill–learning viewpoint; and (3) interactive specialization viewpoint. We then focus in more detail on the interactive specialization viewpoint, assessing its application and implications for understanding empirical evidence from (1) functional brain imaging, (2) the effects of early acquired brain damage, and (3) the consequences of atypical early experience.

THREE PERSPECTIVES ON THE FUNCTIONAL DEVELOPMENT OF THE HUMAN BRAIN

As stated earlier, relating evidence on the neuroanatomical development of the brain to the changes in motor, perceptual, and cognitive abilities during infancy, childhood and adolescence presents a considerable challenge. We now briefly introduce three distinct, but not necessarily incompatible, approaches to this issue (Table 16.1): (1) a maturational viewpoint; (2) skill–learning viewpoint; and (3) interactive specialization viewpoint. Next, we go on to examine the assumptions and predictions of one of the three, the interactive specialization viewpoint, in more detail.

Maturational Viewpoint

According to the maturational viewpoint, newly emerging sensory, motor and cognitive functions are related to the maturation of particular areas of the brain, usually regions of cerebral cortex. An area is said to be mature

TABLE 16.1 Three Perspectives on Human Functional Brain Development

	Brain-cognitive mapping	Primary locale of changes	Plasticity	Cause
Maturational	One-to-one mapping Static over development	Intraregion connectivity matures	A specialized mechanism invoked by stroke or injury	Brain changes cause cognitive development
Skill–learning	Changes during acquisition of skill		Life-long; No clear sensitive period	
Interactive	Networks/neural systems Dynamic changes during development	Interregional connectivity changes and shapes intraregional connectivity	An inherent property—the state of having not yet specialized Sensitive—period determined by state of specialization	Bidirectional relations between structure and function

when it achieves the adult state of functioning, with any different state of functioning classified as being immature. This view tends to emphasize discontinuity, or step-like changes. Abilities are viewed as being suddenly switched on at the time the related brain area becomes adult-like. It is a deterministic epigenesis approach that assumes that development involves a unidirectional causal path from genes to structural brain changes to psychological function, in which the influence of the environment plays little role.

According to the maturational viewpoint, the time when a brain region matures should predict the age when a particular behavior or skill emerges. Conversely, emergence of a new behavior or skill at a given age can be attributed to the maturation of a new brain region previously not functioning due to immaturity. One problem with this approach is that it is circular: emergence of new abilities is evidence of a cortical region becoming mature, and the cortical region's maturation accounts for the emergence of the new skill. For example, the development throughout adolescence of the ability to detect error-related conflict in action monitoring tasks has been attributed to maturation of anterior cingulate cortex over this time (Ladouceur, Dahl, & Carter, 2004), and at the same time changes in children's error detection have been taken as evidence of changes in anterior cingulate function (Epsinet, Anderson & Zelazo, 2013). Functional brain development is, in this sense, depicted as the reverse of adult neuropsychological studies of patients with brain damage: specific brain regions are being added in during development instead of being subtracted out by damage. This view thus sees a static, one-to-one mapping of brain–behavior relations over development: when new structures come on line, the existing (already mature) regions continue to support the same functions they did at earlier developmental stages. This assumption that brain–behavior relationships are static over development is partly why the maturational viewpoint considers it acceptable to study developmental disorders in adulthood and then extrapolate results back in time to early development.

Despite the intuitive appeal and attractive simplicity of the maturational approach, it does not successfully explain all aspects of human functional brain development. One aspect that is difficult to account for within this view is that some of the cortical regions that are slowest to develop by neuroanatomical criteria show activity from shortly after birth and appear to mediate cognitive functions even before they would be considered anatomically fully mature. For example, while prefrontal cortex continues to mature into the teenage years according to neuroanatomical criteria, functional imaging studies show evidence that it can be activated during the first months (see Johnson 2011 for review). Thus, the emergence of new behaviors is not necessarily linked to a previously immature, silent neural region suddenly becoming active when it matures. For example, working memory shows a protracted course of development, which has been attributed to the prolonged development of the frontoparietal network mediating this skill. However, one study of 12-year-old children and young adults showed that 6 weeks of practice can considerably reduce the differences in functional activation between children and adults during working memory tasks (Jolles et al., 2012). This pattern of findings is inconsistent with the idea that brain structures cannot be engaged in a skill before they are fully structurally mature.

Another difficulty for the maturational viewpoint is that associations between neural and cognitive changes based on age of onset are theoretically weak due to the great variety of neuroanatomical and neurochemical measures that change at different times in different regions of the brain. Thus, it is nearly always possible to find a potential neural correlate for any behavioral change.

Skill Learning

The skill–learning view of human functional brain development proposes that the brain regions active in infants during the onset of new perceptual or motor abilities are

similar, or identical, to those involved in complex skill acquisition in adults. While the nature of the skills to be acquired change with development (from basic sensory and motor skills, to complex cognitive ones), the challenge to the brain at a given point in development may be equivalent. For example, Gauthier and colleagues showed that extensive training of adults to identify individual artificial objects (called greebles) eventually results in activation of a cortical region previously preferentially activated by faces, the fusiform face area (Gauthier et al., 1999). This suggests that the region is normally activated by faces in adults, not because it is prespecified to do so but because of our extensive expertise with that class of stimulus. Extended to ontogeny, this view would argue that development of face processing during infancy and childhood could proceed in a similar manner to acquisition of perceptual expertise for a novel visual category in adults (see Gauthier & Nelson 2001). While the degree to which parallels can be drawn between adult expertise and infant development remain unclear, to the extent that the skill learning hypothesis is correct, it presents a clear view of a continuity of mechanisms throughout the life span.

Interactive Specialization

The interactive specialization (IS) viewpoint represents a probabilistic epigenesis approach (Gottlieb, 1982), in which development involves a process of interactions among genes, structural brain changes, and psychological function that are viewed as bidirectional, dynamic, emergent, and influenced by the environment. This sharply contrasts with the maturational approach described previously, in that the latter assumes deterministic epigenesis whereby region-specific gene expression is assumed to effect changes in intraregional connectivity that, in turn, allows new modular functions to emerge.

The interactive specialization viewpoint assumes that postnatal functional brain development, at least within cerebral cortex, involves a process of organizing patterns of interregional interactions (Johnson 2000, 2011). One key idea is that of brain *specialization*: cortical regions may begin with poorly defined, general-purpose functions (and consequently are partially activated in a wide range of different contexts and tasks) but during development their functions sharpen such that their activity becomes restricted to a narrower set of circumstances (e.g., a region originally activated by a wide variety of visual objects may come to confine its response to upright human faces). A second key idea of the interactive specialization viewpoint is that *interactions* between cortical areas are critical for this process of specialization and for emergence of new skills. Thus, the response properties of a specific brain region are partly determined by its patterns of connectivity to other regions, and their patterns of activity. During development, changes in the response properties of cortical regions occur as they interact and compete with each other to acquire their role in new computational abilities.

In the IS view, the emergence of new skills is thus associated with changes in activity over several regions, and not just by the onset of activity in one or more additional regions. Similarly, when a new computation or skill is acquired, there is also a reorganization of interactions between different brain structures and regions (Johnson, 2001). In fact, where functional activity has been assessed by fMRI during a behavioral transition, multiple cortical and subcortical areas appear to change their response pattern (Luna et al., 2001) rather than a few specific areas becoming active. This reorganization process could even change how previously acquired cognitive functions are represented in the brain. Thus, the same behavior could be supported by different neural networks at different ages during development. For example, the prefrontal cortex contributes to working memory in both early and late adolescence and adulthood (Finn, Sheridan, Kam, Hinshaw, & D'Esposito, 2010). However, the hippocampus is also recruited in early adolescence regardless of task demands and performance, whereas in late adolescence and adulthood, the two regions are only co-active under high task demands (Finn et al., 2010). Thus, different neural networks underlie working memory at different points in development. This contrasts with the maturational viewpoint previously described, which assumes that the relation between brain structure and cognitive function is unchanging during development.

The view that cognitive functions are the emergent product of interactions between different brain regions follows views in adult functional neuroimaging. For example, Friston and Price (2001) pointed out that it may be an error to assume that particular functions can be localized within a certain cortical region. Rather, they suggest that the response properties of a region are determined by its patterns of connectivity to other regions as well as by their current activity states. By this view, "the cortical infrastructure supporting a single function may involve many specialized areas whose union is mediated by the functional integration among them" (p. 276). Similarly, in discussing the design and interpretation of adult fMRI studies, Carpenter and collaborators (2001) argued, "In contrast to a localist assumption of a one-to-one mapping

between cortical regions and cognitive operations, an alternative view is that cognitive task performance is subserved by large-scale cortical networks that consist of spatially separate computational components, each with its own set of relative specializations, that collaborate extensively to accomplish cognitive functions" (p. 360). Extending these ideas to development, the IS approach emphasizes changes in interregional connectivity, as opposed to the maturation of intraregional connectivity. While the maturational approach may be analogous to mosaic cellular development, the IS view corresponds to the regulatory development seen in higher organisms in which cell-cell interactions are critical in determining developmental fate. While mosaic development can be faster than regulatory, the latter has several advantages. Namely, regulatory development is more flexible and better able to respond to damage, and it is more efficient in terms of genetic coding. In regulatory development genes need only orchestrate cellular-level interactions to yield more complex structures (see Elman et al., 1996).

Stating that structure–function relations can change with development is all very well, but it lacks the specificity required to make all but the most general predictions. Fortunately, the view that there is competitive specialization of regions during development gives rise to expectations about the types of changes in structure–function relations that should be observed. These predictions are outlined in more detail in the following section.

PREDICTIONS OF THE INTERACTIVE SPECIALIZATION FRAMEWORK

The IS viewpoint expects that widespread networks of brain regions will change their patterns of activation in association with the onset of new behavioral abilities. In addition, regions will become more specialized (finely tuned) in their response properties with experience. A consequence of this specialization is that, on at least some occasions, fewer brain regions are activated with development in certain tasks. Thus, while the exact nature of changes in brain activation will depend on the degree of specialization achieved in different component structures, the IS view predicts a general trend for a *decrease* in the extent of cortical activation and an increasing specificity of the cortex that is activated with increasing development/experience. This stands in contrast to the maturational approach, which would expect that, if we compare two age groups in a task for which they show identical behavioral performance, then we should also expect to see identical patterns of brain activation. The skill–learning view would expect reactivation of one or more skill–learning circuits when a task is first being learned, followed by a different pattern of activation after the skill is acquired and becomes more automated. In this case, in many comparisons between age groups, the younger group will have acquired the skill in less depth than the older group, giving rise to different patterns of underlying brain activation. Interestingly, however, patterns of changing brain activation while adults acquire new skills should mirror the changes seen during development as infants and children acquire simpler skills. Moreover, patterns of activation across age should be the same if the differently aged participants have attained the same level of performance. This stands in contrast to the IS viewpoint, as the state of specialization and interaction of brain regions would be different in the adult and infant brain, which would influence how the learning itself influenced the brain.

The predictions of the IS view can more specifically be divided into those relating to the specialization part of the hypothesis, and those related to the interactive part of the hypothesis (for more detail, see Johnson, 2011). The developmental predictions regarding specialization are (1) that there is an increased neural tuning with age, so that more selective or narrow response patterns are seen; (2) that there is a shrinkage or contraction of the cortical region responsive to a particular type of stimulus; (3) that the increased neural tuning and shrinkage of cortical regions activated will be correlated, since they reflect two sides of the same underlying process; and (4) that the degree of functional plasticity will depend on the degree of specialization attained at a given time, with greater specialization resulting in less plasticity and vice versa. The developmental predictions regarding the interactive aspects are (1) developmental change in cognitive skills or behavior will be accompanied by widespread changes across multiple regions rather than changes in single isolated areas, (2) the process of specialization will scale up from individual brain regions to multiregion networks, and (3) the specialization of individual regions will be shaped by their involvement in one or more functional networks.

In the sections that follow, we focus on evaluating these hypotheses of the IS viewpoint by examining evidence from brain imaging studies of typical development, the effects of early acquired brain damage, and the consequences of atypical early experience. Contrasts with the maturational and skill–learning viewpoints will also be made where they highlight a contrast between the viewpoints.

BRAIN IMAGING OF TYPICAL DEVELOPMENT

In this section we review evidence from the functional neuroimaging of normal development that pertains to the predictions of the IS view described above. We will focus mostly on three of the IS hypotheses for which there is most available evidence: (1) there is an increased neural tuning with age; (2) there is a shrinkage of cortical regions active for a particular type of processing with age; and (3) developmental changes in cognitive skills or behavior are accompanied by widespread changes in multiple regions, because there is the most evidence available for these predictions. The predictions of the IS framework for typical development have been studied in several domains (Johnson, 2011), but perhaps most extensively in face processing, through studies of the emergent core face network, a subnetwork of the cortical social brain. These studies have provided evidence supporting the IS prediction that there is a shrinkage of the cortical area active for a particular type of processing with age. One line of evidence comes from event-related potential experiments with infants, which have indicated that there is increasing localization of processing with age and experience for face processing (de Haan et al., 2002; see Neville, Mills, & Lawson, 1992, for a similar pattern in word learning). That is, scalp recordings reveal a wider area of processing for faces in younger infants than in older ones, whose processing has become more specialized and localized. Within the interactive specialization framework, such developmental changes are accounted for in terms of more pathways being partially activated in younger infants prior to tuning resulting from experience with a class of stimuli. With increasing experience, the increasing localization of one or more of those pathways occurs over time. Changes in the extent of localization can be viewed as a direct consequence of increased specialization, hence the aforementioned prediction that these two developmental changes both reflect the same underlying process. Initially, multiple pathways are activated for most stimuli. With increasing experience, fewer pathways become activated by each specific class of stimuli, and these more limited pathways themselves become more tuned to specific functions and are therefore no longer engaged by the broad range of stimuli as was the case earlier in development. Additionally, there may be inhibition from pathways that are becoming increasingly specialized for that function. In this sense, then, there is competition between pathways to recruit functions, with the pathway best suited for the function (by virtue of its initial biases) usually winning out.

Further evidence comes from studies using fMRI to study the development of cortical activation patterns during childhood involved using the same stimulus array for two different tasks, a face matching task and a location matching task (Passarotti et al., 2003). For the face-matching task, younger children (10–12 years) showed more extensive areas of activation than did older children and adults. In general, the activation shown by the youngest group included the areas activated in adults (such as bilateral activation of the middle fusiform gyrus) but additionally extended to more lateral and anterior regions. In the location matching condition, the children also showed more extensive activation than did adults. While adults had strong right superior parietal activation, children displayed more bilateral activation of this structure, as well as additional activation in right superior frontal gyrus. These results are consistent with a shrinkage or contraction of the cortical region active for a particular type of processing.

Predictions of the IS view about the shrinkage of cortical regions involved in a skill have also been supported in other domains, such as response inhibition. Luna and colleagues (2001) tested participants aged 8 to 30 years in an oculomotor response-suppression task. Their behavioral results showed that the adult level of ability to inhibit prepotent responses developed gradually through childhood and adolescence. The difference between pro-saccade and anti-saccade conditions were investigated with functional MRI, and revealed changing patterns of brain activation during development. Both children and adolescents had less activation than adults in a few cortical areas (superior frontal eye fields, intraparietal sulcus), and several subcortical areas, a finding broadly consistent with maturational hypotheses. However, both children and adolescents also had differential activation in regions not found to show differences in adults. Children displayed increased relative activation in the supramarginal gyrus compared to the other age groups, and the adolescents showed greater differential activity in the dorsolateral prefrontal cortex than children or adults. These findings illustrate that the neural basis of behavior can change over developmental time, with different patterns of activation being evident at different ages, a pattern consistent with both the IS and the skill–learning viewpoints.

A final example of how fMRI studies support the prediction of shrinkage of cortical regions involved in a skill over childhood comes from studies of verbal fluency tasks in which participants are asked to generate words in response to a cue (e.g., to generate examples of a target category, or generate a verb that relates to a cued noun).

Several studies have shown that adults (Lehericy et al., 2000) and school-age children (Gaillard et al., 2000; Hertz-Pannier et al., 1997) typically activate left hemisphere frontal cortical networks including Broca's area, premotor, prefrontal, and supplementary motor areas as well as, less consistently, temporal cortical areas including superior temporal, middle temporal, and supramarginal gyri. In addition, some degree of activation in homologous right frontal regions is almost always found both in adults (Pujol et al., 1999; Springer et al., 1999) and in children (Gaillard et al., 2000; Hertz-Pannier et al., 1997). Two studies have found that both the degree to which activation is bilateral (rather than left dominant) and the extent of this activation is greater in children than in adults (Gaillard et al., 2000; Holland et al., 2001). Thus, as in the other examples discussed before, typical development is associated with a reduction in the extent of activation of cortical areas and, as a consequence, an increased lateralization of activation to the left hemisphere with age (Berl et al., 2014; Holland et al., 2001). However, it should be noted that not all developmental imaging studies have reported decreases in extent of activation with age. For example, in the case of verbal fluency, two studies have reported that laterality and extent of activation did not differ between children and adults (Gaillard et al., 2000; Schlaggar et al., 2002), with one even showing a greater number of pixels activated in left frontal regions in adults compared with children (Gaillard et al., 2000).

Studies of face processing have also addressed the IS prediction that there is an increased neural tuning with age or experience, so that a more selective or narrow response pattern is seen. In functional MRI studies with older children, several investigators have traced the gradual emergence of a high degree of tuning to faces in a particular cortical region; FFA—the fusiform face area. For example, Scherf et al. (2007) used naturalistic movies of faces, objects, buildings, and navigation scenes in a passive viewing task with children (5–8 years), adolescents (11–14 years), and adults. They found that the children exhibited similar patterns of activation of the face-processing areas commonly reported in adults (such as the FFA). However, this activation was not selective for face stimuli only, as the region was equally strongly activated by other complex visual stimuli such as objects and landscapes. Thus, young children had a less narrowly tuned cortical response to faces than did adolescents and adults, who exhibited a more selective pattern of activation. Experience can also induce this type of change, as shown in a study where an individual with developmental prosopagnosia (a congenital disorder of face processing) was trained to recognize faces. As behavioral performance improved, so did the selectivity of the cortical processing of faces as measured by the N170 component of the event-related potential (DeGutis et al., 2007).

While such experiments provide evidence for the increasing specialization (or tuning) of individual regions of cortex during human postnatal development, from the IS viewpoint the next step is to understand how *networks* of different regions, each with their own different specializations, emerge. A key prediction of the IS view is that the process of specialization will scale up from individual brain regions to multiregion networks, and that the specialization of individual regions will be shaped by their involvement in one or more functional networks. Again, face processing provides a good test as a core face network of cortical regions has been well established in adults, and activity in this network is known to be modulated by task demands in adults. To explore these issues, Cohen Kadosh et al. (2011) examined the emergence of the core face network in younger (7–8-year-old) and older (10–11-year-old) school-age children as well as in young adults and found that children showed substantially weaker and more fragmented connectivity within this face network. Further, no evidence was found for the influence of task demands on the effective connectivity within the network in the two children groups. That is, while both child groups exhibited similar overall network structures, these weaker networks were not influenced by top-down task demands.

The IS view argues that emergence of new behaviors requires changes in interregional cortical interaction, thus the finding different patterns of activation in children even in tasks where behavioral performance is similar to that of adults is compatible with the IS viewpoint. In fact, comparing activation in cases where behavioral performance is equated is critical for distinguishing the IS view from both the skill–learning view and the maturational view, as only the former predicts that the pattern of brain activation may differ with age even when performance is equated. Which of the three approaches is adopted has not only theoretical implications but also practical implications for data collection. For example, if one adopts the maturational approach, and is expecting a particular area to become active during development for a particular task, then brain imaging may be focused on that region rather than on the whole brain. As a consequence, any possible changes in more distant brain structures would not be detected. By contrast, if one adopts the interactive specialization approach, then the importance of whole-brain imaging is clearly apparent.

Functional imaging studies also provide support for the IS prediction that younger and older participants will show different patterns of task-related brain activation even in the absence of performance differences. For example, Casey and colleagues (Casey et al. 1997; Thomas et al. 1999) administered a go/no-go task to assess inhibitory control and frontal lobe function to healthy volunteers from 7 years of age to adult. The task involved participants responding to a number of letters, but withholding their response to a rarely occurring X. More than twice the volume of prefrontal cortex activity (in the middle and superior frontal gyri) was observed in children compared with adults (see also Booth et al., 2003; Bunge et al., 2002; Durston et al., 2002; Tamm et al., 2002, for similar results). One explanation of this finding is that children found the task more difficult and demanding than adults. However, children with error rates similar to those in adults showed some of the largest volumes of prefrontal activity suggesting that task difficulty was not the important factor (Casey et a., 1997; Thomas et al., 1999). It is difficult to account for these decreases in the extent of cortical activation in terms of the progressive maturation of these areas. A similar pattern was observed in a study of dimensional shifts of attention (Morton, Bosma, & Ansari, 2009). For both children and adults, dimensional shifting was associated with activity in a distributed frontoparietal network, including superior parietal cortex, dorsolateral prefrontal cortex, inferior frontal junction, and the presupplementary motor region. However, even though children and adults showed comparable behavioral performance, there were still age-related differences in brain activity, with children but not adults showing an effect of dimension shifting in the right superior frontal sulcus, and adults but not children showing an effect of dimension shifting in the left superior parietal cortex and the right thalamus. The finding that children and adults appeared to show different patterns of activation in both studies even when performance was similar is inconsistent with the skill–learning viewpoint, but not unexpected according to the IS viewpoint.

In evaluating fMRI evidence for decreasing or increasing extent of cortical activation underlying a particular skill with age, it is important to be aware that factors other than dynamic changes in the interregional patterns of activation per se could be contributing to the observed differences. Importantly, technical aspects of data collection including coil characteristics, head motion, and physiological age-related differences that could affect the fMRI BOLD signal, could contribute to apparent age-related differences in activation (see Gaillard et al., 2003). For example, a surface coil might identify more activated regions in children than adults because children have thinner skulls and scalp and thus the coil is closer to the brain and can read the signal more clearly than in adults. By contrast, use of a head coil might lead to a finding of greater activation in adults than children, as most head coils are designed for adults and thus children's head position in the coil would not be optimal. Thus, when interpreting the results of functional MRI studies, it is important to keep in mind that technological and developmental factors may affect signal and noise detection that, in turn, may influence an interpretation of age-based differences in activation patterns (for further discussion of these issues see Gaillard et al., 2003; Poldrack, 2002).

Understanding brain networks and the interactions among their component regions is an important aspect of the IS view. It has been hypothesized that the resting state of the brain (when not apparently engaged in a specific task) may provide a critical bridge between structural and functional brain development (Johnson, 2011). The resting states of the brain as measured by fMRI are slow oscillations (under 1 Hz) in which the activity of particular regions cohere into networks (e.g., the default mode network). These patterns of activation appear to reflect averages of sensory and task driven activation patterns over a time period, and consolidation of experience-driven co-activation patterns between regions may require the prolonged activation patterns that resting or default states can provide. Regions that show coherent (in phase) oscillatory activity may maintain or strengthen anatomical connections between them. Other regions that may oscillate at similar frequencies, but that are out of phase, may lose or reduce synaptic connections with the emerging coherent network. Consistent with the Interactive Specialization model, evidence suggests that task-related networks, such as the anterior attention network, develop by increasingly diverging from the resting state or default networks (Gao et al., 2012).

Networks of resting state activity have been used to trace developmental changes in human brain networks, and have even been suggested as the basis for a maturational index (Schlagger et al., 2002). While several studies have shown a developmental shift from local to more long-range connectivity during postnatal development (e.g., Fair et al., 2007), these studies are currently under question for methodological reasons associated with greater motion artifact at younger ages (Deen & Pelphrey, 2012). Another change in network structure during development is that adult networks tend to have a more hierarchical structure that is optimally connected to support top-down relations

between one part of the network and another (Supekar et al., 2009). While hierarchical networks have a number of computational advantages, they are also known to be less plastic and more vulnerable to damage or noise in the particular nodes at the top of the hierarchy. Thus, the less hierarchical network arrangement of children may be more adaptable in response to unusual or atypical sensory input or environmental context.

A final aspect of the transition from child brain network to the adult one is the greater connectivity between cortical and subcortical structures seen at younger ages (Supekar et al., 2009), an observation that may be fundamental for our understanding of the emergence of the social brain and memory systems, as it implies that the specialization of some cortical areas may be initially more dominated by structures such as the amygdala and hippocampus.

Overall, the pattern of findings across studies provides little support for the maturational viewpoint, only partial support for the skill–learning view and is more consistent with the series of predictions from the IS viewpoint. The balance of evidence to date suggests that (1) new behavioral skills, or developmental changes in existing skills, are often accompanied by widespread changes across many regions of cortex, and (2) functional brain development involves the twin processes of increasing stimulus selectivity of the brain's response and increasing localization of regions that respond to a stimulus.

BRAIN IMAGING OF ATYPICAL DEVELOPMENT

In this section, we will examine how the IS viewpoint applies to developmental disorders, acquired brain injury, and atypical childhood experiences. We will focus on four IS hypotheses: (1) there is an increased neural tuning with age, and (2) there is a shrinkage of cortical regions active for a particular type of processing with age, (3) the degree of plasticity following brain injury or atypical experience relates to the degree of cortical specialization attained at the time, and (4) developmental changes in cognitive skills or behavior are accompanied by widespread changes in multiple regions.

Developmental Disorders

Much of the neuroimaging work on developmental disorders to date has been aimed at identifying gross abnormalities in discrete brain regions, structures, or systems. While there have been some specific claims made with regard to such deficits, reviews of the field tend to find instead that evidence regarding developmental disorders is consistent with diffuse damage to widespread parts of the brain. For example, Rumsey and Ernst (2000) summarize their review of functional imaging of autistic disorders as "... studies of brain metabolism and blood flow thus far have yet to yield consistent findings, but suggest considerable variability in regional patterns of cerebral synaptic activity" (p. 171). Other authors reviewing work on autism concur with this conclusion. Deb and Thompson (1998) stated that "various abnormalities of brain structure and function have been proposed, but no focal defect has been reliably demonstrated" (p. 299), and Chugani (2000) concluded that "... data from the various imaging modalities have not yet converged to provide a unifying hypothesis of brain mechanisms" with a range of cortical (frontal, medial prefrontal, temporal, anterior cingulate) and subcortical (basal ganglia, thalamus, cerebellum) structures implicated in different studies. According to Filipek (1999), a similar situation obtains with respect to attention-deficit/hyperactivity disorder (ADHD). She concluded that neuroimaging studies "... have, in fact, confirmed the lack of consistent gross neuroanatomical lesions or other abnormalities in attention deficit" (p. 117). For ADHD, there are abnormalities in widespread cortical areas including, at a minimum, the frontostriatal, cingulate, and parietal regions. In sum, for at least these two disorders there is little support for the notion that discrete lesions to functional cortical areas can be observed in developmental disorders. This is consistent with the IS prediction that developmental changes in cognitive skills or behavior are accompanied by widespread changes in multiple regions, as from this point of view, atypical developmental of cognitive skills or behaviors would be associated with widespread rather than focal cortical abnormalities.

There may be some examples of developmental disorders that show a more focal pattern of brain abnormality. For example, some argue that dyscalculia, a developmental difficulty in understanding simple number concepts and learning number facts and procedures, can be a consequence of a core numerical deficit attributable to dysfunction of a single brain area, the intraparietal sulcus (Rubinsten & Henik, 2009; Wilson & Dehaene, 2007). While evidence supports atypical activation of the IPS in individuals with dyscalculia, it is important to note that the IPS is just one component in a large-scale cortical network that subserves mathematical cognition (Butterworth, Varma, Laurillard, 2011). Moreover, recent evidence suggests that the neural specialization for arithmetical

processing may arise, at least in part, from a developmental interaction between the brain and experience. While adults typically demonstrate activation primarily in the IPS during simple arithmetic tasks, children show significantly lower levels of activity in the IPS arithmetic network but more in frontal regions (Ansari et al., 2005). The observed increases in the recruitment of parietal regions in numerical processing are taken as evidence for a specialization of parietal functioning during ontogeny (Ansari & Dhital, 2006; Holloway & Ansari, 2010). The decreasing involvement of prefrontal areas, on the other hand, is assumed to reflect a developmental disengagement of domain-general processes related to executive control and working memory (Ansari et al., 2005). These results highlighted the possibility that dyscalculia may not result simply from a single, damaged brain region. An important factor may also be that the typical school environment does not provide the right kind of experiences to enable the dyscalculic brain to develop normally to learn arithmetic (Butterworth et al. 2011).

In another example where a focal injury may account for developmental deficits, the KE family shows a genetic disorder of speech and language involving a point mutation of the FOXP2 gene. Behaviorally, the affected members appear to have a deficit in sequencing articulation patterns that results in speech output that is often agrammatical and unintelligible (Vargha-Khadem et al., 1998; Watkins et al., 2002). This impairment is evident from childhood and persists into adulthood. Reports indicate that the brains of affected family members differ from those of unaffected members and controls in several particular regions involved in speech and motor control. Among these, the evidence is most striking for the caudate nucleus, which shows reduced gray matter density and volume (Watkins et al., 2002) and shows abnormalities in activation during language tasks (Vargha-Khadem et al., 1998). While this result might suggest that, at least in some genetic disorders, there may be discrete brain lesions that result in specific behavioral impairments, it is important to note that the caudate nucleus is not the only brain area affected in this family and that imaging studies have not been conducted developmentally to determine whether the pattern of damage is already present and unchanging from early in life (as the maturational or skill–learning views might predict) or evolves with development (as the IS view would predict).

Given the assumption of the maturational approach that there is a static structure-function mapping in the brain during development, it is perhaps not surprising that the vast majority of neuroimaging studies with developmental disordered groups involve participants from middle childhood to adulthood, and that patients are often grouped together over a wide age range (e.g., Kesler et al., 2004; Turner syndrome; 7–33 years; Pinter et al., 2001; Down's syndrome; 5–23 years). For the interactive specialization approach, however, age of testing is critical, and it is especially important to study infancy to understand partial causes of subsequent outcomes (Karmiloff-Smith, 1998; Paterson et al., 1999). For this issue to be assessed, there need to be longitudinal imaging studies of clinical groups, or at least cross-sectional study at different ages**.** Due to the difficulties mentioned earlier, there are very few examples of studies of brain function in infants with developmental disorders. Where these have been investigated, there is evidence that abnormalities in brain structure and function may appear differently at different ages. For example, Karrer et al. (1995; see also Hill Karrer et al., 1998) conducted an ERP study of infants with Down syndrome at 6 months using an oddball paradigm for face recognition and concluded that atypicalities in the responses of infants with Down syndrome were milder than those observed in adults with Down syndrome. There are few MRI studies of developmental disorders that have compared different age groups in infancy or childhood. One recent study of autism found evidence of hippocampal enlargement at all ages but amygdala enlargement only in children (7.5–12.5 years) but not adolescents (12.75–18 years; Schumann et al., 2004). Studies of children with ADHD have reported a decrease in cortical thickness that tends to normalize with development (Narr et al., 2009). There is even evidence that normalization of cortical thinning is related to long-term outcomes. In one longitudinal study, children with more atypical outcomes had a persistent thinning of the left medial prefrontal cortex, whereas children with more typical outcomes showed a normalization of the right parietal cortex (Shaw et al., 2006). In a final example, autism has been related to brain overgrowth, children with autism have abnormally large brains by the second year of life, and, for several years thereafter, their brain size can be multiple standard deviations above normal values. The greater conduction delays and cellular costs presumably associated with the longer long-distance connections in these larger brains are thought to influence developmental processes, giving rise to an altered brain organization with less communication between spatially distant regions (Lewis et al., 2013). Thus in the IS view, autism may in part reflect a failure of the normal process of specialization of multi-region networks. These examples are consistent with the IS view that brain abnormalities in developmental disorders are not necessarily like static lesions but can change as the brain develops.

The interactive specialization view considers that, even if areas of behavioral competence are examined, there will still be differences in the neural processing underlying this performance between children with developmental disorders and those developing normally (Karmiloff-Smith, 1998). This question has been examined in studies of Williams Syndrome, a syndrome portrayed by some theorists as involving islands of sparing (normal performance) amidst clear deficits. Mills and colleagues (2000) focused on an area of behavioral competence in this disorder, face processing, and recorded event-related potentials during a face-matching task. Despite their intact behavioral performance in the task, WS participants displayed different patterns of ERPs including a lack of the normal right-hemisphere asymmetry. Similar findings were obtained in another area of behavioral competence for this syndrome, where the normal left hemisphere asymmetry for words was not observed (Mills et al., 1993; Neville et al., 1994). Event-related potentials in response to faces have also been recorded in participants with autism or Asperger syndrome (McPartland & Panagiotides, 2001). However, in this case face processing is an area of behavioral deficit. Compared with controls, the autism group made more errors on a test of face recognition. Performance on the face recognition task was found to be related to the ERPs in several ways: in controls, a face-sensitive ERP component was larger in amplitude to faces compared with objects, and was more predominant over the right hemisphere. In contrast, the autistic group showed longer latencies of this component to faces compared to objects, in the absence of any clear lateralization. These findings suggest that the poorer performance on face recognition tasks by the autism group is reflected by slower and less lateralized processing (i.e., less specialized) of faces as indicated by their ERPs. In addition, the different distribution of the response to faces between the autistic group and controls may reflect qualitatively different processing strategies. With regard to the IS view, this might reflect an absence of the normal process of localization, so brain processing remains more distributed and less focal than in typical development.

Effects of Early Acquired Brain Damage

The maturational and skill–learning views would both predict that early brain damage should have long-lasting detrimental effects, because the neural substrates through which an ability emerges or is learned and retained are destroyed. While the maturational view allows for some plasticity in response to such damage, it makes no clear prediction that the extent of such plasticity should be greater for children compared to adults. The skill–learning view might predict, at least under some circumstances, more negative outcomes for early lesions to areas involved in skill acquisition, because adults would have previously learned, retained skills to fall back on while children would have fewer established skills. In the interactive specialization view, however, there may be compensation for early damage. Although the damage may affect the areas that under normal circumstances would be most suitable for the task and become specialized for it, if the area is damaged in early life then there is still scope for alternative neural circuitry to be recruited for the task. Thus, the IS view predicts that plasticity following brain damage will be related to the degree of functional specialization already achieved in a given region. A region that is already well specialized will be less plastic in response to later life injury, while a region that is less specialized will have more options for future specialization. It is possible that this compensation could come at some price, however, since the overall amount of brain area that can take on specialized functions would be reduced (e.g., the notion of crowding; for discussion see Vargha-Khadem & Mishkin, 1997). If brain area is damaged later in life, then the outcome may be less optimal, as brain areas would already have specialized for particular skills and there would be less scope for alternative neural circuitry to be recruited, as it will already be taken up by other tasks. In the following sections, we will evaluate evidence relating to these hypotheses from studies of the effects of early lesions in three cognitive domains: face processing, memory, and language.

Face Processing

In adults, damage to the occipito-temporal cortex can result in prosopagnosia, a selective impairment in face processing. Several cases of selective deficits in face processing attributed to damage sustained in infancy have been reported (developmental or congenital prosopagnosia; e.g., Bentin, Deouell, & Soroker, 1999; Farah, Rabinowitz, Quinn & Liu, 2000; Jones & Tranel, 2001; Nunn, Postma & Pearson, 2001). On the surface these results are consistent with both the maturational view (early damage to the cortical face-processing system would result in a similar functional impairment as in adults with similar damage), and the skill–learning view (early damage to the system involved in learning about faces will result in a persistent impairment in this ability). However, there are some characteristics of developmental cases of prosopagnosia that do not seem to fit either of these views. If the maturational view is correct, then it would be expected that the location of damage causing prosopagnosia would

be the same in both early and adult-onset cases (Damasio, Tranel, & Damasio, 1990). However, of the few early-onset cases where structural imaging was obtained, there was no observable structural damage (Nunn et al., 2001) or diffuse rather than focal abnormalities (Laeng & Caviness, 2001). If the maturational view or the learning view were correct, then one would also expect the nature of the face-processing deficit to be similar in early and adult-onset cases. Although some authors have concluded that the two disorders are basically similar in terms of an impairment in encoding for spatial arrangement of facial evidence (Barton et al., 2003), there is some evidence for differences related to age of onset: (1) residual discrimination abilities are more limited in developmental cases (Barton, Cherkasova, & O'Connor, 2001) and (2) covert recognition is absent in developmental cases (Barton et al., 2001; but see Jones & Tranel, 2001). Thus, the impairments in face processing observed in early-onset cases appear to be neither identical in nature to those observed in adult-onset cases, nor a direct consequence of focal damage to brain areas involved in face processing in adults. Finally, if the skill–learning view is correct, and face processing represents a specific example of a more general system for acquiring perceptual expertise, then impairments in face processing might be expected to co-occur with more general impairments in acquiring perceptual expertise. However, a study of two individuals with developmental prosopagnosia showed normal acquisition of perceptual expertise for greebles (Rezlescu et al., 2014). Overall, the pattern of results across these studies is most consistent with the IS view, which would predict that the nature of the deficit would depend on the age of injury.

There is some evidence to support the idea that the problem underlying developmental prosopagnosia is a failure of the normal process of brain specialization and localization. One functional MRI study of face perception in four adult developmental prosopagnosics (Avidan et al., 2005) showed that these individuals recruited the inferior frontal gyrus. This area was not commonly activated during face perception in typical adults, but is activated during face perception in children (Passarotti et al., 2003; Scherf et al., 2007). The difference between children and adults is consistent with the IS prediction that the cortical regions that respond to a given stimulus or task will decrease with age. The finding of additional areas of activation in adult developmental prosopagnosics compared with typical adults suggests that the condition may reflect a delayed or impaired specialization process (see Johnson, 2011, for further discussion).

Other studies have taken a different approach, and instead of finding individuals with face-processing deficits that could be attributed to early lesions, have found children who sustained lesions to areas known to be involved in face processing in adults and investigated the consequences for face processing. In one study of face-processing abilities in 5- to 14-year-olds who had experienced perinatal unilateral lesions, the effects were fairly mild: fewer than half the children showed impaired performance relative to controls on tests of face or object identity recognition (Mancini et al., 1998). Furthermore, (1) face-processing deficits were no more common than object processing deficits following a right hemisphere lesion, (2) face-processing deficits were no more common after right-sided than left-sided damage, and (3) a face-processing deficit never occurred in the absence of an object processing deficit. This general pattern is similar to that reported in other studies (Ballantyne & Trauner, 1999; Mancini et al., 1994), and contrasts with the severe impairments in face or object recognition observed in adults with damage to similar brain regions (Farah, 2000). Together, these results suggest that the infant face-processing system is more widely distributed or more plastic following damage than is the adult system. These results fail to provide convincing evidence for the maturational view or skill–learning view. Instead, they are more consistent with the IS view that, when brain areas that typically mediate a function in adults are damaged early in life, there may be greater recovery of function than following similar damage in adults.

Memory

Memory is among the most fundamental aspects of cognitive development, enabling individuals to amass knowledge about the world (semantic memory) and to recall everyday events (episodic memory). In adults, bilateral damage to the medial temporal lobe results in a global amnesia, reflecting this region's essential role in explicit memory. However, until recently there were virtually no reports of memory impairments following temporal lobe damage in children. This was assumed to be either because the results of such damage were so devastating to the developing child that a global severe mental delay resulted (consistent with skill–learning view) or because the greater plasticity of the developing brain allowed sufficient recovery to prevent clinical appearance of memory impairments (consistent with interactive specialization view). In recent years, however, there have been reports that very early damage to a specific medial temporal lobe structure, the hippocampus, does result in amnesia (Gadian et al., 2000;

Isaacs et al., 2003; Vargha-Khadem et al., 1997, 2003). On the surface, this finding appears consistent with the maturational view, in that early focal damage to a brain region believed to mediate a particular ability in adults results in a specific failure of that skill to develop. Indeed, the pattern of memory impairment observed in these children, where episodic memory is relatively impaired and semantic memory relatively spared, has been used to argue that the hippocampus is necessary for episodic memory in adults (Vargha-Khadem et al., 1997). However, the results of selective, bilateral hippocampal damage occurring in childhood appear to differ from those of similar damage occurring in adulthood (Baddeley et al., 2001; Gadian et al., 2000; Vargha-Khadem et al., 1997). The deficits following early injury appear more subtle: while hippocampal damage in adulthood typically results in deficits in both semantic (facts) and episodic (events) memory, damage during childhood results clear deficits only in episodic memory, showing relatively normal development of semantic memory. For example, they score in the low average to average range on indices of semantic memory, such as general intellectual abilities and academic attainments, but they are severely impaired on indices of episodic memory, such as remembering a name, a message, or where a belonging was placed (Gadian et al., 2000; Vargha-Khadem et al., 1997; 2003; see also Cooper et al., 2014). Also, in cases with neonatal damage, the memory deficits that these children do display become apparent only about the time they first enter school or even later. Lastly, while a study comparing performance in those sustaining damage before 1 year of age and those sustaining the damage between 6–14 years (Vargha-Khadem et al., 2003) found no difference in the degree of episodic memory impairment, there was evidence that those with early damage performed better on tests of immediate memory than those with later damage. This might reflect a greater degree of recovery or reorganization of general memory skills in those with early damage.

Proponents of the maturational or skill–learning view might argue that this difference in outcome can be explained by a difference in the selectivity of the medial temporal lobe (MTL) between the two conditions, such that whereas the hippocampus is damaged in both, only the patients with DA show substantial sparing of the subhippocampal cortices. This possibility is in line with the suggestion that the hippocampus and the subhippocampal tissue serve different components of explicit memory, with the hippocampus mediating episodic recollection and the subhippocampal cortices mediating semantic memory and familiarity-based recognition (Baddeley et al., 2001; Mishkin et al., 1998). However, in the IS view this difference in outcome can be explained by the fact that the degree of postinjury compensation and reorganization differs between the developing and the mature brain, such that only early damage allows for recovery of the functions found to be spared in early-onset amnesia. As there has currently been no published report directly comparing early-onset with adult-onset amnesia controlling for extent of damage, it is difficult to decide between these two possibilities. Interestingly, a functional imaging study of one patient with developmental amnesia (injury neonatally, tested at 22 years of age; Maguire, Vargha-Khadem & Mishkin, 2001), showed that, although his hippocampi are severely damaged (approximately 50% reduced in volume bilaterally), they are activated in tasks in which controls also activate the hippocampus. Specifically, during retrieval of real-world memories, the patient Jon activated the same brain regions as controls, including the hippocampus. Also like controls, activation in Jon's hippocampus was greater for the few autobiographical events he could recall compared to public events and general knowledge. However, in spite of these qualitative similarities, his activation was actually greater than controls. Specifically, he activated many homologus areas on the right which the controls did not, and he also showed a different pattern of connectivity between areas compared to controls (controls showed increased connectivity of hippocampal with parahippocampal regions during retrieval of autobiographical events, whereas Jon showed increased connectivity between the hippocampus and retrosplenial cortex and the medial frontal cortex and retrosplenial cortex). These results are consistent with the IS view, as they suggest that Jon activates a different network because his early lesions have allowed for reorganization and compensation. Similarly to the interpretation of performance in cases of developmental prosopagnosia, Jon's wider spread pattern of activation suggests that there is a delayed or impaired specialization process for brain memory systems.

Language

In adults, left hemisphere lesions that involve perisylvian areas result in a dramatic impairment of speech and language that is typically chronic despite rehabilitation. By contrast, damage to these regions during childhood appears to have no or only subtle effects on ultimate language abilities, and there appear to be no or only subtle effects of side of injury (in cases uncomplicated by epilepsy; e.g., see Vargha-Khadem, Isaacs, Watkins &

Mishkin, 2000; also reviewed in Bates & Roe, 2001). For example, one direct comparison of children (5–8 yrs) and adults found the classic association of left-sided damage with aphasia in adults, but found that children performed within the normal range, with no effect of lesion side (Bates, Reilly, Wulfeck, Dronkers, Opie, Fenson, Kriz, Jeffries, Miller & Herbst, 2001). This result is inconsistent with the maturational view, which would predict a similar pattern of impairment in cases of childhood injury. It is also difficult to reconcile with the skill–learning view, unless the damaged areas are not involved in language learning and are only critical once the skill is fully acquired.

There is some evidence consistent with the idea that the left perisylvian areas critical for language in adults may not be key in language learning in children. This comes from data showing that even in early damage there are significant effects of lesion side and site on first stages of language development, but not involving the left perisylvian areas. For example, early delays in word comprehension and symbolic gesture are somewhat more common with perinatal right hemisphere damage but only between 10–20 months of age (Vicari et al., 2000) and deficits in expressive vocabulary and expressive grammar are more common with perinatal left temporal lobe damage, but only from 10 months to 5–6 years (Thal, Marchman, Stiles, Aram, Trauner, Nass & Bates, 1991). One interpretation is that, when children are struggling to reproduce familiar sounds from their input language for the first time, they have to extract a great deal of perceptual detail from the input. This might normally rely on the left temporal cortex, since it is known to be involved in extracting detail from perceptual inputs.

Overall, evidence suggests that younger children may have less consolidated and more bilateral representations of language processing areas, which derives mostly from increased activation in the right frontal lobe (Gaillard et al., 2000; Holland et al., 2001). For example, PET studies of children who had neurosurgery to treat intractable epilepsy indicate that, especially for language perception tasks, early left hemisphere lesions are associated with enhanced activation of right hemisphere areas, whereas recruitment of regions ipsilateral to the lesion side is limited. Studies with children born preterm support the idea that interhemispheric connections are key in typical language development. One diffusion tractography study of adolescents who had been born preterm showed that 38% showed a language impairment and that a combination of anatomical measures of temporal interhemispheric connectivity (through the splenium of the corpus callosum and anterior commissure) explained 57% of the variance in language abilities (Northam et al., 2013). Thus, a more diffuse, less consolidated distribution of language networks has been proposed as an explanation for recovery from dominant hemisphere brain injury in children that extends, with diminishing capacity, into adolescence (Boatman et al., 1999; Gaillard et al., 2000; Vargha-Khadem et al., 1992). It has been argued that, by adulthood, the functional role of the RH in aphasia recovery may be more limited compared with that of the peri-lesional structures in the LH (Karbe et al., 1998; Weiller et al., 1995).

Effects of Atypical Early Experience

The three perspectives on human functional brain development differ in their views as to the effects of early atypical experience. In the maturational view, differences in experience might influence the speed at which a function matures or the ultimate level of performance; in the skill–learning view any nonoptimal, atypical early experiences can potentially be compensated for later in development as the mechanisms for learning remain in operation in the same way; in the IS view atypical early experiences could have long-lasting effects because they could affect the specialization and localization of function, which may not be able to be altered later in life when there is less scope for plasticity. Recovery from nonoptimal atypical experience will relate to the degree of specialization already achieved for that region—if the region has become atypically specialized, there will be less scope for recovery than if the region is still relatively unspecialized when typical experience resumes.

There have only been a limited number of studies examining the effects of atypical early experience in humans. Several studies have examined the influence of early experience on processing of facial information. For example, Pollak and colleagues have found that perception of the facial expression of anger, but not other expressions, is altered in children who experienced the culturally atypical environment of parental abuse. Specifically, they report that, compared to nonabused children, abused children show a response bias for anger (Pollak, Cicchetti, Hornung, & Reed, 2000), identify anger based on less perceptual input (Pollak & Sinha, 2002), show altered category boundaries for anger (Pollak & Kistler, 2002) and show atypical responding to anger in tasks of selective attention (Pollak & Tolley-Schell, 2003). These results suggest that atypical frequency and content of their emotional interactions with their caregivers results in a change in the basic perception of emotional expressions in abused children. Specifically, in this case children seem to show a hypersensitivity to anger, a finding also supported by ERP

studies with this population (Curtis & Cicchetti, 2011; 2013; Pollak, Cicchetti, Klorman, & Brumaghim, 1997; Pollak, Klorman, Thatcher, & Cicchetti, 2001), even in infants as young as 15 months (Curtis & Cicchetti, 2013). However, whether these effects would disappear with sufficient exposure to a normative environment, as the skill–learning view might predict, or reflect more lasting effects, as the IS view might predict, is not clear.

ERPs in response to facial expressions of emotion have also been assessed in institutionalized children who have experienced extreme neglect and deprivation. In one such study, ERPs to happy, sad, angry and fearful faces were recorded in 5- to 31-month-old institutionalized Romanian children and a similarly aged group of Romanian children who had never been institutionalized (Parker et al., 2005a, b; but see Moulson, Fox, Zeanah, & Nelson, 2009). Institutionalized children showed overall decreased amplitudes of the N170 Nc and PSW responses and, unlike controls, did not show a decrease in Nc amplitude with age. These results appear consistent with the notion that institutionalized children show brain hypoactivation, as well as a distinctive trajectory of brain development. Institutionalized children also showed an absence of hemispheric lateralization for the positive slow wave, whereas controls showed a larger response over the right hemisphere. Moulson and colleagues (Moulson, Westerlund, Fox, Zeanah, & Nelson, 2009; Moulson et al., 2009) also found evidence of hypoarousal in institutionalized children who displayed smaller amplitudes for the P1 bilaterally and the N170 and P400 components over the right hemisphere compared to the never-institutionalized group. Latencies for the P1 and P400 components were also longer among the institutionalized children relative to the never-institutionalized children, thus chronicling slower information processing in children with a history of institutionalization (Moulson, Fox, et al. 2009; Moulson, Westerlund, et al., 2009). After these initial baseline measures were collected, the institutionalized children, as previously noted, were randomly assigned to be placed into foster care or to remain in the institution. At 30 and 42 months of age, ERPs were once again collected during presentation of emotion face stimuli. Results revealed that P1 and P400 amplitudes of children in the foster care group were midway between the institutionalized and never-institutionalized children, suggesting that foster care may be normalizing these components. Interestingly, neither age at placement in foster care nor duration of time there contributed to this outcome. Overall, the results of these studies suggest brain hypoarousal and lack of hemispheric specialization.

Interestingly, while the ERP studies just described provide evidence of cortical hypoarousal, fMRI studies highlight subcortical hyperactivation during face processing in previously institutionalized children. Children who were previously institutionalized have larger amygdalas than those who were never institutionalized and also show hyperactivation of the amygdala to fearful faces and distractor stimuli, but not neutral faces (Tottenham et al., 2011; Figure 16.1). While control children showed no difference in amygdala activation for fearful compared to neutral faces, previously institutionalized children showed greater activation to fearful faces, a pattern similar to that observed in adults and suggesting precocious development of the amygdala. Moreover, while control children showed a coupling of amygdala activity with medial prefrontal cortex activity, previously institutionalized children failed to show this link, a finding consistent with other reports showing reduced white matter between these two areas in this group (Govindan et al., 2010).

Sensory deprivation is another form of atypical early experience. Some studies have investigated the perception of facial information in children who experienced deprivation of patterned visual input in the early months of life due to bilateral, congenital cataracts. These patients were tested years after their cataracts were removed and they were fitted with contact lenses (i.e., years after visual input had been restored), thus any effects of the few months of deprivation following birth would likely be absent or very minimal according to the maturation or skill–learning views. However, investigation of these patients reveals persistent deficits in selective aspects of face processing. One study found that patients showed impairments in matching facial identity over changes in viewpoint (and tended to show an impairment in recognising identity over changes in emotional expression), but performed normally on tests of lip-reading, perception of eye gaze and matching of emotional expressions (Geldart, Mondloch, Maurer, de Schonen & Brent, 2002). A second study demonstrated that this difficulty in processing facial identity may be due to deficits in processing the spacing among facial features, since patients performed normally in discrimination of faces that differed only on individual features (e.g., mouth) but they were impaired in discrimination of faces that differ only in the spacing of the features (Le Grand et al., 2001; see also Le Grand, Mondloch, Maurer, & Brent, 2003, 2004). This was not due to a general impairment in perception of spacing of features, as they performed normally in discriminating non-face patterns whether they differed by the shape of the features or the spacing of the features. These patients also show impairments in holistic

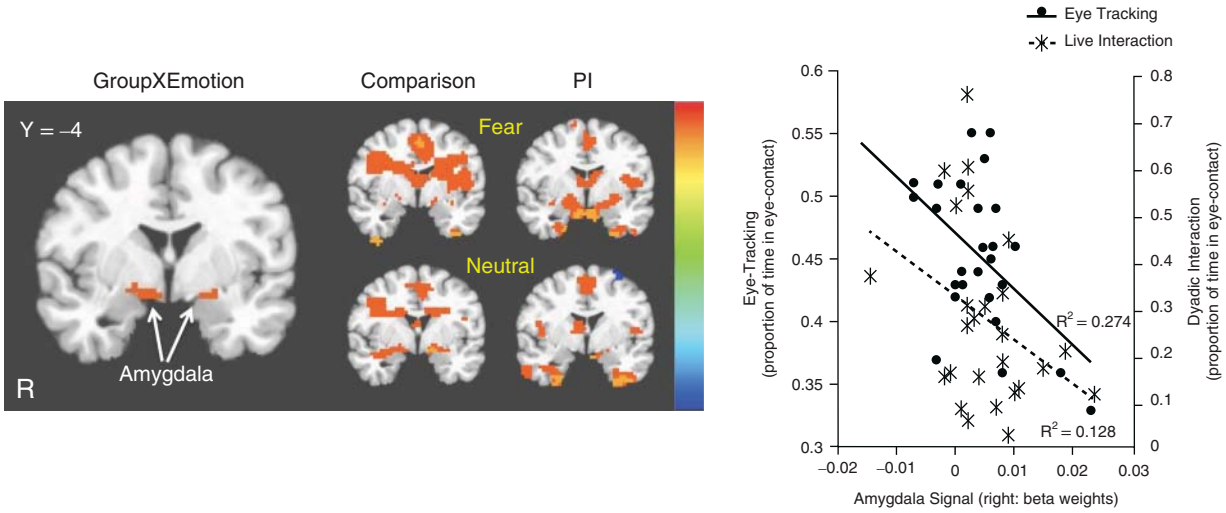

Figure 16.1 Elevated amygdala response to faces following early deprivation. Amygdala signal change to fearful faces and eye contact. Left: A Group × Emotion interaction showed that PI children exhibited greater signal change than the comparison group for fearful faces. Middle: Post hoc *t* tests showed the results for each emotion relative to baseline separately for PI and comparison children. Right: BOLD signal (beta weights) from the group × emotion amygdala ROI was inversely correlated with amount of eye contact children made during eye-tracking (proportion of frames spent looking at the eye region). *Note:* The negative correlation between amygdala signal change and eye-contact during a live dyadic interaction (proportion of time making eye contact) was not statistically significant. See footnote 1. *Source:* From N. Tottenham, T. A. Hare, A. Milner, T. Gilhooly, J. D. Zevin, & B. J. Casey, Elevated amygdala response to faces following early deprivation, *Developmental Science, 14,* 190–204, 2011.

processing of faces, which actually allows them to perform better than controls on certain tasks where optimal performance relies on ignoring the whole and focusing on the features (Le Grand et al., 2004). The fact that these impairments persist even after years of visual input to compensate for the early deprivation is not consistent with the maturational or skill–learning views but is consistent with the IS view that early atypical experience may have long-lasting consequences.

Early experience has also been studied in the context of language development. One question of interest here has been, when adults acquire a second language, does this activate the same network as the primary language learned during childhood (consistent with the skill learning and maturational views) or does it activate a different network (consistent with IS view). Some early reports indicated that bilinguals who learned their second language late showed different activations for the two languages while bilinguals who learned their second language early showed overlapping activations (e.g. Kim et al., 1997). However, subsequent studies have suggested that level of skill in the second language, rather than age of acquisition, is the more important variable in determining the degree of overlap of regions activated by the two languages (e.g., Chee et al., 1999; Dehaene et al., 1997; Perani et al., 1998;), a result consistent with a skill–learning view.

A slightly different approach has been taken by other studies, where the question of whether early exposure to a language has any long lasting consequences has been asked. These studies have examined adults who early in life were exposed to one language for a few months or years but then were removed from that language and exposed to another one either because of adoption or emigration. One study examining Korean adults adopted between 3–8 years of age by French families found no evidence that the subjects could identify Korean words and no differences in brain activation to Korean compared to unknown languages, but did find that the brain activation for French, while it involved the same basic network, was more widespread in the native speakers than the adoptees (Pallier et al., 2003). Another study found that children who had heard or heard and spoken Korean during the first years of life later showed benefits from this limited early experience in learning Korean during the first-year of college (Oh, Jun, Knightly, & Au, 2003). These lasting effects of limited periods of early exposure are difficult to explain in the maturational or skill–learning view points, but can be explained in the IS view as the effects of early experience on the specialization of the areas involved in processing speech and language.

TRANSLATIONAL CONSIDERATIONS

Understanding the dynamic transactions between risk and protective factors plays a central role in building developmentally informed models of prevention. Through increasing the relative balance of protective factors over risk factors, there is greater potential for normalizing developmental trajectories and achieving adaptive outcomes that minimize the emergence of psychopathology. The interactive specialization viewpoint emphasizes the importance of understanding these factors and intervening from early on in development, as with age the brain becomes increasingly specialized and has potentially less scope for alteration. The interactive specialization viewpoint also highlights the need for understanding brain–behavior networks: altering one aspect of risk or protection can have wide-ranging, and potentially unintended, implications for other brain areas or behaviors as a result. Overall, the interactive specialization view points to the importance of (1) obtaining brain–behavior profiles from early in development rather than focusing only on disorders once they are manifest; (2) focusing more on understanding differences in interregional neural interactions in developmental disorders rather than searching for localized, discrete lesions; and (3) moving away from studying only deficits in young children with disorders to also understanding brain-behavior relations for skills in which atypical participants perform as well as typically developing participants (see Johnson, Halit, Grice, & Karmiloff-Smith, 2002). Viewed from an interactive specialization perspective, key diagnostic features of some developmental disorders may even be the result of the brains adaptive responses to an atypical early internal environment (e.g., noisy processing resulting from poor-quality synaptic function), rather than the result of an ongoing neural pathology (Johnson et al., 2015).

CONCLUSIONS

In this chapter, we outlined three perspectives on human functional brain development that have different implications for our understanding of developmental disorders, and the effects of brain damage over the first years of life. By the maturational view, genetic disorders could potentially lead to focal cortical damage, and consequently to selective cognitive, motor, or perceptual disorders. Symptoms of these disorders would be first become evident at the normal age of maturation of the regions concerned. However, reviews have concluded that there are few, if any, human developmental abnormalities of genetic origin that affect only one or two specific regions of cortex (e.g. Johnson et al. 2002). Rather, structural and functional neuroimaging usually reveal subtle but widespread differences in the brains of groups with developmental disorders. Relatedly, claims of domain specific cognitive deficits in syndromes such as autism and Williams syndrome have been challenged, and replaced with hypotheses about different styles or modes of processing (e.g., Karmiloff-Smith, 1998). Finally, it is difficult to explain reports of recovery of functions following early brain damage by the maturational view, without recourse to additional special mechanisms of plasticity.

According to the interactive specialization view, developmental disorders of genetic etiology will often involve disruption of the typical biases and interactions between regions that give rise to adult patterns of cortical functional specialization. By this view, subtle symptoms may be evident from birth, but these will become compounded through the infant's abnormal interactions with its environment. While there are currently few behavioral studies of developmental disorders during infancy, those that do exist suggest discontinuities in the patterns of behavioral and cognitive deficits through postnatal development. For example, in one such disorder, Williams Syndrome, adults present with behavioral deficits in number tasks, but show surprising proficiency in some aspects of language. One study investigated whether this pattern of specific deficits is also observed in Williams Syndrome infants, as would be expected if they have a damaged innate module for number. Standard infant paradigms for assessing number and object naming skills were used with toddlers with Williams Syndrome (Patterson et al. 1999). The toddlers did not show the same behavioral profile as observed in adults with the syndrome, indicating that the profile of behavioral deficits in developmental disorders can change during ontogeny, and that it is not appropriate to characterize such deficits in terms of damage to specific domain-specific modules. In another example, while children and adults with autism show impairments in face processing, infants at risk for autism show a clear orienting response to faces in an array of distracters irrespective of their later outcomes (Elsabbagh et al., 2013) but show atypically quick processing of objects (McCleery et al., 2009). From the interactive specialization perspective it may also be easier to understand recovery of function following early damage since the same mechanisms that ensure specialization during the typical developmental trajectory could also ensure a different pattern of specialization.

The IS view includes a series of predictions about the role of brain specialization and interactions among brain regions in development. Studies reviewed in this chapter support the specific predictions regarding increased specialization and localization of brain response and changes in the dynamics of brain networks with age. However, fewer studies directly address some of the view's other predictions, including the idea that specialization scales up from regions to networks, and that changes in the degree of brain plasticity with functional specialization and localization, and these remain important avenues for further research.

FUTURE DIRECTIONS

Further assessment of the three perspectives on human functional brain development presented in this chapter will require more improved methods for non-invasive functional imaging methods, and more detailed computational models that generate predictions about both neuroanatomy and behavior. With regard to new functional imaging methods, forms of optical imaging (Near InfraRed Spectroscopy—NIRS) offer promise for studying brain function in human infants (Lloyd-Fox et al., 2013). Like functional MRI, NIRS can measure changes in blood oxygenation in the brain that occur following the activation of groups of neurons within an area. While currently lacking the spatial resolution of functional MRI, the method does not involve the exposure to high magnetic fields, noise, and motion sensitivity that make using functional MRI with typical awake infants difficult.

From the age of 6 or 7 years MRI can be routinely used. Recent advances in MRI analysis techniques will allow the investigation of both structural and functional changes during development. The recent studies using diffusion tensor imaging (DTI) to track the development of white matter demonstrate its usefulness for understanding not only structural brain development but also the functional development of brain networks underlying emerging cognitive skills. For example, one study used DTI together with fMRI to study the development of the frontoparietal network involved in working memory. These authors found that DTI measures of frontoparietal white matter correlated with the fMRI response in closely located gray matter in the superior frontal sulcus and inferior parietal lobe. These results suggest that development of white matter could account for increases with age in level of activation of frontoparietal gray matter observed during working memory tasks (Olesen et al., 2003).

While the basic method of EEG/ERP has been available for over 50 years, recent advances in technology and analysis methods have opened up new possibilities for the exploration of brain function in infants and young children. In one such advance, high-density recording systems along individual structural MRI or age appropriate templates allow for improved source localization of ERP activity (Bathelt et al., in press). In another advance, the relation of bursts of high-frequency oscillatory activity in the brain to cognitive and perceptual tasks has begun to be studied in infants, children, and adults (e.g., Csibra et al., 2000). In one experiment, high-frequency oscillations occurred during periods of time when previously visible objects became occluded, potentially providing a neural correlate of object permanence (Kaufman et al., 2003). Advances in wireless EEG/ERP recording systems may also facilitate acquisition of data in a wider range of context and populations.

In order to relate findings on brain structure and development to those on perceptual or cognitive functions we need the explanatory bridge that can be provided by computational modeling of neural networks. While there are currently major efforts to use connectionist models to explain aspects of typical and atypical cognitive development (Thomas et al., 2011), very few of these efforts currently allow interpretation of data from functional imaging or neuroanatomy. These types of investigations will provide information regarding which of the three viewpoints best describes the developmental process, and whether the answer to this question depends on the cognitive domain under study and the context in which it develops. Whatever the outcome of these investigations, a better understanding of functional brain development in human infants and children may have profound consequences for educational, clinical, and social policies (see Casey & de Haan, 2002).

While advances in neuroimaging acquisition and analysis methods will undoubtedly be important for future work in developmental cognitive neuroscience, it will also be useful to better integrate these measures with other levels of analysis, including psychosocial and environmental-contextual ones. The interactive specialization view discussed in this chapter is compatible with this view, but in the future it might be informative to relate its predictions about developing brain-behavior relations with other broad frameworks for understanding child development. For example, multiple levels of analysis (Cicchetti, 2010) and relational developmental systems (Overton & Lerner, 2012) are broad frameworks that emphasize the bidirectional nature of brain–behavior development and

highlight the need to consider biological measures within the broader psychological context in holistic rather than componential, reductionistic way. It is difficult for individual researchers to tackle the many levels of analysis, and thus these approaches also emphasize the future need for collaborative research on a broader scale.

REFERENCES 680

Increasingly, the science of human development may be informed by a neurodevelopmental analysis, with questions of psychological growth and adjustment seen in the new light of the evidence on neural mechanisms. Moreover, advances in understanding the epigenetic regulation of neural development have shown that genetic control of the brain's growth and differentiation is achieved only as life experiences shape the epigenetic regulation of gene transcription. The traditional controversy of nature versus nurture no longer makes sense when genetic control is so strongly mediated by epigenetic regulation, which is, in turn, highly responsive to the child's life experiences.

Considering the new insights into the neural basis of psychological development, we will suggest that it is now possible to consider a single theory in which mind and brain are studied as the same process. Within this theory, the control of neural activity and the resulting growth and differentiation of the brain's connectional architecture can be understood as identical to the child's processes of motivation and self-regulation of psychological development. The process of life is achieved through the ontogenetic coordination of disparate genetic influences required for biological self-organization. The growth and differentiation of the brain are exactly isomorphic to the differentiation and refinement of the self in the context of social relations.

Before outlining this integrated analysis, we first describe the neurodevelopmental process in biological and then in psychological terms. At the biological level, self-organization of the human brain involves not only the instructions of the genome, but the epigenetic modification of those instructions to adapt the genetic code to two related factors: (1) the organism's adaptation of feedback to developing systems to achieve coherent self-organization (classically termed *canalization*); and (2) the organism's ongoing adaptation to environmental conditions (the process of *plasticity*). The recent progress in understanding the molecular mechanisms of gene transcription has offered a new understanding of how each child's genetic endowment must be shaped by the set of life experiences that determine the *epigenetic* control that actualizes the code of the genome. Epigenetic control is highly active in the specification of cells from their pluripotent stems in embryonic differentiation. It remains important in the development of the central nervous system, even after many organ systems have become fully specified. Importantly, epigenetic mechanisms have been discovered to be particularly important to the regulation of neural plasticity that is in turn essential to the child's growth and adaptation.

The implication of these findings is that genetic variations are common, and their impact on the child's

development are strongly regulated—for better or worse—by life experiences. Furthermore, because it is cumulative, and captured in the progressive differentiation of neural architecture, neural plasticity is not necessarily reversible. As a result, both genetic defects and early experiences create patterns of neural and psychological self-regulation that may impair future developmental adaptation. The task is then to appreciate how the genetic and epigenetic variation experienced by a given person interacts with the major control systems regulating neural plasticity and the normal developmental process. These control systems engage mechanisms of activity-dependent synaptic organization that are isomorphic with the process of behavioral learning. In this way, the development of psychological function through motivated learning can be seen as identical to the growth and organization of the brain.

Having outlined this biological model of organismic development in the first section, we then consider the psychological process of developmental self-regulation in the second section. Increasingly, researchers are characterizing the control of development not just through fixed biological maturation, nor just through family and social influences as separate factors, but through the child's capacities in self-organization that mediate the synergistic interactions between social influence and maturational competence. Consistent with this theoretical account, we review evidence that mental disorders can be understood not as diseases but as variations in normal psychological development. Not only the familiar personality disorders, but the spectrum forms of more severe psychopathology such as autism, schizophrenia, and manic-depressive illness are found to vary more or less continuously in the normal population. Recent research on disorders of motivation and self-regulation in psychopathology is providing insight into the ways these disorders diverge from optimal development.

At a certain level of dysfunction, of course, mental disorders may show a precipitous and progressive decline from normal adaptive function. Furthermore, certain genetic neurodevelopmental disorders, such as fragile X syndrome or Rett syndrome, produce unique and discrete neurodevelopmental defects (Day & Sweatt, 2011). Nonetheless, we suggest that theoretical insight into the nature of psychopathology may be advanced most importantly through studying the way that normal developmental controls become disordered, leading to psychopathological outcomes. Many of the genetic variants of critical developmental control mechanisms, including dopamine, serotonin, or oxytocin, produce variations in temperament that are largely within the normal range. Given these general insights, we can appreciate that psychopathology is often a developmental phenotypical, rather than invariant genotypical, result.

Recognizing the continuity of psychopathology with normal neural development can lead to a theoretical analysis of the normal developmental control processes—of motivation, learning, and self-regulation—that become exaggerated or dysfunctional in persons with psychopathology. At the same time, these developmental control processes still confer important capacities for adaptation. In a third and final section of this chapter, we attempt to provide a theoretical analysis of normal developmental self-regulation that helps to explain how the biological vectors of growth and differentiation of the brain are shaped—often irreversibly—by the interaction between the child's social support systems and the child's personal capacity for self-regulation in the context of life stress. We propose that the major syndromes of externalizing and internalizing in psychopathology can be understood as exaggerations of normal neurodevelopmental mechanisms of self-organization. These control mechanisms first shape the embryonic formation of dorsal (externally directed, visceromotor) and ventral (internally directed, viscerosensory) divisions of the telencephalon, and then continue to determine neural activity-dependent specification of cerebral architecture after birth, in the key developmental processes of learning and memory consolidation.

Thus the mechanisms of psychological development that mediate cognitive maturation, through processes of motivation and self-regulation, are literal neurodevelopmental mechanisms, reflecting the ongoing morphogenetic processes shaping the connectional architecture of the brain. Neural morphogenesis begins in the embryo, and it continues to organize the brain's growth throughout life. Cognition is neural development, continued in the present moment.

Because the child's capacity for self-regulation determines the activity-dependent specification of neural plasticity—and thus the growth and differentiation of both cortical and subcortical networks—it controls the process of *self-organization* in a literal sense. In this sense, the personality is not a disembodied mental construct, but the individual's unique pattern of brain development. To understand the epigenetic specification of the endophenotype—the individual child—it is necessary to consider not just the genetic coding for traits, but the full context of developmental self-regulation that shapes the growth of the brain and the personality within the complex social and cultural environment.

The essential mechanisms of self-regulation in normal development can be described broadly as externalizing and internalizing. These mechanisms reflect the operation of the major, dorsal and ventral, divisions of the limbic system, respectively. Through close integration with neocortical representational capacities, the dual limbic circuits in turn elaborate more primitive controls on neural activity emerging from the striatum, diencephalon, and brain stem. In normal brain development, externalizing and internalizing reflect ways the child comes to regulate arousal to mediate the relation between self and world. In the personality disorders, externalizing and internalizing can be understood to reflect exaggerated variations on the normal neurodevelopmental process. More severe forms of psychopathology reflect more severe deficits in the balance of biological control systems that shape the emergence of the self in the context of social relations. For both biological and psychological levels, the self is an important theoretical construct for understanding the control of the developmental process, whether the specific issue is maintaining arousal, acting with confidence, or actualizing the knowledge of self gained in interpersonal interaction.

THE NEURODEVELOPMENTAL PROCESS

The scientific study of biological development over the last century has ranged between more holistic conceptual approaches, such as those based on observation of morphogenetic differentiation of the embryo (Waddington, 1942), and more molecular approaches, such as those that attempt to explain development in terms of biochemical mechanisms (Gould, 1977). In the modern molecular approach, the goal has been to identify specific genes and their transcription processes that code for the organism's traits and their developmental emergence. The dominance of the molecular approach in the modern era has been bolstered not only by the discovery of DNA and the sequencing of the genome, but the success of the neo-Darwinian explanation of evolution. In this account, evolution has progressed first through random genetic mutations that alter the course of ontogenesis, and second through natural selection for those rare molecular defects that prove adaptive (Gould, 1977).

Modern biological approaches to psychopathology have been dominated by the molecular rationale. A widespread assumption seems to have been that once the genetic cause of a specific mental disorder is discovered, it will be treatable through a molecular or pharmacological manipulation. Supporting the molecular approach, there have been important findings of neurodevelopmental disorders such as Rett syndrome in which specific genetic defects lead to symptoms of psychopathology. Furthermore, the alleles or variant forms of certain genes, such as those that regulate serotonin, can be found to be relevant to individual differences in the cognitive and emotional features of mental disorders such as anxiety and depression (Talati, Weissman, & Hamilton, 2013; Tops, Russo, Boksem, & Tucker, 2009).

Without doubt, the remarkable capacity for detailed examination of an individual's genome is presenting powerful new tools for understanding the genetic basis of psychopathology. Researchers naturally take the obvious empirical approach, questioning whether a genetic cause can be found for a disorder such as autism or psychopathy. In psychopathy, for example, genes that regulate oxytocin function have been shown to have specific alleles or variants that are associated with a trait of callousness and non-emotionality that is an important component of psychopathic behavior (Dadds et al., 2009; Moul, Killcross, & Dadds, 2012). Because oxytocin has been found to mediate interpersonal closeness and attachment in both human and animal studies (Tops, van Peer, Korf, Wijers, & Tucker, 2007), this research provides an important implication of a genetic predisposition for psychopathy. Yet the scientific understanding of the role of specific genes—such as those that regulate oxytocin—in psychopathology will require more than an empirical cataloging of associations. Instead, each biological factor must be understood in relation to its contribution to the human developmental process. For example, oxytocin seems to facilitate interpersonal bonding through *suppressing* the anxiety responses of the amygdala (Tops et al., 2007); if anything, psychopathy results from too little anxiety rather than too much. Rather than accepting a simple single cause, scientific insight into developmental factors such the role of oxytocin in psychopathy will require a careful analysis of the interaction between interpersonal bonding and self-regulation in the course of development.

Genetic Control of Ontogenesis

Thus reasoning from genes to psychopathology requires interpreting development. Genes do not control traits of the phenotype; rather, they control the process of ontogenesis that translates from the genome—through what we now appreciate as a complex epigenetic process—into the phenotype of the individual.

Modern biology has recognized the theoretical significance of genetic control of ontogenesis in understanding the mechanisms of evolution. Rather than selecting

for traits, as was often implicitly assumed in the neo-Darwinian modern synthesis of evolutionary theory, genes control the process of ontogenesis, which may result in adaptively significant traits, but only as a result of the developmental process (Gould, 1977). Certain Mendelian traits require little complexity in ontogenesis to be manifested. However, the more complex traits, such as those that regulate behavior and psychopathology, show *reduced penetrance* as a result of complex and probabilistic influences on the phenotype.

Another complicating factor in understanding the genetic control of human development is the extended human juvenile period, during which epigenetic factors operate over long intervals to shape the phenotype. Whereas most mammals achieve maturity in a few months or a few years, humans achieve the capacity for competent adult behavior only after two decades, and even then the capacity for independence is sometimes unclear. Importantly, rather than a defect of the species, human neoteny or developmental delay seems to have been a progressive factor in the evolution of intelligence in a cultural context (Gould, 1977). Recent research in developmental neuroscience continues to illustrate the key role of extended human neoteny.

Cortical thinning is an integral process of brain maturation in adolescence, appearing to reflect a critical stage of synaptic pruning to achieve the adult brain architecture (Mutlu et al., 2013). Remarkably, adolescents whose cortical thinning continues through late adolescence might be thought to suffer from lower intelligence or even mental retardation. Instead, these late bloomers are eventually found to achieve higher levels of intelligence than those who complete cortical thinning earlier (Mutlu et al., 2013). This observation is consistent with the notion that neoteny allows an extended period of juvenile neural plasticity that is integral to human intelligence. Equally remarkably, the individual variability of cortical maturational rate suggests that human evolution has resulted in considerable heterogeneity in the degree of neoteny in current populations.

Epigenetic Canalization and the Cybernetics of Self-Organization

Thus genetic factors creating risk of psychopathology operate through a course of human ontogenesis that is inherently protracted. For example, as the child's development proceeds over decades under the influence of family and cultural influences, a genetic variant influencing serotonin or oxytocin sensitivity does not code for a psychopathological trait, but rather for a regulatory process that shapes the course of ontogenesis, during which the many social and environmental influences interact with the child's capacity for effective self-organization. Genes must therefore act through mediation by the more organismic controls on ontogenesis classically described as *epigenesis* (Waddington, 1942).

At the molecular level, epigenetic mechanisms regulate the process of gene expression. The transcription of the DNA code to specific proteins is modified through processes within the cromatin sheath around the DNA. At each gene locus, epigenetic molecular mechanisms such as methylation act to suppress the transcription of specific genes (Sweatt, 2013). Remarkably, these epigenetic mechanisms may influence not only the immediate transcription process but also may become ingrained in the daughter cells following cell division, thereby propagating through the developmental process for the life of that individual (Sweatt, 2013). It is now clear that environmental influences that shape the epigenetic mediation may include not only chemical insults but also emotional and social experiences of the young animal. Considerable evidence suggests that early experiences, such as maternal licking and grooming for rat pups (Meany, Braike, & Gratton, 2002), may shape a host of biological developmental mechanisms, including epigenetic, hormonal, and immunological processes (Sweatt, 2009).

The increasing evidence of the importance of epigenetic mechanisms has led to renewed theoretical interest in the more global organismic processes that modify the translation from genetic code into the structure and function of the phenotype. In Waddington's (1942) analysis of epigenesis, the genetic control of embryogenesis was seen to require organismic mechanisms that maintained a kind of systems-level continuity in ontogenesis, even in the face of varied discrete effects of specific gene transcriptions. Waddington used the term *canalization* to describe how essential functional channels of embryonic development (*canals*) are maintained, even as the landscape of gene transcription takes on widely varying shapes in response to the code of an individual genome. Waddington's organismic approach is consistent with classical theoretical models of developmental psychology such as those of Jean Piaget (1936/1992) or Heinz Werner (1957), in which broad principles of organismic differentiation and integration establish the context for regulating the developmental process. In modern terms of control theory, the process of canalization can be seen as a *cybernetic* process, in that the individual molecular mechanisms of genetic specification are controlled by feedback within the organ

systems that operate to maintain functional continuity in development.

The essential role of canalization and organismic self-organization can be seen in the process of embryonic neural morphogenesis. In the dominant mode of genetic feed-forward control, the genome provides processes of gene expression that create trophic chemical gradients that guide neuronal migration (Rakic, 2009). An example is the gradient of Emx2 that guides neuronal migration in the dorsal telencephalon. In the modern cookbook model of gene instructions providing the building blocks of life, interlocking patterns of gene expression and trophic factors set the stage for building the brain through each stage of morphogenesis. However, this *feedforward* control from gene expression must be continually modified by *feedback* control from the outcomes of neuronal processes themselves. For example, the migration of precursor pyramidal (spindle) cells from the periventricular region to the cortex is followed by differentiation of middle layers of the cortex under control by the arrival of afferents from the thalamus to layer 4 (Marin-Padilla, 1998). Thus the network's success in functional organization at a systems level guides the connectivity at the molecular synaptic level. Once the gross architecture of the cortex is established—along the lines of the major gradients of trophic factors—it is the spontaneous activity of the neuronal networks themselves that determines the differentiated synaptic connectivity that is retained to support function (Hanganu-Opatz, 2010; Marin-Padilla, 1998).

Embryonic Plasticity and Learning

Activity-dependent self-organization of neural networks in the process of cerebral development is thus becoming increasingly understood at multiple levels, from the epigenetic regulation of gene expression to the ongoing modification of synapses by the consolidation processes of memory and learning. Epigenetic mechanisms are particularly active in the embryo, as cells differentiate from their generic pluripotent forms. These mechanisms are less important once cells achieve the target forms that will remain set throughout development (Sweatt, 2009). However, in the mammalian brain, whereas other organ systems become relatively stable after birth, the brain's continuing developmental process retains a high degree of epigenetic plasticity. This suggests a kind of continuing active development that is described as *neuroepigenetics* (Sweatt, 2013). A remarkable and fundamental realization is that neuroepigenetic mechanisms regulating cerebral architecture are closely related to the neural plasticity that determines functional learning and memory of the juvenile animal.

In general, *neural plasticity* involves changes in brain wiring as a function of experience, wherein inputs, either from the neuronal milieu or external world, influence the functional synaptic architecture. The regulation of neural plasticity is inherently a developmental, self-organizing process, progressing from a somewhat undifferentiated abundance of synaptic connections in the *blooming* stage of the infant brain to a selective differentiation in the *pruning* stage through retaining only those connections that are activated by functional inputs, a process of connection pruning (Greenough & Black, 1992; Greenough, Black, & Wallace, 1987; Markham & Greenough, 2004). Within this overall activity-dependent differentiation, there are critical periods for the development of normal sensory functions, such as vision and audition, when plasticity is prepared for the normal pattern of sensory experience. As a result of critical periods of sensory plasticity, sensory deprivation at these periods impairs the development of sensory maps that are required for normal perceptual functions. Initially, the maps established during these *experience-expectant* periods (Greenough & Black, 1992) were then found to be resistant to change, leading to the concept of a critical period when neuronal adaptation was active. The sensitive neural plasticity during these critical periods was found to be mediated by specialized molecular mechanisms—including neuroepigenetic mechanisms—that are active during these critical periods (Hensch, 2005). The result of successful sensory plasticity is an established neural structure that represents, more or less accurately, the state of the external world (or, more specifically, the effect of the external world on the sensory receptors) that forms the brain's interface with the world during ontogenesis.

Although plasticity is reduced after the critical period, it remains in some form to support learning and reorganization of function in the adult brain. For example, even after the critical period, if sensory inputs are radically altered, such as by amputation of digits, massive reorganization can be induced even in primary sensory cortex (Merzenich et al., 1984).

Neural plasticity thus first appears as a neurodevelopmental mechanism, serving to organize the brain's connectivity in the process of embryological differentiation. It then remains as a neurodevelopmental mechanism after birth, during the critical periods in which environmental interaction adapts the brain's networks to the information in the unique environment that the organism discovers. Finally, neural plasticity continues to support

the brain's functional differentiation throughout life, in the general process of learning and adaptation of behavior and cognition to environmental demands.

Although these developmental stages of neural plasticity have important unique features, in studying humans it may be important to appreciate the continuity in the developmental process, through which the process of ontogenesis involves neural self-organization not only in the differentiation of neural circuitry through mesencephalic, diencephalic, and telencephalic stages of embryonic differentiation, but also through the continued refinement of connectional architecture that marks the maturation of the brain through childhood, adolescence, and adulthood. Psychological development thereby reflects an unbroken continuity with neural development throughout the process of ontogenesis. Cognition and memory continually consolidate the learning process within the fine synaptic architecture of experience (Tucker & Luu, 2012).

This continuity of neurodevelopmental mechanisms can be appreciated by considering how perceptual experience begins with the structure of cortical maps formed in the fetal brain. Recent progress in developmental biology has shed light on the patterns of gene expressions that serve to differentiate cortical maps at specific embryonic stages (Rakic, 2009). Initially, *protomaps* are established in the ventricular zone (VZ). Protomaps appear through the formation of patterning centers. These patterning centers reflect the gradients of expression of neurotrophic molecules across the developing ventricular zone. During the course of fetal development, the patterning centers become more refined as discrete regional genes are expressed. As cells migrate from these centers within the VZ to the cortical plate to form the cortex, their chemical identity, achieved in many cases through epigenetic differentiation, allows these neuronal precursors to attract the appropriate afferents from the relevant thalamic nucleus, as well as to send reciprocal efferents to the same nucleus. It is important to note that the patterning mechanisms that operate on the developing cortex are highly dependent on the morphogenetic mechanisms of subcortical structures. In many ways, the structure of the differentiation of the cortex and telencephalon (limbic structures, basal ganglia) is explained by the earlier developmental differentiation of more primitive subcortical (mesencephalic, diencephalic) levels of development.

After neuronal precursors migrate to the cortical plate, laminar differentiation occurs in two stages. The first stage is the establishment of pyramidal cells in middle layers of the cortex, under control by brainstem norepinephrine projections, with extensive apical dendrites reaching to the superficial cortical layers. A second stage is the development of additional cell types, including the granular layer IV that receives thalamic inputs (Marin-Padilla, 1998). These thalamic inputs are themselves critical organizing influences on the network patterns established in the six layers of the mammalian cortex. Although sensory input will be critical to the differentiation of sensory (and motor) maps in the older brain, much of the protomap is established through spontaneous activity of the developing brain itself, creating a kind of intrinsic activity-dependent cortical map development of the visual, auditory, and somatosensory cortices (Hanganu-Opatz, 2010). An example is the organization of ocular dominance columns. These are not specified during protomap development, yet they are created in the spontaneous activity of primary visual cortex (and thalamus), and are already established prior to the development of functional inputs (photoreceptors) from the retina. Although there are important intrinsic, experience-independent, mechanisms shaping cortical maps, regulated by the expression of specific neurotrophic factors (Rakic, 2009), evidence for the role of spontaneous, self-organizing activity is rather impressive in each species examined.

As reviewed by Hanganu-Opatz (2010), electrical recordings of fetal brain activity show remarkable similarities between species (rats, nonhuman primates, and humans), with periods of activity alternating with periods of little to no activity. The electrical activity is made up of low amplitude higher frequency (higher than delta) activity, superposed on larger amplitude, low frequency (delta and slow wave) activity. As the brain matures, the oscillatory activity increases in duration and amplitude; the quiet periods are correspondingly reduced.

Neural Oscillations, Learning, and Critical Periods

This alternating pattern of electrical activity provides clues to the self-organization of developing networks as it responds to at least three factors. The first is patterned input from sources that are intrinsic to the embryonic brain. In this way, the brain's self-organization is activity-dependent even before much environmental interaction. One of the intrinsic sources is spontaneous inputs from premature sensory organs (such as the retina lacking photoreceptors). Another is spontaneous input from receptors (such as whiskers in rat) that are responsive to initial sensory input but are not organized by mature behavior such as exploration. Removal of sensory receptors reduces the amplitude of the spontaneous electrical activity, but does not eliminate it. This is because there are at least two other contributing mechanisms.

Subcortical regulatory inputs, particularly the nucleus basalis (a source of cholinergic input), appear to be critical. It is well known that cholinergic activity regulates oscillatory electrical activity in the adult brain, but it also regulates spontaneous oscillatory function in the developing brain. In the embryonic brain, cholinergic input is concentrated to the subplate, a layer located above the VZ and intermediate zone but below the cortical plate. This zone eventually develops into layers II through VI of the mature cortex. Cholinergic input synchronizes the activity of cells within the subplate zone (Luhmann, Kilb, & Hanganu-Opatz, 2009). Removal of the subplate eliminates the spontaneous electrical activity noted above. Removal of the subplate also prevents normal cortical organization, such as development of ocular dominance columns. This impairment appears due to the disruption of coupled activity between incoming thalamic inputs and cells in layer IV, and also to removal of inhibitory mechanisms controlled by GABAergic interneurons. In many ways, these same balances of excitatory and inhibitory influences are found to regulate oscillatory activity and cortical plasticity in the adult brain. Specifically, GABAergic interneurons establish oscillatory activity that synchronizes activity from multiple sources in the developing brain. These same GABAergic interneurons serve to synchronize (temporally organize) information exchange among brain regions in the adult brain (Buzsáki, Logothetis, & Singer, 2013).

At birth, sensory systems mature, and the infant's developmental plasticity shifts to the more restricted critical period previously noted as experience-expectant (Greenough & Black, 1992). Environmental inputs then have strong fine-tuning influences on the functional architecture of a given sensory region, such as primary visual cortex (Toyoizumi et al., 2013). During this stage, maturing GABAergic interneurons enable suppression of spontaneous activity and enhancement of external signals to influence synaptic wiring. As noted by Toyoizumi et al., this cortical plasticity mechanism, along with the hierarchical organization of brain regions, can also mechanistically (in addition to other factors, e.g., myelination maturation gradients) account for the maturation gradient (i.e., the later maturation of secondary, association, and limbic regions) of postnatal, experience-dependent brain development.

Some degree of the embryonic and maturational plasticity is retained in the adult animal, such that reorganization of sensory cortices after the critical period occurs in response to alteration of environmental inputs (e.g., Merzenich et al., 1984). The alteration of inputs seems to destabilize the network function of the established circuitry, and thus changes the excitatory–inhibitory balance of the network. As shown by Arckens and colleagues (Arckens et al., 2000), the unresponsive visual cortex that results from retinal lesions shows a reorganizational pattern that starts with an increase in excitability (as indexed by glutamanergic activity) and concordant decrease in inhibitory activities (indexed by GABAergic activity) 2 weeks after the lesion. Over time, GABAergic activity within the reorganizing cortex is gradually restored. Understanding neuropathology and rehabilitation may require a developmental analysis: the change in excitatory-inhibitory balance as a function of altered sensory inputs with the lesion, and subsequent restoration of GABAergic activity, both reflect a similar progression as occurs during the critical period. These processes may be pathological responses to lesions, but when balanced they appear to be the permissive mechanisms that enable cortical reorganization in the adult brain. In fact, Hensch (2005) suggests that a better understanding of the molecular mechanisms that regulate the excitatory–inhibitory balance during development may help explain a variety of psychological disorders that occur when this balance is poorly regulated.

Organismic Mechanisms of Network Self-Regulation

Insight into the specific subcortical circuitry regulating excitatory-inhibitory balance has been provided through the theoretical model of thalamocortical dysrhythmia (Llinas, Urbano, Leznik, Ramirez, & van Marle, 2005). Specific layers of the cortex are connected with both specific and nonspecific thalamic nuclei, including the cholinergic thalamic reticular nucleus. The normal oscillatory control over cortical activity (and thus activity-dependent neural plasticity) may become imbalanced through lesions such as deafferentation, leading to dysrhythmia reflected by abnormal cortical delta and theta activity. Llinas and associates have emphasized that abnormal cortical delta and theta oscillations may be observed in psychiatric as well as neurological disorders. There are interesting parallels between self-organizing mechanisms in embryological differentation of the cortex, regulated by specific neuromodulators, and the thalamocortical dysrhythmia of neuropathology, regulated and dysregulated by the same neuromodulators and intrinsic properties of network synchronization. If they could be extended to explain more complex disorders of cerebral maturation, these parallels may present the opportunity for understanding developmental psychopathology in more explicit neurophysiological terms.

Cortical wiring after critical periods must involve more than just the statistical properties of environmental

inputs, as translated into neuronal signals that influence excitatory–inhibitory dynamics of local circuits. Self-regulation is not just passive reception and organization. Rather, self-regulation, if it is truly adaptive, considers the behavioral relevance or significance of events encountered as an organism explores and learns about the world. It is during this time that the organism learns, and environmental consequences can have adaptive or deleterious effects on cortical organization. By its nature, such organization should involve more than the dynamics of local circuits; it must also include systems that have multiple inputs, from wide ranging areas of the cortex and subcortical structures that are known to be responsive to the internal states of the organism, such as limbic cortices, and project widely throughout the brain. The neuromodulator systems, particularly the cholinergic and monoaminergic systems, are primary candidates for gating the impact of sensory inputs on cortical reorganization. Their projections are widespread, but their influence on cortical plasticity can be highly specific. It has been shown that cholinergic and catecholaminergic (norepinephrine, dopamine) control can facilitate cortical reorganization both at critical periods and later in development (Hensch, 2005). Merzenich and colleagues show that tonotopic maps in primary auditory cortex can be extensively re-organized after the critical period when auditory stimuli are paired with stimulation to the cholinergic nucleus basalis (Kilgard & Merzenich, 1998) or the ventral tegmental area (VTA), a subcortical dopaminergic cell group (Bao et al., 2000). The plasticity of reorganization appears to be spike-timing dependent: the pairing of stimulus presentation with stimulation of the NB and VTA must follow the parameters of learning (i.e., the stimulus must predict stimulation of the NB or VTA) otherwise changes in cortical maps will not be obtained. Bear and Singer (Bear & Singer, 1986a) showed that cholinergic and norepinephrine inputs are critical to cortical plasticity; their removal from the primary visual cortex severely affects cortical plasticity during the critical period. In some way, the local influence of these neuromodulators on cortical plasticity is not just the regulation of activity diffusely; this influence must operate on the local excitatory–inhibitory mechanisms, but exactly how remains to be elucidated.

PSYCHOLOGICAL SELF-REGULATION

Thus the neurophysiology of developmental self-organization is regulated by global controls on plasticity and activity-dependent synaptic specification. In ways that are still not fully understood, the most important global controls may be those regulating arousal of the brain, provided by the monoaminergic and cholinergic brainstem and forebrain neuromodulator systems. These are complemented by the more detailed mechanisms of neural plasticity linked closely to the representational capacities of the cortex, and recognized as the integral operations of memory consolidation (Tucker & Luu, 2006). In psychological terms, these self-regulatory systems—both for global arousal and for representational plasticity—can be seen as integral to the characteristic patterns of arousal and reactivity described in research on temperament and personality. The theoretical challenge is to understand not only the alignment between specific neural maturational processes and specific psychological processes, but organismic patterns of self-representation and self-organization through which arousal and memory consolidation sculpt the individual personality.

There are interesting parallels between the specific corticolimbic networks regulating neuroembryonic differentiation for internal and external processing with the patterns of learning, memory consolidation, and self-regulation that can be described as introversion and extraversion (Tucker, & Luu 2012). In turn, these normal developmental variations can be understood to become disordered in the psychopathological dimensions of internalizing and externalizing (Achenbach, 1982). By reviewing current models of temperament and self-regulation in relation to psychological development in this section, we prepare for the final section in which we attempt to explain how the major dimensions of psychopathology can be understood as disordered exaggerations of what are fundamentally normal variations in the major dimensions of arousal regulation, memory consolidation, and thus neural self-organization.

Dimensions of Temperament

In his review of the literature, Nigg (2006, p. 398) pointed to a growing consensus that temperament and personality are closely linked: "Temperament is viewed as highlighting the psychobiological analysis of traits related to reactivity of core incentive-based neural systems and, in many contemporary models, also their regulation." This account aligns closely with Rothbart and Posner's (2006, p. 466) definition of temperament as "constitutionally based individual differences in reactivity and self-regulation, as observed in the domains of emotionality, motor activity, and attention."

Factor analytic models of temperament and personality have typically identified two to five major dimensions.

There is considerable agreement across the models on the two core affective-motivational dimensions. These dimensions have been referred to as positive emotionality and negative emotionality (Watson & Tellegen, 1985), surgency/extraversion and negative affectivity (Rothbart & Posner, 2006), approach and avoidance (Elliot & Thrash, 2002, 2010), and approach and withdrawal (Nigg, 2006). It is clear these are closely related to the classical personality dimensions of extraversion and neuroticism (Eysenck & Eysenck, 1985; McCrae & Costa, 1987).

Another related model is Gray's (1971) formulation of a behavioral activation system (BAS) and a behavioral inhibition system (BIS). Elliot and Thrash (2002, 2010) found that extraversion, positive emotionality, and BAS loaded above 0.80 on a single factor they termed approach, while neuroticism, negative emotionality and BIS loaded above 0.80 on a single factor they termed Avoidance. When considered in relation to the biological mechanisms of learning and self-regulation, these two opposing dimensions can be seen to form a primitive, reactive control cybernetic that guides behavior, as an organism is motivated to approach positive stimuli and withdraw from potential dangers.

Reactivity of the approach dimension is associated with surgency, extraversion, positive affect, impulsivity, reward sensitivity, behavioral activation, and externalizing behaviors. In contrast, reactivity of the avoidance dimension is associated with negative affectivity, fear, anxiety, withdrawal, anger, frustration, irritability, punishment sensitivity, behavioral inhibition, and internalizing behaviors. Together, these dimensions emerge as controls on learning and motivation that arise from the regulation of cerebral arousal (Tucker & Luu, 2007; Tucker & Williamson, 1984). At the level of learning and memory consolidation, the extraversion or approach dimension describes the motive bias of the dorsal corticolimbic system, whereas the introversion or avoidance dimension describes the motive bias of the ventral corticolimbic system (Tucker and Luu, 2012).

Most models of temperament include a third major dimension related to the ability to self-regulate these reactive tendencies through attention and voluntary control. This has been described as effortful control (Eisenberg, Spinrad, & Eggum, 2010; Rothbart, Sheese, Rueda, & Posner, 2011), or constraint (Depue & Spoont, 1986). A central component of effortful control is the ability to inhibit a dominant response and activate a subdominant one (Rothbart & Posner, 2006), thereby allowing effortful control to modulate both reactive approach/surgency and reactive avoidance/negative affectivity as a function of cognitive evaluation. Read et al. (2010) elaborated a neural network model of personality structure and dynamics, in which approach and avoidance systems provide basic trait biases that become elaborated into more specific motives through the dynamics of psychological experience. Similarly, they include in their model a distinct control system that acts to inhibit or disinhibit baseline activations of the approach and avoidance systems. In contrast to a single higher level control system, Tops and associates (Tops et al., 2009) proposed two additional proactive systems that parallel and overlay the reactive approach and avoidance systems. Thus, building on primitive reactive cybernetics of the approach–avoidance systems, self-regulation comes under additional reflective, proactive regulation mechanisms. Together, both reactive and reflective control mechanisms continue to influence and guide an individual's cognitive and emotional processes and interactions with the internal and external world throughout life.

As reflected in the aforementioned Nigg (2006) and Rothbart and Posner (2006) definitions, temperament is generally viewed as having a genetic predisposition that is expressed in an infant's rudimentary approach and avoidance reactivity biases. These biases continue to influence attention, behavior, experience, and memory during development. When development is successfully organized, these control biases become increasingly differentiated and stabilized in interaction with more volitional self-regulatory mechanisms such as effortful control in the process of forming the child's developing self. In a meta-analysis of 152 longitudinal studies (Roberts & DelVecchio, 2000), the population cross-time correlation estimates (controlling for time interval of longitudinal study) of temperament and trait stability were lowest during early childhood (0–2.9 years = 0.31), increasing to 0.49 from 3 to 5.9 years, dropping slightly into preadolescence (6–11.9 years = 0.43) and adolescence (12–17.9 years = 0.43) and then increasing monotonically throughout adulthood and peaking from 50 to 59 years at 0.74. These correlations indicate considerable stability in temperament overall, alongside opportunities for malleability throughout life, particularly during periods of infancy and adolescence. These are of course the periods of maximal neural plasticity and thus developmental vulnerability.

From birth, individuals differ in their set points along the approach/positive affectivity and avoidance/negative affectivity continua. These differing set points manifest in differing reactivity to the environment in infancy when exposed to appropriate eliciting conditions. For example, Hane and associates (Hane, Fox, Henderson, & Marshall, 2008) found that infants who at 4 months of age displayed strong negative motor reactivity were later

assessed at 9 months of age as more avoidant, whereas those who displayed strong positive motor reactivity at 4 months expressed significantly more approach behaviors at 9 months. In a latent profile analysis of mother ratings of their toddlers' sociability, anger proneness, and activity level at four intervals over the course of 1 year, three profiles emerged: a fearful temperament; high in internalizing problems, an expressive temperament high in externalizing problems; and a typical temperament with well-adjusted behavior (Dekovic, Prinzie, & Asscher, 2010). In a study of 3-year-olds, de la Osa et al. (de la Osa, Granero, Penelo, Domenech, & Ezpeleta, 2014) similarly found a positive relationship of surgency–extraversion with attention-deficit/hyperactivity disorder (ADHD) and externalizing problems, and of negative affectivity with internalizing and emotional disorders. Adolescents who scored high on self-reported behavioral inhibition system (BIS) dimension, also scored high on negative affect, negative emotion regulation style, and anxiety (Balle, Tortella-Feliu, & Bornas, 2013).

From this research, high reactivity set points would appear to place children at risk for either externalizing or internalizing problems (Carver, Johnson, & Joormann, 2008). At the same time, a child's temperament cybernetics, along with effortful control, may provide modulatory, protective effects against maladjustment, depending on the match between the child's temperamental bias and the challenges of the environment. Both fearfulness and frustration are associated with the negative affectivity dimension of temperament, but fearfulness is typically expressed in internalizing, and frustration in externalizing, behavior. A primitive cybernetic analysis of the effect of the child's motive arousal would suggest that frustration may also be related to the surgency–approach dimension, through a reactive response to a blocked goal (Derryberry & Rothbart, 1997). Thus, individuals high in frustration may be high on dimensions of both negative affectivity and surgency, whereas fearful individuals are high in negative affectivity but low in surgency. Consistent with the importance of higher order cognitive regulatory skills, Oldehinkel et al., (Oldehinkel, Hartman, Ferdinand, Verhulst, & Ormel, 2007) found that degree of effortful control at 11 and 13/14 years of age, mitigated the effects of high negative emotionality—fearfulness and frustration—on both internalizing and externalizing problems, respectively (Oldehinkel et al., 2007). Thus, effortful control of negative emotionality can both modulate an internalizing response to fear, and counteract more primitive, reactive response to frustration.

Temperament and the Development of Self-Regulation

The achievement of self-regulation skills thus appears to depend on both the more primitive temperament cybernetics (internalizing and externalizing motive controls) as well as on more sophisticated, cognitive capacities in effortful control. The ongoing interaction with social and environmental factors from infancy onward must be seen to impact both the vulnerability to maladjustment and mental illness, and the resilience to overcoming developmental disorders. Rothbart et al. (2011) proposed that in infancy the regulation of reactive responses is primarily managed through controlling attention, initially guided by the primary caregiver (e.g., distraction from distress) and then through infant-initiated behaviors (e.g., looking away, self-soothing). In the first few months of life, an infant's behavior is characterized primarily by approach or surgency—either positively in smiling and laughing behavior, or negatively in the collapse of the positive affect state with expressions of distress and crying.

Anxiety and inhibitory capacity typically emerge only later in the first year of life, at which time these motives can provide an initial reactive regulation of the approach system. Interestingly, it was reported that infants at 3 months of age who experienced stress by overstimulation could be easily soothed by distraction with novel objects for long periods of time, whereas they began to habituate to caregiver distraction by 6 months (Harman, Rothbart, & Posner, 1997), perhaps through the maturation of increasing anxiety and internal control. Around this same age, infants begin to develop the ability to disengage their attention from distressing stimulation, an ability that stabilizes by the end of the first year and was associated with lower levels of negative affect at 13 months (Rothbart, Ziaie, & O'Boyle, 1992). Thus, it appears that cybernetic control between the approach and avoidance systems develops over the course of the first year, with the habituation bias of the approach system reducing the ability of sustained caregiver soothing at the same time as early self-regulation is enabled by engagement of the avoidance system and the infant's rudimentary ability to withdraw attention from negative stimuli. Factor analysis of parent-report scales of infant temperament identify this as orienting/regulation, a dimension with loadings from scales of low intensity pleasure, cuddliness, duration of orienting, and soothability (Gartstein & Rothbart, 2003). The important theoretical insight is that affective processes are not epiphenomena, but are integral to the motive controls that shape developing cognition and behavior.

At about 3 years of age, a higher level of self-regulation, termed Effortful Control, begins to emerge, appearing to rely on the toddler's developing executive attention system of the frontal and anterior cingulate cortices (Posner & Rothbart, 2009). Factor analysis of the parent-report Children's Behavior Questionnaire (CBQ; Rothbart et al., 2001) shows that scales of inhibitory control, attentional focusing, low intensity pleasure, and perceptual sensitivity load onto the dimension of effortful control (Rothbart, Ahadi, Hershey, & Fisher, 2001). High effortful control is associated with lower levels of negative affect and better adjustment. As it supports increasing cognitive capacity in self-regulation, cognitive control seems to become a protective factor against the development of psychopathology. Components of executive attention, such as the engagement of the anterior cingulate and medial frontal cortex in responding to errors or unexpected outcomes, appear as early as 7 months (Berger, Tzur, & Posner, 2006). Nonetheless, continued development leads to continued sophistication in the ability modify behavior (Jones, Rothbart, & Posner, 2003), as well as to articulate the anatomical connections of the frontal cortex to extended networks for behavioral control well into adolescence (Fair et al., 2009). Grosbras et al. (2007) suggested that it may be the immaturity of interregional connections of frontal cortex that makes it difficult to self-regulate in the face of peer pressure in early adolescence.

Considerable developmental evidence links both the child's reactivity and capacity in early orienting of attention to the subsequent development of executive attention and effortful control. Kochanska and Knaack (2003), for example, found that the development of greater effortful control in children was associated with lower initial reactivity in both anger and joy but greater reactive inhibition to an unfamiliar environment as toddlers. Citing Shulman et al.'s (2009) finding in adults that a novel object appears to activate the executive control network to supplement the attentional orienting network, Rothbart, Sheese, Rueda, & Posner (2011) speculated that the caregiver's presentation of novel objects to an infant may serve to exercise the development of the executive network required for effortful control.

Whereas high reactive inhibition may be associated with subsequent development of higher effortful control, both approach/impulse and avoidance/constraint control mechanisms remain integral to personality and shape the child's flexibility in responding to life challenges. Block and Block (1980) distinguished between ego-control, a reactive inhibitory control over impulsive approach, and ego resiliency, a flexible response to changing situational demands and challenges. This analysis emphasizes the importance of the dynamic balance between impulsivity and constraint for adaptive behavior and adjustment, as well as the role of socialization in shaping this flexibility. Healthy, well-adjusted individuals tend to be high in ego-resilience, with moderate levels of ego-control. They can respond adaptively in varied situations, have high social competence, and are neither overimpulsive nor overconstrained. Individuals with low ego resilience coupled with ego overcontrol tend to exhibit highly constrained emotions, anxiety, and withdrawal, while low ego resilience coupled with ego undercontrol is characterized by impulsive behavior and externalizing behavior problems.

Thus, the ego control construct reflects reactive temperament dimensions, with ego undercontrol descriptive of an individual high on the approach–surgency dimension, and ego overcontrol descriptive of individuals high on the avoidance dimension. In both cases, there is an imbalance in adaptive cybernetics, and inflexibility leading to poor adaptation. In contrast, the more proactive, reflective self-regulation of effortful control characterizes an ego-resilient individual (Rothbart & Posner, 2006). In a recent longitudinal study, Causadias, Salvatore, and Sroufe (2012) found that ratings of ego resiliency, but not ego control, at 3–4 years and 7–9 years of age were strongly predictive of healthy adjustment and of the development of both internalizing and externalizing problems in adolescence and adulthood.

The importance of environment and parenting on the development of self-regulation has received considerable attention. As noted above, parents may scaffold children's emerging self-regulation, exercising the higher-level attention networks engaged in effortful control. They may also provide important modeling of either reactive or reflective self-regulation. However, the interaction between parenting and self-regulation may operate through neurodevelopmental mechanisms as well. In a recent study on the development of self-regulation, Ursache et al. (Ursache, Blair, Stifter, & Voegtline, 2013) found that, in infants with low emotional reactivity, there was no relationship between emotional regulation in infancy and subsequent executive control at 4 years of age, as if these infants had only modest self-regulatory challenges. However, in infants with high emotional reactivity, those who also exhibited high-level regulation skills (orienting, avoidance) had better executive control at 4 years of age than those who exhibited poor regulation skills during infancy. Importantly, the highly reactive infants with high regulation came from homes with positive parenting. Drawing upon a theoretical model

of biological sensitivity to both context and the stress response, Ursache et al. (2013) hypothesized that supportive parenting of highly reactive infants helps to keep stress hormones at moderate levels, thereby promoting synaptic activity and neural plasticity in the prefrontal cortex, whereas negative parenting and adverse environments lead to excessive levels of stress hormone, inhibit prefrontal cortex development, and promote strong, reactive limbic and midbrain responses to perceived threat.

The disruption of attachment and socialization processes between mother and child has been shown to have an important impact on the occurrence of both internalizing and externalizing problems. Positive parenting (supportive, consistent and sensitive behaviors) and negative parenting (hostile, harsh, and negative control behaviors) have been shown to interact with a child's temperament to impact adjustment, but research findings have been mixed. In general, children high in negative affectivity and low in self-regulation appear to be most vulnerable to adverse parenting and environment, usually resulting in externalizing problems.

Kochanska et al. (Kochanska, Kim, & Boldt, 2013), however, showed that effects of adversity were not seen just in children with difficult temperaments. In a study of low-income families, toddlers who initially expressed a willing stance toward socialization, but whose mothers were inadequately responsive due to adverse circumstances, went on to display externalizing problems 10 months later. Adversity also led to internalizing problems, but without the mediating role of undermined maternal responsiveness.

Temperament, Self-Regulation, and Developmental Psychopathology

Because of human neoteny, temperament and self-regulation operate over a protracted developmental course, allowing parental and cultural influences to shape an individual's emerging self and its dynamic mediation between internal motives and needs and external relations. Most often, the developmental process is largely adaptive, with personality variations within the normal range and the experience of only transient adjustment challenges. In many cases, however, initial temperament vulnerabilities and adverse environment can tip psychobiological development toward more serious psychopathologies.

Clark, Watson, and Mineka (1994) distinguished four models relating temperament or personality to psychopathology. The *spectrum model* posits that disorders are extreme expressions of normal temperament development processes. The *vulnerability model* posits that temperament may predispose an individual to a disorder. The *pathoplasty model* suggests that temperament may shape the course of a disorder without being a direct cause. Finally, the *scar hypothesis* suggests that experience of a disorder (e.g., anxiety) causes a change in personality (e.g., increased dependency). Clark and associates emphasize that these models are not mutually exclusive. Considering the development of the self through dynamic psychobiological processes, multiple causal models may interact.

To consider such an interaction, if a child with a more extreme temperament encounters chronic or acute adverse environments, the developmental process—and the resulting self—may become disordered. Vulnerability may be particularly acute during the early childhood and adolescent periods of rapid brain plasticity and reorganization. The developmental disorder involves imbalances in the neurophysiological systems of learning and neuroanatomical differentiation, with corresponding imbalances in the psychological structures of the self and social relations.

An example may be provided by the Ursache et al. (2013) study cited above on the effect of stress hormones on the prefrontal cortex and its role in self-regulation. The most pernicious disorders are those that lead to continued maladaptive responses, such that the developmental process itself results in severe psychopathology rather than adaptive self-correction. Thus, the very dynamics of the psychobiological development of the self may result in chaotic and degenerative feedback mechanisms that permit extreme forms of normal personality differences (spectrum model) to emerge through vulnerabilities (vulnerability model) in the epigenetic process, which may be further shaped by the evolving disorder (pathoplasty model), and be strongly and permanently influenced by highly adverse events and their maladaptive responses (scar hypothesis).

When considering the dimensions of self-regulation that mediate the child's response to vulnerabilities and environmental insults, the typical patterns of developmental psychopathology are sufficiently similar to patterns of temperament to suggest that psychopathology often reflects exaggerations of normal developmental mechanisms. In his influential application of factor analysis, Achenbach (1982) identified two broad clusters of childhood disorders, *externalizing* and *internalizing*. Externalizing problem behaviors are metaphorically described as directed toward others (e.g., hyperactivity, conduct disorder) whereas internalizing problems are described as directed inward (e.g., anxiety, depression). Krueger, Caspi, Moffitt, and Silva (1998) reported that a two-factor model of internalizing and externalizing best explained the relationship between 10 psychological disorders assessed at 18 and 21 years

of age. Specifically, depression and dysthymia, anxiety, phobias, and obsessive-compulsive disorder loaded onto internalizing, whereas conduct disorder, anti-social personality, and alcohol and marijuana dependence loaded onto externalizing.

In considering the development of these disorders, there is considerable empirical support and growing consensus relating externalizing and internalizing personality adjustment disorders to (1) an individual's set points (reactivity) on the approach and avoidance dimensions of temperament; (2) the interplay between these dimensions, and (3) the strength and flexibility of their cognitive self-regulation. In a longitudinal study of children at 6, 7.5, and 10 years, Eisenberg et al. (2009) found externalizing problems to be associated with low effortful control, high impulsivity, and negative emotionality. In contrast, internalizing problems were associated most strongly with low impulsivity and sadness (low approach).

Latent profile analysis of posttraumatic psychopathology revealed that subtypes of a disorder may also be distinguished by variations in temperament (Wolf, Miller, Harrington, & Reardon, 2012). Specifically, while high negative emotionality was associated with both an externalizing and internalizing subtype of posttraumatic stress disorder (PTSD), the externalizing subtype (antisocial, borderline, histrionic and narcissistic elements) was also associated with low levels of constraint (inadequate inhibition due to low anxiety). In contrast, the internalizing subtype of PTSD (with schizoid and avoidant elements) was additionally distinguished by low positive emotionality.

Using latent class analysis in a person-centered, rather than variable-centered, approach to studying the underlying structure of psychopathology, Olino et al. (Olino, Klein, Farmer, Seeley, & Lewinsohn, 2012) identified four major classes: 1) psychologically healthy, 2) externalizing, 3) internalizing, and 4) both internalizing and externalizing. The internalizing class was most likely to suffer from dysthymia, major depressive disorder, social phobia, specific phobia, separation anxiety, posttraumatic stress disorder, generalized anxiety disorder, and panic disorder. This group had higher negative and lower positive affectivity relative to the healthy group. Those in the externalizing class were most likely to meet criteria for conduct disorder, adult antisocial behavior, and substance abuse or dependency. They had higher levels of negative affect and disinhibited temperament compared to the healthy group, though it is unclear whether the disinhibited temperament scale reflects high approach–surgency reactivity or low effortful control. There was an increased probability across a wide range of disorders within the comorbid internalizing and externalizing class, with the exception of conduct disorder and adult antisocial behavior, which were found primarily within the externalizing class only. The comorbid class had higher negative and disinhibited temperament and lower positive temperament than the healthy class. Depression was the most pervasive disorder, significant in all individuals in the internalizing class, appearing in over 90% in the comorbid class, and in over 50% in the externalizing class. Olino et al. (2012) suggested that the high rate of depression in the externalizing class may have occurred because the externalizing problems contributed to repetitive failures, with depression as the eventual result (Burke, Loeber, Lahey, & Rathouz, 2005).

Nigg (2006) stressed the importance of considering multiple levels of analysis in examining the complexity of temperament developmental patterns and outcomes. These levels include behavioral response, psychological experience, neural systems, physiological reactivity, and genetic composition. Nigg considered both a spectrum and vulnerability model of psychopathology, but argued that a vulnerability model is more consistent in explaining a gene × environment interaction. He reviewed evidence on three externalizing disorders emerging in childhood, each of which appears to develop from two different pathways. Type 1 conduct disorder (psychopathy in adults) was found to be related to low withdrawal/fear (and its associated low reactivity to punishment) as well as low affiliation, which then is proposed to interfere with the development of conscience and socialization. In contrast, Type 2 conduct disorder was found to involve high approach, high negative affect/anger, and low reactive or effortful control, resulting in reward and sensation seeking with disregard for others or high reactive aggression. ADHD was found to involve low effortful control, particularly for the inattentive-disorganized symptoms, and very strong approach, as related to the hyperactive-impulsive symptoms. Finally, the influence of anxiety and depression resulted in a more complex pattern, where high withdrawal (avoidance) was associated with a general risk for internalizing behavior. This manifested in depression and generalized anxiety disorder (GAD) when accompanied by low approach and stressful events, and it manifested in GAD specifically when it was accompanied by low effortful control.

As Nigg (2006) pointed out, the failure to develop effective effortful control can contribute to many psychopathologies, depending on the reactivity set point on the approach and avoidance dimensions. The protective influence of high effortful control in psychopathology

underlines the importance of psychological flexibility in healthy adjustment (Kashdan & Rottenberg, 2010). Whereas reactive control is more likely to lead to overregulation and underregulation (Derryberry & Rothbart, 1997), the reflective control of executive processes affords flexibility in response to life events that brings resilience under adversity and adaptive psychosocial functioning. Consistent with this reasoning, King, Lengua, and Monahan (2013) found that in pre-adolescence both effortful control and impulsivity (high approach) were predictors of self-regulation, but that contextual risk factors were related only to the development of impulsivity, whereas positive adjustment was related only to increases in effortful control.

In a major longitudinal study of temperament at age 3 and the development of adult disorders, children who were classified as undercontrolled were more likely to develop a wide range of disorders by the age of 21, including antisocial personality disorder, alcohol dependence, attempted suicide (Caspi, 2000), and gambling disorders (Slutske, Moffitt, Poulton, & Caspi, 2012). Good attention control skills may also buffer children with high dispositional anger from developing externalizing problems (Kim, Deater-Deckard, Mullineaux, & Beekman, 2010). Carver, Johnson, and Joormann (2013) similarly proposed that an individual's emotional reactivity in the absence of cognitive control (reactive versus reflective control) increases vulnerability for either externalizing or internalizing problems. Carver, et al. described this vulnerability as *transdiagnostic vulnerability*. They emphasized that the emergence of the specific type of disorder will depend on an individual's temperament disposition (e.g., high incentive-approach temperament may lead to antisocial impulses). Results from their multiple regression analysis of a wide range of scales indicated that unchecked emotional reactivity was associated with a wide range of psychopathology tendencies, including borderline personality, suicidality, anger, hostility, aggression, and anxiety.

Mineka, Watson, and Clark (1998) proposed an integrative hierarchical model where each disorder is composed of general and unique components of varied weights. Thus, depression shares a common component of negative affect combined with a large specific component of low positive affect that distinguishes it from anxiety. Anhedonic depression is the purest form of this component, and positive affect is most strongly linked to the core symptoms of depression, namely anhedonia, dysphoria, and lassitude (Watson, 2009). This reasoning led to the development of the Inventory of Depression and Anxiety Symptoms (IDAS) for improved assessment of these conditions. Watson and Naragon-Gainey (2010) further argued that whereas social avoidance is indeed associated with low positive affect, it is more specifically associated with the low levels of the closely related personality dimension of extraversion, which encompasses sociability, ascendance, and fun seeking, in addition to positive affectivity.

There is also growing evidence that links temperament to the more extreme psychopathology of schizophrenia. Watson and Naragon-Gainey (2010) reviewed evidence that schizophrenia/schizotypy symptoms are related to both positive and negative affectivity, but in unique ways. Whereas negative affectivity is related to both positive symptoms (e.g., magical thinking, perceptual aberrations, suspiciousness) and negative symptoms (e.g., constricted affect, social aloofness), low positive affect is related most strongly to negative symptoms. Consistent with this observation, schizophrenics have also been found to experience an anticipatory pleasure deficit, leading them to engage in fewer pleasurable activities because they do not expect to enjoy them.

NEURAL CONTROL OF INTERNALIZING AND EXTERNALIZING

Even from the brief overview presented in the first section, it should be clear that a rich set of biological mechanisms regulate neural ontogenesis. These offer ways of explaining the isomorphic dimensions of biological and psychological self-regulation that are reflected in the development of temperament, personality, and psychopathology. Conversely, understanding the psychological challenges of developing the self in the flux of social interactions can help to clarify the context in which biological mechanisms regulate the plasticity of the brain's growth, with dysfunctional as well as adaptive outcomes.

Fusing the biological and psychological levels of analysis, we propose that the dimensions of internalizing and externalizing seen in personality and psychopathology also reflect the major modes of self-regulation in brain development. The embryogenesis of somatic and visceral systems of the brain is regulated differently by primitive control modes of internalizing and externalizing. Continuing in child development, these modes are integral to the internalizing of attention (applying perception and cognition to environmental constraints) and the externalizing of intention (applying perception, cognition, and action regulation to achieve personal goals). Furthermore, these modes of self-regulation are driven by the motives of avoidance—for internalizing—and approach—for externalizing. As we

now propose in this third section, these motives shape not only cognition and behavior but the specific mechanisms of arousal and activity-dependent plasticity that differentiate the major networks of the brain in ontogenesis.

When the motive mechanisms of growth are active and balanced, the development of the brain and personality is also active and balanced. When a bias appears toward one mechanism over the other, the result is the familiar individual differences in personality recognized as Introversion and Extraversion. When these modes of self-regulation are not only exaggerated but also disorganized, the result is the patterns of internalizing and externalizing that have been recognized in the more severe forms of psychopathology (Achenbach, 1982).

The Evolved Structure of Embryonic Development

The neural mechanisms of activity-dependent specification of cerebral development can be seen as mechanisms of self-organization, set in place by the foundations of neuroanatomical differentiation in the embryo, operating to specify the functional connectivity of the embryonic brain, and then continuing to shape the process of learning and self-organization as the child organizes the self in the context of the family, school, and community. As genetic variation changes the substrate for these neurodevelopmental mechanisms, whether through a mutation of a neuromodulator's receptor or a shift in the rate of cortical maturation, the result is imbalanced or ineffective patterns of self-regulation. Nonetheless, even problematic patterns of self-regulation must operate through the fundamental control systems that shape normal development. As a result, understanding psychopathology requires a developmental theory.

In this theory, the major dimensions of developmental self-organization can be understood to be identical with the major dimensions of motive self-regulation. The roots of these dimensions run through the multiple levels of the neuraxis, from the brainstem to the cerebral cortex, such that an evolutionary-developmental analysis is essential to appreciate their functional emergence as control systems for arousal, learning, memory consolidation, and cognitive self-control. The evolutionary-developmental perspective may be novel in psychological science, because our thinking about children is constrained to processes we assume are uniquely human. However, an evolutionary perspective is unavoidable when we consider the developmental anatomy of the brain, as we observe how the process of embryogenesis recapitulates the broad outlines of phyletic evolution (Figure 17.1).

The embryonic brain is first organized through a series of trophic biochemical gradients, before neurons are capable of the activity that organizes the developmental process (Coghill, 1929). As we saw in the first section, these gradients are now understood to be created through developmental patterns of gene expression (Rakic, 2009) that then frame the migrations of neuronal precursor cells, which then organize the architecture of the brain. This pattern of gene expression, migration, and architecture is formed developmentally, through the phyletic progression. Although the process of embryonic morphogenesis is clearly specified by the genome of the species, it involves a complex web of interactions and feedback control mechanisms that require extensive dynamic signaling and epigenetic controls within the individual brain. Even before neurons are active, neural morphogenesis involves patterns of self-organization that reflect primitive functional specialization of both visceral and somatic divisions of the nervous system, and both sensory and motor capacities within each division (Tucker & Luu, 2012). These primitive patterns of functional specialization can be seen as the phyletic developmental foundations of the neurodevelopmental mechanisms of internalizing and externalizing.

The self-regulation of experience and behavior throughout life must build continually on the vertically integrated hierarchy of the neuraxis, as capacities for intention (dorsal limbic) and attention (ventral limbic) integrate the representational capacities of the cortex, which are formed through the memory consolidation and action sequencing from limbic and striatal circuits, which depend in turn on the motive and arousal controls from diencephalic, midbrain, and brainstem projection systems. Because of these interdependencies of the developing neuroanatomy, a biological analysis of the developing mind can be informed by the phyletic architecture of the ontogenetic process, within which the evolutionary history of the organism is integral to a theoretical understanding of current development and function.

As more complex brains have evolved from simpler ones, the more complex circuitry has emerged through progressive mutations of the simpler ontogenetic programs. As a result, there is a continuity of the neurodevelopmental process across evolved levels that may be useful in understanding the continuity of control systems across the multiple levels (rhombencephalic, mesencephalic, diencephalic, and telencephalic) of the neuraxis in child development. The theme of internalizing and externalizing is a fundamental one that can be seen across these multiple levels.

For example, the fundamental input-output specialization—the dorsal organization of sensory functions and

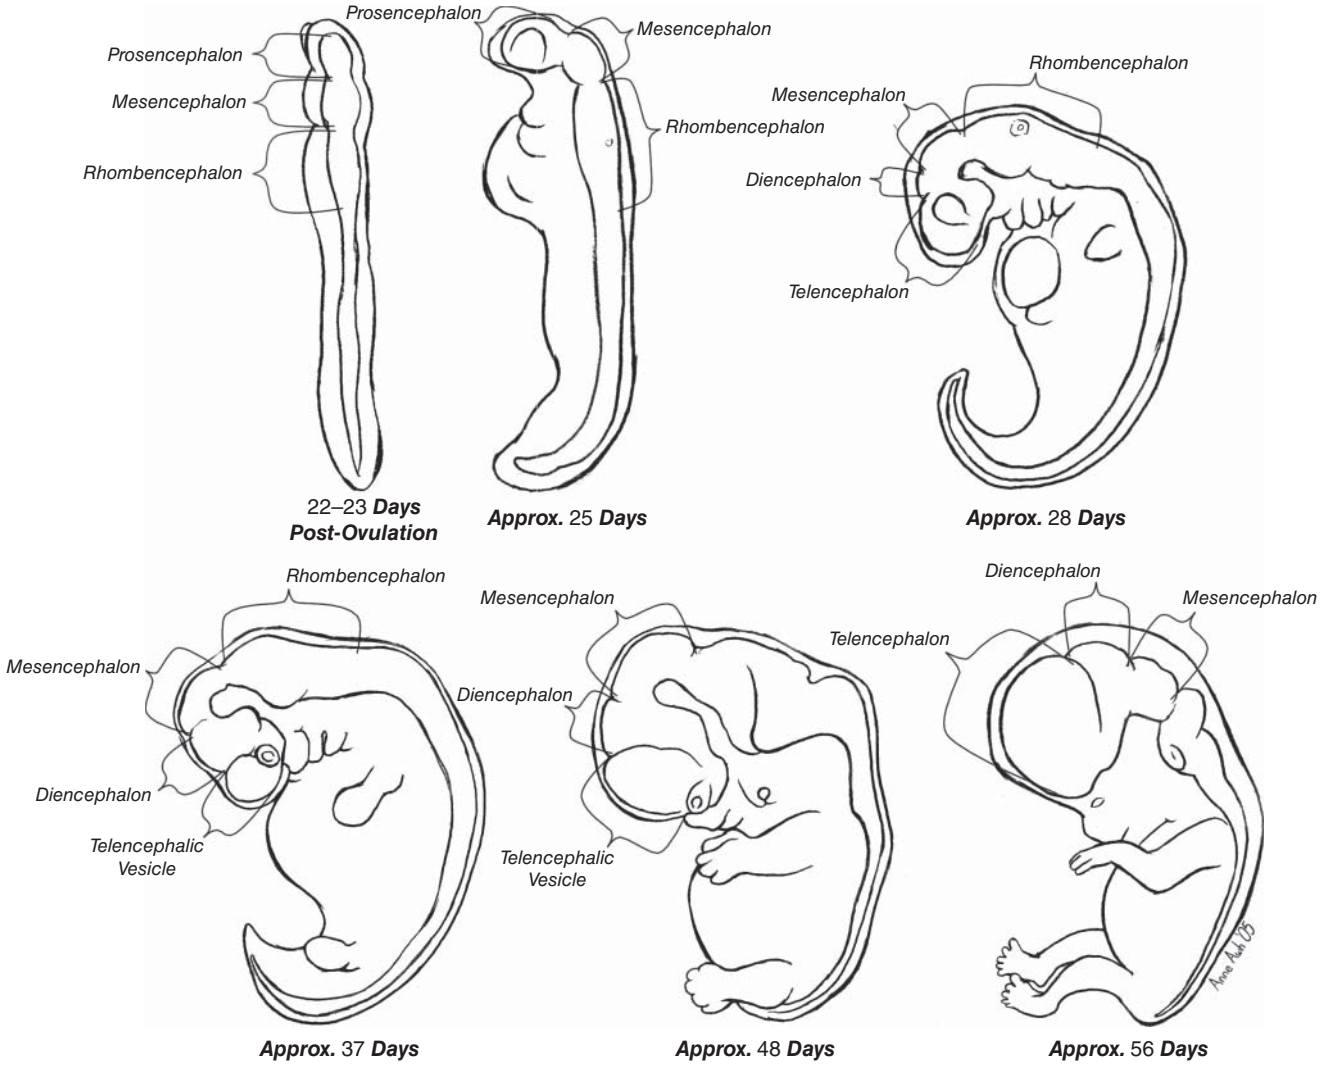

Figure 17.1 Stages in embryogenesis showing the progressive elaboration of more recently evolved (telencephalic and diencephalic) levels of the neuraxis.

the ventral organization of motor functions—can be seen as fundamental to the vertebrate plan. This duality is seen in the topography of the midbrain as examined by Ikemoto (2010). Building on the organization of the spinal cord, sensory processing is carried out in the dorsal regions of the brainstem and midbrain, where the norepinephrine and serotonin neuromodulator controls on arousal and development are particularly important to sensory functions. In parallel, motor processing is carried out in the ventral regions, with dopamine (and acetylcholine) providing arousal controls that are integral to action control and sequencing. The dorsal foundations of externalizing and ventral foundations of internalizing can already be seen at this level of analysis, with approach motivation, for example, reflecting the visceral control circuits of the dorsomedial networks of the ventral tegmental area, operating to set the motive basis for approach. This motive basis is then the foundation for the dopaminergic articulation of action in the more ventrolateral regions of the ventral tegmental area.

This general architecture is replicated in broad outline at the diencephalic and telencephalic levels. At the level of the striatum of the telencephalon, the approach motive appears to be regulated by ventral striatal areas. The articulation and sequencing of actions is then carried out by dorsal striatal (and pallidal thalamocorical) circuits (Ikemoto, 2010).

At the level of the dorsal and ventral divisions of the limbic system, the dorsal division (the Papez circuit of hippocampus, cingulate, anterior thalamus, septum, mammalary bodies) controls the externalizing mode of the approach motive. The dorsal neocortex integrates the holistic, spatial integration of sensory input to the ventral

striatal approach controls through septal and hypothalamic connections. These are the essential motive controls of extraversion, linking the positive motive of approach with the holistic sensory engagement of the environment (Tucker & Luu, 2012).

In contrast, the ventral division of the limbic system appears more important to internalizing, motivated by anxiety and avoidance. Centered on the amygdala, with its links to hypothalamic centers through the stria terminalis—and to perirhinal cortex and frontal lobe through the mediodorsal nucleus of the thalamus—the ventral limbic network organizes the ventral sensory, motor, and object cognition networks of the cerebral hemisphere through negative affect, providing the critical, aversive motive tone of introversion (Tucker & Luu, 2012).

Tucker and Luu (2012) built the case for this general model on several empirical foundations: the animal studies of neurophysiological circuits regulating learning, the effects of lesions on human self-regulation, and several consistent findings in recent neuroimaging research. Equally important is the theoretical explanation for why these global externalizing and internalizing controls are found in these cerebral systems. This explanation is provided by an evolutionary-developmental analysis, in which the continuity of dorsal and ventral divisions at multiple levels of the neuraxis can be observed in the process of embryogenesis. The roots of externalizing, including neuroanatomical, neurophysiological, and cognitive properties, can be traced to the evolution of the mammalian dorsal limbic and cortical networks from the pallium (three-layered cortex) of primitive vertebrates. Even more remarkably, the roots of internalizing can be traced to subpallial origins, the subcortical circuits of the basal ganglia that seem to have been incorporated into ventral limbic and cortical networks with the evolution of the 6-layered mammalian cortex (Tucker & Luu, 2012).

These primordial pallial and subpallial origins can be traced throughout the major phases in the embryogenesis of the mammalian cortex, reflected in the gradients of trophic factors guiding neuronal migration. On the one hand, the pyramidal neurons that define the dorsal cortex are formed through processes that reflect pallial origins. On the other hand, the GABAergic neurons and layer 4 projections that are critical to the ventral cortex are found to emerge from the subpallial substrate.

New tools for characterizing gene expression (Rakic, 2009) have allowed insights into the biochemical gradients that have long been apparent in embryonic neural differentiation and that now can be understood to define these developmental origins. For example, Emx2 shows not only a high concentration in the caudodorsomedial (back, top, center) regions of the developing mammalian (and human) brain, but a decreasing concentration in the rostroventrolateral (front, bottom, side) direction. In contrast, Pax6 is another key trophic factor, and it shows the opposite (rostroventrolateral to caudodorsomedial) concentration gradient. These global trophic gradients not only anchor the opposite anatomical poles to guide neural differentiation; they provide clues to the organization of the mammalian cerebral hemispheres in relation to the externalizing functions of the caudal (posterior) sensory networks, and the internalizing functions of the rostral (anterior) motor networks. In the development of the mammalian cortex and the limbic circuits that control it, these *somatic* sensory and motor networks are themselves organized in a complementary pattern with the dorsal and ventral *visceral* control functions of the dual limbic systems (Figure 17.2; Tucker & Luu, 2012). The rostroventrolateral

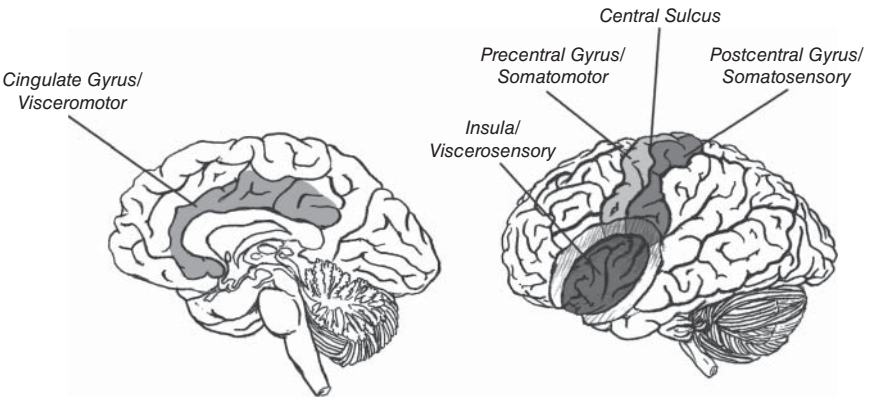

Figure 17.2 The visceromotor functions of the dorsal limbic networks appear to be balanced by the viscerosensory functions of the ventral limbic networks in motivating behavior. This balance complements a similar input–output balance between the somatic motor division of anterior cortex and the somatic sensory division of posterior neocortex.

to caudodorsomedial embryonic trophic gradient thus appears to combine and capture the complementarity of the somatic rostral-caudal dimension with the visceral ventral and dorsal dimension of cerebral organization.

Developmental defects of these major trophic factors provide clues to how these dimensions of the embryonic cerebral hemispheres emerged from their evolved roots in subcortical networks. For example, deficits in Pax6 are associated with impairment of rostroventrolateral structures of the hemisphere, specifically with the differentiation of the ventral corticolimbic anlagen, including the claustrum and piriform cortex (Rakic, 2009). Consistent with the ventral limbic distribution of these cortical structures, dopamine modulation is specifically impaired with disruption of Pax6 control. Consistent with the evolutionary-developmental reasoning outlined above, Butler and associates (Butler & Molnar, 2002) found that these Pax6 sensitive structures of the ventral cortex may have origins in unique striatal regions of the reptilian brain, specifically the anterior dorsal ventricular ridge, classically known as the external striatum (Nauta & Karten, 1970). Whereas the external striatum was the primary target of thalamic sensory and motor projections to the telencephalon in reptiles, the cerebral cortex (layer 4) became the target with the emergence of the 6-layered cortex in mammals. The obvious implication is that the incorporation of the external striatum into the neocortex was a key aspect of the transition to the mammalian 6-layered architecture. The fact that the granular layer 4 is highly developed in the ventral division of the mammalian cortex is additional evidence of the subpallial (striatal) origins of the ventral brain.

Thus both the trophic control of embryological differentiation and the evolutionary anlagen of the mammalian cortex provide clues that the internalizing mode of behavior control can be traced to the integral motive bias of subcortical (originally subpallial, striatal) control systems. In excessive internalizing, such as in obsessive-compulsive disorder, the routinized, stereotyped action and cognition appears to reflect the exaggerated operation of primitive basal ganglia (subpallial) habit and motor control circuits specifically.

Considering the opposite embryological trophic gradient, the high concentration of Emx2 in dorsal cortex is associated with the pyramidal architecture of the dorsal division of the hemisphere. The preferential projection of norepinephrine pathways to the dorsal brain may be integral to the expansive attention and feedforward motor control of dorsal limbic circuits (Tucker & Luu, 2012). In the morphogenetic process, norepinephrine modulation is critical to the formation of pyramidal neuronal connections (Marin-Padilla, 1998), suggesting that the role of norepinephrine in the regulation of attention and learning in psychological development is continuous with the more primitive regulation of neuronal differentiation and synaptic pruning in embryogenesis and critical periods.

Thus, even in the trophic stage of neural differentiation, before intrinsic activity-dependent neuronal function and connectivity can contribute to neural self-organization, there are primitive anlagen of internalizing and externalizing systems that can be recognized in the developmental process. Although we have only outlined these patterns briefly here, they provide clues to how the early ontogenetic self-organization of the brain proceeds along functional lines regulating the internalizing and externalizing modes of behavior that have been critical in guiding vertebrate evolution. For neurodevelopmental theory, evolution is thus as important an explanatory context as is the ontogenesis that recapitulates it.

At birth, the neurodevelopmental mechanisms shift from organizing the global architecture of the embryo and fetus to articulating fine synaptic structure in the child's learning and memory consolidation. At that point, the modes of internalizing and externalizing shift from their roles in anatomical differentiation to new roles in motivating the activity-dependent plasticity underlying the learning process. Based in primitive but fundamental patterns of motive arousal and experiential reactivity, the manifestations of variation in the neurodevelopmental control systems—with internalizing and externalizing as the primitive dimensions—can be seen to create individual characteristics of temperament and personality. These characteristics may be extreme, such as in autism, or more subtle, such as in the strong sense of engagement and agency seen in the extraverted toddler. In whatever form they take in the individual child, these outcomes of embryonic development can be seen to shape self-organization in postnatal life, where they must interact immediately with the requirements for effective social development.

Vertical Integration of Motivation and Learning

In classical neurophysiology, the visceral nervous system, organized around the limbic core of the cerebral hemispheres, was considered to be the motive basis for regulating both development and behavior (Yakovlev, 1948). Figure 17.2 illustrates that the posterior-anterior division between *somatic* sensory and motor systems in the neocortex is paralleled by the dorsal-ventral division between *visceral* sensory and motor systems in limbic circuits. For certain classical neuroanatomists (Coghill,

1929), the study of the origins of behavior was carried out through observing the first actions of the organism, revealed in synchrony with the progressive emergence of neuronal connections in embryogenesis. Following in this tradition, the dimensions of internalizing and externalizing can be seen as two integral modes of negotiating the self-world interchange, regulating both neural development and the organism's behavioral development through the interaction between the visceral limbic motives and the somatic neocortical sensory and motor representation of the interface with the world (Tucker & Luu, 2012). For humans, the core neurodevelopmental mechanisms continue to tune the vector of control between internal and external constraints, balancing the growth and maturation of the brain—and the self—within the complex demands of the social environment.

A key principle for understanding the control of activity-dependent plasticity—both in embryogenesis and in later learning—is the vertical integration of arousal control systems within multiple levels of the neuraxis (Figure 17.3). The motive control circuits of the limbic system regulate neural activity in support of memory consolidation through engaging the neuromodulator-specific arousal systems (norepinephrine, dopamine, serotonin,

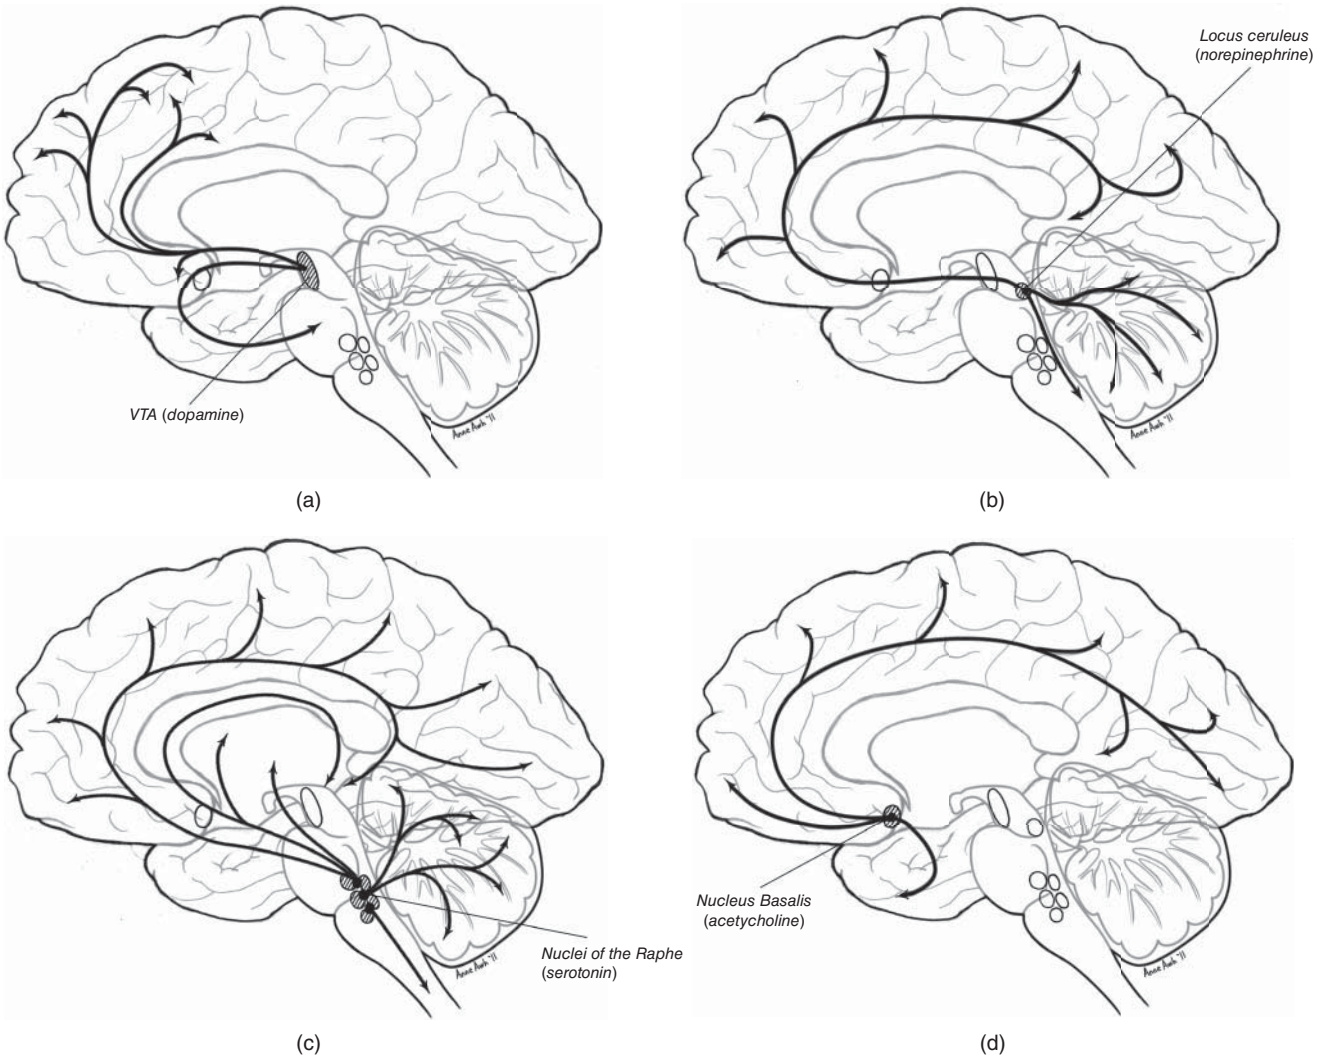

Figure 17.3 The regulation of arousal from brainstem neuromodulators is critical to neural self-regulation. The midbrain control of activation appears to be regulated by dopamine projections from the ventral tegmental area (upper left) and norepinephrine projections from the locus coeruleus in dorsal midbrain (upper right). The raphe nuclei in the lower brainstem (lower left) send widespread serotonin projections that appear to moderate the activating influences. The cholinergic projections are also critical to regulating neural activity, and include not only brainstem but forebrain control centers (lower right).

acetylcholine) of the brainstem (Cooper, Bloom, & Roth, 2002). In psychological terms, these arousal systems regulate both general alertness and more specific intensities of both emotional and cognitive processes (Tucker & Williamson, 1984). Beginning with the spontaneous neural oscillations of the embryo, the brainstem neuromodulator systems provide the initial basis for activity control, suggesting to developmental neuroscientists that these brainstem projection systems are critical to regulating not only the general substrate for neural growth and differentiation (Trevarthen, 1980), but the specific tuning of critical periods, such as in the formation of ocular dominance columns of the visual system (Bear & Singer, 1986b). It must be one of the key realizations in neuroscience that there is extensive if not complete overlap between the mechanisms of neural plasticity in brain growth and the mechanisms of neural plasticity in learning and memory (von de Malsburg & Singer, 1988).

Arousal is an important principle in psychological theory as well as neurodevelopmental theory. Although psychologists have often considered arousal as a unidimensional function that operates independently from the mechanisms determining the valence (good or bad) of affect or experience, the modern psychometric evidence suggests that there are two major dimensions of arousal that regulate psychological function. One is experienced as positive affect (PA) or *elation* and the other as negative affect (NA), including both *anxiety* and *hostility* (Watson & Tellegen, 1985). Considering the brainstem neuromodulator systems underlying these dimensions of affect/arousal (Tucker & Williamson, 1984), Tucker & Luu (2012) theorized that self-regulation of these affect/arousal dimensions is integral to maintaining not only motivational control, but the essential activity control that shapes synaptic differentiation in neural development. The PA system is integral to approach motivation; it facilitates the expansive attention and confident intention that motivate learning under conditions of success. The NA system is integral to avoidance motivation; it facilitates focusing attention on potential dangers and the tonic vigilance required under conditions of threat. Thus, the motive regulation of approach and avoidance in cognition and behavior is simultaneously the regulation of modes of neural activity that shape the connectional architecture of the developing brain.

The early notion of the reticular activating system of the brainstem (Moruzzi & Magoun, 1949) can now be differentiated into specific control systems, each of which plays a specific role in the self-regulation of affect, attention, intention, and cognition. It makes sense psychologically that avoidance motivation would be associated with symptoms of internalizing, and that approach motivation would be associated with symptoms of externalizing. But it is useful to examine the cerebral architecture for higher level control of motivation and arousal to understand exactly how these biases of the self-world orientation are regulated, and what this has to do with controlling neural development.

We have proposed that the primary differentiation between internalizing and externalizing is found in the functional differentiation between ventral and dorsal divisions of the limbic system (Tucker & Luu, 2012). Both these divisions regulate neural activity in part through their control over diencephalic (hypothalamic and thalamic), midbrain (ventral tegmental, collicular), and brainstem (pontine and lower brainstem) systems. The subcortical control of approach motivation in the mammalian brain has been outlined in Ikemoto's comprehensive integration of research on self-stimulation and local self-administration of drugs (Ikemoto, 2010). Many neuroscientists have accepted a fairly simple model of reward being controlled by the mesolimbic dopamine system. In turn, many cognitive neuroscientists have assumed this model explains the fMRI findings of ventral striatal (nucleus accumbens) hemodynamic activity under conditions of approach in human studies. However, Ikemoto points out that, although they are critical to motor readiness, learning, and habit formation, the dopamine circuits are *not* involved in the experience of pleasure, thus contradicting the typical notion of a dopamine reward system in drug use. Furthermore, in Ikemoto's review, the literature on the regions and circuits supporting self-stimulation and self-administration points to a complex subcortical network, involving not only the ventral striatum (including olfactory tubercle) but also the septal area of the limbic system, the supramamillary nucleus of the hypothalamus, and the ventral tegmental area of the midbrain. Ikemoto emphasizes that these are the linked subcortical controls of the limbic system. The integrated function of these limbic, striatal and midbrain networks, and not just mesolimbic dopamine, are critical to organizing approach behavior with reference to fundamental visceral regulatory functions (Figure 17.2).

At a higher level, the subcortical controls on approach motivation reviewed by Ikemoto (2010) may be aligned to what Tucker and Luu (2012) consider to be the dorsal limbic system. This dorsal limbic system was originally described by Papez as the circuit connecting the cingulate cortex to the anterior thalamus, septum, hippocampus,

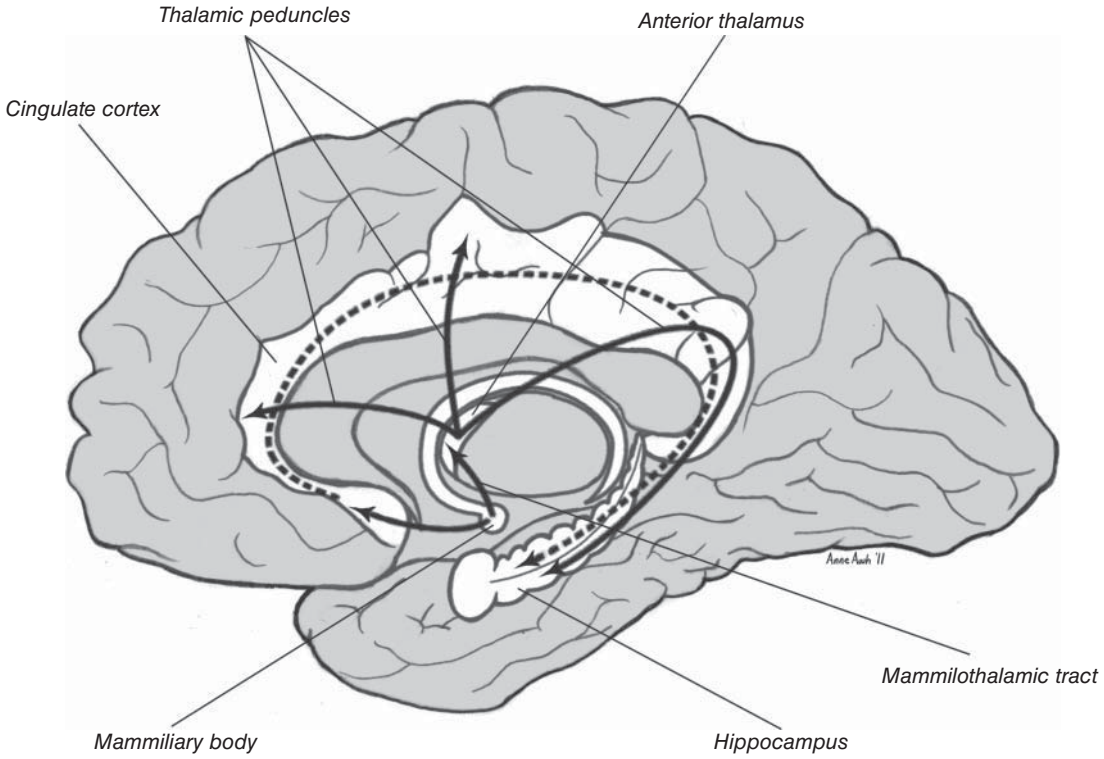

Figure 17.4 The dorsal limbic circuit, centered on the septum and hippocampus and their hypothalamic nuclei, engages the cingulate cortex as described by Papez.

and the mammillary bodies of the hypothalamus (Papez, 1937) (Figure 17.4). Although Ikemoto emphasizes the subcortical control of approach, Tucker and Luu emphasized that the control of learning and neural development requires the integration of the subcortical approach system (with its integral arousal control properties) with the limbic and cortical networks that regulate neural activity within the cerebral hemispheres. The important point is that activity-dependent organization of network function is as much a cognitive function as it is a motive-arousal function, and thus requires the corticolimbic mechanisms controlling memory consolidation. In this view, memory consolidation has not only a psychological outcome (learning) but also a neuroanatomical outcome (self-organizing the differentiation of connectional neuroanatomy).

The specific role of the dorsal limbic system can be seen to engage the subcortical approach system to support the unique form of learning and memory—rooted in the habituation bias of norepinephrine arousal control—that supports the feedforward cybernetics and the holistic conceptual structure of the dorsal brain (Tucker & Luu, 2012). These cybernetic and conceptual features can be understood as basic psychological properties of *extraversion*, and as neurophysiological properties of *externalizing* as a neurodevelopmental mechanism for exercising the growth of the dorsal brain.

The idea of feedforward control in the dorsal brain has come from both neuropsychological (Goldberg, 1985) and neurophysiological (Shima et al., 1991; Tanji & Shima, 1996) studies of action regulation. The control of motor processing by cingulate cortex and mediodorsal regions of the frontal lobe appears to involve a kind of *projectional* control, where the action is engaged in relation to a goal without ongoing guidance. For example, in turning on a light switch, you first reach toward the switch with the action launched by holistic and projectional feedforward control. The action is initially a vectoral impulse. This contrasts with the *constrained* form of action regulation from the ventrolateral frontal lobe (and ventral limbic regions), in which feedback guidance from sensory input becomes integral to fine-grained adjustments. As your hand nears the switch, feedback constraint from vision (or, in the dark, from touch) then becomes essential to assess the difference between the initial projectional trajectory and the precise location of the switch, such that error-correction mechanisms must then be effected through visual or haptic and tactile feedback guidance.

The cybernetics of action regulation from dorsal and ventral limbic and cortical systems can be aligned with the learning mechanisms that are uniquely directed by these brain systems. Drawing particularly on the neurophysiological studies of learning by Gabriel and associates (Gabriel et al., 1996), Tucker and Luu (2007) emphasized that the gradual or operant form of learning context-based associations is mediated by the dorsal limbic system, and is particularly important to engaging the context (externalizing) under conditions of approach.

In contrast, consistent with the neurophysiological evidence (Gabriel et al., 1996), the rapid, focused learning under conditions of discrepancy or threat is mediated by the ventral limbic system (Figure 17.5). These differential cybernetic effects can be seen as unique ways that learning is controlled by the approach (dorsal) and avoidance (ventral) learning systems, extending the function of the specific subcortical control systems into the more general task of regulating the cognitive function of the mammalian cerebral hemisphere (Tucker & Luu, 2007).

The unique cognitive capacities discovered for the dorsal brain, in spatial memory and contextual organization of action, can be seen as emergent from the more elementary motivational control linked with approach systems. The elementary cybernetic properties of dorsal limbic control help to explain basic features of extraversion, in normal personality, and externalizing disorders, in psychopathology. For example, the impulsive child, or one with attention deficit disorder, may operate excessively under feedforward control not only in specific actions but in behavior and self-regulation generally. Similarly, it may be the exclusive reliance on holistic thinking and the lack of constrained, analytic feedback control in cognition and behavior that characterize the impressionistic cognition of the person with histrionic personality disorder. In patients with lesions of the mediodorsal frontal networks, a syndrome of *pseudo-depression* is typically observed (Blumer & Benson, 1975), reflecting a loss of positive affect and the associated impulse toward hedonic engagement that is associated with the normal approach function of the dorsal limbic system.

In a similar fashion as with extraversion and externalizing, the elementary adaptive controls that are exaggerated in introversion and internalizing disorders can be seen to emerge from limbic constraints on affect, cognition, and behavior, specifically from the ventral limbic circuits of the

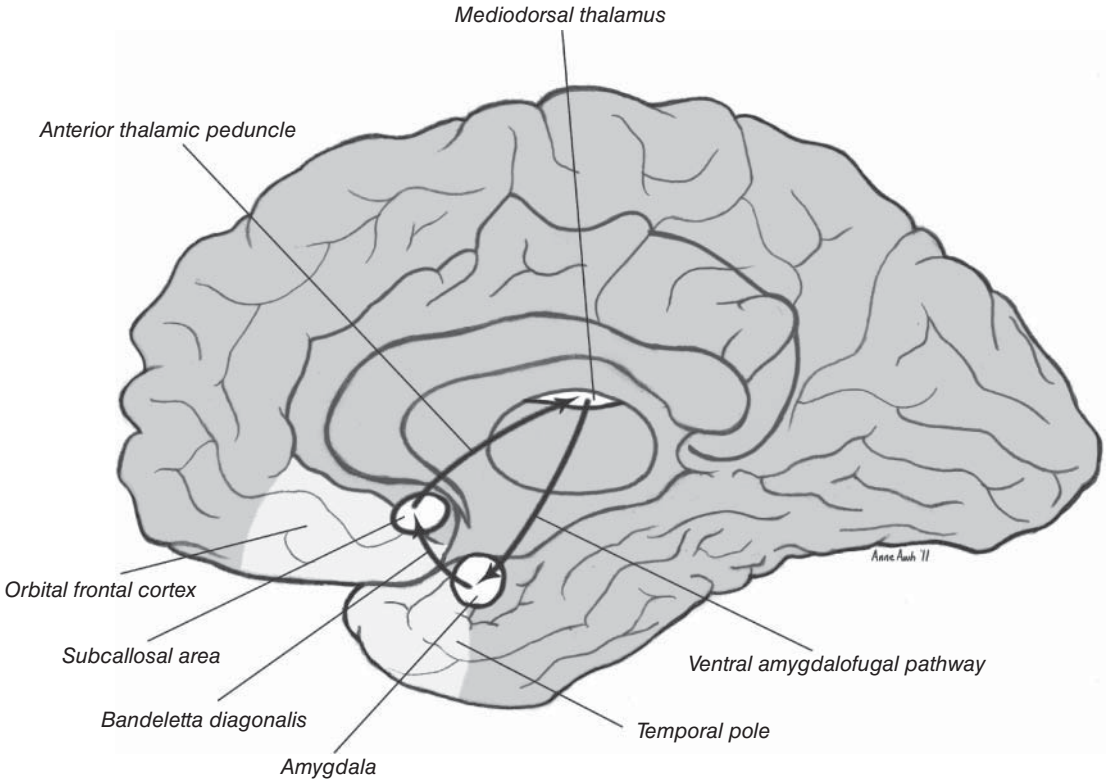

Figure 17.5 The ventral division of the limbic system involves the piriform cortex (paleocortex), the amygdala, and the orbital frontal lobe, coordinated by hypothalamic circuits through the stria terminalis (not shown) and the mediodorsal nucleus of the thalamus.

amygdala, anterior temporal lobe, mediodorsal thalamus, and orbital frontal lobe (Figure 17.5). The hypothalamic base for the ventral limbic network is the ventromedial nucleus, via the stria terminalis (not shown). The avoidance motivation emerging from the ventral division of the limbic system may become chronic in humans as symptoms of anxiety. The dopaminergic and cholinergic forms of neuromodulation that are integral to the basal ganglia support the sensitization or redundancy bias that is engaged by anxiety and hostility (Tucker & Williamson, 1984). Given the important links of amygdala and ventral limbic networks with striatal controls, when anxiety becomes a chronic organizing influence in personality, such as in anxiety disorders or obsessive-compulsive disorders, there is exaggeration not only of the object-oriented perception of the ventral corticolimbic networks, but exaggeration of the sequencing and routinization functions of striatal control over action (Tucker & Derryberry, 1992). These pathological features, consistent with exaggeration of internalizing, can be seen to reflect excessive feedback control and constraint in cognition and affect as well as in behavior. Conversely, the loss of adequate internalizing control with lesions of the orbital and ventrolateral frontal lobe is manifested in the *pseudopsychopathic* syndrome (Blumer & Benson, 1975) in which the person loses the constraint component of normal self-regulation. The result is that the impulsivity of the dorsal approach system is released, no longer modulated by normal ventral frontolimbic feedback constraint.

Thus the developmental mechanisms regulating the embryological differentiation of the major functional systems of the brain may continue to shape the internalizing and externalizing modes of self-regulation throughout psychological development. At birth, there is a key transition, in which the infant must engage the social world. In the embryo, self-organization is self-contained, such that canalization of trophic and activity-dependent mechanisms serves only to correct incipient developmental errors with system-level organismic feedback to create coherent neural systems. For the human infant, the transition from womb to culture creates fundamentally different challenges for the developmental mechanisms of internalizing and externalizing.

Canalization and Primitive Self-Organization in Autism

Autistic children cope in various ways with their challenged neurodevelopmental capacities. The core syndrome of autism might be seen as an effort in self-organization, attempting to create a more or less coherent self through maintaining boundaries against outside influences. The problem with this in autism, of course, is it causes a failure to engage the extensive interpersonal communion that embeds normal human intelligence within the social context. Nonetheless, it may be useful to appreciate that autistic symptoms are a kind of canalization of organismic coherence to form a primitive self. This organismic process may explain the appearance of the typical autistic symptoms as a common final path of canalization in the face of remarkably varied genetic defects.

Because twin and family studies showed high heritability of both autism and autism spectrum disorders, researchers over the last decade or so have applied the recent advances in genetic sequencing to characterize the genetics of autism (Chaste & Leboyer, 2012). Instead of revealing consistent abnormal genes, the results have shown that the genetic defects in autism are often uncommon *de novo* mutations that arise in different forms in different individuals. In addition, the increasing evidence that genetic deficits of autism interact with environmental insults, such as maternal viruses and immune responses during pregnancy, has led autism researchers to focus on gene–environmental interactions, rather than just inherited defects of genetic code (Chaste & Leboyer, 2012).

Genetic defects are more common in children with older parents, implying that they indeed reflect a risk from the reproductive process (Idring et al., 2014; McGrath et al., 2014). Yet this is a diffuse genetic risk, resulting from many inconsistent and varied mutations of the genome. Many of these mutations do have a common path of affecting synaptic regulation, and thus various aspects of neural development. Nonetheless, the fact that a common syndrome of autism results from a variety of neurodevelopmental abnormalities suggests that this syndrome reflects the organism's effort to adapt to a nonspecific developmental insult. We can speculate that the embryonic process is guided by the requirement to maintain the framework for organismic developmental coherence, what may be described as a primitive individual self. It is as if the normal, but intense, process of human interpersonal communion is too challenging for the infantile self that struggles to maintain a fragile organismic integrity. The result is a primitive mode of internalizing.

The autistic self thus seems to be developed at the expense of more challenging capacities in social cognition, such as shared intentionality and intersubjectivity. Unfortunately, these are the exactly capacities that allow the powerful interaction effects of social support for the normal child's mind. Instead, the autistic child manifests exaggerated anxiety and internality. Rather than isolated

symptoms, these responses can be seen as primitive organismic reactions reflecting a self-organizing adaptation. These are clearly maladaptive in that they threaten the essential developmental avenue of acquired intelligence and culture through social interaction. The effective interventions with autism have succeeded through redoubling the social support provided (Gulsrud, Hellemann, Freeman, & Kasari, 2014; Kasari, 2014). Even though the child is poorly prepared to engage this support, it appears to be essential to allow the socially competent self that is prepared to adapt to the ongoing social developmental process.

Progressive Neurodevelopmental Dysfunction in Adult-Onset Psychopathology

In forms of severe psychopathology with adolescent and adult onset, the disorders of the self can also be seen as fundamental, and they often preclude the normal adaptation and self-regulation that could allow correction of pathological patterns.

For example, in mania and depression the strong mood states themselves appear to be pathogenic, with later episodes predicted by the severity of earlier episodes (Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Lewinsohn et al., 1994). Given what we are learning about neuroepigenetics (Day & Sweatt, 2011; Sweatt, 2013), it is tempting to think that an epigenetic mechanism of kindling, activated by the extreme mood state itself, may be involved in mood-specific learning. This mechanism might be suspected to mediate the biological sensitization that causes mania or depression to predispose the person to augmenting mood responses in the future. Although it is thus likely that a specific biological mediation is responsible for the sensitization or kindling effect of repeated mood disturbance (Harkness & Tucker, 2000; Post, 1986), the pathological effect of the strong mood states may also have an organismic psychological basis, biasing the operation of the self in ways that are mood-congruent but highly maladaptive. In a manic state, the person is grandiose, impulsive, and optimistic to a fault. Transitioning to depression, the same person loses all confidence, cannot find hope, and may become intensely self-critical to the point of suicide. These mood shifts are fundamentally shifts in self-regulation, and they seem to be incorporated within the organization of the self as well as specific sensitizations of neurophysiology.

The mood shifts of mania and depression involve positive affect in greater or lesser degrees, and appear to reflect the operation of the dorsal limbic approach system and its externalizing function, ranging from strongly engaged to fully suppressed (Tucker & Luu, 2007). There is of course a fundamental continuity of the self through these mood states, but the normal mood-congruent self-regulation becomes exaggerated to the point that any perspective that could be provided by knowledge of the historical self is lost in the presence of strong affective modulation.

In a different example of severe psychopathology, the schizophrenic episode, the distortion of experience and behavior is associated with severe anxiety. Yet, unlike the nonpsychotic anxious person, the internalizing cognition of the schizophrenic person is not simply routinized, overly focused, and biased toward threat, but it becomes disorganized to the point of a breakdown in the capacity to maintain contact with reality. The disorganization of the neuropsychological process in the schizophrenic break seems to reflect a fundamental, and often irreversible, breakdown in the organization of the self. The fact that first schizophrenic episodes often occur toward the end of adolescence emphasizes the importance of neurodevelopmental mechanisms; this is a point in time when the completion of adolescent cortical thinning suggests a maturation process that is normally associated with the crystallization of the adult personality (Mutlu et al., 2013).

With its typical features of severe anxiety and autism, schizophrenia can be seen as an internalizing disorder, reflecting an exaggeration of the ventral limbic avoidance system and its strong dopaminergic and cholinergic modulation. However, the disorganization of the schizophrenic person reflects profound defects of the self that must also be seen as loss of the capacity for externalizing. There is typically a loss of the normal feeling of agency and intentionality, such that the schizophrenic person's own thoughts and actions are interpreted as controlled by an external agent (Blakemore & Frith, 2004).

That these effects are disorders of the normal externalizing function is shown by the parallel symptoms of loss of personal agency with lesions of the dorsal limbic and frontal networks. In the anarchic hand syndrome, for example, the patient experiences actions of a hand or a leg as caused by someone else (Goldberg & Bloom, 1990). In the person with mediodorsal frontal lesions, the loss of agency is a circumscribed defect, associated with a particular limb. In the schizophrenic person, the loss of agency is fundamental to the fragmentation of the self, such that ongoing self-regulation is then carried out with reference to delusional assumptions. As a result, self-regulation becomes ineffective in integrating the accurate interpersonal feedback that is essential to coping with society.

The Interpersonal Context for the Developing Self

The disorders of the self in psychopathology may appear in infancy, in the autistic child's failure to engage the sharing of perspectives in interpersonal communication, or they may become progressively more apparent, leading to the young adult's schizophrenic break. Although neural development is cumulative, with each stage of organization building the base for later growth, ontogenesis is remarkably protracted in humans, such that there is a long period of social support that provides even the genetically challenged child with time to find a way to adapt. When parental and societal support is effective, we might consider it as cultural canalization.

Human evolution has resulted in an extended neoteny, providing a long period of brain maturation that may be integral to the capacity for developing intelligence. Extending the juvenile stage of neural plasticity allows the child to self-organize through the motive cybernetics of learning and memory while incorporating the rich cultural information of human society. Human neuroembryology can be understood to create a complex neural substrate, yet one that is profoundly immature at birth, requiring major support by parental caregivers.

The primordial neural mechanisms for regulating neuroembryological development, organized around the internalizing and externalizing modes of self-regulation, must transition at birth to the complex tasks of intersubjectivity, engaging the available parenting that is critical to organizing a socially competent self. Even the most biologically robust child is unlikely to escape some degree of enduring psychopathology in the face of abusive and neglectful parenting. Conversely, the temperamentally vulnerable child may succeed with developmental challenges only through skillful social support from family, peers, and the community.

The major dimensions of internalizing and externalizing thus take on new roles as the self-regulatory tools for coping with the considerable developmental challenges of socialization. Forming effective dependency relationships is an essential function of externalizing. The specific cybernetics of the dorsal limbic system are relevant to this function, with a strong hedonic tone motivating the approach to social contact, and the extraversion of intentionality (habituation bias, feedforward control) supporting the learning process within the attachment relation.

For example, in acquiring language, the toddler learns the meaning of words through *social referencing*, interpreting the intention of the mother as she communicates (Baldwin, 1993; Baldwin et al., 1996). In this way, the child's developing capacity for extraversion supports incorporating the intentionality of the mother, a process described by philosophers and psychoanalysts as *intersubjectivity*. The interpersonal context is thus critical to the child's early experiences with cognitive and emotional development that are integral to the organization of the biological substrate. The neural mechanisms of self-regulation must support the development of the self, through the incorporation of interpersonal bonding with the caregiver. The capacity for externalizing is essential to this process of bonding and identification.

After the first year, the child's increasing autonomy will lead to struggles with the dependency relationship of infancy, and the capacity for internalizing will become an essential counterpoint for individuating a more autonomous self from the family context (Mahler, 1968; Tucker & Moller, 2007). In embryogenesis, the ventral limbic networks organize the substrate for avoidance (internalizing) in the ventral division of the hemispheres. Operating through the fundamental mechanisms of anxiety and hostility, these networks are now challenged by the complex task of establishing the autonomy of the toddler self. This task requires both separation from parental control and effective individuation of the capacity for effortful agency.

In these familiar interpersonal dynamics of the family, recapitulated in the struggles for individuation in adolescence, neurodevelopmental mechanisms optimally balance the modes of introversion and extraversion. Yet imbalance is common, with exaggeration of one mode creating not only the familiar personality types but the variety of personality disorders. We have emphasized the primitive controls provided by the motive mechanisms of internalizing and externalizing. Yet through their integration with complex cognitive capacities, these motive modes support more sophisticated self-regulatory processes that may be integral to what has been described in the temperament literature as *effortful control.* This capacity for executive self-regulation may arise through unique contributions from both internalizing and externalizing modes of control. The cognitive operations of internalizing, for example, draw on its motive basis of anxiety and hostility. In the effortful control of attention, anxiety allows the child to anticipate problems and dangers, but also to solve problems through analytic and sequential reasoning (Derryberry & Tucker, 1992). Hostility supports the individuation of a personal perspective, and when appropriately integrated with cognitive processes of effortful control, may be essential to the development of critical thinking (Tucker, 2007). In its pathological forms, internalizing provides the motive basis of debilitating anxiety, obsessions, and paranoia. But it may be integral

to adaptive cognitive control as well, providing the focused attention and motivated engagement required for analytic reasoning (Derryberry & Tucker, 1992).

Similarly, externalizing may be an essential component motive process in effortful control, with important implications for the successful child's ability to develop interpersonal skills. Emerging from the dorsal corticolimbic networks, externalizing may develop from primitive impulsiveness to support more complex processes of intentional effort. Closely linked to the interpersonal engagement of extraversion, externalizing supports identification with significant others, and the capacity for mentalizing that is required for socialization and education. The holistic thought supported by the dorsal corticolimbic pathways is specifically engaged by the positive affect of extraversion, and it provides the child with the optimism that is often necessary to persist in effortful self control under adverse challenges.

Motives are thus integral to more complex operations of the personality that become engaged in effortful control. For each child, the self is an important construct for understanding both primitive and sophisticated processes of self-regulation. Psychologically, the self is the coherent system of concepts, memories, and regulatory capacities for attention and intention that operate to maintain internal consistency, as well as consistency in interpersonal relations. For the embryo and fetus, the self is the biological process of organizing internal consistency, through the cybernetic capacity for canalization. Through many specific biological mechanisms of functional feedback control, canalization in embryogenesis achieves a coordinated, viable phenotype through the capacity for developmental self-regulation that normalizes the variations of the genotype (Waddington, 1942). In neurogenesis, this must be achieved by the multiple developmental mechanisms for trophic and activity-dependent neuronal self-organization. For the child and adolescent, the same neurodevelopmental process of maintaining internal consistency continues, but now achieved within the social context to create the integrated psychological patterns of a coherent self. When self-organization fails, the result may be the fragmented self of psychopathology.

CONCLUSION AND FUTURE PERSPECTIVES: CONTINUITY AND DIVERSITY IN THE HUMAN ONTOGENETIC PROCESS

In this chapter, we have proposed that it now may be feasible to explain the developmental processes leading to both normal personality and psychopathology in common biological terms. We think that a better integration of biological and psychological theory will be important to translating from the remarkable advances in modern biology to improve assessment and treatment of mental illness. Students of human development can draw from new insights into genetic mechanisms and the specific workings of neural plasticity. Yet these mechanisms cannot be interpreted in isolation but must be understood within an organismic theory of psychological development. In such a theory, epigenetic mechanisms broadly conceived serve to maintain the coherence of systems within the whole organism, even in light of extensive human genetic variability.

Organismic mechanisms of self-regulation maintain the continuity of the self. These biological cybernetics begin as the control systems that coordinate embryonic morphogenesis at molecular and neurophysiological levels. They continue to operate throughout ontogenesis, forming the substrate of psychological self-organization, where the process of learning through neural plasticity must not only maintain homeostatic internal coherence of the self, but must achieve effective interchange with the social environment.

We have outlined a theoretical approach to basic dimensions of internalizing and externalizing that guide the process of self-organization. This process begins with the differentiation of sensory and motor systems in the embryo, regulated by the evolutionary mechanisms for controlling not only somatic sensorimotor systems, but also the visceral sensorimotor systems that provide the homeostatic regulation of neural activity. Internalizing appears to reflect the viscerosensory bias of the ventral limbic system, externalizing the visceromotor bias of the dorsal limbic system. With these specific motive bases, the process of neural differentiation and plasticity continues after birth to support the child's learning and memory consolidation, as internalizing and externalizing provide adaptive control of intelligence in the child's cultural context.

Even though we have emphasized the adaptive continuity of human ontogenesis—from embryogenesis through adolescence—it is also clear that human development involves remarkable individual diversity. The evolution of the human brain has resulted in extensive phenotypical variability at the same time that neural maturation has been prolonged to extend the period of juvenile plasticity and parental instruction. It may be that these aspects of human uniqueness have evolved together. In the context of two decades of parental support, diversity in the genome, and thus developmental process, may have evolved in modern populations because of the availability of increasingly effective human cultures.

Human intelligence cannot be traced to a single mutation, with some novel developmental capacity, but is associated with a genome that includes a mosaic of diverse ontogenetic factors. This diversity of the genome—perhaps amplified further by epigenetic diversity—may have only become possible with the expanding cultural capacity for tolerating individual differences.

For simpler mammals, the instructions of the genome must code for adaptive behavior, within the narrow limits of adjustments provided by elementary capacities for learning and memory consolidation. For humans who are sheltered by family and community over a juvenile period spanning decades, greater diversity may have been tolerated within the genome. Individual variations, including not only biases toward internalizing and externalizing, but highly unique mutations, may have been protected by the presence of social support such that they propagated to succeeding generations. We can even speculate that, within the few millennia that have seen the explosive process of human cultural evolution, the protection of genetic diversity may in turn have conferred adaptive ability to the reproductive group under more widely varying conditions, such as unusual environmental threats or creative opportunities.

Although it is often said that the human brain has not changed since the Stone Age, this is almost certainly not true. First of all, if cultural success really has fostered reproductive success of diverse ontogenetic variations, it may not even be true for the genome, which now may span considerably greater variety than existed in the small populations of our Stone Age ancestors. Furthermore, once we appreciate how neural plasticity allows self-organization of the neural architecture through engagement with the culture, it becomes clear that the functional architecture of the brain itself is a kind of cultural artifact. Although there are, of course, important capacities of intelligence achieved by a child in a Stone Age culture, it is a very different brain that emerges through literacy, an effective education, and a rich set of cultural experiences.

In current times, the multiplicity of individual outcomes can thus be reinterpreted in light of the diversity of the human genome, as highly unique children encounter the wide range of social support in existing cultures, from devastating insults and pernicious trauma to the fortunate cases of skilled and highly invested parenting. Considering this perspective, the high degree of both genetic and cultural heterogeneity in current human populations may have created a range of developmental psychopathology that is itself uniquely human.

NEUROCONSTRUCTIVE PROCESSES

The construction of the human brain requires a long and protracted process. In fact, it has been argued that a defining characteristic of the human species is its long developmental time scale, including not only infancy but also childhood and adolescence (Thompson & Nelson, 2011). In some respects, adolescence may be our species' adaption that provides prolonged opportunity dedicated to learning and refinement of brain circuitry via extended exposure to environmental input. No other species dedicates as high a percentage of its lifetime to development (Thompson & Nelson, 2011). The goal of this chapter is to review and consider the functional significance of adolescent brain development with the aim of characterizing some primary aspects of the construction of the human brain.

General Principles

Unlike understanding the mechanics of a simple machine, it is not possible to understand the construction of the human brain through deconstruction of its component parts. This commonly used analogy rests on the principle of hierarchical construction (Quartz & Sejnowski, 1997). Brain development occurs hierarchically, where the phenotype of one circuit depends heavily on the phenotype of previously developed circuits. For example, expert face processing abilities observed in the majority of adults rests critically on the proper formation of several earlier developing processes, including the development of basic visual, attentional, and social motivation processes. If one of these processes develops in an atypical way, the odds of face processing skills developing in a typical manner are greatly diminished (Le Grand, Mondloch, Maurer, & Brent, 2001).

Central to a hierarchical organization is the factor of development timing. Evolutionary developmental (evo-devo) theorists have posited that time itself, that is, the mere duration of developmental processes, is a critical factor in the ultimate phenotype of brain systems (Charvet & Finlay, 2012). Both phylogenetically and ontogenetically, humans experience a prolonged immature state,

which if temporally modified, significantly impacts neural phenotypes. On an ontogenetic scale, maturational timing of systems has been considered to give rise to developmentally unique phenotypes in behaviors (Casey, Galvan, & Hare, 2005; Somerville & Casey, 2010; Steinberg, 2010). For example, subcortical systems, including regions such as the nucleus accumbens that mediate reward-related processing, show evidence of developmental timeline that is distinct from cortical regions, like the prefrontal cortex that can regulate arousal of the nucleus accumbens (Galvan et al., 2006; Somerville, Hare, & Casey, 2011). Therefore, adolescence is a period when there is a temporal imbalance of subcortical arousal without the regulatory influence of top-down prefrontal input. Another way of saying this is that adolescence marks a time of differential timing between subcortical and cortical maturation.

Another aspect of timing involves the age-related timing of environmental exposures. Each stage of development presents new niches and changing needs to be satisfied by environmental input. A priming or readiness of a particular neural system may be referred to as either a sensitive period or a critical period. A sensitive period is a period in development during which certain capacities are readily shaped or altered by experience (Knudsen, 2004). Critical periods are a special class of sensitive periods that result in irreversible changes in brain function. In other words, these special periods allow for developmentally unique moments for learning, which will shape later brain function and behavioral output. It is this learning aspect of sensitive periods that we wish to emphasize because there are other important periods that are distinct from sensitive or critical periods. For example, there are other periods of development when large individual differences in behavior emerge or are finally observed. We would argue that these other developmental moments are distinct from sensitive or critical periods because they encompass the expression of the phenotype, not the learning of the system. This point will become important in this chapter as we discuss behavioral domains for which adolescence is a sensitive period.

The notion of sensitive periods relies on the principle of brain plasticity, a concept referring to the likelihood that brain structure and function change as a result of environmental influence. This concept, although common in modern scientific literature, replaced the long-held belief that the brain is a static tissue that results from genetic unfolding. The shift in thinking about plasticity dates back to the Nobel Prize–winning work of Hubel and Wiesel in the 1960–1970s (Hubel & Wiesel, 1970) showing that environmental light input shaped cellular organization in the visual cortex. Although genotype sets large architectural constraints on brain development, the state of the science recognizes the ubiquity of gene–environment (GxE) correlations (Caspi & Moffitt, 2006; Gottlieb, 2007), which emphasizes the interdependence of environmental input on gene activity to influence phenotypic outcome. More recently, this perspective has been amended to incorporate developmental timing, with the appreciation that gene expression varies across different ages resulting in the concept of gene–environment–development (GxExD) interactions (Casey, Glatt, et al., 2009).

On one hand, plasticity is beneficial to brain development in that it allows for learning from environmental input. However, life-long plasticity is likely to be detrimental to the organism. At some point in development, it benefits the organism to sacrifice plasticity for efficiency. Thus, some have argued for a plasticity–efficiency trade-off in development (Lebel et al., 2012; Lu et al., 2009). This perspective argues that plasticity is adaptive early in life when a system is undergoing massive learning and developing optimal strategies. However, a plastic system lacks efficiency, much in the way that a town full of several dirt roads (high degree of options) does not allow for the fast travel that one with paved super highways does (high degree of efficiency). Once information is learned and strategies are optimized, the system should shift to an efficient one at the sake of plasticity. According to this perspective, early life is designed for learning and practicing skills, whereas later life (e.g., adulthood) represents a period of performance, where those learned skills are now put into use. This perspective harkens back to the concept of a protracted childhood mentioned earlier. The long period of immaturity afforded to humans allows for a long period for learning (or establishing of systems via mechanisms of plasticity) that enables the complex behavioral repertoires humans are able to express in adulthood.

The Importance of Animal Models

Although the focus of this chapter is on human brain development, central to the arguments that will be presented is the large body of work produced by animal models. There are several important and large differences between humans and animals of other species, such as rodents or even nonhuman primates. However, the state of human neuroscience is much newer relative to what has been learned in these other species, and as will become clear in this chapter, many of the hypotheses and theories about brain development upon which we currently rely have been

generated by animal models. In addition to the shorter life spans, and thus the facility with which nonhuman animal brain development can be studied, animal models allow for investigations that are either ethically or practically impossible in human samples. Of course, animals can provide only a model of a system, as a rodent is the product of a very different dynamic system from a human. However, great insights into mechanisms of brain development can be gleaned from these models. Another concern raised regarding the use of animal models to study human brain development pertains to the appropriate age comparisons. For example, a reasonable question is whether neural substrates that mediate mother–pup relationships during infancy correspond to the same mechanisms in a human infant (who at the cellular level may be at a very different age from a rodent pup). However, another perspective to take when regarding these comparisons is to consider the developmental niche or needs of the organism at that time. So, while the infant pup may be at a very different age than a human infant, both species are altricial (or at least semi-altricial) and require maternal input for survival. The needs of the infant are analogous, although not always identical (good maternal care in the rat would include high levels of licking and grooming—not so in the human). However, both species require analogous input, for example, contingent and reliable care from a primary caregiver. Similarly, adolescent rodents, monkeys, and humans have similar goals in transitioning toward adulthood and mature sexually. Thus, we, as many others have (Casey, Ruberry, et al., 2009; Cohen, Tottenham, & Casey, 2013), argue that animal models are highly valuable to the field of human brain development.

Connectivity

Animal models have been very important in heightening awareness of connectivity of systems. Although much of the research presented in this chapter focuses on one or possibly a few brain regions, these regions are highly interconnected with each other and several other regions, which the field of developmental systems neuroscience works toward understanding and characterizing. This idea is consistent with the notion of the development of dynamic systems in the behavioral domain (Smith & Thelen, 2003). The central tenet of these system approaches is that the function of brain activity is an emergent property of the connectivity of the system. We will provide a more in depth description of recent advances in adolescent brain development that have been revealed through analysis of connectivity patterns across development.

WHAT IS ADOLESCENCE? A HISTORICAL PERSPECTIVE

Prior to the 1900s, there was no formal recognition of the developmental period of adolescence. However, the behavioral phenotypes that typically emerge during adolescence had been noted throughout history. Aristotle observed, "The young . . . are naturally as hot-blooded as those who are drunken with wine . . . Their life is guided by their character rather than by calculation" (Aristotle [460 BC]. The Art of Rhetoric. p. 249). Socrates characterized youth as inclined to "contradict their parents" and "tyrannize their teachers" (Arnett, 2011.p. 277). In a landmark two-volume series, Granville Stanley Hall is credited with being the first to formalize the study of youth in the second decade of life and coined the phrase "storm and stress" with reference to adolescence (1904). This phrase was taken from the German Sturm und Drang movement, which was composed of three key aspects: conflict with parents, mood disruptions, and risky behavior. Hall argued that this is characteristic of most adolescents, biologically based and influenced by culture (Arnett, 2011). Psychoanalytic theorists, especially Anna Freud (1946, 1958, 1968), strongly endorsed Hall's proposed model of adolescence. They viewed adolescent storm and stress as the manifestation of Oedipal conflicts from early childhood (Blos, 1962), which, in their view, provoked emotional volatility (as the adolescent ego attempted to conquer resurgent instinctual drives), depressed mood (as the adolescent mourned the abandonment from the Oedipal parent), and conflict with parents (Blos, 1962). In contrast, Margaret Mead led fellow anthropologists in countering the universality of storm and stress in adolescence by drawing on multiple examples in non-Western cultures in which the characteristic adolescent behavior was not observed (Mead, 1928). Although most contemporary adolescent theorists do not accept the claim of storm and stress as universal, they do acknowledge its relevance to understanding behavioral changes during adolescence and that although not all adolescents experience storm and stress, adolescence is a period highly characterized by these behaviors.

Despite all the discussion, proposed theories and plausible predictors and biological explanations regarding adolescence, the field has, remarkably, failed to agree on an operational definition of this important developmental period. The number of studies and public interest in adolescents has sharply increased in the last decade (Galván, 2014) and many consider adolescence as a transitional period in life between childhood and adulthood (Dahl, 2004; Spear, 2000; Steinberg, 2010), but there is no general

consensus about when adolescence begins and when it ends. Generally speaking, the onset of puberty marks the beginning of adolescence and the full independence from caregivers signifies the end of adolescence. However, both of these biological and psychosocially defined constructs are complex and multi-faceted.

Sexual maturation in girls involves three events that typically proceed in the following manner: breast development, pubic hair growth and first menses. It would therefore be most precise for adolescent researchers interested in puberty as an adolescent milestone to report age of first breast growth. Instead, most reports that include puberty use the age of first menses as an adolescent-onset marker (Blakemore, Burnett, & Dahl, 2010). The reason for this convention is a methodological one: obtaining accurate pubertal measures is laborious, expensive, and challenging (Dorn, Dahl, Woodward, & Biro, 2006). Therefore, many researchers simply dichotomize the measure by asking girls if they have or have not begun menstruating and then classify the sample as either prepubertal (pre-menses) or post-pubertal (menses begun). This approach precludes differentiation of pubertal status along the fine-grained spectrum that includes various stages of breast and pubic hair growth. It is therefore plausible that a prepubertal group in a study includes girls who are truly prepubertal (typically under age 8) and those who are on the cusp of sexual maturation. Similarly, a postpubertal group might include girls who menstruated early (as is more common in underrepresented minorities or girls with stressful family contexts (Herman-Giddens, 2007) as well as those who are both biologically and psychosocially more mature.

Perhaps more challenging than defining when puberty begins is defining when adolescence ends. It has been argued that one function of adolescence is to establish independence from the family unit and caregiver (Casey, Getz, & Galván, 2008). In nonhuman animals, this autonomy typically involves leaving the natal troop to seek out new sexual mates, food resources, and sleeping burrows or trees (Spear, 2000). In humans, the split is not as discernible. The very definition of independence varies across generations, adolescents, parents, and societies. Most countries define the end of adolescence when an individual is mature enough to be trusted with certain responsibilities, including driving a vehicle, having legal sexual relations, serving in the armed forces or on a jury, purchasing, selling, and drinking alcohol, voting, finishing certain levels of education, marriage, and renting a car. But even the age at which these rights and privileges are granted varies within a single nation or culture. Even more perplexing is that the set legal age limits seem arbitrary relative to the legal age for comparable or more significant activities. For instance, youth can hold employment in many U.S. states at the age of 14 but are not legally allowed to drive, vote, and buy alcohol until the ages of 16, 18, and 21 years, respectively. They can fight in wars and serve in the armed forces at age 18 but cannot rent a car until age 25.

By some standards, individuals transition from adolescence into adulthood when they are either married or financially independent, or both. In previous generations, these events typically coincided with the graduation from high school (age 18). However, since approximately the late 1980s, youth have remained more financially dependent on their parents for longer and are marrying later. One obvious reason for this trend is that there has been an increase in the number of people (particularly women) who are attending college or university. In fall 2012, a record 21.6 million students enrolled in American colleges and universities, an increase of about 6.2 million only since fall 2000 (NCES, 2012). In 1970, 42.3% of the college-attending population was women; today, women make up 56.8% of the college population (NCES, 2012). This increase makes individuals more dependent on parents or government loans for financial support, particularly as the costs of college continue to rise steadily. Adjusting for inflation and represented in current dollars, the average total cost of college in 1976–77 including tuition, fees, room, and board was $7,146 for a public university and $14,686 for private institutions; for the 2010–2011 academic year the costs were $15,605 and $31,975 for public and private institutions, respectively (NCES, 2012). College-attending youth also marry later in modern times compared with previous generations: in 1976, the average age of first marriage was 23.8 for men and 21.3 for women. In 2012, the age of first marriage was 28.7 and 26.5 for men and women, respectively. The economic downfall in 2008 further contributed to continued financial dependence on parents, as college graduates struggled to find jobs and moved back home with parents in record numbers. A 2011 Pew Research Center analysis of U.S. Census data found that 39% of adults ages 18 to 34 say they either live with their parents or moved back in at some point in recent years. Among 18- to 24-year-olds, 53% said they live at home or moved in temporarily, compared with 41% among adults ages 25 to 29, and 17% among those ages 30 to 34, and 60% reported being financially linked to their parents (Pew Research Center, 2012).

Although attaining maturation in terms of physical, biological, and neurobiological milestones occurs in the majority of individuals by the late teens, the delayed emotional and financial dependence undoubtedly contributes

to the protracted transition from adolescence into young adulthood. Given the seemingly endless possible definitions of adolescence, adolescent researchers face a daunting task in deciding how to define the adolescent group in their research studies. Some scientists have identified adolescence as "the gradual period of transition from childhood to adulthood" (Spear, 2000. p. 417). While this broad definition is useful when describing heterogeneous bodies of work, as in literature reviews, it is not the most suitable way to define participant samples to be included in developmental studies (Galván, 2010). In general, neuroscience studies on human adolescents have defined adolescence in one of the following ways: age (van Leijenhorst, Zanolie, et al., 2010); grade level (Galván et al., 2006; Geier & Luna, 2009); or pubertal status (Goddings, Burnett Heyes, Bird, Viner, & Blakemore, 2012).

Trajectories of Human Brain Development

Compared with other species, human brain development is a protracted process. In particular, early childhood and adolescence seems to be lengthened in the human species compared with most other species (Thompson & Nelson, 2011). The elongation of these periods may serve the purpose of extending opportunities during which learning can occur, particularly with regard to complex social learning. Large longitudinal MRI studies have shown that in the human, developmental changes are observed in cortical development throughout young adulthood (Caviness, Kennedy, Richelme, Rademacher, & Filipek, 1996; Giedd et al., 2008; Giedd & Rapoport, 2010; Lenroot et al., 2007; Reiss, Abrams, Singer, Ross, & Denckla, 1996; Sowell et al., 2004; Sowell, Thompson, Tessner, & Toga, 2001).

By the time an individual reaches adolescence, the majority of basic anatomical structural development has occurred. However, late occurring organizational development can have significant impacts on behavioral refinement that occurs during adolescence. Development occurring during adolescence and early adulthood involves a process of cortical thinning, which may reflect changes at the cellular level, such as synaptic pruning. This hypothesis is drawn from post mortem findings, which have shown an overproduction of neural synapses in the early stages of a system's development followed by a period of synapse pruning, or selective activity-based elimination (Bourgeois, 1997; Huttenlocher & Dabholkar, 1997; Petanjek et al., 2011). Synapse overproduction and subsequent pruning occurs in sequential waves following a general pattern of caudal to rostral, or back to front, of the brain, such that an area like the visual cortex, which is in the back of the brain, reaches maturity (i.e., a pattern of synapse pruning that most likely reflects a history of activation) earlier than areas like the prefrontal cortex. This pattern of development characterized by post mortem studies has been recapitulated in structural MRI studies such that by charting the relative thickening and thinning of cortex, investigators have been able to establish an index of regional variations in brain age (Houston, Herting, & Sowell, 2014). From these types of studies, it has been shown that the prefrontal cortex is the latest to develop relative to other cortical regions.

It has been hypothesized that synapse overproduction supports moments of increased learning from the environment. Based on activity, or frequency of use, certain circuits are maintained, while others are pruned through programmed cell death and synapse elimination (Greenough, Black, & Wallace, 1987). Taken together, these findings would support the argument that adolescence may be a time of enhanced plasticity of the prefrontal cortex; that is, adolescence may be an optimal developmental moment for prefrontal cortex mediated learning about the environment because adolescence is a time when the prefrontal cortex is undergoing large developmental change.

In addition to a gradual reduction or thinning of grey matter, adolescence is also marked by a gradual increase in white matter (Giedd, 2004; Sowell, Thompson, Holmes, Jernigan, & Toga, 1999). The timing of white matter maturation in the life span of a human is critical when considering plasticity. Myelination is the final stage of neural development and once it occurs, neural efficiency is significantly increased. However, there is a trade-off for efficiency, in that neural plasticity is lost (Lu et al., 2009). Indeed, animal models have shown that genetic knock-out animals who were designed to have degraded white matter retain their neural plasticity throughout life (Yang, Lin, & Hensch, 2012). Thus, the increases in white matter during adolescence and early adulthood, particularly in the frontal cortex, may signal that the period of plasticity is ending to replaced by a period of efficiency.

Functional MRI studies have provided additional insights into adolescent brain development. Resting state methods measure functional brain activity from participants without the presence of a task. The primary measure of interest is the stability of connectivity, or correlations, in spontaneously recorded brain activity. This measure is fairly robust to momentary fluctuations in cognition and whether eyes are open or closed. Using this method, researchers have identified the existence of stable brain networks across individuals (Dosenbach et al., 2007). Using a sample of over 200 participants between the ages

of 7 and 30 years old (a sizeable sample for an fMRI study), researchers have shown that stable networks exist in young children, but that developmental change across this span is largely characterized by the weakening of short-range functional connections between adult brains' major functional networks (Dosenbach et al., 2010). In other words, brain development during childhood and adolescence may generally be described as transitioning from shorter range connections to longer range ones. These findings seem consistent with the findings that layer II in cortical regions develop earlier than layer III, with the former responsible for local connections and the latter for establishing longer distance connections (Landing, Shankle, Hara, Brannock, & Fallon, 2002). Taken together, such changes may facilitate the increasing integral capabilities that emerge over development and allow for more efficient and cooperative neural processing that characterizes mature human cognition. In the following sections, we focus on how such neural changes operate across adolescence in several key behavioral domains.

NEUROPERCEPTUAL CHANGES DURING ADOLESCENCE (FACE PROCESSING)

Although the majority of sensory and perceptual development occurs very early in life, there is evidence of continued change that extends through adulthood (Cohen Kadosh, Johnson, Dick, Cohen Kadosh, & Blakemore, 2013; Germine, Duchaine, & Nakayama, 2011). The domains that exhibit refinement tend to be those skills with which humans exhibit behavioral expertise. A prime example is visual processing of human faces. Humans demonstrate profound expertise in face memory and recognition. Faces can be discriminated from other objects in less than 200 ms (Allison et al., 1994), perhaps even as early as 125 ms (Schendan, Ganis, & Kutas, 1998) or 100 ms (Liu, Harris, & Kanwisher, 2002) in adulthood. Because humans seem to process faces in a special manner, this has been considered a special type of cognitive process (Diamond & Carey, 1986) (Farah, Wilson, Drain, & Tanaka, 1998a; Turati, Valenza, Leo, & Simion, 2005). As a consequence, a debate about the etiology of face perception has ensued (Scott & Nelson, 2004).

By adulthood, most of us are face experts, although we usually take this skill for granted. Face perception is a skill that requires an extensive developmental period and continues to develop through adolescence (Carey, Diamond, & Woods, 1980; Cohen Kadosh & Johnson, 2007; Itier & Taylor, 2004). Faces are objects for which we have representational expertise, and face representations become more robust than nonface objects at a much faster rate from childhood to young adulthood (Tottenham, Leon, & Casey, 2006), arguably because of the massive amount of experience acquired with faces throughout development. The large literature on face processing in infants, children, and adolescents suggests that faces became special as a consequence of a *developmental process*.

Within the first 30 minutes of life, neonates will track a moving face farther than they will other patterns of equal contrast, complexity, and spatial frequency (Johnson, Dziurawiec, Ellis, & Morton, 1991), suggesting dedicated circuitry that creates a preference for faces at birth. Despite the initial preference for faces during infancy, such a preference does not signify expertise with faces per se (Cassia, Turati, & Simion, 2004). Face processing improvements during childhood and adolescence seem to be the result of adopting expert strategies for visual representation.

Adult Strategies

Adults excel at face processing as a result of their expert strategies used with faces, strategies that have been classified as configural, holistic, or second order relational strategies (Diamond & Carey, 1986; Farah, Wilson, Drain, & Tanaka, 1998; Rhodes, 1988). Adults' use of configural strategies interferes with their ability to identify the constituent parts of a composite face (top and bottom are different individuals (Young, Hellawell, & Hay, 1987), as evidenced by slower reaction times for identification of the top half of, for example, Richard Nixon's face when it is aligned with the bottom half of Prince Charles's face because alignment with Prince Charles's face changes the configuration of the entire face.

Configural processing refers to visually processing the object in its entirety, rather than focusing on its constituent parts. One thing that separates experts from novices is the experts' relative reliance on configural processing. For example, car, dog, greeble (i.e., computer generated artificial objects), and face experts (i.e., normal adults) all use configural information when discriminating their respective objects of expertise from each other (Gauthier & Tarr, 1997; Tanaka & Farah, 1993; Yin, 1969; Young et al., 1987). These visual strategies are orientation-specific (Carey, 1992), and adults perform worse on face identification tasks when the face stimulus is turned upside down relative to when it is right side up (Yin, 1969). This inversion effect is exaggerated for faces relative to other nonface objects and is often used as evidence that faces are

a special category of object processing. Although it is still debated when face processing reaches maturity (Freire & Lee, 2001; Itier & Taylor, 2004; Pellicano & Rhodes, 2003), most studies find that children under 10 years old are less sensitive to the configural properties of faces than those over the age of 10 years old are (Baenninger, 1994; Diamond & Carey, 1977; Flin, 1985; Tanaka, Kay, Grinnell, Stansfield, & Szechter, 1998). This ability improves until late adolescence (although it temporarily declines around 12 years old; Carey, 1992; Carey & Diamond, 1977).

It has been argued that children do not use configural strategies when processing faces (Carey et al., 1980; Diamond & Carey, 1977) because when asked to identify faces containing salient features, children under 10 are easily distracted from correct identification by any strong physical features. The argument is that since children do not appreciate the configural properties of an upright face, their performance is not facilitated when right side up relative to the inverted condition. Instead, children rely on featural processing in that they tended to use isolated features to make their decisions. Similarly, Pedalty and colleagues (1985) found that children under the age of 10 years use fewer features at one time when processing faces than adults do. The N170, an ERP component that is potentiated by whole faces, continues to develop until adulthood, whereas a mature N170 to eyes was present at 4 years old (Taylor, Edmonds, McCarthy, & Allison, 2001), suggesting that processing of constituent face parts develops first.

Puberty

Although age-related increases in face processing skills have been observed across a number of behavioral studies (Carey et al., 1980; Flin, 1985; Golarai et al., 2007; Goldstein, 1975; Lawrence et al., 2008), so has a performance dip in skills during the transition between childhood and adolescence. Some studies have found this shift in performance has been tied to pubertal changes (Carey et al., 1980), and yet others have not (Lawrence et al., 2008). Using a face-encoding task, prior work has suggested a role of puberty in face processing in that regardless of age, girls in the midst of puberty (summed score of 5–7 on breast and pubic hair development) encoded faces less efficiently than other girls (Diamond, Carey, & Back, 1983). It has been speculated that this dip was a result of pubertal changes that spur reorganization in the face processing system. Diamond et al. (1983) suggested that these data are evidence for genetic control of face processing skills and that this dip is necessary for adult processing (via a switch to mature configural processing) to develop. Alternative possibilities remain, however; puberty may be a period of life when attention to faces increases because of increased interest in faces (one's own or others'). Thus, the increased amount of time (and experience) looking at faces may contribute significantly to the reorganization of face-processing skills.

Neurobiological Correlates

Taken together, the behavioral findings suggest that the transition from childhood into adolescence is marked by an increased reliance on adult-like configural strategies for face processing. Face perception is supported by a distributed neural network (Haxby, Hoffman, & Gobbini, 2000). However, distinguishing faces from other object categories and from each other distinctively activates the fusiform gyrus (FG) (Haxby et al., 1991; Kanwisher, McDermott, & Chun, 1997; Puce, Allison, Asgari, Gore, & McCarthy, 1996; Sergent, Ohta, & MacDonald, 1992). Expert strategy use has been associated with recruitment of the FG, a functional region within the ventral occipitotemporal cortex portion of the ventral visual processing stream, which is especially sensitive to faces. It has a response that is greatest to whole faces (Tong, Nakayama, Moscovitch, Weinrib, & Kanwisher, 2000) and upright faces (i.e., is sensitive to inversion) (Kanwisher, Tong, & Nakayama, 1998) relative to partial or inverted faces. The response is slightly right lateralized, although the left fusiform gyrus also responds to faces. The fusiform gyrus response to faces is a reflection of high-level shape processing, not low-level feature extraction or an indication of increased visual attention (Kourtzi & Kanwisher, 2001).

The identification of a face-selective neural region has contributed to a long-standing debate in neuroscience, which is whether the brain represents information in modular form or in a distributed manner (Cohen & Tong, 2001). The modular view claims that the brain is organized into subcomponents that are dedicated to processing and representing a particular type of information in a domain-specific way (Kanwisher, 2000). The distributed view maintains that information is represented in a distributed manner such that regions of cortex process information in a domain-general way (Gauthier, Curran, Curby, & Collins, 2003; Haxby et al., 2001; Haxby et al., 2000). These responses overlap with each other, but are unique in their pattern of maximal and submaximal responses, such that the object category being viewed by the subjects could be discerned by other naïve subjects simply on the basis of the pattern of activity seen within the ventral occipito-parietal cortex. These patterns are

established, presumably, through experience, such that objects tune the cells in the ventral occipito-parietal cortex to respond with characteristic maxima as well characteristic minima. These minima are not captured by the typical image subtraction techniques (e.g., faces minus objects) that have been presented thus far. We will return to this issue of subtractive methodology in the next section on fusiform development.

Fusiform Development

Developmental fMRI studies have shown that responses of the fusiform gyrus in response to faces change across childhood and adolescence. When comparing responses to faces and houses (an example of subtractive methodology, a standard approach in fMRI data analysis), adolescents, but not younger children, showed significantly more activation in bilateral fusiform gyri for faces than for houses (Aylward et al., 2005). These types of contrasts are useful for obtaining an index of face selectivity (that is those voxels that show a stronger response for faces relative to another object). Using wide age ranges, researchers have identified large age-related change in FG responses to faces between 7 and 37 years old (Cohen Kadosh et al., 2013). Unlike many behavioral studies that had identified a shift in face processing skills, fMRI studies tend to show a linear increase in FG face selectivity with age.

Passarotti and colleagues (2003) investigated the development of response to faces relative to a location-processing task. Although no between-group statistics were performed on the imaging data, the authors suggest that the FG response to faces is more diffuse in children and becomes more focal with increasing age. These results are consistent with the notion that the representations of object categories are more overlapping at younger ages, comparison of the response to faces with response to another object category, like houses, would solidify those conclusions.

Other studies that have provided statistical age comparisons have confirmed an age-related increase in the spatial extent of face-selective suprathreshold activation within right FFA (Peelen, Glaser, Vuilleumier, & Eliez, 2009). Specifically, linear age-related increases were observed in the FFA selectivity to faces, and the age-related change was associated with an increasing perimeter of face-selectivity as age increased. The expansion of FFA into surrounding cortex was correlated with a behavioral improvement in recognition memory for facial identity (Golarai et al., 2007). A more focal, intense response in the FG to faces with increasing age is consistent with experiential tuning and refinement of the representation across adolescence. With development and experience, representations of face information (and other objects) should become more focal (or even appear modular if only their respective maxima are examined (reviewed in Burnett, Sebastian, Cohen Kadosh, & Blakemore, 2011).

Multivoxel pattern analyses (MPVA), which do not face the problem described earlier of subtractive methodology, detect differences between conditions with higher sensitivity than conventional univariate analysis by examining distributed patterns of activity across a swath of voxels. This approach has shown that the degree of FG distinctness for faces (over neural representations of other objects) is significantly lower in adolescents compared with adults (Golarai et al., 2007). The use of dynamic displays of faces has also been associated with an age-related increase in size of face-selective FFA between childhood and adolescence (Scherf, Behrmann, Humphreys, & Luna, 2007). In this study, no further changes in functional specificity for face processing were noted between adolescence and adulthood, although activity became more bilateral with age.

Thus, the neuroimaging evidence suggests that large changes occur in the neural representations of faces in the FG across childhood, adolescence, and adulthood. The changes appear to be linear, which is in contrast to many behavioral studies of face encoding and representation. It is possible that the resolution of the neural methods do not allow for the observation of shift-like changes in neural activity that are observed in behavioral data. Alternatively, it is possible that linear age-related changes in neural activity can nonetheless give rise to nonlinear changes in behavior. Another important change is that of changing connectivity between cortical and subcortical regions with the FG. Inputs into the FG may show large change from childhood into adolescence. For example, age-related changes in top-down modulation of FG connections have been observed from childhood through adulthood (Cohen Kadosh, Henson, Cohen Kadosh, Johnson, & Dick, 2010). Changes in connectivity will change the behavior of FG and hold promise in explaining much of the age-related variance for such a highly refined perceptual process that requires at least three decades to reach peak performance levels. The face processing literature has provided not only important information about how high-level visual perception develops across adolescence, but also more broadly provides a useful framework for considering how environmental factors and biological readiness interact to shape the social brain during adolescence. In the following section, we continue with this theme to consider the affective domain during adolescence.

NEGATIVE AFFECT-RELATED NEUROBIOLOGY DURING ADOLESCENCE

Large changes occur in processes related to negative affect across development, beginning in infancy and extending to adulthood. The common observation of adolescent moodiness warrants examination of changing negative affect neural circuitry during this time (Somerville, Jones, & Casey, 2010). Moreover, the increased incidence of mental illness, in particular clinical anxiety and depression (Kessler et al., 2005) with the onset of adolescence has led many neuroaffective researchers to target this developmental period.

The neurobiology of negative affect is complex, and typically involves interactions between subcortical and cortical regions. In adults, negative affect has been associated with differential activity in several cortical regions, most notably the prefrontal cortex and anterior cingulate cortex, and several subcortical areas, including the amygdala, hippocampus, periaqueductal grey, septal area, and ventral striatum. Among all of these regions, the amygdala's role in mediating negative affect has been most well characterized (particularly developmentally) and will be the focus of this section on negative affect.

The amygdala is a phylogenetically old structure (reviewed in Laberge, Muhlenbrock-Lenter, Grunwald, & Roth, 2006), present in all vertebrates in some form. The amygdala is in fact not one structure, but is composed of at least nine different nuclei; however, the ability to examine individual nuclei in humans is either extremely challenging or impossible, and therefore, most of the existing data in humans does not distinguish between nuclei. The amygdala rests subcortically and mediates emotional learning. One of the most well-characterized behaviors associated with amygdala function is Pavlovian fear conditioning, a basic form of learning by associating two events, one emotional and one neutral. However, the amygdala's role in affective behaviors may be broader and may include directing attention to emotionally relevant stimuli for the purposes of learning and maintaining arousal (Davis & Whalen, 2001).

The amygdala is also an ontogenetically old structure (reviewed in Tottenham & Sheridan, 2010). The basic architecture of the human amygdala is present at birth (Humphrey, 1968; Ulfig, Setzer, & Bohl, 2003), undergoes massive structural growth during early infancy (Gilmore et al., 2012; Uematsu et al., 2012), and then exhibits much more volumetric stability after this period. The same pattern has been identified in nonhuman primate models using longitudinal MRI methods (Payne, Machado, Bliwise, & Bachevalier, 2010). Despite these early structural developments, additional volumetric growth is also observed later around the transition into adolescence (Ostby et al., 2009). Boys who experience puberty at younger ages show greater amygdala volumetric growth than late maturers (Bramen et al., 2011), suggesting puberty might be one last period of additional growth. In fact, in this study, amygdala growth in boys was associated with circulating testosterone. There was no effect on pubertal timing in the girls, which may be a sign that the girls had already experienced their maturational amygdala growth by the ages examined in this study. This assertion is supported by the finding that amygdala volumes may reach a volumetric peak between 9 and 11 years old (with girls showing their peak 1.5 years earlier than boys) and may start to show normative decreases in volume after this age. Thus, maturation after puberty may be associated with declines in amygdala volume (Blanton et al., 2012).

Rodent Studies of Amygdala Development

Despite early structural development, rodent models have provided evidence that the amygdala remains functionally dormant for some time before exhibiting adult-like plasticity. For example, during the infant period, the amygdala is typically not recruited either by arousing stimuli (e.g., a male intruder; Moriceau, Roth, Okotoghaide, & Sullivan, 2004) or during odor-shock cued conditioning (Moriceau, Wilson, Levine, & Sullivan, 2006). This inactive functional period of the amygdala is due in part to the presence of the mother and in part to the developmentally normative low levels of glucocorticoid production, a neurohormone that is necessary for amygdala function onset (Moriceau et al., 2004). Glucocorticoids are the one of the primary products of the hypothalamic pituitary adrenocortical (HPA) axis, and seem to play a large role in the initial onset of amygdala functional engagement by environmental stimuli. This protracted developmental period in amygdala dormancy is striking considering the early structural development that occurs during the post-natal period.

Changes in amygdala reactivity have been observed beyond the infant period in rodent models. In rodent models, significant changes in amygdala-based function have also been identified in the juvenile (post-weaning, prepuberty) and adolescent (pubertal, preadulthood) period. As mentioned above, fear conditioning is a common paradigm used to test amygdala function. Cued fear conditioning pairs an unconditioned stimulus, for example a foot or tail shock, with a conditioned cue, for example a tone or an odor. This association relies heavily on amygdala-based learning. Freezing behavior is typically

used as an index of learned fear when conditioned stimuli are presented. During cued fear conditioning, freezing behavior (a threat-related behavior) is at its highest at early ages (during the juvenile period) and then attenuates to adult levels during adolescence (P35; Pattwell et al., 2012). This finding, although a behavioral index, may suggest a linear decrease in amygdala reactivity from the early juvenile period through adulthood during cued fear conditioning.

Contextual fear conditioning paradigms are designed to examine learning to express fear to a particular context that has been paired with an unconditioned stimulus. It is well understood that context conditioning relies on both intact amygdala and hippocampal-based learning (Zelikowsky, Hersman, Chawla, Barnes, & Fanselow, 2014). Using contextual fear conditioning paradigms, researchers have shown that unlike juvenile and adult mice, adolescent mice suppress expression of the learned fear response (Pattwell, Bath, Casey, Ninan, & Lee, 2011). The fear is clearly learned because retesting the adolescent mice in adulthood shows the emergence of the fear that was learned in adolescence. That is, the evidence seems to suggest that although adolescent mice learned the fear association with a particular context, the animals do not express the fear behaviorally during adolescence (i.e., via freezing measures). The source of fear learning expression suppression during adolescence was blunted synaptic activity in the basal amygdala and decreased intracellular signaling in the hippocampus. Thus, the fear conditioning literature taken together would suggest that, at least in the rodent, the amygdala exhibits very little reactivity during infancy, after which is exhibits a robust developmental switch to very high levels during the juvenile period, and attenuates across development, showing adult-like levels during cued fear conditioning, and may exhibit a suppression during adolescence (during contextual fear conditioning).

Human Studies of Amygdala Development

Fear conditioning studies have been used to study amygdala function in human adolescents. Relative to adults, adolescents showed greater amygdala recruitment during fear learning, although behaviorally, they reported less discrimination between threat and safety cues (Lau et al., 2011). In another study with only adolescent participants, those who reported increased fear showed amygdala increases during both the threat condition (aversive puffs of air to the eye) as well as the safe condition (Monk et al., 2003). These responses were lateralized, with the right amygdala being recruited for the threat condition and the left for the safety condition. This study showed that for adolescents, learning that certain cues are *not* associated with aversive puffs of air to the eye (i.e., safe conditions) is paralleled by recruitment of the amygdala in adolescents.

Although in many ways, using conditioning paradigms to examine amygdala learning in adolescence is ideal, the overwhelming majority of information about amygdala function in adolescence comes from using facial expression stimuli. In part, the challenge of using fear conditioning with developmental samples may limit their use. Facial stimuli, in contrast, provide a child-friendly means of obtaining reliable amygdala increases. As pointed out by Whalen et al., (2013), facial expressions are naturally conditioned stimuli that allow researchers to investigate normative variations in amygdala function. However, caution must be used when interpreting developmental amygdala findings in response to emotional stimuli because the nature of the neural response may interact with developmental experiences with those stimuli.

The use of facial expressions as stimuli has led to large advances in our understanding of human amygdala development. For example, several studies have shown increased amygdala response to facial expressions in adolescents relative to adults (Gee, Humphreys, et al., 2013; Guyer et al., 2008; Hare et al., 2008; Monk et al., 2003; Swartz, Carrasco, Wiggins, Thomason, & Monk, 2014; Vink, Derks, Hoogendam, Hillegers, & Kahn, 2014), with some studies showing higher and some showing lower reactivity in adolescence than childhood. This age related difference has been observed for facial expressions that have been masked and therefore not consciously perceived (Killgore & Yurgelun-Todd, 2007), suggesting that the amygdala during adolescence is highly sensitive to emotional cues even when presented below awareness thresholds. There is some evidence that pubertal development may drive some of these changes, although the findings are mixed, with some evidence for increased amygdala response with increasing pubertal change (Moore et al., 2012) and some for decreased amygdala response with increasing pubertal development (Forbes, Phillips, Silk, Ryan, & Dahl, 2011).

Some of the differences across studies may be attributed to differences in facial stimuli used. For example, longitudinal changes in amygdala reactivity were not observed from 10 years old to 13 years old when averaged across emotional expressions, but were observed in response to sad faces (Pfeifer et al., 2011). Similarly, a linear decrease with age was observed in response to fear faces (Gee, Humphreys, et al., 2013; Swartz et al., 2014; Vink et al., 2014), whereas adolescent-limited hyperactivity of the

amygdala has been observed in response to facial emotions when averaged across fear, happy, and calm faces (Hare et al., 2008).

The nature of the task may matter when considering amygdala reactivity during adolescence. For example, when the identifying emotional expressions in the context of a behavioral regulation task (Hare et al., 2008), inhibitory control processes may interact in important ways with amygdala signal. Indeed, the prefrontal cortex, a primary mediator of regulatory behaviors, undergoes significant change across development (Alahyane, Brien, Coe, Stroman, & Munoz, 2014; Casey, Giedd, & Thomas, 2000; Raznahan et al., 2011; Somerville et al., 2011). These changes are often reflected in changes in connectivity between PFC and the amygdala (discussed next).

Developmental Change in Amygdala–PFC Connectivity

Connections between the prefrontal cortex, in particular the medial prefrontal cortex (mPFC) support regulation of amygdala activity. Human neuroimaging studies in adults have revealed both structural (Kim & Whalen, 2009) (Johansen-Berg et al., 2008; Swartz et al., 2014) and functional (Gabard-Durnam et al., 2014; Hare et al., 2008; Roy et al., 2009) connections between the amygdala and mPFC similar to those identified in animal models (Amaral et al., 1992; Croxson et al., 2005; Ghashghaei, Hilgetag, & Barbas, 2007). The identification of inverse coupling between amygdala and mPFC activity in many fMRI studies may indicate top-down connections with a theorized regulatory role of the mPFC in controlling amygdala reactivity (Hare et al., 2008; Hariri, Mattay, Tessitore, Fera, & Weinberger, 2003; Kim, Somerville, Johnstone, Alexander, & Whalen, 2003; Pezawas et al., 2005). Interactions between the amygdala and mPFC are fundamental to emotion regulation (Delgado, Nearing, Ledoux, & Phelps, 2008; Goldin, McRae, Ramel, & Gross, 2008; Lieberman et al., 2007; Ochsner et al., 2004; Wager, Davidson, Hughes, Lindquist, & Ochsner, 2008) and extinction (Delgado et al., 2008; Hartley, Fischl, & Phelps, 2011; Milad et al., 2007; Phelps, Delgado, Nearing, & LeDoux, 2004) in adults. Moreover, individual differences in the strength of amygdala–mPFC functional connectivity have predicted greater amygdala habituation to affective stimuli (Hare et al., 2008), more effective emotion regulation (Banks, Eddy, Angstadt, Nathan, & Phan, 2007), and lower temperamental anxiety (Pezawas et al., 2005; Monk, 2008).

Evidence from nonhuman animal studies has confirmed the presence of top-down connections from the mPFC to the amygdala (Aggleton, Burton, & Passingham, 1980; Amaral & Insausti, 1992; Carmichael & Price, 1995; Ghashghaei & Barbas, 2002; Ghashghaei et al., 2007). The mPFC likely regulates through input to the basolateral nuclei of the amygdala and the intercalated cells, which inhibit amygdala activity by regulating inputs from the basolateral nuclei to the central nucleus (Akirav, Raizel, & Maroun, 2006; Milad & Quirk, 2002).

In humans, the prefrontal cortex exhibits protracted development and connections between the amygdala and the prefrontal cortex undergo large developmental change across middle childhood and adolescence (Gee, Gabard-Durnam, et al., 2013; Gee, Humphreys, et al., 2013; Perlman & Pelphrey, 2011; Swartz et al., 2014). In these studies, the nature of connectivity differs between children and adolescents, suggesting reorganization in the circuitry between these two time points. Correspondingly, regulation of emotion improves across this period and is mediated by the switch in connectivity (Gee et al., 2013). Adult-like connections between amygdala and mPFC are present during adolescence and are correlated with regulatory ability (Hare et al., 2008), a finding suggesting that the circuitry is functional, although the strength of the connections increases from adolescence to adulthood. Illustrating the immaturity of these connections during adolescence, Monk et al., (2003) showed that external constraints on affective processing (task demands) moderated the difference between adults' and adolescents' amygdala reactivity to emotional faces. That is, age-related differences were not observed when the task focused attention to a nonemotional feature (e.g., nose width of the stimulus), but adolescents' amygdala reactivity increased above adults when attention was not constrained by the task, suggesting that regulatory ability during adolescence is yet immature when compared with adults.

This interpretation of the functional MRI data has been supported by rodent data examining the development of the prefrontal cortex in emotional tasks. Extinction learning refers to a decrease in a behavioral response to a learned fear association, and is believed to be a new memory that is learned, which actively suppresses the original learned fear. In this way, extinction learning is a form of emotion regulation in that the animal learns to regulate its emotional response. In adult animals, this new learning is dependent on inputs from the medial prefrontal cortex, specifically the infralimbic cortex (IL; Milad & Quirk, 2002). In young rats, it has been shown that extinction learning is independent of the IL, and once the animal enters the juvenile period (prepubertal), extinction learning begins to be mediated by the IL as in the adult. Inactivation of IL in infant rats does not

impair extinction learning as it does in the adult and the juvenile animal (Kim, Hamlin, & Richardson, 2009; Kim & Richardson, 2009). This qualitative difference in the neural mechanics involved in extinction training in very young rats mirrors the qualitatively different patterns of amygdala–mPFC connectivity observed in young children (Gee et al., 2013), suggesting that the period before adolescence (i.e., childhood/juvenile period) is a developmentally unique period for amygdala–mPFC connectivity.

During adolescence, the circuitry beings to resemble to adult, although adolescent rats do not show complete maturation of amygdala–mPFC circuitry. The circuitry is more mature than the infant and juvenile, but it is not used as effectively as in the adult. Using extinction learning paradigms, it has been shown that adolescents exhibit decreased learning compared with adults, and notably compared with juveniles (Kim, Li, & Richardson, 2011; Pattwell et al., 2011; Pattwell et al., 2012). Pattwell et al., (2012) also showed that this decrease is present in adolescent humans, who did not show the typical decrease in galvanic skin conductance following extinction training. This decrease in extinction learning seems to be a suppression during adolescence, as extinction that is learned during adolescence (and is not expressed in adolescence) will be expressed later in life (Pattwell et al., 2012). In the IL, adolescent rats show decreased levels of phosphorylated mitogen-activated protein kinase (pMAPK), part of an intracellular cascade that is involved in producing long-lasting changes in synaptic efficacy. However, with increased training pMAPK increased in the IL in adolescents and extinction learning was achievable (Kim, Li, et al., 2011) . These findings are highly consistent with those from human adolescents who exhibit amygdala–mPFC connectivity that is adult-like, but still less robust than the adult (Gee et al., 2013).

Early-Life Adversity and Amygdala–PFC Development During Adolescence

Adversity early in life, particularly when it involves caregiving, is a potent stressor for the developing human (Fisher, Van Ryzin, & Gunnar, 2011; Gunnar & Fisher, 2006; Lewis, Dozier, Ackerman, & Sepulveda-Kozakowski, 2007; Tottenham, 2012). Stress can be defined as exposure to events that negatively impact emotional or physical well-being to an extent that exceeds an individual's ability to cope (Gunnar & Quevedo, 2007). A large clinical literature has established a strong link between early-life adversity and subsequent deficits in emotion regulation processes (e.g., anxiety and depression; Cicchetti, Rogosch, & Oshri, 2011; Dackis, Rogosch, Oshri, & Cicchetti, 2012; Valentino, Cicchetti, Rogosch, & Toth, 2008) that in adults and older adolescents have been associated with alterations in amygdala–PFC neurobiology (Burghy et al., 2012; Herringa et al., 2013; Kim, Loucks, et al., 2011). These deficits often emerge during the transition from childhood into adolescence, with a sharp increase in clinical anxiety and depression emerging after age 10 years (Angold & Rutter, 1992; Kessler et al., 2005; Kessler & Magee, 1993).

Although biological responses to acute stressors are adaptive for the organism in that they allow for management of potential challenges and increase the tone of stress systems that facilitate future stress regulation (Gunnar & Quevedo, 2007; McEwen, 2000), chronic exposures can overwhelm regulatory systems and ultimately result in mental health difficulties. These processes have been examined extensively in nonhuman animal studies of early-life adversity, which have frequently demonstrated that the amygdala is targeted by early caregiving adversity. For example, as reviewed in Tottenham & Sheridan (2010), the amygdala is particularly sensitive to early-life adversity perhaps because of its early development (Calabrese, Badea, Watson, & Johnson, 2013; Gilmore et al., 2012; Payne, Machado, Bliwise, & Bachevalier, 2010; Ulfig et al., 2003), thus being functionally available as a substrate for stress effects. At the molecular level, the amygdala is rich with stress hormone receptors starting at an early age (e.g., post-natal day 2 in the rat (Avishai-Eliner, Yi, & Baram, 1996; Fenoglio, Brunson, Avishai-Eliner, Chen, & Baram, 2004; Vazquez et al., 2006) and may even be more susceptible stress at early ages compared with adulthood. This position is supported by the findings that the amount of corticotropin releasing hormone (CRH; a stress hormone present in the central nervous system) needed to induce amygdala-mediated seizures in the developing rat is 200 times smaller than in the adult animal (reviewed in Baram & Hatalski, 1998).

CRH is a major hormone produced within the hypothalamic-pituitary-adrenocortical axis (HPA), a major stress regulatory axis of mammals. Psychosocial stress can adversely impact brain development largely through dysregulated activity of the HPA axis (reviewed in Loman, Gunnar, Early Experience, & Neurobehavioral Development, 2010). The activity of the HPA axis leads to peripheral (systemic) glucocorticoid increases via hypothalamus, pituitary, and adrenal gland activity and increases in central CRH (Makino, Gold, & Schulkin, 1994). Eventually peripheral glucocorticoids make their way to the brain by readily passing through the blood–brain barrier (Pardridge, Eisenberg, Fierer, & Kuhn, 1986) and binding

to receptors in numerous brain regions, including the amygdala. In the rodent (Moriceau, Roth, & Sullivan, 2010; Sapolsky & Meaney, 1986), and possibly in the human as well (Gunnar & Donzella, 2002), early life may represent a stress hyporesponsive period, during which time it is unlikely that a young animal will mount a full glucocorticoid response to a stressor. Because the developmental onset of amygdala function relies on increases in glucocorticoid production, the amygdala remains functionally dormant during this period under typical caregiving circumstances (Moriceau, Shionoya, Jakubs, & Sullivan, 2009; Shionoya, Moriceau, Bradstock, & Sullivan, 2007; Shionoya et al., 2006).

When caregiving conditions are suboptimal, as in the cases of abuse and neglect, the activity of the HPA axis changes, such that in the rodent infant, the stress hyporesponsive period comes to a premature end (and the infant exhibits glucocorticoid increases in response to environmental threats (Shionoya et al., 2006). As a result of increased glucocorticoid production under stressful conditions, the amygdala's functional dormancy ends prematurely (Moriceau & Sullivan, 2006; Moriceau et al., 2006). In other words, caregiving adversity (either abuse or maternal deprivation) has been shown to accelerate amygdala development as well as extinction learning in the rat (Callaghan & Richardson, 2011, 2012; Moriceau et al., 2006; Ono et al., 2008). There are remarkable parallels across species such that in humans too, there is evidence of accelerated amygdala–mPFC development following early caregiving adversity (Gee et al., 2013). This acceleration may be an adaptive response of the limbic-cortical circuitry to environmental cues that early maturation of defensive systems is warranted and might increase short-term survival. Although speculative, this acceleration may be seen as a short-term resilience factor (although it may have long-term costs).

The interpretation of this atypical behavioral and neural development as evidencing an ontogenetic adaptation (such that development is accelerated to meet the short-term needs of the young animal or human) has been described in the literature on resilience following early adversity (e.g., Cicchetti & Blender, 2006). The resilience literature is founded on the observations that not all individuals exhibit maladaptive developmental outcomes following exposure to adversity, and some even show great strength and gains in the face of adverse environments. One important question for future research to address is whether the stress-induced phenotypes described in this section are the neurobiological sources of resilience observed at the level of behavior. These types of interpretations are distinct from traditional views of early adversity influences in that they highlight the organism's adaptive response to environmental cues to develop in ways to maximize its performance in that context (even if the context is adverse).

In slightly older rats that have been exposed to maternal deprivation (post-natal day 17; prepubertal juveniles), similar accelerating effects of caregiving adversity have been observed for amygdala development. Typically, young rats exhibit infantile amnesia for learned fear memories; that is, typical juvenile rats exhibit forgetting of fear associations learned 10 days earlier. However, juvenile rates with a history of maternal separation exhibited near perfect retention of the memories, and it was suggested that early-life adversity removes the brakes on infant fear memories (Callaghan & Richardson, 2012). This effect was replicated by testing rats whose mothers drank the glucocorticoid cortiscosterone, who retained fear memories for up to a month—a finding that suggests premature fear learning is mediated by HPA axis activity.

Adversity that occurs in infancy can have long-term effects that are observable into adolescence, although the behavioral phenotypes in adolescence may differ compared with earlier ages. For instance, in rodents, exposure to either maternal abuse (induced by providing mothers with insufficient bedding) or exposure to olfactory classical conditioning in infancy is followed by depressive behaviors in adolescence (that were not observable at earlier ages) (Raineki, Cortes, Belnoue, & Sullivan, 2012; Sevelinges et al., 2011). Depressive behaviors were measured as willingness to continue swimming in a forced swim test, and animals with a history of early adversity gave up swimming earlier than controls. This giving up behavior was shown to be amygdala mediated such that temporary deactivation of amygdala rescued the depressive behaviors. These findings suggest that adolescence may be a period when emotional behaviors that result from early-life adversity manifest differentially than at younger ages.

Adolescence in humans is also a period that has been shown to reveal new emotional phenotypes following early adversity. Unlike anxiety, which tends to be elevated in both young children and adolescents following early-life neglect (postinstitutionalized [PI] children), depression symptoms are elevated in adolescents relative to children (Goff et al., 2013), mirroring epidemiological reports showing mood disorders exhibit a sharp rise after age 10 years. In a separate group of PI children adopted from Romania, parents reported that emotional problems exacerbated once children transitioned into adolescence (Colvert et al., 2008).

Given that rats and humans are both (semi-)altricial species that depend critically on species-typical caregiving for optimal development (reviewed in Cicchetti & Valentino, 2006; Tottenham, 2012), it is likely that early-life caregiving adversity operates through similar neurobiological pathways in both species. Children who have been exposed to maltreatment have exhibited alterations in HPA axis activity as measured by the glucocorticoid cortisol (Hart, Gunnar, & Cicchetti, 2008), particularly when the maltreatment occurred early in life (compared with later life maltreatment; Cicchetti, Rogosch, Gunnar, & Toth, 2010). The nature of HPA axis dysregulation seems to differ by the nature of adversity, as it has been found that children with a history of severe physical neglect tend to show very low levels of morning cortisol, whereas children with a history of severe emotional maltreatment tend to show elevated levels of morning cortisol (Bruce, Fisher, Pears, & Levine, 2009). Children with a history of extreme neglect in the form of institutional care (e.g., orphanages) have also been shown to exhibit very low levels of morning cortisol (Koss, Hostinar, Donzella, & Gunnar, 2014). These findings suggest that although patterns may differ as a function of type of adversity and timing, the HPA axis in developing humans is sensitive to adverse caregiving during development.

PI youth have also exhibited altered amygdala development, as has been demonstrated in the developing rodent. Using structural MRI, researchers have shown that youth who had experienced institutional care through their first birthday (and then been subsequently been adopted into stable families) exhibited enlarged amygdala volumes relative to peers (Mehta et al., 2009; Tottenham et al., 2010) (although see Hanson et al., 2015; Sheridan, Fox, Zeanah, McLaughlin, & Nelson, 2012)). Enlarged amygdala volume in PI youth was associated with greater internalizing problems and trait anxiety by parent report as well as poorer behavioral regulation in the context of negative emotional information (Tottenham et al., 2010). Amygdala enlargement was observed in a separate study examining children (10-year-olds) who had been exposed to maternal depression, suggesting that low maternal interaction had served as a stressor for the developing infant even within a more normative range (Lupien, McEwen, Gunnar, & Heim, 2009). Functional MRI showed that amygdala reactivity was also elevated in PI youth (Gee, Gabard-Durnam, et al., 2013; Tottenham et al., 2011), and amygdala hyperactivity mediated group differences in eye contact (Tottenham et al., 2011). That is, youth with greater elevations in amygdala reactivity tended to exhibit decreased eye contact, which may serve as a short-term emotion regulation strategy to combat emotional overarousal that accompanies direct face-to-face contact. Although speculative, hyperactivity in the amygdala observed in this study may reflect an earlier development of amygdala function that has been observed in rodent studies of early adverse care.

More normative variations in care have also been shown to impact amygdala-PFC development. In a longitudinal study, early-life maternal stress measured when the child was 4 years old was associated with altered functional connectivity between the amygdala and prefrontal cortex at 18 years old. This association was fully mediated by salivary cortisol obtained during childhood (Burghy et al., 2012). Importantly, these associations were only observed in female participants suggesting that the circuitry between amygdala and PFC may be more sensitive to early-life stress in females and may explain increased rates of internalizing problems commonly found in females.

Developmental changes in the neurocircuitry supporting negative affect can be observed well into childhood and adolescence. Some changes are quantitative in nature and some exhibit qualitative shifts across this age span. These changes appear to define sensitive periods of development, or at the very least, developmental moments of increased plasticity. Adverse experiences that occur in infancy or childhood have significant effects on negative affect and associated neurobiology that can be observed in adolescence. Important directions for future research will include continued examination and identification of human sensitive periods that inform outcomes in adolescence.

MODELS OF ADOLESCENT RISK TAKING AND REWARD-SEEKING BEHAVIOR

Many experts in the field of adolescent development have written about the adolescent paradox (e.g., Chick & Reyna, 2011; Dahl, 2004): the notion that while adolescents are old enough to know better (Chick & Reyna, 2011) and are stronger, bigger, and faster and smarter than children (Dahl, 2004), they are at their lifetime peak of engaging in emotionally driven, impulsive, and potentially harmful behaviors. This paradoxical phenomenon is often explained by dual process models (Galván, 2012). There are many variations of the standard dual process model, but most distinguish between a fast, automatic, unconscious way of processing information and a slow, deliberative, conscious and advanced way of processing (Chick & Reyna, 2011; Evans, 2008). These systems or

processing methods have also been called impulsive versus reflective (Strack & Deutsch, 2004), holistic versus analytic (Nisbett, Peng, Choi, & Norenzayan, 2001), heuristic versus analytic (Evans, 2006) and experiential versus rational (Epstein, 1994).

From a neurobiological standpoint, analogous categories have been made in the form of β (which reflects weight placed on outcomes that are immediate) and δ (which represents delayed outcomes) systems, mediated by limbic structures and lateral prefrontal cortex, respectively (McClure, Laibson, Loewenstein, & Cohen, 2004), and an impulsive amgydala-based system and reflective prefrontal system (Bechara, 2005). Specific to neurobiological development in adolescence, overlapping theories have been described: a subcortical versus cortical system (Casey et al., 2008), an early emerging bottom-up system that expresses exaggerated reactivity to motivational stimuli and later maturing top-down cognitive control system (Casey & Jones, 2010) and a socio-emotional versus regulatory system (Steinberg, 2008). While these models have incorporated emotion synonymously with the bottom-up, automatic system, it is worth noting two models that have taken a more nuanced view of the role that emotion can play in behavior. Reyna and colleagues have proposed and put forth empirical evidence in support of the fuzzy trace model, which does not assume that the "influence of emotion on decision making is always primitive and usually maladaptive" and instead aims to integrate aspects of emotion that may lead to more mature choices (Chick & Reyna, 2011. p. 407). For instance, they posit that in mature decision makers quick, valenced choices (good–bad, approach–avoid) are not simple-minded but rather are the product of experience and insight. They also argue that mood can influence choices (e.g., negative feeling states encourage detailed representations of options and longer time to make a choice while positive feeling states tend to yield quicker, reactive processing; Storbeck & Clore, 2005). Finally, they note that arousal, or physiological reactivity, interacts with neural systems to influence decision making (Reyna & Rivers, 2008). The triadic model is another well-known model of adolescent motivated behavior (Ernst & Fudge, 2009). The model comprises three neural nodes that each holds functional control over distinct cognitive constructs: approach (striatum); avoidance (amygdala); and behavioral regulation (prefrontal cortex). Involvement of these systems depends on the context in which the motivated behavior occurs. For instance, in appetitive contexts, the model predicts that amygdala signal will be weak and does not elicit a withdrawal response while the striatal response is robust, eliciting an approach response with minimal input from the relatively immature regulatory system (Ernst, Romeo, & Andersen, 2009).

The models discussed in this section are beginning to help us explain and predict adolescent behavior but they are under constant refinement. New empirical evidence and reassessment of the interpretations and implications of the models help fine-tune how the field conceptualizes adolescent behavior and the role that changing neural systems play in normative development. For instance, recent calls have asked the field revisit the notion that cognitive control capacity in adolescents can be enhanced or impaired based on contextual factors (Somerville & Casey, 2010), note the need to place greater emphasis on how increased behavioral and neural sensitivity to affect may help confer adaptive advantages (Crone & Dahl, 2012) during this transitional developmental window and encourage network-based approaches that will help disentangle the complexity of adolescence behavior (Pfeifer & Allen, 2012). It is clear that no one model will completely explain adolescence but collectively, these models may set the stage for understanding the role that changing neurobiological systems play in development.

Changes in Reward Sensitivity Across Adolescence

Adolescence is characterized by heightened reward sensitivity. Relative to children or adults, converging evidence suggests that adolescents exhibit increased behavioral motivation to obtain rewards and greater arousal in response to rewards (Galván, 2013). In almost every measurable domain, adolescents exhibit greater interest and sensitivity to rewards than children or adults. For instance, there is a peak in reward and sensation-seeking behaviors (Steinberg et al., 2009), sensitivity to monetary incentives (Smith, Xiao, & Bechara, 2011) and social rewards (Chein, Albert, O'Brien, Uckert, & Steinberg, 2011), and even greater reactivity to sweet substances in mid-adolescence (Galván & McGlennen, 2013; Post & Kemper, 1993). These findings led to an explosion of interest in characterizing the neurobiological correlates that underlie these striking behavioral changes across adolescence, particularly as they relate to increased risk for psychopathology and addiction.

Dramatic increases in the onset of psychiatric disorders occur during the adolescent period. A United States population-based study of over 9,000 adults revealed that the median age of onset for any psychiatric disorder was 14 years (Kessler et al., 2005). Notably, prevalence of onset is greatest in disorders in which dysfunctional motivation or reward-related processes are implicated (Fairchild,

2011), including depression and substance use disorders. A recent survey of 10,123 adolescents (aged 13–18 years) by the National Institutes of Mental Health (Merikangas et al., 2010) reported that the prevalence of major depressive disorder increased two-fold over the adolescent period, while the rate of substance use disorders were six times higher in 17–18 year olds relative to 13–14 year olds (Fairchild, 2011). As will be discussed, emerging evidence suggests that, indeed, adolescents afflicted with psychiatric disorders exhibit aberrant recruitment of reward circuitry.

Neurochemical Changes

Reward sensitivity appears to be conserved across evolution, as many mammalian species, including rodents and nonhuman primates, show similar patterns of reward-related behavior as humans (Spear, 2011). Studies in juvenile rats show an inverted U-shaped developmental trajectory in the realms of reward and novelty seeking (Douglas, Varlinskaya, & Spear, 2003), risk-taking social interactions (Douglas, Varlinskaya, & Spear, 2004), and consummatory behavior (Friemel, Spanagel, & Schneider, 2010; Spear, 2011). For instance, adolescent rats are more sensitive than adult rats to the hedonic properties of sucrose (Wilmouth & Spear, 2009). They also demonstrate enhanced behavioral responses to novelty (Douglas et al., 2003) and social peers (Varlinskaya & Spear, 2008) compared with adult rats. The increased proclivity toward drugs in human adolescents versus adults is also observed in rats (Brenhouse & Andersen, 2008; Torres, Tejeda, Natividad, & O'Dell, 2008) and nonhuman primates (Nelson et al., 2009). This conservation of reward sensitivity has facilitated our understanding of the neurochemical and neurobiological correlates of this characteristic adolescent behavior. As described below, most studies are driven by the hypothesis that changes in dopamine circuitry account for reward-seeking behavior in adolescence.

Dopamine is the neurotransmitter most commonly linked to reward, as it is essential for detecting, responding to, and learning from rewarding events (Schultz, Dayan, & Montague, 1997). Burst firing of dopamine neurons occur in dopamine target regions in response to rewards (Roitman, Wheeler, Wightman, & Carelli, 2008), social interactions (Robinson, Heien, & Wightman, 2002) and unexpected events or stimuli (Takahashi et al., 2009). Importantly, this neurochemical reactivity to reward leads to increased approach behavior (Robinson, Zitzman, Smith, & Spear, 2011).

Much of the neurochemical development of the dopamine systems has been performed in rodent models. These models have shown that the mesocorticolimbic dopamine system undergoes significant changes during adolescence. In the striatum, dopamine levels increase during adolescence (Andersen, Dumont, & Teicher, 1997; Teicher, Andersen, & Hostetter, 1995) and dopamine D1 and D2 receptor expression in ventral striatum (VS) increases from pre-adolescence to adolescence, with some studies suggesting that binding in adolescence is higher than in adulthood (Doremus-Fitzwater, Varlinskaya, & Spear, 2010). Several reports have also noted that there is dopamine receptor over-production followed by pruning during adolescence (Teicher et al., 1995). Striatal dopamine receptor binding of D1 and D2 receptors peaks in adolescence at levels that are about 30–45% greater than those seen in adulthood (Tarazi, Tomasini, & Baldessarini, 1998, 1999; Teicher et al., 1995). Using autoradiography in male and female rats, Andersen et al. (1997) showed a sexual dimorphism of this effect, such that adolescent males had greater overproduction (approximately 4.6-fold) and elimination of striatal D1 and D2 striatal receptors than adolescent females (Andersen et al., 1997). Bolanos et al. (1998) showed that striatal slices from adolescent rat brain were more sensitive to the dopamine uptake inhibitors cocaine and nomifensine than adults (Bolanos, Glatt, & Jackson, 1998). These neurochemical and structural changes seem to have functional significance; functional studies show that compared with adults, the adolescent rat brain releases more dopamine if stimulated by environmental or pharmacological challenges (Laviola, Pasucci, & Pieretti, 2001), despite reduced dopamine release in basal conditions (Andersen & Gazzara, 1993; Stamford, 1989), and exhibit longer sustained dopamine release following a social interaction (Robinson et al., 2011).

A similar pattern of dopaminergic reorganization during adolescence is observed in prefrontal cortex, albeit with a more protracted elimination period (Andersen, Thompson, Rutstein, Hostetter, & Teicher, 2000). Confocal microscopy has revealed that retrogradely traced cortical output neurons in the prefrontal cortex express higher levels of D1 receptors during adolescence than older or younger rodents (Brenhouse, Sonntag, & Andersen, 2008). Similar U-shaped trajectories are observed in the firing rates of dopamine neurons (McCutcheon & Marinelli, 2009) and the number of dopamine neurons that are activated in anticipation of reward (Sturman & Moghaddam, 2012), peaking in adolescence. Together, these data suggest that during adolescence rewarding events may result in larger dopamine release, when compared with adults (Laviola, Macri, Morley-Fletcher, & Adriani, 2003).

Neurobiological Correlates

To investigate the neural phenotype of heightened reward sensitivity in humans, researchers typically pair fMRI with computer tasks that have a rewarding component. From these studies, we have learned that during adolescence there is an exaggerated neural activation in the VS to reward (Ernst et al., 2005; Galván et al., 2006; Geier, Terwilliger, Teslovich, Velanova, & Luna, 2010; van Leijenhorst, Zanolie, et al., 2010). However, it is important to note that some reports have reported diminished activation to reward (Bjork, Smith, Chen, & Hommer, 2010) and either hyperresponding or hyporesponding during different stages of reward processing (e.g., anticipation of reward versus reward receipt) (Geier & Luna, 2009). Plausible explanations for differences across studies as well as implications for adolescent behavior are reviewed elsewhere (Galván, 2010).

Our own work suggests nonlinear patterns of striatal development. In an fMRI study, children, adolescents, and adults performed a youth-friendly computerized reward task in which they were presented with three cues that were each associated with increasing monetary values (small, medium, and large) (Galván et al., 2006). The task was similar to a reward learning task previously used in monkeys to show that dopamine firing patterns temporally shift to track the most meaningful information in the task (Fiorillo, Tobler, & Schultz, 2003). In brief, the monkey work showed that in the beginning of the task, the dopamine response is greatest when reward is received; however, as the animal learns that a particular cue predicts the reward outcome, the dopamine neurons become increasingly more responsive to the reward-predicting cue. By the end of the experiment the dopamine neurons are minimally responsive to the actual reward delivery and most responsive to the cue (Fiorillo et al., 2003). In our study, all age groups showed strong VS activation to the reward outcome. However, interesting developmental differences emerged when we examined how the temporal dynamics of the task influenced VS activation. By the end of the experiment, adolescents showed the overall greatest activation to the large monetary reward, while adults showed the least. However, within the adult group, the greatest activation was to the cue and not to the actual reward outcome, which paralleled the monkey data. Particularly interesting is that these neural patterns of activation mapped onto the behavioral differences between groups. In the beginning of the experiment, none of the groups showed differences in reaction time (RT) to the three reward types. However, by the end of the experiment, adults had learned to discriminate between them, as evidenced by faster RT to the large reward and slowest RT to the small reward. Adolescents became significantly slower to the small reward and children continued to show no differences in reaction between the three reward types. From this study, we concluded that neural discrimination of reward value is paralleled by changes in behavior and that adolescents show heightened VS sensitivity to reward compared with children and adults (Galván et al., 2006).

Other work supports this hyperresponsive view as well. For example, a probabilistic monetary reward task was used to show that adolescents demonstrated significantly more VS activation than adults when they earned money (Ernst et al., 2005). It has also been shown that adolescents exhibit heightened VS activity both in anticipation of reward (Geier et al., 2010; Jarcho et al., 2012) and to expected (van Leijenhorst, Moor, et al., 2010) and unexpected (J. R. Cohen et al., 2010) reward outcomes. Even in response to liquid rewards (e.g., sugar water), the adolescent brain shows greater striatal activation than adults (Galván & McGlennen, 2013). Together, these findings demonstrate that across different labs, methodological techniques, participant samples, and reward tasks, the adolescent brain is hyperresponsive to one or more aspects of reward processing, compared with other age groups. This unique sensitivity to reward is behaviorally meaningful, as it has been tied to task performance as well as real-world reward sensitivity (e.g., drug use, thrill-seeking behavior).

Individual Differences in Reward Sensitivity

It is important to note that not all adolescents exhibit heightened reward sensitivity. In fact, the likelihood of reward seeking behavior is largely influenced by individual differences, including reward availability, gender, and personality traits. For instance, reward-seeking and risk-taking behaviors are more frequent in individuals with elevated novelty and sensation seeking (Rao et al., 2011) and in those who report greater risk taking among their peers. More recently, studies using fMRI have suggested that neural variability may also help explain individual differences in reward sensitivity.

Neuroimaging data in adults shows that individual differences in activation of the VS predict reward-related risks (Kuhnen & Knutson, 2005). For example, individuals who exhibit greater VS activation in response to appetitive cues are subsequently more likely to make risky choices to obtain monetary reward (Kuhnen & Knutson, 2005), to consume unhealthy snacks (Lawrence, Hinton, Parkinson, & Lawerence, 2012), to gain weight and report

greater sexual desires (Demos, Heatherton, & Kelley, 2012). Recent work using positron emission tomography, a technique used to examine dopamine function in adult humans (Tatsch & Poepperi, 2012), found that individual differences in dopamine function in the VS and ventromedial prefrontal cortex were correlated with a willingness to expend greater effort for larger rewards (Treadway et al., 2012), further implicating dopamine in reward sensitivity.

These associations between VS activation and reward have also been observed in developmental populations. By examining individual neural responses to reward and correlating them with self-reported risk-taking behavior, we found a positive association between VS activation in response to monetary reward and the likelihood of engaging in risky behavior across development; that is, individuals more likely to report higher frequency of risky behavior in real-life showed greater VS recruitment (Galván, Hare, Voss, Glover, & Casey, 2007). A more recent study found similar results in adolescents, with a positive association between individual differences in reactivity of the VS during anticipation of reward and externalizing behaviors such as drug use (Bjork, Smith, Chen, & Hommer, 2011).

Psychopathology, Addiction, and Reward Circuitry

Research over the past decade has yielded new insights into neural alterations in psychopathology. A number of studies have implicated reward circuitry in underlying internalizing and externalizing disorders, albeit with opposite effects. While internalizing disorders such as depression are typically associated with blunted striatal responses to upcoming rewards, externalizing disorders are usually characterized by enhanced activation of striatal regions (Fairchild, 2011).

Anhedonia, the inability to experience pleasure, is a leading symptom in major depressive disorder. Neuroimaging studies have found that depressed children and adolescents exhibit reduced neural sensitivity to rewards (Forbes et al., 2009) and to happy faces (Monk et al., 2008) in striatal and orbitofrontal cortex. Interestingly, girls who have a high familial risk for depression but who themselves have not been diagnosed with depression also show disruptions in reward-related brain activity (Gotlib et al., 2010). These developmental findings are consistent with studies in adult depressives, which show reduced activation in the ventral striatum (McCabe, Cowen, & Harmer, 2009; Steele, Kumar, & Ebmeier, 2007), caudate (Pizzagalli et al., 2009), cingulate, and ventromedial prefrontal cortex (McCabe et al., 2009).

Numerous studies have suggested that individuals with substance use disorders exhibit impairments in reward processing. For instance, adolescent and adult substance abusers are more likely to take risks to gain large rewards than nonstimulant users (Leland, Arce, Feinstein, & Paulus, 2006), discount delayed rewards more steeply than control subjects (Kollins, 2003; Petry & Casarella, 1999), and to be more influenced by potential rewards available on a simulated gambling task than controls (Stout, Rock, Campbell, Busemeyer, & Finn, 2005). However, neuroimaging findings across different labs are not as consistent as the behavioral findings. While some fMRI studies report blunted striatal activation in substance-dependent adults (Buhler et al., 2010; Goldstein et al., 2007), there is also evidence showing increased activation in dependent adults (Bjork, Smith, & Hommer, 2008). Surprisingly, many fewer studies have examined reward processing in adolescent substance users. One study in adolescent smokers found decreased striatal activation during reward processing relative to nonusers (Peters et al., 2011). Another study examined children of alcoholics and found that ventral striatal activation was positively correlated with precursive externalizing risk, as well as current and lifetime alcohol consumption (Yau et al., 2012). In a large sample of 14-year-old adolescents ($N = 324$), the IMAGEN Consortium found that personality traits (impulsivity, sensation seeking, extraversion) were more predictive of early onset drinking than reward-related brain activation (Nees et al., 2012).

In sum, the growing literature on adolescent reward circuitry suggests that characteristic increases in reward sensitivity during adolescence are due to neurobiological changes. These changes appear to be nonlinear in nature, such that there is a study increase in both reward behaviors and reward-related brain activation as children become adolescents, followed by a gradual decrease from adolescence into adulthood. Numerous theories about the role of reward circuitry in psychiatric disorders and substance use have been put forth (Ernst, Pine, & Hardin, 2006), but much more empirical work is necessary to delineate the exact mechanisms by which aberrant reward sensitivity contributes to the onset and maintenance of these disorders.

RISK TAKING IN THE DEVELOPING BRAIN

Adolescence and young adulthood are characterized by increased risk-taking behavior. Typically, the occurrence of these risk-taking behaviors follows an inverted U-shape

pattern across development, being relatively low in childhood, increasing and peaking in adolescence and young adulthood, and declining again thereafter (for overviews, see, e.g., Reyna & Farley, 2006). This behavioral pattern is intricately tied to neurodevelopmental changes in brain regions critical for decision making and risky behavior, namely, frontostriatal circuitry, and has significant implications for both positive and negative outcomes. On one hand, increased drive, motivation and willingness to take risks help adolescents become fervid activists, leaders, and explorers. It is no coincidence that young people are often at the forefront of new ideas, impassioned defenders of ideals, and the ones having the most fun. The risk-seeking nature of the teenage brain undoubtedly contributes to the energy and passion we as adults admire and envy in youth. From an ecological perspective, this increased proclivity toward exploration and willingness to take risks, regardless of the potentially harmful consequences facilitates important developmental milestones. Seeking out potential mates, self-reliance, and new adventures is at the very core of transitioning from a state of dependence on caregivers to one of relative independence. In fact, risk taking around the time of sexual maturation is not unique to humans; like their human counterparts, rats undergoing the developmental transition of adolescence show a significant increase in the amount of time spent in social interactions with peers (Varlinskaya & Spear, 2008) and at play. They also are more likely to engage in risk-taking behavior, and they seek out new situations and explore unknown areas more avidly than they do at either a younger age or in adulthood (Spear, 2000). In humans, Shedler and Block (1990) proposed that modest amounts of risk taking may be constructive. According to their findings, adolescents who engaged in moderate amounts or risk taking were found to be more socially competent both in childhood and adolescence than were those who abstained or who were more frequent risk takers (Shedler & Block, 1990).

However, excessive or high-stakes risk taking may lead adolescents to stumble into harmful behaviors. Risk taking that takes the form of drug experimentation, thrilling but dangerous behaviors (e.g., speeding or car racing), or recklessness can lead to irreparable negative outcomes. As such, the public health concerns of teenage risk taking, along with the potential for positive exploration and growth, have led to a vigorous interest in understanding risk taking and decision making in the adolescent brain (Casey & Jones, 2010; Ernst & Fudge, 2009; Reyna et al., 2011).

As reviewed in the previous section, there is significant neurobiological change in frontostriatal circuitry during adolescence. Neural regions in this system are also those that exhibit robust sensitivity to risk. Early neuroimaging studies of risk in adults used task paradigms that manipulate variance in the probability distribution of reward, enabling the identification of neural responses associated with objective risk defined in economic terms (Schonberg, Fox, & Poldrack, 2011). This work identified risk-related responses in several regions, mainly the striatum (e.g., (Preuschoff, Bossaerts, & Quartz, 2006) anterior cingulate cortex (ACC), lateral orbitofrontal cortex (OFC) and insula, all of which are also responsive to monetary gains or losses (Critchley, Mathias, & Dolan, 2001). The posterior parietal cortex, dorsolateral prefrontal cortex (DLPFC) and anterior insula were found to be more active during a choice of risky versus safe options (Paulus, Rogalsky, Simmons, Feinstein, & Stein, 2003); in addition, fMRI activation levels in the right insula following a negative outcome were negatively correlated with subsequent risky choices. Similarly, in a study using a financial decision-making paradigm risky (as opposed to safe) choices were predicted by increased activation in the ventral striatum immediately preceding the risky choice (Kuhnen & Knutson, 2005).

Developmental fMRI studies of risk taking report similar circuitry, albeit at varying degrees of activation. Using a child-friendly gambling task, van Leijenhorst and colleagues (2010) examined brain activation during risk taking in a sample of children, adolescents, and adults. Behaviorally, there were no age-related differences in risk-taking behavior for gambles associated with high rewards; all participants were more likely to take risks as the potential reward increased. However, developmental differences emerged at the neurobiological level: activation in dorsal ACC showed a linear decrease with age, whereas activation in VMPFC and VS showed an inverted U-shaped developmental pattern, with a peak in adolescence (van Leijenhorst, Zanolie, et al., 2010). Similar findings were reported using a different risky decision-making task in high-risk behavior induced greater activation in dorsal ACC, ventrolateral OFC and mPFC than the control condition (Shad et al., 2011).

These activation patterns during risk taking are predictive of individual differences in actual risk-taking behavior. Neuroimaging data in adults shows that individual differences in activation of the VS predict reward-related risks (Kuhnen & Knutson, 2005). For example, individuals who exhibit greater VS activation in response to appetitive cues are subsequently more likely to make risky choices to obtain monetary reward (Kuhnen & Knutson, 2005), to consume unhealthy snacks (Lawrence et al.,

2012), to gain weight and report greater sexual desires (Demos et al., 2012).

These associations between VS activation and reward have also been observed in developmental populations. By examining individual neural responses to reward and correlating them with self-reported risk-taking behavior, we found a positive association between VS activation in response to monetary reward and the likelihood of engaging in risky behavior across development; that is, individuals more likely to report higher frequency of risky behavior in real life showed greater VS recruitment (Galván et al., 2007). A more recent study found similar results in adolescents, with a positive association between individual differences in reactivity of the VS during anticipation of reward and externalizing behaviors such as drug use (Bjork et al., 2011).

Risk Taking in Context

As converging evidence provides the empirical link between reward circuitry and risk taking, attention has started to shift toward understanding the contextual factors that interact with risk taking and associated brain function. Broadly speaking, researchers are empirically testing the notion that risky choices differ based on whether the decision to engage in risk is made under hot or cold contexts, with the former referring to choices made under emotionally arousing circumstances and the latter referring to choices made in more deliberate, nonemotional or cognitive contexts. Studies using the hot and cold versions of the Columbia Card Task (CCT). Figner, Mackinlay, Wilkening, & Weber (2009) have shown that heightened involvement of affective processes in risky decision making (in the hot CCT) leads to increased risk taking in adolescents compared with children and adults (Burnett, Bault, Coricelli, & Blakemore, 2010; Figner et al., 2009). In contrast, when risky decisions are made involving mainly deliberative processes and no or little affect (cold CCT), adolescents show the same levels of risk taking as children and adults (Figner et al., 2009). (See also van Duijvenvoorde & Crone, 2013 for similar hot/cold differences in adolescents). These findings show similarities to findings from research using a simulated driving game in which the presence of peers leads to increased risk taking in adolescents (but not adults) when making choices between driving through versus stopping at traffic intersections with a yellow light (Chein et al., 2011; Gardner & Steinberg, 2005). This socioemotional influence of peers on adolescents is not surprising given that much risk taking in adolescents occurs in the presence of peers (Gardner & Steinberg, 2005), and more broadly, given the changes in social motivations during this period, with adolescents achieving greater independence from their parents and, in turn, peers growing in importance (Blakemore, 2008).

Peers

Why do peers influence risk taking? Mounting evidence suggests that social interactions and the presence of peers elicit emotions that subsequently engage affective neural systems. Given the lower threshold with which rewards yield exaggerated neural signals in adolescents compared with adults or children, peers are conditioned stimuli that engage the reward-sensitive striatum. Research suggests that changes in brain development during adolescence orients teens toward the social world (Blakemore, 2010) and heightens neural sensitivity to peers (Guyer, McClure-Tone, Shiffrin, Pine, & Nelson, 2009). Further, recent work suggests that there is a relationship between resistance to peer influence, risky behavior and ventral striatal activity (Pfeifer et al., 2011). As such, peers induce significant contextual changes at both the behavioral and neurobiological levels. Chein and colleagues (2011) provided convincing fMRI evidence in support of this hypothesis (Chein et al., 2011). Building on work by the same group showing that adolescents took more risks on a computer-simulated driving game than adults (Gardner & Steinberg, 2005), they demonstrate that the presence of peers increases teen risk taking by enhancing activity in the brain striatal (reward) circuitry (Chein et al., 2011). These compelling findings lend further support for the notion that context (in this case, peers) can alter the relative contribution of neural mechanisms underlying reward seeking and risk taking.

Stress

Due to the significant changes in social landscape, expectations and identity development, adolescence is marked by increased stress and heightened reactivity to acute stress, compared with children and adults (Dahl & Gunnar, 2009; Dorn et al., 2006). Adolescence bears many types of stressors (Persike & Seiffge-Krenke, 2012) including family, academic (Arnett, 2002; Bynner, 2000), and peer (Eccles et al., 1993; Smetana, Campione-Barr, & Metzger, 2006) pressures. For example, demanding coursework and preparation for college placement often lead to stressful increases in schoolwork (McAndrew, Akande, Turner, & Sharma, 1998). Socially, adolescents frequently experience stressors in the domain of romantic relationships and peer networks

(Hand & Furman, 2009; Kuttler & LaGreca, 2004). Also common is elevated stress associated with developing more intimate friendships while maintaining family relationships and establishing autonomy (Laursen & Collins, 1994; Nieder & Seiffge-Krenke, 2001). Ethnographic data demonstrates that these effects are observed globally, as adolescents from over 140 cultures report high feelings of stress in these domains (Schlegel, 2001). These normative life stressors are paralleled by higher basal cortisol levels in older adolescents or more pubertally mature adolescents (Adam, 2006; Netherton, Goodyer, Tamplin, & Herbert, 2004). Stroud and colleagues used laboratory-based manipulations to demonstrate a heightened stress response to psychological stressors in adolescents relative to children (Stroud et al., 2009). In response to typical laboratory stressors (e.g., public speaking) and to a novel social stressor (e.g., peer rejection), adolescents showed a greater response in salivary cortisol and other physiological measures compared with children (Stroud et al., 2009). These results parallel more traditional investigations that utilized performance and/or academic stressors (Adam, 2006; Klimes-Dougan, Hastings, Granger, Usher, & Zahn-Waxler, 2001). In addition, Gunnar and colleagues (2009) show nonlinear patterns of heightened basal HPA activity and greater stress reactivity to a stressor across development, with adolescents showing the most robust effects compared with children and young adults (Gunnar, Wewerka, Frenn, Long, & Griggs, 2009). This increase in actual and perceived stress has consequential implications for risky behavior and decision making because the neural systems most sensitive to stress.

A recent survey by the National Center on Addiction and Substance Abuse (CASA) in a large sample of adolescents (n=1987; aged 12–17) reported an alarmingly strong association between high rates of poor health choices and high levels of stress. The survey found that high-stress teens (those who report high levels of perceived stress with ratings of 7–10 on stress scale) are twice as likely as low-stress teens (those who report low levels of perceived stress with ratings of 0–3 on stress scale) to smoke, drink, and use illegal drugs. A separate, longitudinal study in a sample of younger youth (4th–8th graders) found that higher perceived acute stress is associated with increased risk for alcohol use and higher likelihood of driving in a car with a drunk driver (Rew, Horner, & Brown, 2011). The results are also consistent with findings that greater perceived acute stress levels are significantly associated with greater risk taking among older adolescents (Fields, Leraas, Collins, & Reynolds, 2009; Schepis, McFetridge, Chaplin, Sinha, & Krishnan-Sarin, 2011). These results are intriguing in that they beg a causal question: does stress cause adolescents to engage in risky decisions, or does risky decision making in adolescents lead to greater feelings of stress?

In a large sample of 89 late adolescents, Johnson and colleagues (2012) found that participants who experienced a cognitive or social laboratory stressor exhibited greater risk taking behavior on a computerized risk-taking task than those in a control no-stress condition (Johnson, Dariotis, & Wang, 2012). A separate study examined whether perceived stress influences delay discounting (i.e., the preference for a smaller, immediate reward over a larger, delayed reward). Adolescents with higher perceived daily-life stress were more likely to have difficulties delaying rewards (Fields et al., 2009), which is consistent with a similar study in adults (Diller, Patros, & Prentice, 2011).

Work from our own group suggests that acute stress perturbs decision making in adolescents and young adults (ages 14–21) (Galván & McGlennen, 2012). In this study, participants' daily, self-perceived stress was monitored via text messaging for 2 weeks. Each participant visited our lab twice during the study—once when he or she endorsed a high level of stress and once when he or she endorsed a low level of stress. At the lab, they each performed a risky decision-making task and a response inhibition task. By administering these different cognitive challenges, we were able to determine whether any observed stress effects were bestowed upon cognition in general or decision making in particular. Participants made riskier decisions under conditions of high versus low stress (Galván & McGlennen, 2012). In a follow-up fMRI study in adolescents and adults using the same design, all participants exhibited worse response inhibition under high, versus low, stress states, an effect that was significantly stronger in adolescents. At the neural level, there was a significant age by stress interaction, such that adolescents exhibited less recruitment of the dorsolateral prefrontal cortex (DLPFC) during inhibition under high-stress versus low-stress; adults evinced the opposite activation pattern in DLPFC (Rahdar & Galvan, 2014). These data suggest that the developing brain may be a more vulnerable target to the cognitive and neurobiological effects of daily stress.

Family

More recently, work has extended the study of how social relationships influence risk taking by examining the role of the family unit on this behavior. The changing nature of family relationships during the adolescent years can have significant implications for risk taking and associated

health consequences, such as substance use and externalizing problems (Gfroerer & de la Rosa, 1993; Warner et al., 2006). Family obligation—the importance of spending time with the family, high family unity, family social support, and interdependence for daily activities (Cuellar, Arnold, & Gonzalez, 1995; Fuligni, 2001)—is a key aspect of family relationships that may have significant consequences for adolescents' health. Family obligation and family pride have been associated with reduced likelihood and delayed onset of drug use and lower rates of externalizing problems (German, Gonzales, & Dumka, 2009; Gil, Wagner, & Vega, 2000; Kaplan, Napolos-Springer, Stewart, & Perez-Stable, 2001; McAndrew et al., 1998; Romero & Ruiz, 2007; Vega, Zimmerman, Warheit, Apospori, & Gil, 1993). Moreover, neuroimaging research shows that family assistance is associated with activation in neural regions responsive to reward (Telzer, Masten, Berkman, Lieberman, & Fuligni, 2010). Together, these studies suggest that family obligation is associated with feelings of value, meaningfulness, and intrinsic reward, which may deter adolescents from engaging in health compromising risky behavior.

Family obligation may reduce risk taking because it is a meaningful activity that increases adolescents' motivation to control their own impulses and desires for the sake of their family as well as provides opportunities to practice engaging in self-control. For example, adolescents who value family obligation report greater negative consequences for engaging in risky behavior because risk taking reflects poorly upon their family (German et al., 2009). Therefore, the negative consequences of risk taking may be more consequential for these youth, and so risk taking becomes comparatively less rewarding. Risk taking is amplified during states of affective arousal among adolescents, such as in the presence of peers (Chein et al., 2011; Figner et al., 2009; Gardner & Steinberg, 2005). In contrast, during cold deliberative states of decision making, heightened risk taking is not always found among adolescents (Figner et al., 2009). Therefore, family obligation values may decrease the affective nature of risk taking, reducing reward sensitivity during risk. In the absence of heightened arousal, cognitive control capacities may come online and reduce risky decision making. Likewise, adolescents who value family obligation may be more motivated to engage in self-control to avoid risky behaviors. Indeed, scholars refining the dual systems model suggest that cognitive control capacities are not necessarily immature during adolescence, but, rather, there is a great deal of flexibility, and the degree to which adolescents engage in cognitive control is strongly influenced by the motivational salience of the context (Crone & Dahl, 2012). Thus, reward sensitivity and self-control may be altered by adolescents' motivation to avoid risk taking. To test this hypothesis, Telzer and colleagues (2013) examined whether family obligation related to neural markers of risk taking. Participants performed the Balloon Analogue Risk Task (BART), a computerized assessment of risk taking, while undergoing fMRI. They also provided measures of family obligation values and self-reported risk-taking behavior. Results suggest that adolescents with greater family obligation values show decreased activation in the ventral striatum (VS) when receiving monetary rewards and increased dorsolateral prefrontal cortex (DLPFC) activation during behavioral inhibition. Reduced VS activation correlated with less real-life risk taking behavior and enhanced DLPFC activation correlated with better decision-making skills. Thus, family obligation may decrease reward sensitivity and enhance cognitive control, thereby reducing risk-taking behaviors (Telzer, Fuligni, Lieberman, & Galván, 2013).

SOCIAL COGNITIVE DEVELOPMENT

Similar to other primates, humans are social creatures. We are highly interested, responsive to, and dependent on social interactions. It is thus unsurprising that cognitive neuroscientists have mapped out neural regions that are particularly attuned to social information. This system is commonly referred to as the social brain and is composed of the medial prefrontal cortex (mPFC), the temporoparietal junction (TPJ), the posterior superior temporal sulcus (pSTS), the amygdala, the anterior insula, and the anterior insula. Together, these brain regions work in concert to facilitate different aspects of social cognition that are critical for forming and maintaining social bonds, including thinking about the mental states of others (often called mentalizing), observing and interpreting faces, recognizing conspecifics, and making decisions that consider social information.

During adolescence, there is an increased interest in social information, a phenomenon that has been termed *social reorientiation* (Nelson, Leibenluft, McClure, & Pine, 2005). During this period, there is refinement of social processes and cognition, such as the understanding of others' emotions, intentions and beliefs, increased motivation for social change and heightened self-consciousness and intensification of peer relationship (Steinberg & Morris, 2001). Perhaps not coincidentally, there are marked structural and functional neurodevelopmental changes in regions of

the social network. In a recent study of almost 300 youth and 900 scans, Mills and colleagues examined changes in the structural developmental trajectories of social brain regions in the longest ongoing longitudinal neuroimaging study of human brain maturation (Mills et al., 2012). Structural trajectories of grey matter volume, cortical thickness, and surface area were analyzed using surface-based cortical reconstruction software and mixed modeling in a longitudinal sample of 288 participants (ages 7–30 years, 857 total scans). Grey matter volume and cortical thickness in medial prefrontal cortex, TPJ, and pSTS decreased from childhood into the early 20s. The anterior temporal cortex increased in grey matter volume until adolescence and in cortical thickness until early adulthood. Surface area for each region followed a cubic trajectory, peaking in early or preadolescence before decreasing into the early 20s (Mills et al., 2012).

These structural changes appear to have functional consequence, as the myriad studies that have addressed questions of social cognition have found significant changes in these same regions. Mentalizing has been studied a variety of ways, including through the use of tasks that asked participants to decide whether a speaker was being sincere or ironic (Wang, Lee, Sigman, & Dapretto, 2006), to think about one's own intentions (Blakemore, den Ouden, Choudhury, & Frith, 2007), to engage self-reflective processing (Pfeifer, Lieberman, & Dapretto, 2007), and to consider intent in animation-based characters (Moriguchi, Ohnish, Mori, Matsuda, & Komaki, 2007). Despite the diversity of tasks, there was a consistent neurodevelopmental pattern of decreasing mPFC activation with age, with adolescents showing heightened engagement of this region relative to adults. In addition, there is evidence for differential functional connectivity between mPFC and other parts of the mentalizing network across age (Burnett, Bird, Moll, Frith, & Blakemore, 2009). During scanning, adults and adolescents asked to think about scenarios in which a social (e.g., embarrassment and guilt) or a basic (e.g., disgust and fear) emotion would be experienced. Compared with adults, the adolescent group showed stronger connectivity between the mPFC and pSTS/TPJ during social relative to basic emotion, suggesting that there are developmental changes in functional integration within the mentalizing system (Burnett et al., 2009). Using dynamic casual modeling and a task that requires participants to take into account another person's perspective to guide the selection of an action, Hillebrandt and collegues examined effective connectivity between prefrontal and posterior brain regions (Hillebrandt, Dumontheil, Blakemore, & Roiser, 2013). They found that social demands modulate the backward connection from the mPFC more strongly than the forward connections from the superior occipital gyrus and medial temporal gyurs to the mPFC (Hillebrandt et al., 2013).,

A number of functional neuroimaging studies have investigated the neural correlates of facial-expression recognition from childhood to adulthood (Goddings et al., 2012). An fMRI study reported increased activity in a number of lateral and superior prefrontal regions (bilaterally for girls, right sided for boys) in response to fearful faces in individuals between the ages of 8 and 15 years (Yurgelun-Todd & Kilgore, 2006). In a different study, adolescents (aged 9–17 years) showed activation of the ACC and left OFC during passive viewing of fearful faces (relative to neutral faces), whereas adults (aged 25–36) did not (C. Monk et al., 2003). When attention was directed to a nonemotional aspect of fearful faces, activity in the ACC was higher in adolescents than in adults. Therefore, in this study, frontal activity tended to decrease between adolescence and adulthood (C. Monk et al., 2003). In addition the findings indicate that, whereas adults modulate brain activity based on attention demands, adolescents modulate activity based on the emotional nature of a stimulus. This suggests that the neural basis of the ability to pay attention to a nonsalient stimulus (in this case, the nose of a fearful face) in the presence of emotionally evocative, attention-grabbing stimuli (the eyes of a fearful face) is still undergoing maturation between adolescence and adulthood (Blakemore, 2008).

In sum, converging evidence from numerous, laboratories around the world have independently found that during social cognitive tasks, the mPFC shows decreasing activation as adolescents become adults. This phenomenon is not yet understood but two nonmutually exclusive explanations have been put forward. One possibility is that the cognitive strategy for mentalizing changes between adolescence and adulthood (Blakemore, 2008). A second possibility is that the functional change with age is due to neuroanatomical changes that occur during this period, an argument that has received greater support with the recent paper described above.

TRANSLATIONAL IMPLICATIONS

Changes in behavior across the transitions into and out of adolescence have significant implications for both positive and negative outcomes. These changes facilitate the important developmental milestone of transitioning from a state of dependence on caregivers to one of relative independence. However, in the quest for autonomy, individuals may encounter challenges that are rooted in the changing brain.

Neurodevelopmental changes in limbic regions and auxiliary brain networks are implicated in psychiatric disorders, addiction, and impulse control problems. Dramatic increases in the onset of psychiatric disorders occur during the adolescent period. A United States population-based study of over 9,000 adults revealed that the median age of onset for any psychiatric disorder was 14 years (Kessler et al., 2005). Notably, prevalence of onset is greatest in disorders in which dysfunctional motivation or reward-related processes are implicated (Fairchild, 2011), including depression and substance use disorders. A recent survey of 10,123 adolescents (aged 13–18 years) by the National Institutes of Mental Health (Angst et al., 2010; Swendsen et al., 2010) reported that the prevalence of major depressive disorder increased two-fold over the adolescent period, while the rate of substance use disorders were six times higher in 17–18 year olds relative to 13–14 year olds (Fairchild, 2011). As new research on the neural correlates of symptomology is conducted, emerging evidence suggests that, indeed, adolescents afflicted with psychiatric disorders exhibit aberrant recruitment of reward circuitry.

In both internalizing and externalizing disorders, a number of studies have implicated reward circuitry, albeit with opposite effects. Whereas internalizing disorders such as depression are typically associated with blunted striatal responses to upcoming rewards (Forbes & Dahl, 2010) compared with healthy controls, externalizing disorders are usually characterized by enhanced activation of striatal regions (Fairchild, 2011). Anhedonia, the inability to experience pleasure, is a leading symptom in major depressive disorder. Neuroimaging studies on anhedonia report that depressed and anxious children and adolescents exhibit reduced neural sensitivity to rewards (Forbes et al., 2009) and to happy faces (Monk et al., 2008) in frontostriatal circuitry. Interestingly, girls who have a high familial risk for depression (Gotlib et al., 2010), or who endorse depressive symptoms (Goff et al., 2012), but who themselves have not been diagnosed with depression also show disruptions in reward-related brain activity. These developmental findings are consistent with studies in adults who suffer from depression, which show reduced activation in the ventral striatum (McCabe et al., 2009; Steele et al., 2007), caudate (Pizzagalli et al., 2009), cingulate (McCabe et al., 2009), and ventromedial prefrontal cortex (McCabe et al., 2009).

Limbic regions are also at the core of neural impairments in individuals with substance use disorders but the exact mechanism of influence is unclear. While some fMRI studies report blunted striatal activation in substance-dependent adults (Buhler et al., 2010; Goldstein et al., 2007), there is also evidence showing increased activation in dependent adults (Bjork et al., 2008). Surprisingly, very few studies have examined reward processing in adolescent substance users, despite the tight link between measures of reward hypersensitivity and substance use (Bava & Tapert, 2010; O'Conner, Stewart, & Watt, 2009). One study in adolescent smokers found decreased striatal activation during reward processing relative to nonusers (Peters et al., 2011). Another study examined children of alcoholics and found that ventral striatal activation was positively correlated with precursive externalizing risk, as well as current and lifetime alcohol consumption (Yau et al., 2012). In a large sample of 14-year old adolescents (N=324), the IMAGEN Consortium found that personality traits (impulsivity, sensation seeking, extraversion) were more predictive of early onset drinking than reward-related brain activation (Nees et al., 2012). These heterogeneous findings highlight how little is known in this important area of research. Without a mechanistic understanding of what leads some individuals to simply be experimenters in the teenage years versus those who come to abuse substances throughout life, it will be challenging to implement preventative approaches or effective treatment.

So how can research on brain development help ameliorate symptoms or negative outcomes? A long-standing goal of developmental psychopathology has been to do just that: bridge fields of study in ways that leverage basic research into real-world contexts (Cicchetti & Toth, 2009). Principles from developmental psychopathology provide guidance as to how best to marry these disparate fields: investigations at multiple levels of analysis, including clinical, biological, psychological, and social-contextual, are necessary to translate basic research information into application (Cicchetti & Toth, 2009). To this end, developmental psychopathology practice engages research in both typical and atypical population, and in maladaptive and adaptive processes, in an effort to understand development from a multi-faceted perspective. With the advent of more sophisticated tools, such as fMRI and ERP, the time is ripe to include additional levels of analyses to holistically address symptoms. This type of knowledge has led to improved efforts in assessing, diagnosing, and treating psychopathology but the field still has much to gain and the application of this perspective will only facilitate further insight into how to bridge basic and applied research.

SUMMARY AND FUTURE DIRECTIONS

The field has made great strides in characterizing the neurobiological changes that underlie social, emotional, and cognitive changes during adolescence. However, as new methods, questions, and ideas emerge, probing more

deeply into how the developing brain processes influences behavior will become possible. In particular, the field would benefit greatly from addressing a few questions that have direct relevance to translational applicability (Cicchetti & Toth, 2009).

First, a greater focus on developmental timing is warranted. If one goal of clinical application is to ameliorate symptomology, then knowing *when* the introduction of prevention or intervention strategies will be most effective is critically important. Currently, most researchers categorize individuals into age groups with rather large age ranges due to funding and resource-related constraints but moving forward will require meticulous attention to variations in behavioral and neural response based on age. Identifying the basic mechanisms and timing of change allows us to identify moments when the system is in its most dynamic state. Identification of these sensitive periods is crucial to identifying moments when interventions would have their greatest impact on mental health outcomes. For instance, recent translational research suggests that there are significant individual and developmental differences in the efficiency of fear-regulatory circuitry (Hartley & Casey, 2013). These data have significant implications for the treatment of disorders such as anxiety, which typically involves exposure therapy based on extinction-learning principles. One might imagine that if there normative changes in fear learning across development that there are, similarly, points in development when this type of therapy will be more or less effective. Although empirical support for this notion has yet to be garnered, a future clinical study examining exposure therapy efficacy across development is necessary.

Second, once optimal points of intervention have been identified, it will be important to determine how to manipulate sensitive periods. In other words, knowing how to reopen early-life sensitive periods in adolescence or reopening adolescent sensitive periods later in life to redirect a problem phenotype will significantly impact clinical intervention.

Third, it is important to underscore the strengths of adolescence. Although extensive statistics and literature serve as important reminders of the vulnerabilities associated with this period of development, only recently have the possibilities associated with adolescence been highlighted (Casey & Caudle, 2013; Crone & Dahl, 2012; Galván, 2014). At no other time in life are individuals faced with as much novelty, opportunity, excitement, and thrill than during adolescence. Youth are intrinsically motivated to learn about the world, to change policies and ideas they oppose and to make as many social links as possible. These normative characteristics are important for our species, as they ensure that we challenge existing principles, create new inventions, and stay connected to one another. Although previous media portrayals of adolescent brain research focused on the negative aspects of adolescence, researchers have used empirical research to show that ontogenetic changes in the adolescent brain are adaptive for the individual. Future research should focus on better determining how society can leverage normative adolescent phenotypes to enact healthy outlets for adolescent tendencies and appropriate responses to adolescent behavior.

Finally, with the inclusion of research from nonadolescent humans in this chapter, our goal was to illustrate the importance of considering transitions in and out of adolescence. As BJ Casey noted in a recent special issue, "we cannot know which behavioral and brain changes are specific to adolescence if we don't know what they looked like before and after this period of development" (Casey & Caudle, 2013. p. 80). This transitional approach will help the field differentiate adolescent-specific from adolescent-emergent from adolescent-nonspecific changes. Importantly, it will allow us to move beyond using age as an independent variable and instead focus on understanding the process by which change occurs, the agents of change that are highly correlated with age such as puberty and changes in social structure, and the vast individual differences that contribute to observable behavior.
