In fact, several researchers have found that relational aggression is associated with difficulties in dyadic relationships with peers. Interestingly, evidence indicates that relationally aggressive youth often do have close, dyadic friendships. For instance, Rys and Bear (1997) found that relationally aggressive children were just as likely to have a friend as their nonaggressive peers (see also Burr, Ostrov, Jansen, Cullerton-Sen, & Crick, 2005; although see Johnson & Foster, 2005). However, although relationally aggressive youth often have close friends, these negative social behaviors may lead to poor-quality relationships over time. In fact, relationally aggressive youth are more likely than their nonaggressive peers to exhibit difficulties within friendships, including high levels of jealousy and a tendency to use relational aggression against close friends (Grotpeter & Crick, 1996). Banny, Heilbron, Ames, and Prinstein (2011) provided longitudinal evidence that relationally aggressive talk in the context of a friendship interaction (e.g., gossip about others) was associated with increases in negative relationship quality across 6 months. Similarly, Kamper and Ostrov (2013) found that the perpetration of relational aggression in the fifth grade predicted lower friendship quality 1 year later, even when controlling for engagement in physical aggression. Romantic relational aggression is also associated with negative relationship qualities. For instance, Linder et al. (2002) reported that the use of relational aggression against romantic partners was positively associated with feelings of frustration, ambivalence, jealousy, and anxious clinging and negatively associated with trust in the relationship. Interestingly, this study also found evidence of cross-contextual continuity, indicating that poor relationships with peers and parents may play an important role in the development and maintenance of relational aggression in romantic relationships (Linder et al., 2002).

Taken together, then, evidence indicates that relational aggression is associated with impaired peer functioning, at both the dyadic and the peer group levels. However, several factors may be important to consider in research regarding relational aggression and peer outcomes. For instance, findings may differ by gender; in fact, a study in middle childhood found that physical aggression was predictive of social problems for boys, whereas relational aggression

was predictive of social problems for girls (Preddy & Fite, 2012). In a recent longitudinal study, relational aggression predicted increases in relational victimization over the course of 8 months in adolescent girls but not boys (Zimmer-Gembeck & Duffy, 2014). Crick et al. (2009) suggested that relational aggression may be more strongly related to poor peer outcomes for girls because these behaviors disrupt the interpersonal goals central to female peer groups. There may also be cultural differences in the strength of the association between relational aggression and negative peer outcomes. Peer problems such as peer rejection have been documented in youth who engage in high levels of relational aggression in numerous cultures (e.g., a large sample of Italian preschoolers; Nelson, Robinson, Hart, Albano, & Marshall, 2010). However, relational aggression may be especially disruptive to peer functioning in some cultures; for instance, relational aggression may interfere with the social expectations typical of collectivistic cultures (Kawabata et al., 2012) and thus may be more strongly related to rejection by peers in this context (see the "Cultural Perspectives" section). Associations between relational aggression and peer outcomes may also be moderated by individual differences in functioning in other domains; for example, past research has shown that relational aggression was associated with conflictual friendships (a marker of negative friendship quality) for children who were rejected by their peers but not for those who were perceived as popular (Rose, Swenson, & Carlson, 2004). In another study, relationally aggressive girls with high levels of sensitivity to relational threats (e.g., rejection sensitivity, fear of negative evaluation, and intimacy avoidance) were at particularly high risk for concurrent and future relational victimization (Zimmer-Gembeck & Duffy, 2014). Importantly, although impaired peer functioning is often conceptualized as an outcome of relationally aggressive behavior, it is likely that associations are bidirectional in nature (see the "Risk Factors: Social Processes" section).

Substance Use and Abuse

Relational aggression may place youth on trajectories toward risky behaviors such as substance use (e.g., Kamper & Ostrov, 2013; Spieker et al., 2012). In fact, emerging research findings have documented positive associations between relational aggression and substance use (e.g., Burt et al., 2012; Storch et al., 2004). For instance, self-reported relational aggression has been significantly correlated with self-reported cigarette use, alcohol use, marijuana use, and advanced alcohol use in a typically developing sample of eighth graders (Sullivan et al., 2006). Some researchers have documented gender differences in these associations; after controlling for initial levels of physical aggression and baseline drug use, Skara et al. (2008) found that relational aggression predicted cigarette use and marijuana use for females but not for males (see also Burt et al., 2012). Relational aggression within the context of romantic relationships has also been shown to be associated with alcohol and drug use (Bagner, Storch, & Preston, 2007).

Several peer processes may underlie the relation between relational aggression and substance use problems. For example, relationally aggressive youth may increasingly associate with aggressive and delinquent peers (e.g., Sijtsema, Ojanen, et al., 2010; Werner & Crick, 2004), resulting in socialization toward delinquent acts, such as early substance use and abuse. Moreover, peer difficulties resulting from relational aggression (e.g., rejection, victimization) may promote substance use. That is, relational aggressors may engage in substance use as a maladaptive coping mechanism to deal with their peer difficulties, including being targeted by peer victimization (see Sullivan et al., 2006). Kamper and Ostrov (2013) recently documented that negative friendship quality mediated the longitudinal association between childhood relational aggression and adolescent risky behaviors, including substance use. Future research is needed to further delineate the specific developmental mechanisms underlying substance use among relationally aggressive youth, with particular attention to the role of peer difficulties, such as victimization and poor friendship quality.

Personality Pathology

In recent years, several associations between relational aggression and dimensions of personality pathology have been posited and tested (see Cicchetti & Crick, 2009; Tackett & Ostrov, 2010). Although relational aggression has been shown to be associated with several forms of personality pathology including antisocial personality disorder symptoms (e.g., Ostrov & Houston, 2008; Werner & Crick, 1999), the focus of this review is on borderline personality disorder (BPD) features, narcissism, and psychopathy.

With respect to symptoms of borderline pathology, Geiger and Crick (2001) conducted a content analysis of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorder*s (*DSM-IV*) criteria for diagnosis of personality disorders, and five childhood indicators of BPD were identified. These included: (1) hostile/paranoid view of the world; (2) intense, unstable, inappropriate affect; (3) overly enmeshed and close relationships; (4) impulsivity;

and (5) lack of a coherent sense of self. Difficulties within close interpersonal relationships, chronic anger, impulsivity, and a hostile worldview (i.e., HAB) are some of the core features that are shared by both relational aggression and BPD (Crick, Murray-Close, & Woods, 2005; Ostrov et al., 2011). From this perspective, stable behavioral patterns in childhood, including engagement in relational aggression, may reflect risk for the development of borderline symptoms (Crick et al., 2005).

Consistent with this hypothesis, Crick and colleagues (2005) provided evidence indicating that relational aggression may be a unique developmental precursor to and predictor of borderline personality features in children. Subsequent research has supported a conceptual model in which relational aggression is a developmental antecedent of BPD features (e.g., Ostrov & Houston, 2008; Stepp, Pilkonis, Hipwell, Loeber, & Stouthamer-Loeber, 2010). For instance, Vaillancourt et al. (2014) recently reported that relational aggression at age 12 predicted higher levels of borderline symptoms at age 14. Research has further documented prospective associations between social aggression and BPD features (Underwood et al., 2011). Werner and Crick (1999) were the first to empirically document that relational aggression was associated with heightened BPD features in emerging adults. In recent years, this association has been replicated several times (e.g., Ostrov & Houston, 2008; Ostrov et al., 2011), although Burnette and Reppucci (2009) failed to find an association between relational aggression and borderline symptoms in a sample of incarcerated adolescent girls. In one recent longitudinal study of the association between forms of aggression and borderline pathology in a Russian sample, preschool aggression was not associated with later borderline features. However, among males and females, borderline features were concurrently associated with both physical and relational aggression in adolescence (Nelson, Coyne, Swanson, Hart, & Olsen, 2014).

Narcissistic personality traits may also be associated with relational forms of aggression. Narcissistic individuals by definition have an enhanced sense of self and status relative to peers; moreover, these individuals desire power and control over others and often exploit and manipulate their peers (Barry, Grafeman, Adler, & Pickard, 2007). This goal for social dominance over peers may promote the use of aggression among individuals with narcissistic traits (Barry et al., 2007). In addition, narcissistic youth may engage in aggression when their inflated self-views are threatened (Bukowski, Schwartzman, Santo, Bagwell, & Adams, 2009). Consistent with these hypotheses, several researchers have reported positive associations between relational forms of aggression and trait narcissism (Burt et al., 2012; Golmaryami & Barry, 2010; Lau & Marsee, 2013; Ojanen, Findley, & Fuller, 2012) and in particular with maladaptive subtypes of narcissism (i.e., entitlement, exhibitionism, and exploitativeness; Barry, Pickard, & Ansel, 2009). Associations between narcissistic traits and relational aggression have also been documented in non-Western cultures (e.g., Japan; Onishi et al., 2012). Moreover, although a large body of work has documented heightened levels of physical forms of aggression among individuals with narcissistic traits, Bukowski et al. (2009) reported that narcissism was more strongly related to relational than physical forms of aggression.

Finally, psychopathy, a maladaptive personality disorder that includes traits such as lack of remorse, superficial charm, blunted or shallow affect, manipulation of others, and egocentricity (J. D. Miller & Lynam, 2003), has been found to be associated with relational forms of aggression. As discussed in the section titled "Risk Factors: Cognitive and Emotional Processes," impaired emotional responses may be a mechanism linking psychopathic traits and relationally aggressive conduct. Initial studies showed links between the two-factor model (i.e., impulsive antisociality and fearless dominance) and relational aggression (e.g., Ostrov & Houston, 2008; Schmeelk, Sylvers, & Lilienfeld, 2008; Warren & Clarbour, 2009; cf. J. D. Miller & Lynam, 2003). Regardless of the methodological approach, robust associations have been documented between relational aggression (or indirect aggression, Coyne & Thomas, 2008; Vaillancourt & Sunderani, 2011) and measures of psychopathy or CU traits, even after controlling for the variance associated with physical aggression (e.g., Czar et al., 2011; Ostrov & Houston, 2008; Schmeelk et al., 2008). These links have been found with regard to both peer and romantic relational aggression (Coyne et al., 2010; Czar et al., 2011).

There are several important directions for future research regarding the association between relational aggression and personality pathology. For instance, some evidence has emerged indicating that distinct personality traits may interact in the prediction of relational aggression (e.g., narcissism and CU traits or measures of psychopathy; Kerig & Stellwagen, 2010). Additionally, personality pathology (e.g., borderline pathology; narcissistic traits) may be more strongly associated with relational aggression in females than in males (Banny, Tseng, Murray-Close, Pitula, & Crick, 2014; Marsee et al., 2005). In fact, in one recent longitudinal study, the indirect effect linking relational aggression at age 10 with borderline symptoms at age 14 via relational aggression at age 12 was significant

for girls only; these findings suggest that stable levels of relational aggression may be a stronger risk factor for borderline pathology in females as compared to males (Vaillancourt et al., 2014). Relations between forms of aggression and personality pathology may also differ depending on the function of the aggression (see Banny et al., 2014; Crapanzano, Frick, & Terranova, 2010; Ostrov & Houston, 2008). In one study, proactive but not reactive relational aggression significantly and uniquely predicted CU traits in a sample of adolescent detained girls (Marsee & Frick, 2007). Other work has highlighted mechanisms that might underlie the association between personality traits and relational aggression; for instance, some evidence indicates that the direct association between narcissism and relational aggression is mediated by Machiavellianism (i.e., a tendency to manipulate others and to exploit them for one's own goals; Kerig & Stellwagen, 2010). These findings highlight the need for additional longitudinal research exploring associations between personality pathology and relational aggression, with a particular emphasis on underlying mechanisms and moderating factors.

Finally, relational aggression may be conceptualized as both a predictor (e.g., Marsee & Frick, 2007) as well as an outcome (e.g., Onishi et al., 2012) of personality pathology. For instance, Bukowski et al. (2009) argued that narcissistic youth may use relational aggression to defend their inflated self-views. Narcissistic traits may also serve as a risk factor for involvement in relational aggression because they interfere with appropriate emotional responses regarding aggression (e.g., guilt; Onishi et al., 2012). Banny and colleagues (2014) posited that core features of borderline pathology, such as affective instability, may lead to the use of relational aggression; consistent with this suggestion, these authors reported that borderline features were longitudinally associated with increased relational aggression in girls. Some evidence also emerged for the alternative direction of effects, such that earlier relational aggression was associated with the development of borderline pathology; however, whereas reactive relational aggression was marginally associated with increases in borderline features over time, proactive relational aggression was related to *decreases* in these symptoms (Banny et al., 2014). As with studies of externalizing behavior problems, it will be important for future research to evaluate the extent to which relational aggression can be conceptualized as a behavioral manifestation of personality pathology. Such work would help clarify the mechanisms underlying the likely dynamic bidirectional associations between relational aggression and personality pathology across development.

DEVELOPMENTAL OUTCOMES: POTENTIAL POSITIVE CORRELATES

In considering correlates of relational aggression or similar constructs (indirect or social), one of the most intriguing and controversial foci is the assessment of what may be viewed as positive correlates. In particular, studies have sought to determine whether relational aggression may prove to be a useful tool in securing significant social status (termed *hierarchy ascension*; Hawley et al., 2007). Traditionally, aggression has been considered to align with peer difficulties such as rejection, which may in turn provoke a host of negative outcomes including more aggressive behavior (see the "Developmental Outcomes: Maladaptive Correlates" section). For example, Murray-Close and Ostrov (2009) found that children who were socially excluded tended to react to the stress of their situation by becoming more relationally aggressive over time. However, in recent years, the idea that relational aggression is uniformly related to maladaptive outcomes has been challenged on both theoretical and empirical grounds. Researchers have instead argued that some aggressive youth exhibit social competence as well as high aggression, and they hold enviable social status positions in the peer group (i.e., are considered popular, socially central, and socially dominant).

Evidence of this co-occurrence of aggressive behavior and positive positions in the peer group is apparent in early studies of physical aggression and dominance relations among children (Strayer & Strayer, 1978). The research has rapidly expanded over the past decade to include relational (social, indirect) aggression and to consider how these correlations might vary by child gender. Importantly, aggression itself does not predict status so much as how effectively the child makes use of it to achieve social goals (Prinstein & Cillessen, 2003; Walcott, Upton, Bolen, & Brown, 2008), suggesting that relational aggression may be most likely to translate into popularity among youth who combine these negative behaviors with high social skills or prosocial behavior. In fact, Puckett, Aikins, and Cillessen (2008) found that perceived popularity was associated with social self-efficacy, leadership, cooperation, and peer sociability, highlighting the importance of positive social skills in establishing a position of high status in the peer group. Notably, there is considerable overlap between membership in the perceived popular category and the controversial sociometric status group (Prinstein & Cillessen, 2003). Controversial-status children are frequently selected by peers for both liked and disliked peer nomination items,, and studies of this group point

to their high levels of aggression as well. For example, controversial preschool children are just as aggressive as their rejected counterparts, but engagement in average levels of sociability buffers against full-scale rejection by peers, both in the United States (Nelson, Robinson, & Hart, 2005) and in Italy (Nelson et al., 2010). These findings suggest that youth who exhibit a mix of aggressive and socially competent behaviors may not experience significant problems in the peer group and, in some cases, may actually benefit from high-status positions. Moreover, many children already appear to be proficient at this mix of behavior by preschool (Nelson et al., 2005).

A related perspective draws from evolutionary theory, highlighting the role of aggression in securing access to important resources and promoting one's own self-interest (Hawley, 2003a; Hawley, Little, & Card, 2008). Specifically, Hawley (2003a) has proposed that some youth are bistrategic controllers, opting for a combination of prosocial and coercive control tactics in their bid to control resources. For these youth, significant social intelligence and savvy appear to be central to effective engagement in relational aggression (Andreou, 2006). This group is similar to perceived popular or controversial youth in that relational aggression is combined with positive social behaviors and is used effectively to gain access to social resources (e.g., a socially central position in the peer group; Hawley, 2003a; Hawley et al., 2008).

An impressive number of studies have documented the positive association between relational aggression and high social status. Particularly influential are the studies that have assessed the interplay of these factors over the course of time. Cillessen and Mayeux (2004) have shown that as children move into adolescence, relational aggression becomes increasingly associated with high perceived popularity but low social preference. Relational aggression and perceived popularity are particularly connected for girls. Accordingly, there are ample reinforcements (social benefits) for those who become proficient in their use of relational aggression in the peer group. Rose, Swenson, and Waller (2004) additionally found that for older girls, the positive relations between relational aggression and perceived popularity were bidirectional in nature. Many of these connections appear to be relevant not only for Caucasian U.S. children but also for ethnic minorities (Waasdorp, Baker, Paskewich, & Leff, 2013). Similar associations are found in a number of samples outside of the United States and Canada, including Greek (Andreou, 2006), Belgian (Kuppens, Grietens, Onghena, Michiels, & Subramanian, 2008) and Italian (Nelson et al., 2010) samples. However, there are findings which indicate cultural differences as well (see the "Cultural Perspectives" section), perhaps reflecting cultural variability in the tolerance of aggressive behavior.

Relational aggression appears to promote high status across several relational contexts; for instance, Pellegrini and Long (2003) established that, in middle school, relational aggression is connected to dating popularity, particularly among girls. Being relationally aggressive does not appear to hamper friendship formation for popular aggressive youth either. Friends tend to be similar in their levels of aggression and popularity, creating further insularity from real-world consequences of their aggression toward others (Rose, Swenson, & Carlson, 2004; Peters et al., 2010). The friendships of bistrategic controllers are characterized by positive qualities, such as high intimacy and fun, although they also tend to include high levels of conflict (including overt and relational aggression; Hawley et al., 2007). Some longitudinal evidence also indicates that relational aggression is associated with increases in positive friendship qualities across time, although effects for negative relationship qualities were observed as well (Banny et al., 2011). Banny and colleagues (2011) suggested that relationally aggressive behaviors are one way that youth may establish feelings of closeness, intimacy, and alliance among close friends. As peer censure and difficulties are one of the primary mechanisms thought to account for associations between relational aggression and poor adjustment outcomes (e.g., depressive symptoms; see the "Developmental Outcomes*:* Maladaptive Correlates" section), popular relationally aggressive youth may not exhibit many of the problems typically associated with such conduct. Consistent with this suggestion, Rose and Swenson (2009) found that perceived popularity buffered relationally aggressive youth from internalizing problems.

Leadbeater, Boone, Sangster, and Mathieson (2006) have cautioned against the impression, however, that aggressive yet popular youth do not pay a price for their hostility toward others since aggression tends to invite retaliation and stress in peer relationships. Based on her work with students in middle childhood, sociologist Donna Eder (1985) described a "cycle of popularity" whereby views of popular girls moved from being positive to very negative (see the "Developmental Outcomes: Maladaptive Correlates" section). Underwood (2004) also noted that popular girls consistently struggle with a balancing act. They want to avoid a reputation for meanness, and nonverbal forms of social aggression (glares, eye rolls, and the silent treatment) may seem the least toxic approach to aggressively defending their status. The irony is that, in doing so, they engage in behaviors that may earn them the

reputation of being stuck up, a label they dread (Merten, 1997). What drives the desire for social dominance may also be problematic. Ojanen et al. (2012) provided evidence that narcissistic personality is associated with dominance goals, which are in turn predictive of relational and physical aggression.

More important, there is evidence of long-term dysfunction for many popular youth. Perceived popularity predicts increases in general externalizing problems over the course of several years (Sandstrom & Cillessen, 2006), which could place popular youth on a trajectory ill-suited for successful relationships beyond the peer group. Indeed, Sandstrom and Cillessen (2010) have demonstrated how levels of perceived popularity in high school may interact with engagement in relational aggression to predict how students will fare in their emerging-adulthood years. In particular, greater high school popularity predicted more engagement in risk behaviors post–high school, even after controlling for prior risk behaviors. Boys who were not popular but were highly relationally aggressive in high school had pronounced adjustment problems after high school. For girls, being highly relationally aggressive in high school was associated with less post–high school depression but higher workplace victimization. Additional longitudinal study is needed to fully understand the long-term consequences of being aggressive yet popular.

There are several important directions for future research on the association between relational aggression and positive peer outcomes. For instance, researchers should consider whether contextual factors, such as classroom dynamics, moderate the extent to which relationally aggressive youth are able to garner positive peer regard. In one recent study, Moore, Shoulberg, and Murray-Close (2012) reported that relationally aggressive girls were more likely to be popular, and less likely to be rejected, if their teachers liked them. Popularity with teachers may also enhance these children's ability to aggress with relative impunity, as teachers may not look for or see aggressive behavior as readily in children they generally consider to be socially competent (see Hawley, 2003b). The association between relational aggression and high status may also depend on additional classroom factors, such as levels of status hierarchy (Garandeau, Ahn, & Rodkin, 2011).

Additionally, as relational aggression is often conceptualized as a strategy that youth use to achieve status and power with peers, it will be important for researchers to examine whether individual differences in social status motivations (e.g., desires to be well liked or popular in the peer group) are associated with relationally aggressive conduct. In fact, Li and Wright (2014) found that self-reported popularity goals predicted higher levels of self-reported, but not peer-reported, relational aggression in a sample of middle schoolers. Dawes and Xi (2014) found that self-reported popularity goals were associated with higher levels of peer-reported social aggression among popular, but not unpopular, middle schoolers. The authors suggested that popular youth who endorse popularity goals may have the social resources necessary to effectively use social aggression. Other researchers have also documented the important role of actual peer status in the association between popularity goals and relational aggression; for instance, Shoulberg, Sijtsema, and Murray-Close (2011) found that having a reputation for valuing popularity was generally predictive of girls' engagement in relational aggression. The association was strongest, however, for two groups of girls who valued popularity: (a) popular girls who exhibited blunted physiological reactivity to social exclusion and (b) unpopular girls (wannabes) who demonstrated heightened physiological reactivity to exclusion. The lower stress reactivity of popular girls may allow them to pivot quickly and use relational aggression to achieve or maintain status. In contrast, the reactivity of unpopular girls may lead to aggressive responses to any perceived social slight, which further compounds their popularity problems.

Future research may also benefit from considering whether some manifestations of relational aggression are more strongly associated with positive outcomes than others. Research suggests that popular yet aggressive children adopt a wide range of aggressive behaviors in their bids for social dominance. In the context of social aggression, these children may employ both verbal and nonverbal expressions of relational manipulation. Glares of contempt, rolling of the eyes to signal disgust, and the silent treatment are nonverbal forms of social exclusion that can exert tremendous influence (Underwood, 2004). The verbal/nonverbal distinction is a useful one; when controlling for both overt and verbal social aggression, nonverbal social aggression uniquely accounts for variance in children's social status (Blake et al., 2011). Fanger et al. (2012) investigated various types of exclusionary behavior among preschoolers and argued, however, that not all types may be considered aggressive. For example, a child may seek to keep high-quality interactions going with certain peers by not allowing others to interrupt the flow. Many of the exclusionary behaviors exhibited by preschoolers are relatively indirect (subtle) in nature or focused on simply ignoring a play overture. Better-accepted preschoolers, in particular, frequently employ these forms of exclusionary behavior, and they may not hold hostile intent

toward the peers they exclude. These findings highlight the importance of research assessing whether distinct relationally aggressive behaviors have differential associations with positive outcomes, such as popularity (see the "Developmental Manifestations of Relational Aggression" section). Additional research is clearly necessary to explore the significant heterogeneity among relationally aggressive children, including the fact that some youth appear to suffer from rejection whereas others exhibit significant social status benefits as a result of their aggressive conduct.

CULTURAL PERSPECTIVES

Studies of relational aggression and similar constructs (e.g., indirect and social aggression) have been conducted across a number of diverse cultures. Similar to the study of physical aggression, a major impetus of this research is to gauge cross-cultural similarity or difference in the quantity, quality, and meaning of relationally manipulative behaviors. This work has provided significant insight into the development of relational aggression in context and has highlighted both challenges and opportunities for relational aggression researchers. More specifically, cross-cultural research underscores the need to develop culturally sensitive tools for assessing relational aggression, to consider the contextual processes that might encourage engagement in relational aggression, and to investigate potentially distinct predictors and developmental outcomes associated with relationally aggressive conduct.

A significant challenge in cross-cultural research is the development of measures that are appropriate for use across cultural contexts. In many of the existing studies of relational aggression conducted outside of the United States and Canada (the source of the majority of relational aggression research to date), existing measures are translated for use in other languages, and their psychometric properties are assessed (e.g., Kawabata et al., 2012; Lansford et al., 2012). The standard procedure of forward- and back-translation helps to ensure the linguistic and conceptual equivalence of the measures across the languages of interest. In regard to these goals, measures of relational aggression developed in Western countries appear to work rather well in diverse cultures. For instance, teacher-report measures developed in the United States exhibited high internal consistency when administered to a sample in China (e.g., Kawabata et al., 2012). Researchers have also documented configural invariance (similarity of factor structures) in measures of physical and relational aggression across cultures, suggesting that relational aggression is distinct from physical aggression and that similar behaviors (e.g., exclusion) underlie relational aggression in diverse settings (e.g., Lansford et al., 2012).

Although an emerging body of research suggests that Western measures can be translated and used effectively in other cultures, such an approach may obscure the unique manifestations of relational aggression that may exist across cultures. In fact, some researchers have argued that relational aggression may be expressed in distinct ways in different cultures; for instance, subtle relationally aggressive behaviors (e.g., threatening to tell teachers bad things about a peer) may be more typical in collectivistic than in individualistic societies (e.g., Kawabata et al., 2012). Thus, extant measures may need to be adapted to best capture the various types of relationally aggressive behaviors that are most common in distinct cultural contexts. Culturally unique manifestations of relational aggression may not lend themselves to cross-cultural comparison; however, they may play a significant role in children's adjustment. Accordingly, observational or qualitative studies of aggression may provide significant insight regarding culturally sensitive approaches to assessing relational aggression.

A significant body of research has examined relational aggression in countries other than the United States and Canada. For instance, relational aggression and/or victimization have been successfully measured in studies conducted with youth in Colombia (Velásquez, Santo, Saldarriaga, López, & Bukowksi, 2010), Italy (Nelson et al., 2010; Tomada & Schneider, 1997), China (e.g., Li et al., 2011; Nelson et al., 2006), Russia (Hart et al., 1998), Indonesia (French, Jansen, & Pidada, 2002), Japan (e.g., Kawabata et al., 2012), Greece (Andreou, 2006), Belgium (Kuppens et al., 2008), India (Bowker et al., 2012), and Australia (e.g., Hemphill et al., 2010; Pronk & Zimmer-Gembeck, 2010). Studies of indirect aggression have also included samples from diverse countries, such as the United Kingdom (Coyne, Archer, & Eslea, 2006), Germany (Möller & Krahé, 2009), Australia (Owens, Shute, & Slee, 2000), Finland (Österman et al., 1994, 1998), Poland (Österman et al., 1994, 1998), Israel (Österman et al., 1998), and Italy (Österman et al., 1998). These studies, with participants ranging in age from preschool to adolescence, have documented that relational aggression occurs with some frequency across a wide span of cultural settings.

Moreover, evidence indicates that youth spontaneously identify relationally aggressive behaviors as common in peer interactions in varied cultural contexts. For example, French et al. (2002) conducted a study in which U.S. and Indonesian children were asked to describe disliked peers, and coders documented their references to

physical, verbal, and relational aggression. Findings showed that youth in both countries frequency cited relationship manipulation (e.g., ignoring peers), social ostracism, and rumor-spreading as behaviors that elicited their dislike. Moreover, girls in both countries were more likely than boys to identify relationally aggressive behaviors in their descriptions. These findings suggest that relational aggression is a common behavior across two cultures that otherwise differ considerably in regard to gender roles, attitudes toward aggression, and along the individualism/collectivism dimension.

A critical question is whether relational aggression is uniquely tied to cultural elements, such as a society's place on the collectivism/individualism continuum. Of significant import, therefore, are studies of relational or indirect aggression that directly compare data from diverse cultures. Österman and colleagues (1994) hypothesized that children will select aggressive behaviors based on their risks versus benefits. It is likely that both the normative nature of aggression subtypes and the likelihood that youth will be punished for engaging in these behaviors vary significantly across cultural contexts; as a result, cultural differences in the benefit-to-risk ratio are expected. For instance, given the focus on interpersonal harmony in collectivistic cultures, relational aggression may be less tolerated and thus less common in these contexts (e.g., Forbes, Zhang, Doroszewicz, & Haas, 2009). Consistent with this suggestion, Forbes et al. (2009) documented that engagement in indirect aggression was more common in individualistic (United States) as compared to collectivistic societies (China) or hybrid societies with elements of both individualism and collectivism (Poland). Similarly, Österman et al. (1994) compared levels of physical, verbal, and indirect aggression for children in Finland (Finnish or Swedish), the United States (Chicago, IL: African American or Caucasian), and Warsaw, Poland. Results revealed significant differences in the frequency of aggressive behavior across countries, such that youth in the United States were especially aggressive.

As with gender differences (see the "Toward an Integrated Gender-Linked Model of Aggression" section), however, it may be especially important for cross-cultural researchers to compare cultural differences in within-group preferences for relationally versus physically aggressive behaviors. For instance, collectivistic cultures may discourage the use of all types of aggression because they interfere with harmonious group functioning; however, when youth from collectivistic societies are aggressive, they may be particularly likely to adopt relationally aggressive rather than physically aggressive behavioral strategies (see Kawabata et al., 2012). Recently, Lansford and colleagues (2012) examined this possibility in their comparison of levels of relational aggression versus physical aggression in nine different countries. Results indicated that children reported being more relationally than physically aggressive in China, India, and Thailand. In contrast, Jordanian and Kenyan children reported more engagement in physical than relational aggression. In the remaining four countries (Colombia, Philippines, Sweden, and the United States), there was no significant difference in levels of engagement in these forms of aggression. These findings hint at distinct cultural norms for aggression and underscore the importance of considering cultural differences in within-group preferences for relational versus physical aggression, in addition to potential cross-cultural differences in mean levels of relational aggression.

Evidence from several studies also highlights meaningful differences in the use of relational aggression *within* countries, perhaps reflecting distinct subcultural values and experiences. For instance, Li, Wang, Wang, and Shi (2010) demonstrated that individual differences in endorsement of collectivism or individualism were predictive of Chinese adolescents' engagement in overt and relational aggression. As expected, Chinese adolescents who endorsed more individualism were more aggressive than their collectivism-minded peers. Religious subcultures might also promote moral emotion and thereby reduce youth involvement in aggression. Consistent with this possibility, Landau, Björkqvist, Lagerspetz, Österman, and Gideon (2002) reported that levels of direct and indirect aggression were higher among secular as compared to religious Israeli children and adolescents. Taken together, findings underscore the need for research that examines subcultural variations in the development of relational aggression. Differences in socioeconomic status (SES), urban/rural environment, and religious and familial value systems may all provide significant insights in this regard.

Cultural identity may also serve a protective function against the development of relational aggression. Although cultures may vary in their prescriptions for mature social behavior, a positive sense of identification with ancestral culture may provide an important psychological foundation for psychosocial maturity. As a result, cultural identification may promote a more tolerant and less aggressive atmosphere among children and adolescents. Consistent with this suggestion, Flanagan and colleagues (2011) found that aboriginal Naskapi youth in Quebec, Canada, who exhibited a strong cultural identity with their native culture, exhibited less engagement in both relational and physical forms of aggression. In addition,

Belgrave et al. (2004) conducted a cultural intervention for African-American girls called the Sisters of Nia, in which relevant cultural values and beliefs (tied to ethnic identity, gender roles, and relational orientation) were strengthened. Findings indicated that the intervention was successful in increasing awareness and adoption of these values and beliefs; moreover, participants in the intervention exhibited marginally lower levels of relational aggression postintervention than those in the comparison group.

A critical question for cross-cultural research is whether the developmental outcomes associated with relational aggression differ across cultural contexts. This perspective highlights the importance of the goodness of fit between cultural norms and engagement in relational aggression. For example, relational aggression may prove more disruptive in collectivist cultures, which may in turn decrease the likelihood that such conduct will garner positive peer regard and increase the risk of poor adjustment outcomes among aggressors. Consistent with this possibility, Butovskaya, Timentschik, and Burkova (2007) found no connection between popularity and verbal, physical, or indirect aggression (based on peer ratings) among Russian adolescents. Moreover, Tseng and colleagues (2013) reported that relational aggression was related to decreases in perceived popularity across the fifth grade among Taiwanese youth. Similarly, Bowker et al. (2012) found that relational aggression was negatively associated with perceived popularity (after accounting for overt aggression) for a sample of adolescents in India. In contrast, overt aggression was related to heightened levels of perceived popularity. These findings suggest that, in India, overt aggression may be the more attractive and socially acceptable way to assert dominance. Additionally, research by Kawabata and colleagues (2010) documented that relational aggression was more strongly associated with symptoms of depression in a Japanese sample than in a contrasting U.S. sample. These findings are consistent with the notion that the stress associated with engagement in relational aggression may be greater in collectivistic, as compared to individualistic, cultures. More generally, findings suggest that children in collectivistic societies may not view relational aggression as favorably as children in individualistic societies; as such, these behaviors may be particularly likely to result in poor developmental outcomes in these contexts. Interestingly, recent research in the United States has documented that relational aggression is more strongly associated with internalizing pathology among Asian American, as compared to European American, youth (Kawabata & Crick, 2013), underscoring the importance of exploring differences in outcomes across racial and ethnic groups within as well as across countries.

In summary, a growing body of research has highlighted the salience of relational and indirect aggression across cultural settings. However, additional research is clearly needed to investigate cultural differences in the prevalence of and the developmental outcomes associated with relationally aggressive conduct. It will also be important for future research to explore cultural differences in the manifestation of relational aggression and to develop culturally sensitive tools for assessing these behavioral patterns. Such knowledge will be crucial for researchers developing interventions to reduce relational aggression across cultural contexts. We also anticipate that culturally universal elements will continue to emerge in much of this work. For example, harsh and manipulative parenting may be expected to predict relational aggression across cultural settings (e.g., Nelson et al., 2006). Accordingly, a cultural emphasis need not detract from important commonalities that may be pursued to enhance the lives of children in diverse contexts.

RELATIONAL AGGRESSION INTERVENTIONS

Since the first publication using the term *relational aggression* (Crick & Grotpeter, 1995), a robust body of research has emerged indicating that both relational aggressors and relational victims are at risk for a number of adjustment difficulties (e.g., peer rejection, internalizing problems, externalizing problems; see the "Developmental Outcomes: Maladaptive Correlates" section). As such, there has been substantial interest among researchers and other professionals in the development of interventions to reduce relational aggression. As others have noted, programs that have been designed to address physical aggression may not be easily adapted for use with relational aggression (Ostrov et al., 2009; Zahn-Waxler et al., 2006), highlighting the need for interventions that specifically target relationally aggressive conduct. An exhaustive review of relational aggression interventions by Leff and colleagues (2010) yielded 21 separate interventions with a focus on relational aggression or related constructs (i.e., indirect aggression, social aggression, social exclusion). Although this total may seem high for an area of research that has systematically been around for only two decades, only 9 of the 21 programs meet the criteria for establishing efficacy as outlined by the Society for Prevention Research (see Flay et al., 2005). However, preliminary findings indicate that several of these programs hold significant promise

in efforts to reduce children's involvement in relational aggression (for a review, see Leff et al., 2010).

A review of the various programs that have been developed to date is beyond the scope of this chapter; however, a brief overview of exemplar interventions targeting relational aggression at different points in development can be illuminating in terms of both program structure and efficacy findings. Although very few interventions have been developed for the early childhood years, the Early Childhood Friendship Project has shown a great deal of promise (Ostrov et al., 2009). The program is a classroom-based intervention that is designed to reduce relational aggression and relational victimization. The initial intervention (Ostrov et al., 2009) was a 6-week program using observational assessments of relational aggression and victimization in nine randomized intervention classrooms and nine control classrooms. Each week, a different lesson was introduced and reinforced throughout the week. Two of the six lessons focused on relational themes (i.e., relational aggression and relational inclusion). In this study, classrooms were the unit of analysis, and researchers found that effect sizes indicated that the intervention classrooms tended to have greater reductions in both relational aggression and relational victimization.

A second illustrative intervention, the Walk away, Ignore, Talk it out, Seek help (WITS) program, was created by Leadbeater, Hoglund, and Woods (2003) and was initially conducted with children in grades K–3. This program focuses specifically on relational victimization and adopts an ecological approach including parents, siblings, and local police in addition to the school-based component. The core of the program utilizes a literacy-based approach that can be readily incorporated into the existing curriculum and lesson plans. For instance, one component of this intervention involves reading books with lessons on social behaviors to participants and then providing them with the opportunity to discuss the story and complete activity sheets. Some evidence supports the efficacy of the WITS intervention; for instance, researchers have found that relational victimization decreased in all of the program schools and in the low-poverty control schools but increased in the high-poverty control schools. The program has since been expanded through sixth grade, also with encouraging results (Hoglund, Hosan, & Leadbeater, 2012; Woods, Coyle, Hoglund, & Leadbeater, 2007).

The Friend to Friend program (Leff et al., 2009) uses a social information-processing approach to target relational aggression among third- through fifth-grade girls in an urban setting. The inner-city context, in addition to the participatory action research framework and its cultural sensitivities, is a particular strength of this program. The program utilizes a social-cognitive retraining model consistent with the Crick and Dodge (1994) reformulated social information-processing model. Specifically, it was designed to help relationally aggressive girls explore and practice the identification of feelings and signs of physiological arousal, calming strategies, interpreting intentions of others, and generating and evaluating alternative behaviors to enact. Empirical evaluations of the efficacy of this program indicated that relationally aggressive girls, randomized to the program, had large decreases in teacher-reported relational aggression (Leff et al., 2009). Findings underscore the promise of interventions informed by social information-processing theory in reducing relational aggression.

Finally, one recent intervention targeting bullying in Finnish schools, the KiVa program (Kärnä et al., 2011), was developed to address the potential social status benefits of aggressive behavior. More specifically, KiVa builds on the idea that interventions can successfully reduce levels of aggressive behavior by changing the reactions of peers to bullying behaviors (Kärnä et al., 2011). For instance, if bystanders defend victims rather than reinforce displays of aggression, aggressive behavior may no longer serve as a mechanism for youth to gain social power and status. One of the primary components of the KiVa program focuses on helping youth develop skills to support victims of bullying. Recent research highlights the efficacy of the KiVa program in reducing aggressive behavior across developmental periods (e.g., Kärnä et al., 2011), although some evidence indicates that the program is more robustly efficacious in younger as compared to older samples (Kärnä et al., 2013). Importantly, preliminary evidence supports the notion that this program is effective at reducing relational forms of aggression, such as social exclusion, though effect sizes tend to be smaller for these forms of aggression than for physical aggression (Salmivalli, Kärnä, & Poskiparta, 2011).

Despite promising findings in this area, research regarding relational aggression interventions is still in its infancy, and several important directions for future research remain. Leff and colleagues' (2010) review of extant relational aggression interventions indicates that the majority of the programs to date have been designed and evaluated for late elementary and/or early middle school children. This is surprising from a developmental standpoint, given that it is likely easier to change behaviors before they become an ingrained part of children's behavioral repertoires. Additionally, the vast majority of these interventions were conducted in a school or after-school setting, highlighting the need for intervention programs that target

maladaptive family processes that may contribute to the development of relational aggression (see the "Risk Factors: Social Processes" section). Interestingly, very few of the programs to date have been directed toward relational victims (Leff et al., 2010). Although it is likely that decreases in relational aggression will also benefit the targets of these behaviors, separate programs may be needed to ameliorate the difficulties encountered by victimized youth. Additionally, research is needed to explore whether different intervention programs are most efficacious across different points in development, for males versus females, or for youth in different cultural settings.

DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVES

Developmental Tasks

A developmental psychopathology perspective advances our understanding of relational aggression in several important ways. First, developmental psychopathologists emphasize the importance of the successful negotiation of key developmental tasks in the emergence of disorder (Cicchetti, 1993). From this perspective, many of the risk factors for relationally aggressive conduct reflect a failure to master salient developmental tasks. As an example, the ability to manage negative emotional reactions increases throughout childhood, and a failure to develop these skills is associated with maladaptive behavioral and emotional patterns (Izard, Youngstrom, Fine, Mostow, & Trentacosta, 2006). Similarly, establishing positive relationships with peers, including garnering acceptance from the peer group, is a key developmental task during middle childhood (Masten & Coatsworth, 1998). As these examples illustrate, both child characteristics (e.g., emotional processes, accurate attributions of others' behaviors) and social risk factors (e.g., peer rejection) for relational aggression can be conceptualized as deviations from typical developmental pathways that reflect a failure to master salient developmental tasks.

A developmental psychopathology framework also highlights the possibility that distinct risk factors for relational aggression may emerge across developmental periods. As key tasks differ across developmental stages (Masten & Coatsworth, 1998), it is possible that the factors that are most strongly associated with relational aggression change throughout development. A failure to inhibit angry reactions to frustration, for instance, may be most strongly associated with relational aggression during developmental periods in which mastery of these capacities is salient (e.g., early childhood). In contrast, a failure to establish positive relationships with peers may be most strongly associated with relational aggression when relationships with peers are especially important (e.g., middle childhood and adolescence). However, successful negotiation of key tasks in any given developmental period provides the foundation for later achievements (e.g., the ability to regulate angry reactions likely facilitates the establishment of positive peer relationships; see Cicchetti, 1993); thus, it is critical to understand how the risk factors for relational aggression work together across development to promote maladaptive behavior patterns.

A developmental tasks perspective may also provide significant insight regarding the association between relational aggression and maladaptive outcomes. Masten and Coatsworth (1998) argued that engaging in rule-governed conduct, including inhibiting aggressive impulses, is a key developmental task of middle childhood; however, empirical work regarding normative developmental change in relational aggression highlights the possibility that some involvement in relational aggression may be fairly common during middle childhood and early adolescence. In these developmental contexts, low levels of relational aggression may not portend adjustment difficulties (see Underwood et al., 2011, for an application of this idea to social aggression). In contrast, frequent and high-intensity displays of such conduct may reflect a failure to master this key developmental task and may in part emerge as a result of earlier developmental failures (e.g., an inability to develop appropriate emotion regulation capacities; see Underwood et al., 2011). Thus, a developmental tasks perspective may help researchers identify patterns of relationally aggressive behaviors (e.g., high intensity, frequent, and resulting from dysregulated reactions to stress) that signify particularly high levels of risk for poor adjustment outcomes.

Multilevel Perspectives

Consistent with the suggestion by developmental psychopathologists that multilevel perspectives are critical to understanding maladaptive behavior patterns (e.g., Cicchetti, 1993), the development of relational forms of aggression appears to reflect processes ranging from genetic factors to socialization experiences. In recent years, theorists have begun to propose mediation and moderation models that integrate these distinct risk factors.

Mediation Models

The mechanisms involved in the development of relationally aggressive behavior may occur across multiple

levels of analysis, and several lines of research suggest that biological risk factors influence relational aggression via alterations in cognitive, emotional, and social functioning. For instance, researchers have highlighted the need to consider endophenotypes, including psychophysiological and cognitive patterns, in evaluating the processes that link genetic risk with developmental outcomes (Brendgen, 2012). Similarly, cognitive and emotional processes may help explain the association between psychophysiological risk and engagement in relationally aggressive conduct. In fact, several theoretical perspectives suggest that physiological stress arousal is related to aggression because it reflects emotional experiences of anger, fear, or anxiety (see Murray-Close, 2013a). Physiological arousal may also lead to aggression by interfering with accurate cognitive processing of threat or provocation. In fact, Williams, Lochman, Phillips, and Barry (2003) found that increases in heart rate following threat were associated with increases in HAB. These results are consistent with the suggestion that exaggerated negative emotional responses to stress lead to social-cognitive impairments that promote involvement in aggressive behavior (Frick & Morris, 2004).

Biological factors, including genetic and physiological risk, may also lead to increases in relationally aggressive conduct because they alter children's social environments. In fact, theorists have suggested several processes whereby children's genetic makeup affects the social environments that they encounter (Brendgen, 2012). For instance, genetically influenced traits may lead children to actively select specific environments (i.e., active gene-environment correlations) and/or to elicit distinct reactions from others (i.e., evocative gene-environment correlations) that in turn increase their risk for involvement in relationally aggressive conduct (Brendgen, 2012). As an example, a child who has genetic risk for emotion dysregulation may be more likely to choose aggressive friends and to elicit rejection from peers; these social experiences, in turn, have been found to increase risk for relationally aggressive conduct (see the "Risk Factors: Social Processes" section). Similarly, a tendency to experience exaggerated physiological arousal during peer conflict situations may make youth easy targets of peer victimization (Murray-Close, 2013b), a social stressor that has been found to increase aggressive responses (see the "Risk Factors: Social Processes" section).

Mechanisms of influence across multiple levels of analysis are likely bidirectional in nature; thus, alterations in genetic and physiological processes may also serve as mediators of the association between social experiences and relationally aggressive behavior. For instance, exposure to peer victimization may modify gene expression through epigenetic processes, thus increasing risk for social behaviors such as aggression (Brendgen, 2012). Similarly, an emerging body of research has documented that victimization by peers is associated with alterations in stress physiology (see Murray-Close, 2013a, for review); these findings highlight the possibility that negative peer treatment may lead to physiological profiles that in turn promote relationally aggressive conduct. Social-cognitive risk factors for aggression, such as HAB, may also help explain why social experiences such as peer victimization and media exposure are related to elevated levels of aggressive conduct (e.g., Gentile, Coyne, et al., 2011; Hoglund & Leadbeater, 2007; Ostrov et al., 2011). Mediation models across levels of analysis may further help elucidate the mechanisms that link relational aggression with negative developmental outcomes, such as peer victimization (e.g., Ostrov, 2008; Ostrov & Godleski, 2013) and psychopathology (Kamper & Ostrov, 2013).

Although preliminary, these findings highlight the critical need for multilevel, transactional research examining the processes linking risk factors to involvement in relationally aggressive conduct. Recent statistical advances, including developmental cascades models, allow for longitudinal tests of how functioning in one area can spill over into other domains of functioning (Masten et al., 2005). Developmental cascades approaches that span multilevel domains of functioning (see Cox, Mills-Koonce, Propper, & Gariépy, 2010) may be especially useful in enhancing our understanding of the longitudinal processes involved in the development of relational aggression.

Moderation Models

Multilevel perspectives regarding the development of relational aggression also highlight the possibility that risk factors may interact across levels of analysis in the prediction of relationally aggressive conduct. In fact, a large body of research regarding aggression has emphasized a diathesis–stress model of aggression, whereby an underlying trait or vulnerability is activated through exposure to environmental stressors. Although most work in this area has focused on physical forms of aggression, several recent findings highlight the potential role of diathesis–stress processes in the development of relational forms of aggression. For instance, Mathieson et al. (2011) reported that girls with cognitive (i.e., HAB) and emotional (i.e., emotional reactivity to provocation) vulnerability for relational aggression were most likely to engage in such conduct when they were exposed to social risk (i.e., relational victimization by peers). Diathesis–stress models have also been employed in the study of physiological risk for relational

aggression. For instance, Murray-Close and Rellini (2012) found that physiological risk was associated with relational aggression only among women with a history of sexual abuse, a contextual factor that has been found to predict relational forms of aggression in previous research (Cullerton-Sen et al., 2008). Similarly, Murray-Close (2011) found that physiological risk was most strongly associated with romantic relational aggression among women who also exhibited cognitive (i.e., HAB) and social (i.e., relational victimization) vulnerabilities for such conduct.

It will be important for future research to examine the diathesis–stress model in the context of genetic risk factors for relational aggression. In fact, G×E interactions highlight how genetic vulnerabilities may result in aggressive behavior only when they interact with environmental stressors, such as maltreatment by parents or peers (Brendgen, 2012). To date, little research has explored gene-environment interactions in the development of relational aggression. In preliminary research in this area, Brendgen et al. (2008) found that genetic risk interacted with friends' aggressive behavior in the prediction of physical, but not social, forms of aggression. The authors suggest that children may be likely to emulate social aggression from friends, regardless of genetic vulnerability, given the relatively low costs (e.g., low likelihood of adult intervention) and potential benefits (e.g., high social status) associated with social aggression (Brendgen et al., 2008). However, it will be important for future research to further explore diathesis–stress models regarding genetic vulnerabilities for relational aggression. Such work may benefit from adopting molecular genetic designs and investigating candidate genes implicated in the development of physical aggression and antisocial behaviors (see Brendgen, 2012). It will also be important for this work to focus on the unique social stressors that may activate genetic risk for relational aggression; for instance, environmental pathogens that are uniquely associated with the development of relational aggression (e.g., parental psychological control; see the "Risk Factors: Social Processes" section) may be particularly important to explore in studies of G×E interactions.

In contrast to diathesis–stress models of relational aggression, some researchers have proposed that biological vulnerabilities may be most likely to translate into aggressive or antisocial behavior in the context of *benign* environmental contexts (e.g., high SES). More specifically, the social push hypothesis suggests that adverse environments may overwhelm biological risk for aggression; in these contexts, social risk factors may be the strongest predictors of such conduct. In contrast, genetic and physiological differences may exert a stronger effect on aggressive behavior in social contexts that do not promote aggression. This perspective is similar to the discussion of suppression effects in genetic studies, in which some environmental factors reduce the role of genetic influences on behavior (Brendgen, 2012). Although several studies have provided support for the social push perspective in the development of physical aggression and antisocial behavior (see Raine, 2002, for a review), there is less support for this model in the development of relational forms of aggression. One exception is a study documenting that blunted morning cortisol and flattened change in cortisol across the day were more strongly associated with relational aggression in nonmaltreated, as compared to maltreated, youth (Murray-Close et al., 2008). It is important to note that both maltreated and nonmaltreated participants in this study experienced significant social risk (e.g., low income), highlighting the possibility that severe environmental contexts (e.g., abuse) may be more likely than moderate stressors (e.g., peer victimization) to overwhelm biological factors in the development of relational aggression.

In recent years, researchers have proposed that individuals differ in their susceptibility to environmental influence, such that those who exhibit heightened physiological reactivity to stress, are more malleable or plastic, for better or worse (Boyce & Ellis, 2005). This theoretical approach is an outgrowth of the diathesis–stress model but extends the idea to argue that the very same individuals who are most negatively affected by adverse environmental input will also benefit most from supportive contexts (Ellis et al., 2011). Thus, individual differences in biological processes that have been proposed as risk factors for aggression (e.g., high physiological stress reactivity) may in fact reflect the organism's ability both to prepare for challenges in the face of adversity as well as to benefit from the resources available in supportive contexts (Boyce & Ellis, 2005). This hypothesis suggests that it will be important for studies to include assessments of positive social contexts (e.g., relational inclusion) to examine whether biological factors that serve as risk factors for relational aggression in adverse contexts portend beneficial outcomes in supportive contexts.

Equifinality and Multifinality

Developmental psychopathologists have also highlighted the importance of examining pathways to maladaptive behavior patterns (Cicchetti & Rogosch, 1996; Egeland,

Pianta, & Ogawa, 1996; Sroufe, 1997). The concept of *equifinality* suggests that a particular outcome may be achieved via a number of distinct pathways (Cicchetti & Rogosch, 1996). This notion highlights the possibility that there may be multiple trajectories, each with a different set of risk factors, to relational aggression. As discussed, researchers have documented two distinct physiological profiles associated with relational aggression; on one hand, some evidence indicates that low-stress reactivity, hypothesized to reflect temperamental fearlessness, predicts heightened involvement in relationally aggressive conduct (e.g., Sijtsema et al., 2011). On the other hand, findings from other studies suggest that relational aggression is related to physiological overarousal in response to negative experiences with peers, perhaps because this pattern reflects angry reactions to peer conflict (Murray-Close & Crick, 2007). The concept of equifinality underscores the possibility that both suggestions may be correct; in effect, blunted and exaggerated physiological reactivity in response to peer stress may promote phenotypically similar displays of relational aggression via distinct trajectories (see Frick & Morris, 2004, for a discussion of these pathways in the development of physical aggression). An important task for researchers in this area, then, is to identify the underlying processes as well as the moderating factors that channel youth into each pathway. For example, heightened physiological reactivity may promote relational aggression when it occurs in individuals who are frequently exposed to contextual factors that elicit stress reactions (e.g., victimization) and who interpret these stressful events as intentional and hostile (e.g., exhibit HAB; Murray-Close, 2011). In contrast, blunted physiological reactivity may promote relational aggression among individuals with relatively low levels of HAB (Murray-Close, 2011).

The related concept of *multifinality*, which suggests that a single etiological factor can result in multiple developmental outcomes (Cicchetti & Rogosch, 1996), may also inform the study of relational aggression in several ways. First, researchers frequently argue that relational and physical forms of aggression are both manifestations of externalizing behaviors (Crick & Zahn-Waxler, 2003; Tackett et al., 2009). From this perspective, similar underlying vulnerabilities or traits may promote both forms of aggression, with specific manifestations depending on factors such as the gender, age, or social goals of the aggressor (Burt et al., 2012; Crick & Zahn-Waxler, 2003; Lagerspetz & Björkqvist, 1994). In fact, some studies have demonstrated overlapping genetic (Brendgen et al., 2005), social (e.g., maltreatment; Cullerton-Sen et al., 2008), and personality (Burt et al., 2012) risk factors for physical and relational aggression. In future work in this area, it will be particularly important to identify moderating factors (e.g., gender; see Cullerton-Sen et al., 2008, for an example) that can help explain the circumstances or contexts in which a shared risk factor results in the manifestation of relationally, rather than physically, aggressive behaviors. Additionally, as some studies have found unique risk factors for physical versus relational forms of aggression (e.g., Godleski et al., 2010; Sijtsema et al., 2011), theoretical and empirical work must also consider distinct developmental pathways toward such conduct. In effect, it may not always be appropriate to use theory and past research on physical aggression to justify predictions regarding relational aggression.

The concept of multifinality also highlights the possibility that behavioral displays of relational aggression may be related to distinct sets of developmental outcomes. As reviewed earlier, a large body of research indicates that youth who engage in relational aggression are at risk for social, psychological, and behavioral maladjustment. However, there has been considerable debate regarding whether relational aggression may at times serve adaptive functions, such as allowing youth to establish dominant and high-status positions within the peer group (e.g., Hawley et al., 2007). In fact, an emerging body of research indicates that some relationally aggressive youth enjoy relatively high levels of social power or prominence with peers, depending on factors such as their gender, age, and prosocial behavior (Cillessen & Mayeux, 2004; Hawley, 2003a; Hawley et al., 2007). These findings are consistent with the concept of multifinality and suggest that the meaning of relationally aggressive conduct may be different for youth depending on where they fall on a constellation of other traits. Moreover, findings highlight the potential utility of person-centered approaches in identifying profiles of relationally aggressive youth who experience negative versus positive developmental outcomes (see Hawley et al., 2007, 2008). An important extension of this work will be to assess the relative dispersion of outcomes (i.e., multifinality) associated with relational aggression as compared to other facets of externalizing pathology or antisocial behavior (see Egeland et al., 1996, for a comparison of dispersion for early internalizing and externalizing pathology).

FUTURE DIRECTIONS

Antisocial behavior is one of the most well-researched topics in developmental psychopathology, and the inclusion of relational aggression in this work has dramatically altered our understanding of aggressive behavior problems

in youth. Since Crick and Grotpeter's (1995) seminal publication on the topic of relational aggression two decades ago, several important directions for future research have emerged.

Understanding How Relational Aggression Relates to Antisocial Behaviors

Critical questions remain regarding the overlap between forms of aggressive behavior. For instance, although social, indirect, and relational forms of aggression are conceptually similar, we do not believe that these terms are interchangeable (see the "Defining Relational Aggression" section). There may be theoretically meaningful differences in the etiology and outcomes associated with each subtype of behavior; relational aggression, for example, may be particularly likely to occur during early childhood and may be more strongly tied to close, intimate friendships and other close relationship systems. Researchers also should explore relational bullying, defined as repeated perpetration of relationally aggressive acts in the context of a relationship characterized by a power imbalance (e.g., the target is physically smaller or less popular than the aggressor; Gladden, Vivolo-Kantor, Hamburger, & Lumpkin, 2014; Terranova, Morris, & Boxer, 2008). Researchers have yet to evaluate the extent to which relational aggression and relational bullying are theoretically and empirically distinct. It will be particularly important to isolate effects that are specific to relational bullying versus more general acts of relational aggression. For example, much work on relational aggression in the context of close friendships likely does not address relational bullying. In contexts that may include both relational aggression and relational bullying (e.g., classroom peer relationships), it is unclear whether relational bullying is associated with more problematic outcomes than relational aggression. Moreover, initial studies suggest that relational aggression exhibits significant overlap with electronic forms of aggression (Werner, Bumpus, & Rock, 2010), with some longitudinal evidence indicating that relational aggression precedes electronic aggression (e.g., Hemphill et al., 2012; Werner et al., 2010). A critical question for future research is whether relational and electronic aggression are distinct or whether they are analogous behaviors manifested in different formats (i.e., face to face versus using electronic media; see Wright & Li, 2013).

Future research must also evaluate the degree to which relational aggression is best conceptualized and assessed as a distinct behavior versus a manifestation of antisocial behavior and externalizing pathology (e.g., Burt et al., 2012; Crick & Zahn-Waxler, 2003; Tackett, Daoud, De Bolle, & Burt, 2013). Researchers often integrate measures of relational aggression into instruments assessing a broader range of aggressive or antisocial conduct, a practice that is supported by evidence indicating that relational aggression: (1) is highly correlated with other aggressive behaviors (e.g., physical aggression; Card et al., 2008); (2) significantly loads on a single antisocial behavior factor with physical aggression and rule-breaking behaviors (Tackett et al., 2013); and (3) exhibits similar correlations with personality factors as other facets of antisocial conduct (Tackett et al., 2013). Nevertheless, as reviewed in this chapter, some evidence suggests that relational and physical aggression have unique developmental precursors and outcomes. These findings underscore the critical need for empirical tests of whether the developmental trajectories associated with relational aggression are similar to (or distinct from) trajectories of other indices of antisocial conduct, such as physical aggression.

We believe that a top priority for the next decade of research on relational aggression should be to improve the conceptual clarity in the field regarding how relational aggression relates to various facets of antisocial behavior. To this end, we have several suggestions for future work in this area. First, it is especially important for future researchers to adopt the terminology that was originally intended for the measures used (e.g., relational aggression versus relational bullying versus indirect aggression). Second, researchers must examine the empirical overlap across measures (and across items within measures) to test the extent to which these constructs are similar versus distinct. One practical implication of this recommendation is that researchers must include multiple items assessing each subtype of behavior rather than integrating single items of relational aggression into broader assessments of antisocial conduct. New studies should be developed with the aim of testing the shared and distinct causes and correlates of relational aggression versus other forms of aggression and antisocial behavior; incorporating multiple facets of antisocial behavior in these studies will be essential to understanding the processes of equifinality and multifinality (see Egeland et al., 1996). Moreover, researchers should evaluate the extent to which interventions exhibit specificity in reducing different behaviors (e.g., physical aggression, relational aggression, relational bullying, and electronic aggression). This work will have critical implications for applied efforts to reduce aggressive and antisocial conduct. For instance, given emerging research highlighting the unique risk factors for relational aggression, it may be necessary to develop

additional interventions that specifically target relational aggression because methods and approaches developed for physical aggression or other antisocial behaviors may not be efficacious.

Moving Beyond "Mean Girls"

In early research, relational aggression was often conceptualized as a behavior primarily enacted by child and adolescent girls (see Crick & Grotpeter, 1995). This has led to the popular notion that relational aggression is a problem of *mean girls*. Consistent with this perspective, the inclusion of relational forms of aggression is essential to research on the aggressive behavior patterns of girls, both because physical aggression is uncommon among girls and because the overlap between these two forms of aggression appears to be lower for girls than for boys. Thus, when girls are aggressive, they tend to engage in relational, but not physical, forms of aggression. A failure to include measures of relational aggression will lead researchers to overlook the vast majority of aggressive females.

At the same time, mounting evidence has highlighted the need for research to expand beyond these circumscribed gender and age boundaries. For instance, relational aggression is not only perpetrated by females; evidence indicates that males engage in these behaviors with some frequency. Moreover, the vast majority of research on relational aggression has concentrated on these behaviors during early childhood through adolescence. This narrow focus has likely emerged from the persistent view that relational aggression is problem of adolescence, a perspective that has been allowed to thrive in the absence of good estimates of the incidence of relational aggression across developmental periods. Nonetheless, as relational aggression is theorized to promote social power and resource control in groups (e.g., Hawley, 2003a), such conduct may emerge with some frequency in adult contexts, such as the workplace. For instance, relational aggression may be used to climb the corporate ladder or to denigrate career competitors. Despite these possibilities, we know little about the use of relational aggression in dyadic (e.g., close friendships and romantic relationships) and group-based relational contexts (e.g., the workplace) during adulthood.

As researchers expand the study of relational aggression beyond mean girls, we have several recommendations regarding the most critical research priorities. First, we need epidemiological studies regarding the prevalence of relational aggression in males and females across developmental periods. Second, researchers should examine the use of relational aggression in adulthood (particularly beyond the college years); such work has the potential to provide important insights into adult adjustment and inform interventions aimed at improving group dynamics (e.g., workplace productivity) and functioning in close relationships (e.g., marital harmony). Third, researchers should conduct longitudinal studies of the long-term impact of continuity in relationally aggressive behavior. Studies that assess trajectories of relational aggression (see Cleverley et al., 2012, for an excellent example) have the potential to identify why some individuals desist from such conduct as well as inform the debate regarding the developmental outcomes of relational aggression. In fact, some of the costs and benefits of relational aggression may emerge during the adult years (see Sandstrom & Cillessen, 2010). Finally, it is critical for researchers to continue to explore the role of gender in the correlates of relational aggression as the meaning and consequences of such conduct may be gender-linked (see Ostrov & Godleski, 2010).

Developing New Methods and Research Designs to Study Relational Aggression

We believe that an essential direction for the next generation of relational aggression research is the inclusion of novel measures and research designs. For instance, few approaches beyond behavioral observations allow researchers to capture relationally aggressive behaviors in vivo. Techniques that allow researchers to study relational aggression while it is emerging, including potential factors that precipitate these behaviors as well as their immediate outcomes, would provide researchers with a more fine-grained understanding of the transactional processes underlying such conduct. It is particularly important for researchers to move beyond trait-based conceptualizations of relationally aggressive behavior and associated outcomes (e.g., reactively relationally aggressive youth tend to be victimized) to examine the dynamics of specific interactions using the time scale in which these processes are most likely to occur (e.g., a peer provokes the child, the child responds with reactive relational aggression, the peer then ignores the child, etc.; see Orobio de Castro, Thomaes, & Reijntjes, 2015). Such approaches would provide a rigorous test of the transactional processes theorized to underlie relational aggression and would allow researchers to link long-term developmental change with short-term exchanges (see van Geert & Steenbeek, 2005).

It is also critical for researchers to adopt methodological approaches that can test the causal pathways hypothesized to underlie relational aggression (see Orobio de Castro et al., 2015, for a discussion of integrating experimental

designs into peer relationships research). To date, the vast majority of work in this area is correlational and cross-sectional in nature; the incorporation of experimental designs promises to further clarify the mechanisms associated with relational aggression. Hypothesized developmental precursors of relational aggression that can be manipulated, such as exposure to aggressive media, should be examined in the context of experimental research designs (e.g., Coyne et al., 2008). Evaluation of the effects of interventions may also provide insight into the causes of relational aggression, particularly in contexts where ethical constraints prohibit random assignment to experimental conditions (e.g., child maltreatment). Finally, factors that cannot be directly manipulated (e.g., culture, genes, gender) can be included in experimental designs as moderators. Long-term longitudinal designs that incorporate rigorous controls of earlier functioning (e.g., developmental cascades; Masten et al., 2005) should also be employed to better clarify directional associations between relational aggression and putative risk factors and outcomes.

We believe that researchers should increasingly incorporate person-centered analyses (e.g., latent profile analysis, latent class growth analysis) to identify heterogeneity among relationally aggressive youth. For instance, emerging evidence indicates that there may be distinct subgroups of relational aggressors: Some perpetrators appear to enjoy social power and status (e.g., popularity) whereas others suffer poor social outcomes (e.g., rejection). The inclusion of person-centered analyses may help clarify distinct pathways to relational aggression (equifinality) and the differing developmental outcomes related to such conduct (multifinalty; see Cicchetti & Rogosch, 1996). Further, this research could be integrated into intervention work: Interventions for popular relational aggressors may need to identify ways to replace the social status benefits of aggression in a manner that facilitates youth buy-in (Leff, Waasdorp & Crick, 2010). Interventions with low-status youth, in contrast, may be most efficacious when they promote social skill development.

Culture and Context

Extant research has highlighted the critical role of context in the development of relational aggression. It is essential for future researchers to broaden this focus to encompass a wider range of relational and cultural contexts, including relationship types (e.g., friendships, siblings), countries, SES, urban/rural environments, school contexts, and religious and familial value systems. In fact, although there are an impressive number of studies of relational aggression in countries other than the United States, explorations of how these behaviors differ across multiple countries or across diverse populations within a single country are still relatively rare. We believe that a top priority for this work should be the adoption of multilevel perspectives that investigate interactions and bidirectional associations across various levels of analysis (i.e., from genes/cells to communities). Importantly, studies of contextual effects should move beyond a singular focus on differences in the *frequency* of relational aggression to consider differences in the *meaning* of such conduct across these contexts (Kawabata et al., 2010). For example, it is crucial to investigate whether pathways to relational aggression and associated developmental outcomes vary as a function of distinct contexts (see Kawabata et al., 2010, for an example).

It is also important for researchers to investigate the mechanisms hypothesized to link contexts to relationally aggressive behavior (i.e., mediation models). As an example, some work has documented SES differences in the use of relational (or indirect) aggression, although the direction of effects has varied across studies (e.g., Bonica et al., 2003; Vaillancourt et al., 2007). In an effort to understand the processes that lead to these differences, it is necessary to integrate factors that may be related to SES and that have been implicated in the development of relational aggression (e.g., parenting behaviors, family stress and conflict; see the "Risk Factors: Social Processes" section). These approaches may also inform our understanding of within-group differences in relational aggression; for instance, there is likely substantial heterogeneity in parenting behaviors within SES backgrounds, and these differences may in turn have important implications for children's involvement in relational aggression.

In sum, we believe that there are several critical future directions that have the potential to advance the study of relational aggression in new and exciting directions. As we embark on the next generation of relational aggression research, it will be crucial to engage in significant theory building and to ground new research studies in theory. Additionally, given the clear need for direct replication in psychological research (see Pashler & Harris, 2012), new approaches to the study of relational aggression should be augmented with studies developed to replicate early relational aggression findings.

CONCLUSION

Research on relational aggression has burgeoned in recent years, and this work has significantly altered the ways in which aggressive and antisocial behaviors

are conceptualized both in research and in practice. Theoretically, the construct of relational aggression has forced developmental psychopathologists to reconsider the long-standing assumption that girls do not exhibit significant behavioral problems prior to adolescence. Moreover, this work has challenged parents, teachers, and clinicians to seriously consider the developmental ramifications of relational aggression. Despite these significant advances, critical questions remain. For instance, why are some relationally aggressive children highly rejected, whereas others hold coveted positions in the peer group? When is relational aggression a normative behavior, and when does it serve as an index of risk for poor developmental outcomes? How can parents, teachers, and clinicians intervene with perpetrators and victims of relational aggression? We believe that the theoretical, methodological, and data-analytic advances in the field of developmental psychopathology hold great promise in helping researchers address these and other significant questions regarding the etiology and developmental outcomes of relational aggression.

CONCLUSIONS, PRACTICAL IMPLICATIONS, AND FUTURE DIRECTIONS 756
REFERENCES 758

The role of culture in human development is one of the major issues in sociology, anthropology, psychology, and clinical science. Research findings have indicated considerable variations in children's and adolescents' behaviors, emotions, and cognitions across cultures. Cultural norms and values are involved in development through various processes, such as facilitation and suppression of specific behaviors (Weisz, Weiss, Suwanlert, & Chaiyasit, 2006). Culture also provides a frame of reference for social judgments of behaviors and thus ascribes meanings to the behaviors (X. Chen & French, 2008). Therefore, whether a behavior is viewed as adaptive or maladaptive depends on cultural context (e.g., García Coll, Akerman, & Cicchetti, 2000; Kleinman, 1980). Moreover, how adaptive and maladaptive behaviors develop in a society or community is determined, in part, by cultural factors.

Developmental theorists and researchers have traditionally been interested in the socialization role of adults, especially parents and educators, in transmitting cultural values to the young generation (e.g., Goodnow, 1997; LeVine et al., 1994; Vygotsky, 1978). However, the processes of cultural influence on development, particularly in socioemotional areas, are more complicated and more comprehensive than the transmission of the cultural system from senior members of the society. Many cultural norms and values, such as self-control, that serve to promote positive interpersonal interactions and group functioning do not have inherent benefit per se and thus may not be readily appreciated by children. Moreover, adult influence becomes more distal as children develop greater independence with age and as children engage in more activities

The writing of this chapter was supported by grants from the National Science Foundation (#BCS-1225620) and the Social Sciences and Humanities Research Council of Canada (SSHRC) to X. Chen.

outside the home and classroom. Thus, cultural norms and values that are endorsed in peer groups, which may or may not be compatible with the adults' cultural system, become increasingly important in guiding children's and adolescents' behaviors.

X. Chen (2012) and X. Chen and colleagues (e.g., X. Chen & French, 2008) argued that cultural influence on individual development involves peer interactions and relationships. According to this view, while peer interactions and relationships contribute to children's and adolescents' adaptive and maladaptive development, culture affects the processes of peer interactions and features of peer relationships.

The significance of peer interactions and relationships for social, behavioral, and cognitive development has long been well recognized in the literature (e.g., Hartup, 1992; Piaget, 1932; Rubin, Bukowski, & Parker, 2006). Peer interactions provide opportunities for children to learn social and problem-solving skills, such as negotiation and cooperation, from one another (e.g., Hartup, 1992). The experience of peer interactions helps children understand standards for appropriate behaviors in different settings. Moreover, social affiliations established through interaction are a main source of feelings of security and belonging, which in turn constitute a basis for the development of psychological well-being (e.g., Sullivan, 1953). Thus, achieving and maintaining appropriate behaviors and establishing desirable relationships in the peer context are major developmental tasks in childhood and adolescence (Masten & Tellegen, 2012; Rubin, Bukowski, & Bowker, 2015). Failure to behave competently in peer interactions, obtain acceptance in the peer group, or form constructive relationships and networks is a significant indication of developmental psychopathology and may have enduring and cascading effects on children's adjustment in broad areas (Masten & Cicchetti, 2010; Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006). Consistent with these arguments, empirical results have indicated that peer interactions and relationships are associated with various developmental outcomes (Coplan, Prakash, O'Neil, & Armer, 2004; Dodge, Greenberg, & Malone, 2008; Rubin, Bukowski, et al., 2006; Ladd & Troop-Gordon, 2003).

Peer interactions and relationships are shaped, however, by cultural conventions, norms, and values in the society (X. Chen & French, 2008; Edwards, de Guzman, Brown, & Kumru, 2006). According to Hinde (1987), different levels of social experiences are embedded within the cultural system. Similarly, Schneider, Smith, Poisson, and Kwan (1997) pointed out that culture may affect many aspects of peer interactions and relationships. Indeed, cross-cultural research has indicated that cultural beliefs and practices, particularly those pertaining to socialization and developmental goals, affect the nature, function, and features of peer interactions and relationships such as friendships and social networks in children and adolescents (e.g., DeRosier & Kupersmidt, 1991; Farver, Kim, & Lee, 1995; French, Pidada, & Victor, 2005). For example, cultural norms and values may serve as a basis for the interpretation of particular behaviors and for the judgment of the appropriateness of these behaviors in peer interactions. The social interpretation and evaluation in turn regulate the processes of peer interactions and the formation of dyadic and group relationships. In addition, the role of culture is reflected in how it affects the relations between peer experiences and adjustment outcomes.

In this chapter, we focus on how culture is involved in children's peer interactions and relationships and the implications of peer interactions and relationships for the development of social, behavioral, and psychological problems. We first discuss some conceptual issues in the study of culture, peer relationships, and developmental psychopathology. Then we review research on the prevalence of major social behaviors and problems in peer interactions and relationships among children across cultures. Next, we discuss culturally directed social attitudes and responses (e.g., parental attitudes, peer evaluations and regulations) toward specific behaviors within the peer context. In our discussion, we pay particular attention to how macro-level social and cultural conditions and their changes, through directing the social interaction processes, determine the functional meanings of behaviors and promote or undermine their development. Then we focus on the developmental outcomes of peer experiences in different cultures. The chapter concludes with a discussion of general issues, implications, and future directions in the study of culture, peer relationships, and developmental psychopathology.

THEORETICAL PERSPECTIVES ON CULTURE, PEER RELATIONSHIPS, AND ADAPTIVE AND MALADAPTIVE DEVELOPMENT

Two major theories of culture and human development are the socioecological theory (Bronfenbrenner & Morris, 2006) and the sociocultural theory (M. Cole, 1996; Rogoff, 2003; Vygotsky, 1978). According to both theories, culture affects socialization beliefs and practices, which in turn contribute to developmental outcomes in various areas. In addition to these broadband theories, a cultural anthropological perspective (Benedict, 1934) focuses on how culture

affects the judgment of behaviors in different societies. These theoretical perspectives have guided research on culture and normal and abnormal development for the past 50 years. X. Chen (2012) and X. Chen and French (2008) recently proposed a contextual-developmental perspective focusing on peer interaction as a context for cultural influence on socioemotional development. This perspective emphasizes the role of the social evaluation and regulation processes in peer interaction in facilitating the links between culture and development.

The Role of Culture in Development: Traditional Perspectives

According to the socioecological theory (Bronfenbrenner & Morris, 2006), the cultural beliefs and practices that are endorsed within a society or community, as a part of the socioecological environment, play an important role in children's socioemotional and cognitive development. In the early version of the theory (e.g., Bronfenbrenner, 1979), culture was considered a distal influence in the outmost layer of the environment in which the child did not directly participate. In more recent conceptualizations, however, cultural factors have been integrated with proximal socialization forces such as the community and family (Tietjen, 2006). Culture influences human development through organizing various social settings and activities. From the socioecological perspective, providing desirable cultural conditions is critical for promoting adaptive development and for preventing developmental problems, although it is unclear what specific cultural aspects or processes may lead to normal and abnormal outcomes. Largely consistent with the socioecological perspective, Super and Harkness (1986) proposed a developmental niche model, which focuses on three main interacting subsystems: the physical and social settings; the historically constituted customs and practices of child care and child rearing; and the psychology of the caretakers, particularly parental ethnotheories shared with the community. Culture may affect human development through these subsystems. According to Super and Harkness, deprived or disadvantaged settings, disorganized child-rearing practices, and inappropriate socialization beliefs are the main risk factors in psychopathological development.

The sociocultural theory focuses on the internalization of cultural systems, such as language and symbols, from the interpersonal level to the intrapersonal level (Vygotsky, 1978). Participation in social and cultural practices may exert a significant influence on the process and pattern of human development. Changes in sociocultural structures and associated social practices may lead to the reorganization of mental systems and the formation of new psychological functions (Luria, 1976). For example, the transformation of traditional rural villages to communities with more complex and planned social activities may produce new forms of knowledge and ways of thinking. Consistent with the sociocultural perspective, cross-cultural studies (e.g., Beach, 1995; Luria, 1976; Rogoff, 2003; Scribner & Cole, 1981) have shown that, relative to their counterparts who participated in formal education or urbanized activities, children and adults in villages in Africa, Asia, and Central and South America who lived traditional lifestyles tended to display more concrete practical or graphic-functional thinking and context-specific calculation or visual representation that were constrained by the physical features of the circumstances. The mental processes of individuals in these societies became more decontextualized, sophisticated, and logical as they engaged in more commercial activities and formal school learning (Luria, 1976; Vygotsky, 1978).

A long-held perspective in psychopathology, proposed mainly by Benedict (1934) and Mead (1928), stresses cultural relativity in the judgment of normal and abnormal behaviors. According to this perspective, normality is defined by culture because a behavior viewed as abnormal in one culture may be viewed as normal in another. In all societies, there are substantial individual variations on behaviors and personality characteristics. However, different societies may place different values on specific behaviors and characteristics and define specific ranges of these behaviors and characteristics as normal or desired. Normality represents a segment of human functioning that is approved within a culture, and abnormality is the term for the segment that is incompatible with the norm in the society.

Thus, normal behaviors and characteristics are the ones that are considered within the limits of the society; those beyond the limits are viewed as problematic. Accordingly, individuals who display culturally acceptable and desirable behaviors are likely to receive social approval and prestige and to obtain social status within the society or the community. In contrast, individuals who display behaviors not in agreement with the ones selected in that society or community are regarded as abnormal, even though these behaviors are valued in other cultures. As indicated by Benedict (1973), "We must face the fact that even our normality is man-made, and is of our own seeking" (p. 76). During the process of socialization, culture serves to facilitate the development of valued behaviors and suppress those behaviors considered abnormal and

unacceptable. Benedict argued that most individuals are plastic to the molding force of the society into which they are born. Consequently, the vast majority of the individuals in any group are socialized to fit with the cultural expectations (p. 74).

Benedict's relativist perspective is not necessarily incompatible with the universalist view that mental or psychological disorders have universal core symptoms although cultures may vary on the presentations and perceptions of the disorders. The universalist view asserts that the underlying psychopathological problems are the same, but the manifestation of the problems and the threshold of what is judged as problematic may differ across cultures (e.g., Bird, 2002; Roberts & Roberts, 2007). For example, it has been reported that the rates of attention-deficit/hyperactivity disorder in Hong Kong are double those reported in some Western countries (T. Ho, Leung, Luk, & Taylor, 1996). According to both Benedict's (1934) and the universalist views, the different rates may be due to the threshold effect. Since Asian cultures value the suppression of emotions such as anger and disruptive behaviors, parents and mental health practitioners may have a lower threshold for the judgment of hyperactive behavior, which increases the likelihood of reporting hyperactive behaviors (Canino & Alegría, 2008). Indeed, compared to American clinicians, when they judged the same vignettes, Chinese and Indonesian clinicians gave significantly higher scores for hyperactive behavior (Mann, Ideda, Mueller, & Takahashi, 1992).

A more thorough relativist view (e.g., Kleinman & Kleinman, 1991; Weisz et al., 2006) claims that culture affects the manifestation and judgment of a specific behavior as well as the development of the behavior per se. Cultural conditions shape the occurrence, magnitude, duration, and form of the behavior and social responses to the behavior. Thus, a symptom or syndrome may be observed in some cultures but not in others. Social and cultural factors can be important determinants of behavioral and psychological problems.

Between the universalist and relativist views, many researchers and practitioners believe that whereas problems derived from neural pathology (e.g. autism, schizophrenia) may be universal, more common problems are likely to be affected by social and cultural circumstances (García Coll et al., 2000; Rutter & Nikapota, 2002; also see Canino & Alegría, 2008). How a specific behavior or problem occurs and is viewed in a society and how culture plays a role may depend on the nature of the behavior or problem. Our discussion of culture and developmental psychopathology in the next sections focuses mainly on relatively common behaviors, such as aggression, defiance, shyness, and social anxiety, although there is evidence indicating biological foundations for the development of these behaviors (e.g., Fox, Henderson, Marshall, Nichols, & Ghera, 2005).

Researchers in the field of developmental psychopathology have recently noticed that distinct functions observed in cultural and ethnic minority populations, such as Asian and Latino children in the United States, may represent strengths, rather than deficits as traditionally viewed, in their adaptation to the environment (e.g., García Coll et al., 2000; X. Chen & Tse, 2008). Thus, largely consistent with the relativist perspective, it has been argued that psychopathological issues, such as risk, mental illness, resilience, and protective factors, should be examined with particular cultural standards for minority groups (García Coll et al., 2000). According to Cicchetti and Toth (2009), to fully comprehend the complexities in the experiences of psychopathology, it is necessary to investigate biological, psychological, and social aspects of normal and abnormal development at multiple levels of analysis. The analysis at the cultural level may provide useful information about how different aspects of development are associated with, and facilitate and constrain, each other in specific contexts. Research on culture and developmental psychopathology not only helps us understand the broad, dynamic processes underlying individual adjustment and maladjustment but also informs the diagnosis and treatment of problems.

Culture, Peer Relationships, and Adaptive and Maladaptive Development: The Contextual-Developmental Perspective

The contextual-developmental perspective, developed by X. Chen (2012) and X. Chen and French (2008) and based mainly on the socioecological and sociocultural theories (Bronfenbrenner & Morris, 2006; Vygotsky, 1978), emphasizes the links between cultural values and children's socioemotional functioning and the role of the social interactions in mediating the links. This perspective focuses on two fundamental dimensions of socioemotional functioning: social initiative and self-control. *Social initiative* is concerned with the tendency to spontaneously initiate and maintain social participation, especially in stressful settings. Whereas some children may readily engage in interactions in potentially challenging situations, others may experience internal anxiety and fear, leading to exhibition of low levels of social initiative (Asendorpf, 1990). The display of shy-inhibited and withdrawn behaviors is a major indication of low social initiative. *Self-control* represents the regulatory ability to modulate behavioral and emotional reactivity to maintain appropriate

behavior in social activities. The dimension of control, indicated often by the display of compliant-cooperative and defiant-aggressive behaviors, is concerned with fitting in with others and, more broadly, achieving interpersonal harmony and group well-being.

Different cultures may value social initiative and norm-based behavioral control in children and adolescents to different extents. In Western self-oriented or individualistic cultures, where acquiring autonomy and assertive skills is an important socialization goal, social initiative is viewed as a major index of competence; the display of inhibited or restrained behavior is often considered immature and incompetent (X. Chen et al., 1998). Self-regulation and control, in general, are perceived as necessary for adaptive functioning. However, individuals are encouraged to learn how to maintain a balance between the needs of the self and those of others. Consequently, behavioral control is less appreciated and endorsed, especially when it conflicts with the attainment of individual goals (Triandis, 1990). In group-oriented cultures, social initiative may not be highly emphasized because it may not have evident effects on the harmony of the group. To maintain group harmony, however, individuals need to restrain personal desires to address the interests of others, and thus self-control is more strongly emphasized (X. Chen, Rubin, et al., 2003; D. Y. E. Ho, 1986). The lack of control is viewed as highly unacceptable. Cultural values of social initiative and self-control may affect adults' and children's attitudes toward specific aspects of socioemotional functioning, including aggression-defiance (high social initiative and low control), shyness-inhibition (low social initiative and adequate control to constrain behavioral and emotional reactivity to self), sociable-cooperative behaviors (active social initiative with effective control), and affective disturbances such as depression and loneliness (low social initiative and low control).

According to the contextual-developmental perspective, social evaluation and response processes play a significant role in maintaining the links between culture and human development. During interactions, adults and peers evaluate children's behaviors according to cultural norms and values that are endorsed in the community. Moreover, adults and peers across cultures may respond differently to specific behaviors and express different attitudes toward children who display these behaviors. To acquire acceptance and approval in the group, children need to understand social standards and expectations and to adjust their behaviors according to the standards and expectations. Thus, social evaluations and responses, particularly in peer context, serve to regulate children's behaviors and their development (X. Chen, 2012).

Whether and to what extent children can regulate their behaviors or behavioral styles according to culturally directed social evaluations is associated with adjustment outcomes. Children whose behaviors are incompatible with group expectations are likely to receive negative feedback from others, which creates a pressure on children to alter their behaviors. In antisocial or other socially deviant groups, the social interaction processes may promote individual deviant behaviors, which may lead to problems in the larger social environment, especially in the long run. Relative to other members in the group, children who are able to resist the peer pressure may be more resilient to maladaptive group socialization. In prosocial groups, however, peer evaluations and responses in interactions serve to facilitate the development of socially constructive behaviors and characteristics. Children who can regulate their behaviors to improve their social relationships with others may increase their opportunities to learn from others and gain emotional support and other benefits, which reduce the likelihood of developing social, cognitive, and psychological problems. However, children who fail to do so may obtain increasingly unfavorable experience in interactions, which may elicit frustration, anger, and other negative emotions. These negative emotional reactions may lead to further externalizing problems, such as aggression, if directed toward others; internalizing problems, such as loneliness and depression, if directed toward the self, or both.

By focusing on peer interaction processes, the contextual-developmental perspective emphasizes the active role of children in socialization and development. The active role of children may be reflected in their sensitivity and response to social influence. With age, the active role of children becomes increasingly evident through their participation in adopting existing cultures and constructing new cultures for social interactions (Corsaro & Nelson, 2003). As argued by Tamis-LeMonda et al. (2008), the construction of new cultures may be most likely to take place in social activities of children with different backgrounds. Migration and communication across nations during globalization have created a changing context with diverse values for children and adolescents in most societies. As a result, exposure to different beliefs and lifestyles has become a part of the youth experience. The cultural systems that youth develop through incorporating different, and perhaps complementary, values and behavioral norms provide guidance for them to engage in mutual

evaluations in interaction and to maintain their behaviors according to cultural norms.

SOCIOEMOTIONAL FUNCTIONING AND PROBLEMS IN PEER SETTINGS ACROSS CULTURES

In general, behaviors that are formed on the basis of high social initiative and high self-control, such as cooperative and prosocial behavior, are regarded as appropriate and desirable in most societies (e.g., Eisenberg, Fabes, & Spinrad, 2006), although the extent to which they are valued may vary across cultures. Behaviors formed on the basis of low levels of social initiative, self-control, or both and categorized as internalizing and externalizing are typically viewed as maladaptive and abnormal in Western cultures (Achenbach, 2008; Cicchetti, 2006) but not necessarily in other cultures. The cultural values of these behaviors play a major role in determining how they are exhibited, particularly in social situations.

A number of studies have been conducted to examine cross-cultural similarities and differences in the display of children's behaviors and problems. Most of the studies, however, have relied on parental ratings or self-reports, which suffer from methodological problems, such as judgmental biases, response style biases, and reference group biases (e.g., Schneider, French, & Chen, 2006). The methodological weaknesses and problems have led to inconsistencies and confusions of the results. Nevertheless, some patterns have emerged from cross-cultural studies of children in Asian, Latino, European, and North American societies. For example, studies based on parental reports (e.g., Gartstein et al., 2006) indicated that children in some Asian cultures were less emotionally expressive than children in European and North American cultures in early childhood. These results are consistent with what has been found in observational studies conducted by Camras and her colleagues (Camras et al., 1998; Camras, Chen, Bakeman, Norris, & Cain, 2006) in East Asian and European American infants. The cross-cultural differences in the early years are interesting because they may indicate the developmental origins of socioemotional functioning and problems among children in specific societies.

Shyness-Inhibition, Social Anxiety, and Loneliness

Researchers have observed that children display different reactions to stressful or challenging situations (e.g., Asendorpf, 1991; Fox et al., 2005; Kagan, 1997; Stevenson-Hinde, Shouldice, & Chicot, 2011). Whereas some children are relaxed and display relatively little distress, others tend to be vigilant, anxious, and wary. The term *behavioral inhibition* has been used to characterize individual differences in children's reactions to novel social and nonsocial situations (García Coll, Kagan, & Reznick, 1984; Schmidt & Buss, 2010). Whereas inhibition in infants is assessed mainly in terms of their latency to approach novel objects or nonsocial stimuli, research on inhibition in older children often focuses on their reluctance to interact spontaneously with unfamiliar adults or peers (e.g., Asendorpf, 1991). Inhibition of approach to unfamiliar peer situations is typically characterized by onlooker, unoccupied, and other anxious behaviors (e.g., watching others playing without joining in, whining, nail biting) (e.g., Asendorpf, 1991; Rubin, Coplan, Fox, & Calkins, 1995).

From a different perspective, researchers who study shyness as a personality trait, especially in adults, focus on feelings of self-consciousness and anxiety in social interactions (e.g., Cheek & Buss, 1981). Asendorpf (1991) characterized shyness as deriving from an internal conflict of approach and avoidance motivations in social settings. Shy children are interested in social interactions, but this approach motivation is hindered by fear and wariness. Shyness and inhibition both seem to tap individual reactivity to challenging situations, with the former focusing on the anxious response to social novelty and the latter focusing on the dispositional characteristic to be fearful when encountering unfamiliar social or nonsocial situations (Coplan & Armer, 2007; Rubin, Coplan, & Bowker, 2009; Schmidt & Buss, 2010).

Considering the conceptual and empirical overlap between shyness and inhibition and their similar behavioral manifestations, X. Chen and French (2008) used the term *shyness-inhibition* to refer to children's wary and anxious reactivity to stressful or challenging social situations. Shyness-inhibition is similar to reticence, anxious solitude, shyness-sensitivity, and some other constructs that researchers use to describe behaviors that indicate internal fearfulness in social settings (e.g., Coplan & Armer, 2007; Gazelle & Ladd, 2003). However, it is different from those constructs representing social withdrawal, such as unsociability or social disinterest due to the lack of desire to interact with others (e.g., "would rather be alone") (Coplan & Armer, 2007). Distinction between shyness-inhibition and unsociability or social disinterest is important in cross-cultural research because they may be valued differently in different cultures. For example, in Western individualistic societies, relative to shyness-inhibition, unsociability that is driven by preference for solitude may be viewed as more normal because it is sometimes

considered indicative of personal choice and conducive to performance on constructive tasks and emotional health (e.g., Burger, 1995; Coplan et al., 2004; Leary, Herbst, & McCrary, 2003). In contrast, in some group-oriented cultures, shyness-inhibition may be viewed as acceptable or even desirable, but unsociability is regarded as anticollective and abnormal, a risk factor in development (Casiglia, Lo Coco, & Zappulla, 1998; X. Chen, Wang, & Cao, 2011; Valdivia, Schneider, Chavez, & Chen, 2005).

A major aspect of socioemotional functioning that largely overlaps with shyness-inhibition is social anxiety. The construct of social anxiety taps fear, concern, and worry about negative social evaluations and distress in familiar and unfamiliar social situations (American Psychiatric Association, 1994). Whereas shyness-inhibition is mainly concerned with behavioral manifestations of internal conflict or fearful feelings, social anxiety focuses on emotional aspects of individual reactions to challenging social situations. Shyness-inhibition has traditionally been conceptualized from temperament or personality and peer relationship perspectives, whereas the experience of social anxiety is often discussed in the framework of psychopathology. In addition, researchers use various methods, including observations, peer evaluations, and self-reports, in the assessment of shy-inhibited behavior, but research on the emotional experience of social anxiety relies mostly on self-reports and clinical assessments. Nevertheless, the literature has indicated robust links between shyness-inhibition and social anxiety in children and adolescents, both having considerable implications for peer interactions and relationships (e.g., Rubin et al., 2009; West & Newman, 2007).

As another peer-relevant aspect of socioemotional functioning, loneliness is associated with both shyness-inhibition and social anxiety (e.g., Rotenberg & Hymel, 1999; Rubin et al., 2009). Loneliness typically refers to the subjective experience of dissatisfaction with one's social-relational life and related emotional reactions of sadness and emptiness (e.g., Asher & Paquette, 2003). Research indicates that children as young as preschool age report loneliness and social dissatisfaction, and loneliness in childhood is associated with unpleasant feelings and perceptions of unfulfilled relational needs such as lack of companionship and support (e.g., Cassidy & Asher, 1992; Coplan, Closson, & Arbeau, 2007). Moreover, like shyness-inhibition and social anxiety, feelings of loneliness are stable over time and may predict adjustment problems, such as depression, suicide, and psychosomatic problems (e.g., Aanes, Mittelmark, & Ketland, 2010; Qualter, Brown, Munn, & Rotenberg, 2010).

Shyness-Inhibition Across Cultures

One of the primary issues in cross-cultural research is whether children in different societies engage in different levels or types of social interactions (e.g., Whiting & Edwards 1988). Edwards (2000), for example, found that children in relatively close and rural societies (e.g., Kenya and India) had significantly lower scores on overall social engagement than children in more open and urban societies (e.g., Okinawa and the United States) where peer interactions were encouraged. Researchers also found that, compared with their North American counterparts, children in many non-Western rural societies, such as Bedouin Arab, Kenya, Maya, Mexico, and India (Ariel & Sever, 1980; Edwards, 2000; Farver & Howes, 1993; Gaskins, 2006), tended to be less expressive of their personal styles in peer interactions and engaged in little sociodramatic activities that required control of social-evaluative anxiety. These later results are particularly interesting because the lack of self-expression and assertiveness in social interactions is closely related to shyness-inhibition.

Researchers consistently found that East Asian children were more shy-inhibited than North American children in social settings (e.g., X. Chen, 2010; Farver & Howes, 1988). In a study of play behavior in Korean preschools in the United States, for example, Farver, Kim, and Lee (1995) found that, compared with European American children, Korean American children displayed more shy behaviors. Moreover, Korean children's play included less self-expressive themes and Korean children used less self-assertive communicative strategies (Farver & Shin, 1997). Similarly, Rubin, Hemphill, et al. (2006) found that Korean and Chinese children exhibited higher inhibition and anxiety than Australian, Canadian, and Italian children in the laboratory situation, with the former displaying more vigilant and reactive behaviors such as staying closer to their mothers and being reluctant to explore in free play sessions or in interactions with a stranger. When the child was asked by the experimenter to touch a scary toy robot, the mean latency to touch the toy was 18.97 and 13.97 seconds in Korean and Chinese children but was 7.74, 7.70, and 7.74 seconds in Australian, Canadian, and Italian children. The percentage of children who did not touch the toy in the whole period was 52.2% and 44.4% in Korea and China but 17.3%, 23.4%, and 28.8% in Australia, Canada, and Italy, respectively.

X. Chen and Tse (2008, 2011) examined social behaviors in peer context of Chinese Canadian and European Canadian children. The participants included first-generation immigrant Chinese, Canadian-born Chinese, and European (primarily third or later generations) Canadian

children in multiple public elementary schools in Canada. Data on shyness-sensitivity were obtained from peer evaluations (e.g., "Someone who is very shy," "Someone whose feelings get hurt easily"). The results first indicated that both immigrant and Canadian-born Chinese children, particularly girls, had higher scores than European Canadian children on shyness. Moreover, for the Chinese immigrant group, English-language proficiency and length of residence in Canada were negatively associated with shyness, suggesting that children who were more exposed to Western values tended to display less shy-sensitive behaviors in peer interactions.

Consistent with X. Chen and Tse's findings (2011), Paulhus, Duncan, and Yik (2002) found that a higher rate of Asian Canadian college students (68%) self-reported being shy than did their European Canadian counterparts (44%). Among the Asian students, the rate of shyness declined with increasing length of residence in Canada, although the rate among Asian Canadians (58%) remained higher than that among European Canadians (42%) for those who were born and raised in Canada. In addition, Paulhus et al. (2002) found that, based on observations, Asian Canadian students were less active in classroom participation (e.g., asking and answering questions, providing opinions) than European Canadian students were.

A similar pattern of relations between acculturation and shyness was found in a study that Gudiño and Lau (2010) conducted with Hispanic American children. In this study, the researchers examined associations between parental cultural orientation and children's shyness. Results indicated that parental level of acculturation to American culture was negatively associated with child and parent reports of children's shyness; parents who reported less familiarity with and affinity for American culture reported more shy behavior in their children, and their children also self-reported more shy behavior. Gudiño and Lau (2010) suggested that the extent to which Hispanic parents adopted American values and attitudes might play a role in changing their children's shy behavior.

Social Anxiety Across Cultures

Similar to the findings on shyness-inhibition, results from a variety of cross-cultural projects indicate that Asian youth report higher levels of social anxiety than their Western counterparts (e.g., Dong, Yang, & Ollendick, 1994; Lau, Fung, Wang, & Kang, 2009; Okazaki, 1997). Austin and Chorpita (2004), for example, examined social phobia and anxiety among five ethnic groups of children in Hawaii and found that Chinese Americans, Filipino Americans, Japanese Americans, and native Hawaiians had higher scores on anxiety than European Americans. It has been argued that the emphasis of interdependence and group harmony in East Asian cultures may encourage children to be sensitive to others' opinions and evaluations, which in turn increases their vulnerability to social evaluative concerns (L. Y. Ho & Lau, 2011). It has also been suggested that strict rules designed to ensure group harmony in East Asian societies may evoke self-consciousness and social anxiety due to the fear of negative consequences when rules are violated (Schreier et al., 2010).

In a cross-cultural experimental study, Norasakkunkit and Kalick (2009) primed Japanese and U.S. college students to access an independent mode of thought by instructing them to write down as many examples as they could think of that they could remember from their personal experiences representing this situation: "I enjoy being unique and different from others in many respects." Then the students completed measures of social anxiety and fear of social evaluation (i.e., apprehension about other's evaluation, distress over their negative evaluation and the expectation that others would evaluate one negatively). It was found that the Japanese students scored significantly higher than the Americans on anxiety and fear of social evaluation, indicating that the Japanese students were more reactive to challenging social situations and more emotionally distressed than their American counterparts. Moreover, independent priming caused a decrease in social anxiety and fear. The results suggest that individual cultural self-construals of independence are directly and causally linked to negative emotional reactivity to stressful social situations.

Lau et al. (2009) examined whether concerns about interpersonal attunement such as face loss explained the differences between Asian and European American adolescents on social anxiety. Face loss concerns make one highly attentive and sensitive to the expectations of others and motivated to prevent negative evaluations by others. Consistent with the hypothesis, the researchers found that compared with European Americans, Asian Americans had higher scores on face loss concerns and social anxiety. Moreover, face loss concerns mediated, or accounted for a significant amount of, ethnic differences in social anxiety.

Increasing research has been conducted on social anxiety in Latino youth, but the findings are largely mixed. Whereas some studies showed that Latino and European American youth differed on social anxiety (e.g., Pina & Siverman, 2004), others failed to find significant differences (e.g., Schreier et al., 2010). When cultural or ethnic differences were found, Latino children and adolescents tended to display higher levels of social anxiety (e.g., Gudiño &

Lau, 2010; Pina & Siverman, 2004; Varela et al., 2004). Polo and Lopez (2009) found that compared with U.S.-born Mexican American youth, immigrant Mexican American youth reported significantly higher social anxiety, indicating that cultural values and acculturation might affect adolescents' social anxiety. Different arguments have been made about social anxiety in Latino youth. On one hand, it is suggested that as in many East Asian societies, collectivistic values of social connectedness and interdependence are emphasized in Latino societies, which may enhance children's sensitivity to social evaluations and vulnerability to social anxiety (Polo & Lopez, 2009). On the other hand, Schreier et al. (2010) argued that whereas collectivistic values in East Asia may increase self-consciousness and social-evaluative concerns, which in turn increase social anxiety, the emphasis on social harmony in Latino societies does not necessarily lead to heightened social anxiety. Latino cultures value sociability and avoidance of rejecting others, which may reduce anxious behavior in stressful social situations. In other words, people in Latino cultures are expected to be likable, fun, easygoing, and talkative in interactions. The socialization experience and the social context in Latino cultures may evoke lower levels of social anxiety than those in East Asian cultures. Therefore, the broad system of individualism-collectivism or independence-interdependence may not fully characterize cultural conditions for individual socioemotional functioning.

Finally, researchers have found mixed results about social anxiety among African-American children and adolescents. Whereas some researchers found that African Americans had a higher prevalence of social anxiety and phobia than European Americans (e.g., Neal & Turner, 1991), others did not find differences (e.g., Ferrell, Beidel, & Turner, 2004). Moreover, it was reported (e.g., Compton, Nelson, & March, 2000; Himle et al., 2009) that relative to their European American counterparts, African-American children and adolescents had lower levels of social anxiety although they might be more likely to experience other types of mental problems, such as posttraumatic stress disorder. The theoretical rationale for group differences between African-American youth and their counterparts in other ethnic groups is unclear. Thus, further research is needed to clarify the issue.

Loneliness Across Cultures

It has been argued that in societies and communities where group orientations are highly valued, children are likely to develop feelings of group belonging and interpersonal connectedness (e.g., Medora, Woodward, & Larson, 1987; Mijuskovic, 1992; Triandis, 1990). Socialization for individuality and endorsement of personal pursuits in social interaction in contemporary Western society may promote feelings of social alienation and loneliness (Mijuskovic, 1992). The cultural emphasis on individual achievement, competitiveness, and independence may lead to a decline in interpersonal contacts and group activities. Although members of the young generation in Western nations, particularly North America, are surrounded by many people, they may form relatively few intimate relationships with others, which may contribute to the experience of loneliness and social isolation (Rokach, 2007).

X. Chen, He, et al. (2004), however, suggested that, in a context that emphasizes interpersonal interdependence and communality, the threshold for feelings of loneliness may be relatively low; unfulfilled expectations for social connection or group affiliation may result in salient negative emotional responses. This context may make children and adolescents particularly sensitive to social difficulties and vulnerable to feelings of loneliness. In other words, in a society where group affiliation and connectedness are encouraged, even if the context can protect children from being alone, it may not protect children from feeling lonely. In self-oriented societies that encourage autonomy, assertiveness, and positive self-regard, children may be more resilient to social and psychological stress and distress because the emphasis on independent skills and self-confidence during socialization helps them develop competence in managing adverse socioemotional experiences.

There is evidence supporting the traditional view on the link between individualistic values and loneliness. In several cross-cultural studies, Rokach and colleagues (e.g., Rokach, 2007) assessed loneliness in Canadian, Portuguese, and Czech youth. The results indicated that Canadian youth reported substantially higher scores than the other two groups on the indicators of loneliness such as unfulfilling intimate relationships and significant separation (e.g., "I often felt I didn't fit in," "Breakdown of intimate relationship," "Separate from my friends for a long period of time"). Triandis, Bontempo, Villareal, Asai, and Lucca (1988) found that, in both the United States and Puerto Rico, higher scores on individualism were correlated with greater loneliness among college students, although no group differences were found in the mean loneliness scores.

Yet findings supporting X. Chen, He, et al.'s argument (2004) have also been reported in several studies. Birman and Taylor-Ritzler (2007), for example, examined acculturation and loneliness of Russian adolescents in

public middle and high schools who immigrated to the United States from the former Soviet Union. The acculturation measure included subscales of identity (e.g., "I consider myself American/I consider myself Russian") and behavioral acculturation (e.g., "how much do you eat Russian/American food"). The results indicated that acculturation to American cultures contributed negatively to the prediction of feelings of loneliness, whereas the weak relations between acculturation to Russian culture were mediated by family relationships. The results suggested that when immigrant adolescents became more individualistic in their values and behaviors, they experienced lower levels of loneliness.

In a multicultural comparison, X. Chen, He, et al. (2004) found no significant differences on loneliness among children in Brazil, Canada, China, and Italy. The mean scores were similar to those in American children. In a recent within-cultural study of Chinese children, however, X. Chen, Wang, Li, and Liu (2014) found that as urban areas of China became a more competitive, market-oriented society over the past two decades, children reported lower levels of loneliness. Specifically, the researchers collected data on loneliness from multiple groups of elementary school children in China, including three urban cohorts (1992, 1998, and 2002) in Shanghai, an urban group in 2005 in Beijing, and a rural group in 2007 in a northern region of China near Beijing. The time points represented different phases of the social transformation in urban China, and the groups across the regions (2002 Shanghai and 2005 Beijing groups and 2007 rural group) mainly represented urban-rural context. It was found that children in the 1992 and 1998 Shanghai groups had higher scores on loneliness than those in the 2002 Shanghai and 2005 Beijing groups. Moreover, relative to their urban counterparts in 2002 and 2005, rural children in 2007 reported higher loneliness. Thus, the dramatic social change toward urbanization and modernization was associated with a decrease in children's loneliness.

Aggressive, Violent, and Other Externalizing Behaviors

Cross-cultural differences in children's aggression and other externalizing behaviors have been shown in a number of studies using different methods, including observations, adult reports, peer reports, and self-reports, and narrative assessments. In general, cultures that value competitiveness and the pursuit of personal goals seem to allow for more aggressive and coercive behavior, whereas cultures that emphasize group harmony and personal control tend to inhibit aggressive behavior.

Cross-Cultural Differences in Aggressive and Violent Behaviors

Research results indicate that children in some Asian countries, such as China, Korea, and Thailand, in Australia, and in some European nations, such as Sweden and the Netherlands, tend to exhibit less aggressive behavior than North American children (e.g., Bergeron & Schneider, 2005; Russell, Hart, Robinson, & Olsen, 2003; Weisz et al., 1988). Zahn-Waxler, Friedman, Cole, Mizuta, and Hiruma (1996) found that Japanese children showed less anger and aggression than U.S. children in their responses to hypothetical situations involving conflict. P. M. Cole, Tamang, and Shrestha (2006) found that Brahman children were more likely to endorse aggressive behaviors than Tamang children in Nepal. Brahman children reacted to difficult social situations, such as peer conflict, with anger and other negative emotions more often than Tamang children.

To obtain an in-depth understanding of cross-cultural differences in aggression, Farver, Welles-Nystrom, Frosch, Wimbarti, and Hoppe-Graff (1997) examined preschool children's narrative stories involving aggression in the United States, Sweden, Germany, and Indonesia. The children were asked to tell stories with two different toy sets that facilitated imaginative play. The first set of toys suggested neutral themes, such as family figures (mother, father, children), a car, and other pieces related to culturally appropriate themes; the second set of toys suggested aggressive play themes, including police figures, motorcycles, and handcuffs. Children were told to play with the toys in any way they wished and at the same time tell the researcher what they were doing with the toys. Children's stories were coded according to words related to aggression, such as *guns*, *kill*, *shoot*, *punch*, and *hit*, and sounds made when characters in the story harmed themselves or another figure (e.g., Ouch! Pow! Bang! Crash!). Story contents were also coded for the description of the behaviors of the characters, such as engaging in physical aggression with the intent to harm, destroy, or protect self.

It was found that in stories with both neutral and aggressive toys, American children had higher scores on aggressive themes and words, physical aggression, and mastery of situations with aggression than did German, Swedish, and Indonesian children. The narratives of Indonesian children contained less aggressive figures and more features of mastering situations without aggression. For example, the proportions of aggressive words in narratives with neutral toys were .41, .26, .01, and .11 for American, German, Swedish, and Indonesian boys and .10, .01, .02, and .03 for American, German, Swedish, and

Indonesian girls. The proportions of content involving mastering situations with aggression in stories with neutral toys were .13, .01, .01, and .03 for American, German, Swedish, and Indonesian boys and .09, .00, .01, and .00 for American, German, Swedish, and Indonesian girls. In contrast, the proportions of content involving mastering situations without aggression in stories with neutral toys were .10, .03, .04, and .20 for American, German, Swedish, and Indonesian boys and .15, .08, .01, and .32 for American, German, Swedish, and Indonesian girls. The results for stories with aggressive toys were similar for the groups. Moreover, the cultural differences based on narratives were consistent with those based on teacher ratings of children's aggressive behavior in the classroom peer interaction context (see Farver et al., 1997).

According to Farver et al. (1997), the contrasts between the American and Indonesian children's narratives reflect different norms for conflict resolution and different levels of intolerance of aggressive behavior. The self-orientation in the American society may increase the tolerance of aggressive behavior. In conflict situations, American children are socialized to be assertive in reaction to physical assault, insult, or attack on possessions. In contrast, Indonesian society values behavioral attributes that promote group harmony, deference to authority, emotional restraint, and cooperation. To maintain social harmony, children in Indonesia are taught to view community members as *paguyban* (family). Within *paguyban*, individuals are interdependent and can collectively discipline children for misbehavior, such as being impolite, disruptive, or aggressive, through guilt, shame, and other means. Children are socialized to avoid conflicts with others and to solve problems through negotiation rather than aggression.

Cross-cultural differences in aggressive and antisocial behaviors between southeast Asian and North American children appear more evident in adolescence. Greenberger, Chen, Beam, Whang, and Dong (2000) investigated self-reported misconduct in samples of senior high school students (mean ages = 16–17 years) in Los Angeles, the United States, Tianjin, China, and Seoul, Korea. It was found that U.S. adolescents had higher scores than Korean adolescents, who in turn had higher scores than Chinese adolescents on externalizing behaviors including risk taking and physical aggression toward others. The proportion of U.S. adolescents who engaged in various aggressive acts was twice that of Korean, Chinese, or both (e.g., 52%, 18%, and 11% engaged in "hitting or threatening to hit someone" in the United States, Korea, and China, respectively). Moreover, U.S. adolescents reported more aggressive behaviors among family members, friends, and school peers than did either of the two Asian groups. Korean adolescents reported more aggressive behaviors among family members, friends, and school peers than did Chinese adolescents. The results might be due to the fact that Korean youth had experienced more substantial and long-term social and cultural changes than Chinese youth and that Korean youth were exposed to more Western individualistic values and lifestyles than did Chinese youth (Greenberger et al., 2000).

In the literature (e.g., Eisenberg, Zhou, Liew, Champion, & Pidada, 2006), self-regulation or self-control is considered a major developmental antecedent of aggressive, disruptive, and antisocial behaviors. Research has shown that children across cultures differ on regulatory or control behavior (e.g., Gartstein et al., 2006; D. Y. E. Ho, 1986). For example, Chinese and East Asian children are often rated by their mothers as higher in self-control than U.S. and other Western children, and the differences tend to increase with age (Gartstein et al., 2006). X. Chen, Rubin, et al. (2003) found that Chinese toddlers maintained their compliant behaviors without adult intervention during a clean-up session, indicating committed and internalized control, more often than Canadian toddlers. Oh and Lewis (2008) also found that Chinese and Korean preschool-age children performed more competently than their U.S. counterparts on executive function tasks that are related to the activity of the prefrontal cortex of the brain.

In a study of attention and behavioral control, Brewis, Schmidt, and Casas (2003) observed that Mexican school-age children displayed more inattentive and impulsive behaviors than American children. Gartstein, Slobodskaya, and Kinsht (2003) found that Russian infants exhibited lower levels of regulatory functioning than U.S. infants. Interestingly, Gartstein, Peleg, Young, and Slobodskaya (2009) recently reported that, compared to their counterparts in the United States, Russian infants in Israel showed a higher level of regulation and their parents described them as requiring shorter time to recover from distress. The authors argued that the differences might be due to the fact that, in Israel, coping with stress was an inherent part of everyday life, which made effective regulation, including recovery from distress, critical to adjustment in the environment. The study also found that for the Russian immigrants in Israel, greater parental involvement in the Israeli (host) culture was related to higher levels of infants' duration of orienting/persistence of attention, an index of regulatory capacity.

X. Chen and Tse (2008) conducted a study of social behaviors in samples of Canadian-born school-age children with Chinese and European backgrounds using a peer

evaluation measure. The results indicated that compared with European Canadian children, Chinese Canadian children were viewed by their peers in Chinese, European, and other ethnic (e.g., non-Chinese Asian, Latinos) groups as less aggressive (e.g., "Gets into a lot of fights," "Picks on other kids"). According to Chen and Tse (2008), Chinese children are often required by their parents to learn skills to control their impulsive and disruptive acts from an early age. The early socialization experience has an enduring impact on children's behaviors in the peer context. Thus, Chinese Canadian children engage in less aggressive behavior and consequently experience fewer problems in peer relationships than their counterparts in some other ethnic groups.

In a series of studies with Latino adolescents, Smokowski and colleagues (e.g., Smokowski & Bacallao, 2006; Smokowski, Buchanan, & Bacallao, 2009) examined relations between acculturation and social, behavioral, and psychological adjustment. The studies revealed that the length of residence in the United States, involvement in Latino cultural activities, and the maintenance of Latino cultural values were negatively associated with aggression, whereas involvement in European American cultures was not meaningfully associated with social behaviors or any adjustment outcomes. Thus, Latino adolescents who maintained stronger connections with their culture of origin were less likely to engage in aggressive behavior. Like Chinese and perhaps other collectivistic cultures, the Latino culture might have deterrent effects on the development of aggression.

Cultural Values and Aggressive and Violent Behaviors

Findings from empirical work suggest that children and adolescents in more traditional and rural societies tend to display less aggressive, violent, and antisocial behaviors (e.g., Smokowski et al., 2009; Weenink, 2011). To understand how specific cultural aspects facilitate or hinder the development of aggressive and violent behaviors, researchers have investigated relations between cultural norms and values, particularly those regarding interpersonal and group harmony, and aggression at the individual and societal levels.

In a study of relations between values and violent behavior in Jewish and Arab high schools in Israel, Knafo, Daniel, and Khoury-Kassabri (2008) focused on several values that were believed to be relevant to adolescent social behaviors including (1) power, defined as aspiration for social status through gaining control of resources and dominance over people, (2) conformity, which refers to controlling actions that may violate social expectations and norms, and (3) universality, which is concerned with the understanding, appreciation, and tolerance of the welfare of all people. The analysis revealed that values of power were positively associated with the display of violent behavior, whereas values of conformity and universalism were negatively associated with the display of violence. Moreover, the associations between adolescent values and their violent behavior were stronger in ecologically risky environments, such as schools with high levels of violence, than in nonrisky environments. Knafo et al. (2008) argued that in environments where violent behavior is more common, social pressure against violence is likely to be lower. Consequently, the individual values of adolescents are more influential in directing their behavior.

Bergeron and Schneider (2005) analyzed relations between cultural values and aggressive behavior at the national level. The authors coded cultural values of a series of nations in Asia, South America, Europe, and the United States according to the Hofstede (1994) and S. H. Schwartz (2009) systems and examined how the values were associated with aggression. The results first indicated that societies characterized as more individualistic had higher aggression scores. Aggression was lower among individuals in collectivistic societies in which a higher value was placed on the needs of the group over those of the individual. Aggression was also lower in societies with higher levels of egalitarian commitment and moral discipline. In addition, aggression was positively associated with values of mastery (mastering and controlling the environment as primary goals) and negatively associated with values of hierarchy (maintaining status and social order) and conservation (conformity to social standards). The results of this study suggest that children and adolescents in societies that emphasize the pursuit of personal needs and desires, controlling the environments using power, are more likely to display aggressive behavior than those in societies that place a high value on group harmony, social order, responsibility, and compliance with social standards.

In Latino societies, a particular value orientation, familism, has been documented to be associated with low aggressive and violent behavior in children and adolescents. *Familism* refers to respect for family members, loyalty to the family, pride of the family, and emotional support among family members. Smokowski and Bacallao (2006) found that low familism and high parent-child conflict were salient risk factors that contributed to externalizing behaviors including aggression and violence. In contrast, high familism, such as family support and parental involvement in children's social and school lives, helped

adolescents cope with stress and frustration and control their behaviors. Familism accounted for a significant amount of variance in the relations between acculturation and aggression. Germán, Gonzales, and Dumka (2009) found that the values of familism endorsed by Latino adolescents and their parents were negatively associated with externalizing behaviors in schools. Moreover, familism moderated the relations between affiliation with deviant peers and behavioral problems; the relations were significantly weaker for adolescents who valued families than for adolescents who did not. Similarly, Lim, Stormshak, and Falkenstein (2011) found that identification with one's culture of origin attenuated the links between deviant peer association and substance use among Cambodian and Vietnamese youth in the United States.

Peer Conflict and Conflict Resolution

Peer conflict, defined as overt behavioral opposition (C. U. Shantz, 1987), is different from aggression and other externalizing disorders. Although conflict can lead to aggression, it is often displayed as verbal disagreement and resolved quickly without adult intervention (Perry, Perry, & Kennedy, 1992; C. U. Shantz, 1987).

Various features of the environment may affect children's behaviors in peer conflict situations. For instance, ecological conditions, such as resource availability, may be directly associated with the frequency and nature of conflict in peer interactions (Hartup, French, Laursen, Johnston, & Ogawa, 1993). More important, cultural norms and ideals for interpersonal relationships guide the way children address and respond to conflict. Cultural beliefs, such as those concerning references for direct versus indirect resolution strategies and the role of adults in resolving children's conflict, may be directly associated with children's behaviors in the development and resolution of peer conflict (Killen & Sueyoshi, 1995). Researchers have often used the framework of individualism and collectivism to explain cultural differences in children's peer conflict. It is theorized that low assertiveness and high cooperativeness are favored by those in collectivistic cultures when dealing with conflict as a way to maintain interpersonal harmony, whereas high assertiveness and low cooperativeness are favored by those in individualistic cultures, as they promote the achievement of personal goals (Elsayed-Ekhouly & Buda, 1996; J. L. Holt & DeVore, 2005). Although the broad framework may be useful for understanding the results of conflict studies conducted in some societies, it has been criticized widely for its overcategorization of complicated cultures and neglect of considerable within-culture variations in children's conflict experiences (e.g., French, 2011).

Research on the strategies by which children manage conflict may be more relevant to understanding the cross-cultural differences of peer conflict prevalence, given that the display of peer conflict depends on the strategies that children take to engage or promote the conflict or, conversely, to prevent or minimize its occurrence. In an ethnographic study among 3- to 6-year-old children from Bologna, Italy, Corsaro and Rizzo (1990) observed peer interactions in which children questioned or challenged others' opinions. The researchers found that children often added emphasis to their claims and dramatized their positions, a form that was also exhibited by adults in discussion. This particular manner of discourse during conflict engagement was thought to be even more important than resolving the conflict itself (Corsaro & Rizzo, 1990). In another ethnographic study, Goodwin (1982) recorded conversations during play activities among 4- to 14-year-old African-American boys from West Philadelphia. It was found that the boys engaged in argumentative discourse that offered proofs for their positions in ways that established and maintained positions of relative power within peer relationships. While often thought of as disorderly behaviors, researchers have suggested that these types of argumentative exchanges allow children to develop deductive reasoning within a social context. Moreover, during the exchanges, children recognize the opinions of others and demonstrate interdependence with others, which in turn affirms a sense of community. Interestingly, the demonstration of independence or position within a social hierarchy by exerting one's opinion may foster greater interdependence in cultures that are considered relatively collectivistic (Bologna, Italy) and in the African American community in West Philadelphia. Such overt displays of conflict likely appear more frequently in cultural groups that are open to conflict than in those that tend to minimize it.

Haar and Krahe (1999) compared German and Indonesian adolescents on their preferred strategies for resolving hypothetical conflicts with parents, peers, and teachers. Indonesians were more likely to select a submissive solution than a confrontational solution (Haar & Krahe, 1999). Similarly, French and colleagues (French, Riansari, Pidada, Nelwan, & Buhrmester, 2001; French, Pidada, Denoma, McDonald, & Lawton, 2005) found that relative to Western children, Indonesian children were more likely to disengage from conflict. Specifically, through interviews with U.S. and Indonesian 9- to 11-year-olds about conflicts with peers, the researchers found that conflicts

were quickly settled without the use of aggression for both groups. However, Indonesian children, compared to U.S. children, tended to report disengagement as a strategy for dealing with conflict. Some Indonesian children referenced *musuhan* (acting as enemies), a strategy involving avoidance of the person they disagreed with and reengagement once they no longer felt the emotions from the conflict. In Western cultures, whereas negotiation and compromise are preferred methods for resolving conflict, disengagement typically is viewed as reflecting passivity (Iskandar, Laursen, Finkelstein, & Fredrickson, 1995; Laursen, Finkelstein, & Townsend-Betts, 2001). In contrast, passivity appears to be not only acceptable but also preferable among Indonesian children. The Indonesian value for maintaining interpersonal harmony is closely aligned with the collectivistic orientation, which may explain the avoidance of outward manifestations of contention (Magus-Suseno, 1997); overt exhibitions of disagreement can be a disruption to the social harmony and hierarchy (Geertz, 1961).

Chinese children tend to use similar strategies to avoid conflict (Xu, Farver, Chang, Yu, & Zhang, 2006), which may be related to the fact that Chinese children experience less conflict than North American children (Benjamin, Schneider, Greenman, & Hum, 2001; Navon & Ramsey, 1989; Orlick, Zhou, & Partington, 1990). In a study designed to elicit potential conflict, French et al. (2011) presented groups of four 7-year-old children with one toy in a laboratory setting. Whereas in 46% of the Canadian groups one or two children emerged as a leader to invoke a rule that would structure their play with the toy, this occurred for 78% of the Chinese groups. The authors attributed this hierarchical approach to common conflict management scripts as reflecting community mediation systems in the Chinese society, where community members rely on a mediator, an authority who intervenes in conflict situations and keeps order within the group (Wall & Blum, 1991). Another comparative study showed that 8- and 9-year-old Taiwanese children reported significantly less conflict in their friendships than their Canadian counterparts (Benjamin et al., 2001). Moreover, Taiwanese children tended to agree more than Canadian children on the prevalence rate of conflict in their relationships. The prospect of conflict might be particularly salient to the Taiwanese children, leading to their greater tendency to agree on the presence of conflict. The lower rates of conflict in Taiwanese and the higher tendency to be aware of conflict are consistent with the Confucian model of conflict resolution, which emphasizes the importance of tolerance and forgiveness (Wall & Blum, 1991).

Gender roles may be involved in cultural effects on conflict management. In an ethnographic study, Kyratzis and Guo (2001) observed verbal strategies to diffuse conflict during play among 5-year-old children in the United States and China. In same-sex group interactions, U.S. girls were more likely to reframe the play to avoid conflict, but Chinese girls and U.S. boys tended to be directive. Chinese girls invoked third-party censures ("What for do you scold others as pigs?") and rhetorical mocking questions. Both Chinese girls and U.S. boys used commands ("Give it to me") and even threats. Finally, Chinese boys used a combination of direct and indirect strategies, including reasoned argument. The authors argued that the assertiveness of Chinese girls in conflict management likely reflected women's increased social status and influence in informal settings in contemporary China. The authors also tentatively proposed the notion that Chinese girls might take their social groups for granted and thus did not make great effort to maintain group relationships, given the generally high interdependence in the society.

It has been argued that children in individualistic cultures tend to assert self-interest behaviors during conflict episodes (Markus & Lin, 1998). Western children are socialized from early childhood with principles involving possession of property or space, and they utilize the scripts that invoke sharing or turn taking during conflict (Dunn & Munn, 1987; Ross, 1996). These principles are derived from Western cultural ideals for personal ownership and are reinforced by parents when children engage in peer conflict (Ross, 1996). Nevertheless, variations exist among children within Western nations (Markus & Lin, 1998). Schneider, Fonzi, Tomada, and Tani (2000) observed dyads of 8- and 9-year-olds from central Italy and Canadian children participating in structured tasks designed to simulate everyday situations of potential conflict. In discussing how they would share a single chocolate egg with a toy inside, Italian youngsters made fewer proposals but were still able to achieve a greater discrepancy between initial and final negotiating positions. The authors concluded that Italian children were more efficient than Canadian children at avoiding and resolving conflicts between friends. Italian children were more likely than Canadian children to avoid and resolve conflicts by adherence for the rules of the game that were described prior to their participation in the game.

Medina et al. (2001) examined preschool children in the Netherlands and Andalusia in conflict situations and found that Dutch children were more assertive and imposed their personal views during conflicts more often than Andalusian children. Moreover, conflict arose among Andalusian

children due to issues of control regarding play activity conditions or personal opinions (e.g., who should play Sleeping Beauty or Snow White), with concerns often involved in the coordination of communality of a social group. In contrast, the conflicts among Dutch children were largely due to the control of objects or space (e.g., who should be the one to play with the blocks). The authors suggested that the coordination of play within a group among the Andalusian children might be more characteristic of a collectivistic society, whereas competition for objects or space might reflect the value of autonomy and individuality among the Dutch. These findings were consistent with previous observations where conflict focused less on object disputes in Japanese preschool children than in U.S. preschool children (Killen & Sueyoshi, 1995).

Bullying and Victimization

As a type of peer conflict, bullying is described as aggressive behavior or intentional harm carried out repeatedly over time in an interpersonal relationship characterized by an imbalance of power (Olweus, 1993). Prevalence rates of bullying among school-age children vary by country. In a self-report survey across 25 predominantly Western countries assessing involvement in bullying as a bully, victim, or both bully and victim (bully-victim), Nansel, Craig, Overpeck, Saluja, and Ruan (2004) found that Sweden and Wales had the lowest rates of bullies while Denmark had the highest prevalence, at 20%. Sweden had the lowest rates of victims and bully-victims, both at 1%, while Lithuania had the highest rate of victims and bully-victims, at 20%. In a 28-country comparison of mostly Western countries on the prevalence of victims stratified by sex, Due and colleagues (2005) found that Sweden showed the lowest rate, at 5.1% for girls and 6.3% for boys. Lithuanian had the highest prevalence rate with 38.2% of girls and 41.4% of boys as victims. Eslea and colleagues (2004) found in a study conducted in seven countries, including Asian countries, that 5.2% of children in Ireland were classified as victims compared to 25.6% of Italian children from Florence. The percentage of bullies was lowest in Chinese children (2%) and highest in Spanish children (16.9%). Finally, only 0.8% of English children were considered bully-victims compared to 19.6% of Spanish children.

A number of factors may be related to the cross-cultural differences in bullying rates. First, it is possible that the understanding of bullying in the culture may affect self-reports of involvement in bullying incidents. Certain terms, such as *prepotenza* in Italian, refer to not just physical, verbal, and social-exclusionary bullying but also to even-handed fighting, which may result in the overestimation of bullying (Smith et al., 2002). In Japan, *ijime* refers to bullying that aims to cause emotional (e.g., humiliation) rather than physical suffering, with the bully being part of a dominant peer group (Nesdale & Naito, 2005). In a culture where high value is placed on group membership, such ostracism may have severe consequences. Relatedly, specific behaviors that children display in bullying situations may differ across cultures, which is likely to influence cross-cultural comparisons. Dussich and Maekoya (2007), for example, found that Japanese victims reported slandering and shunning as the most common bully behaviors, whereas name-calling and slandering were the most common in South America and in the United States. The use of physical methods in bullying was much more common in the United States than in Japan and South America. High values of group harmony in East Asian and South American cultures appear to make physical aggression less acceptable than slander, which may be reflected in cross-cultural differences in the presence of different forms, and perhaps overall prevalence, of bullying behaviors.

Peer Involvement, Isolation, and Friendship Exclusivity

Social and cultural circumstances are related to the extent to which group integration or development of specific peer relationships, such as friendships, is encouraged (Hinde, 1987; Sharabany, 2006). In rural villages, such as Yucatan Mayan villages, children mostly interact with age-mates within extended family networks of siblings and cousins, leaving few opportunities to form relationships with nonkin (Gaskins, 2006). Sharabany and Wiseman (1993) found that the main feature of peer relationships among children in kibbutz communities in Israel is group involvement rather than dyadic friendships. In most contemporary societies, schools congregate large numbers of same-age children and provide opportunities for children to develop relationships with each other. Nevertheless, cultural expectations and norms concerning social affiliation and connectedness may shape the structural and functional features of peer relationships and individual experiences within the relationships, such as intimacy and exclusivity.

Studies conducted with school-age children in most societies show that relatively small proportions of children and adolescents, ranging from 5% to 30%, do not have mutual friends or group networks (e.g., Attili, Vermigli, & Schneider, 1997; Cairns & Cairns, 1994; X. Chen, Chang, & He, 2003; French, Jansen, Riansari, & Setiono, 2003; Kiesner, Poulin, & Nicotra, 2003; Kindermann, McCollom, &

Gibson, 1995; Liu & Chen, 2003; Salmivalli, Huttunen, & Lagerspetz, 1997). In general, more boys than girls are friendless, and boys' friendships are less stable over time (e.g., Benenson, Apostoleris, & Parnass, 1997; Schneider, Fonzi, Tani, & Giovanna, 1997). However, boys are more likely than girls to belong to groups, and boys' groups tend to be larger than girls' groups (e.g., Benenson et al., 1997; Dekovic, Engels, Shirai, De Kort, & Anker, 2002; Salmivalli et al., 1997).

Peer groups are often homogeneous on social-behavioral characteristics. It was found that in North America, group members were similar on the exhibition of deviant behaviors, such as aggression, smoking, drinking, and drug use (e.g., Cairns & Cairns, 1994; Urberg, Degirmencioglu, & Pilgrim, 1997). Brown (1990) identified a variety of adolescent peer groups, including those labeled as jocks, brains, populars, greasers, partyers, druggies, nerds, loners, and burnouts (e.g., Brown, 1990). Salmivalli et al. (1997) found that children in Finland who behaved in similar or complementary roles in bullying situations (bullies, assistants/reinforcers, victims, defenders, and outsiders) tended to form group networks. X. Chen and colleagues (Chen, Chang, & He, 2003; Liu & Chen, 2003) found that peer networks in Chinese children were organized based on prosocial orientation, aggression, and learning problems. Taken together, research results suggest that children and adolescents may hang around together and develop relationships and groups on the basis of social, behavioral, and other attributes that are significant in the culture.

Different arguments have been made about culture and intimacy in peer relationships. Intimacy is defined as mutual receptiveness, harmonious communication, and a shared sense of identity in relationships (Shwalb et al., 2010). Triandis et al. (1988) argued that peer relationships in collectivistic cultures are more intimate than those in individualistic cultures. Sharabany (2006), however, suggested that dyadic relationships, such as friendships, are typically characterized as low in intimacy in collectivistic societies because of the availability of other sources of emotional support, reduced exclusivity, and the threat of exclusive dyadic relationships to the cohesiveness of the larger group. Supporting Triandis et al.'s argument (1988), French, Lee, and Pidada (2006) found that South Korean children and adolescents formed highly intimate peer relationships. Moreover, intimate friendships in Korean youth were represented by high exclusivity and clear and strong boundaries between close friends and nonfriends. Youth in central and southern Italy reported more close and intimate friendships than did Canadian youth (Schneider et al., 1997; Schneider, et al., 2000). Friendships among Italian children, particularly among girls, were more stable and remained intact more than did those among Canadian children. Scharf and Hertz-Lazarowitz (2003) found that Arab elementary school students rated their peer groups as more intimate than did Jewish students, a finding that was believed to be congruent with the fact that Arab society was more collectivistic than Jewish society. In addition, Latino and Black adolescents in the United States reported their friendships as more intimate and closer than did their counterparts with a European or other cultural background (Gonzalez, Moreno, & Schneider, 2004; Way, 2006).

Cross-cultural findings about adolescent peer relationships in some other studies seemed to support Sharabany's argument (2006), however. For example, adolescents in Indonesian, Israeli kibbutz, and rural Arab societies reported lower intimacy in their friendships than their North American counterparts (e.g., French, Pidada, et al., 2005, 2006; Sharabany, 2006). Jay (1969) indicated that relative to American youth, Indonesian youth were less likely to develop close friendships because they focused more on integration into peer networks and the larger community. Beit-Hallahmi, Sharabany, Dana-Engelstein, Rabin, and Regev (1982) also indicated that people in Israeli kibbutzim, communities that shared property and responsibilities, preferred a large number of friends with superficial connections to a few close friends. Consistently, the results of a study conducted by Sharabany and Wiseman (1997) showed that children raised in the kibbutz were less intimate with their best friends on several aspects of intimacy compared with city children. Although kibbutz children indicated doing more activities with their best friends, they were less open and communicative with them and reported less trust and exclusiveness in the relationships than city children.

Although researchers have discussed the features, such as intimacy and exclusivity, of peer relationships using the collectivism-individualism framework, as it is commonly done in other areas, the framework may be too broad to explain some results. For example, although intimacy and exclusivity appear to be important in the friendships of children in Korea (French et al., 2006) and Cuba (González el al., 2004), two countries that are considered collectivistic, children in Indonesia, a country that is considered more collectivistic than many Western countries, do not differ with U.S. children on friendship intimacy (French, Pidada, et al., 2005), and peer relationships of Indonesian children are largely inclusive rather than exclusive.

In summary, empirical research has revealed cross-cultural and within-cultural ethnic variations in major

aspects of children's socioemotional functioning, including shyness and social anxiety, reactivity to stressful situations, aggressive and antisocial behaviors, and peer conflict and bullying, and peer involvement and isolation. Cultural values, such as individualism, autonomy, conformity, and familism, may account for the cultural variations in children's behaviors and relationships. To understand the relations between culture and children's behaviors and problems, it is important to explore how culturally directed socialization and social interaction processes play a role in development and, more specifically, how cultural values serve as a frame of reference for judging and evaluating children's behaviors.

CULTURE AND PARENTAL ATTITUDES

People in different societies may hold different attitudes toward specific behaviors. Parental attitudes, particularly those related to child rearing, are a part of the society's general cultural belief system and at the same time guide parental behaviors in parent-child interactions. Research on parental child-rearing attitudes and practices is important for our understanding of the psychopathological nature of children's behaviors in cultural settings.

Parental Attitudes Toward Shyness-Inhibition and Social Anxiety

Studies of relations between parental attitudes and children's shyness-inhibition and social anxiety have shown that compared with parents in other societies, in general, parents in Western societies are less accepting of children who display higher levels of inhibition and social anxiety (e.g., Muris & Merckelbach, 1998; Rapee, 1997). Lieb et al. (2000) found that children's social phobia was associated with parental rejection. Comparing clinic-referred anxiety-disordered children with normal children on maternal behaviors, Hudson and Rapee (2001) noticed that mothers of anxious children were less accepting during mother-child interactions than mothers of nonanxious children. Dumas, LaFreniere, and Serketich (1995) identified anxious and nonanxious preschool children based on teacher ratings and compared maternal behaviors in the two groups during a mother-child problem-solving task. The results indicated that mothers of anxious children displayed more negative and rejecting behaviors. Similarly, Rubin and Mills (1992) found that parents of socially anxious and withdrawn children were more concerned of their children's behavior and used more negative parenting such as power assertion and punishment.

X. Chen and colleagues (1998) investigated the relations between maternal attitudes and toddlers' reactivity to novel social situations in Canada and China. The results showed that toddlers' reactivity was positively associated with mothers' negative child-rearing attitudes, such as punishment orientation and rejection, in Canada. However, the pattern was the opposite in China: child reactivity was positively associated with maternal warm and accepting attitudes and negatively associated with maternal rejection. Positive parental attitudes toward anxious and reactive behavior in children and adolescents have also been found in China. X. Chen, Rubin, and Li (1997) found that shyness-anxiety in school-age children was associated with maternal acceptance. In a separate study with Chinese children, X. Chen, Dong, and Zhou (1997) found that shyness was negatively associated with paternal rejection and power assertion in both boys and girls and with maternal negative attitudes in girls. J. Kim, Rapee, Oh, and Moon (2008) investigated relations between several types of social withdrawal and social support among Australian and South Korean adolescents. The results showed that the patterns of relations between unsociability or social disinterest, isolation by peers, and withdrawal due to depressed mood, on one hand, and parental attitudes, on the other, were similar in the two samples. However, similar to the findings in Chinese and Canadian children (e.g., X. Chen et al., 1998), shyness or social anxiety was positively associated with parental support and positive parent-child relationships in Korean adolescents but not in Australian adolescents.

Relatively positive parental attitudes toward shy-anxious behavior have been found in Latino youth. Varela, Sanchez-Sosa, Biggs, and Luis (2009) examined relations between parental acceptance and control and children's anxiety in samples of Latin American, European American, and Mexican children. The results first indicated that Latin American and Mexican children had higher scores on anxiety than European children, which was consistent with some previous findings (e.g., Gudiño & Lau, 2010; Pina & Siverman, 2004). More important, the analyses revealed group differences in the relations between parenting and children's anxiety; whereas maternal acceptance was generally not related to anxiety in Mexican children, the relation was significant and positive in Latin American and European American children, with the magnitude of the relation greater in Latin American than European American children. Paternal control, which tapped power assertion in parenting, was positively associated with child anxiety in the European American group but negatively associated with child anxiety in the Latin American group.

The results indicated that the attitudes of Latino parents toward their children's anxious behavior appeared to be more supportive and accepting than those of European American parents. An interesting finding of the study was that the relations between parenting and child anxiety in the Mexican group appeared different from those in the other two groups. Further investigation is needed to clarify this issue.

Parental Attitudes Toward Aggression, Anger, and Self-Regulation

There is evidence that parents in different cultures may react differently to children's behaviors, such as aggression and defiance, that involve self-control, which may have implications for developmental psychopathology. Compared with Canadian parents, for example, Chinese parents tend to expect their children to maintain a higher level of behavioral control (X. Chen, Rubin, et al., 2003; D. Y. E. Ho, 1986). The greater emphasis of Chinese parents on behavioral control is related to the traditional values of *li* (propriety)—a set of rules for actions—that are used to encourage children to promote innate virtues (D. Y. E. Ho, 1986). Consequently, Chinese parents tend to express more negative attitudes than Western parents toward children who display defiant and disruptive behaviors.

Keller et al. (2004) found cross-cultural differences in parental attitudes toward children's self-regulation rural Cameroonian Nso, Costa Rica, and Greece. In the study, rural Cameroonian Nso toddlers displayed more regulated behaviors than Costa Rican toddlers, who in turn had higher regulation scores than Greek toddlers, as indicated by their compliance with maternal requests and prohibitions. Consistent with the differences in toddler behaviors, Cameroonian Nso mothers were higher than Costa Rican mothers, who were higher than middle-class Greek mothers, on body contact and body stimulation, which was believed to indicate a proximal parenting style that facilitates child obedience and regulation. According to Keller et al. (2004), whereas behavioral control may be viewed as interfering and undermining the child's autonomy in Western individualistic cultures, behavioral control and compliance are viewed as a duty, reflecting competence, in group-oriented cultural contexts.

P. M. Cole et al. (2006) studied caregivers' attitudes and reactions to children's anger and undercontrolled behavior in two different villages in Nepal: Brahmans and Tamangs. Brahmans are high-caste Hindus who value hierarchy and dominance, whereas Tamangs place higher value on social equality, compassion, modesty, and nonviolence. Consistent with the cultural orientations, it was found that most responses of Tamang caregivers involved rebuking the angry child, whereas responses of Brahman caregivers often involved supporting the angry child to feel better. The results suggested that Tamang parents were more likely than Brahman parents to send the message to children that the display of anger and undercontrol was unacceptable.

Hackett and Hackett (1993) examined attitudes toward various behaviors through interviews with Gujarati and English parents of 4- to 7 year-old children in Manchester, England. The Gujarati community, members of which arrived from India and East Africa during 1970s, consisted of three largely endogamous groups based on Hinduism and the Gujarati language. The researchers found that Gujarati parents were less tolerant of their children's aggressive behavior than English parents. In response to a hypothetical situation in which their child was hit by a peer in school playground, 19% of Gujarati parents and 51% English parents said that they would tell their children to retaliate. Sixty percent of Gujarati parents compared with 12% of English parents would disapprove if their child hit back, and 39% of Gujarati parents had told their children to stand up for themselves physically in such situation, as opposed to 62% of English parents.

According to parental reports, when their child had a fight with a peer, 51% of Gujarati parents and 20% of English parents would stop such fights immediately and punish their children, whereas 6% of Gujarati parents and 51% of English parents would ignore the fight and allow it to subside. Moreover, 43% of Gujarati parents and 29% of English parents said they would arbitrate and try to find out who started the fight. If a peer grabbed a toy from their child when playing outside, 33% of Gujarati parents and 16% of English parents said they would expect their child to come and tell them, and 5% of Gujarati parents and 51% of English parents expected their child to get the toy back by force.

Several studies revealed that relations between parental attitudes and practices and aggressive behavior were different toward African-American and European American children (e.g., Hill & Bush, 2001). Deater-Deckard, Dodge, Bates, and Pettit (1996) assessed harsh parenting, such as physical punishment, using interviews, hypothetical vignettes, and questionnaires and analyzed its relations with aggressive and externalizing behaviors in African-American and European American children. The results indicated that harsh or negative parenting was positively associated with aggression in European American children but not in African-American children. Similarly, Hill and Bush (2001) found that ethnicity moderated the relations between parenting styles and strategies and children's behaviors. Parental hostile control was positively associated with externalizing behaviors including aggression in

both African-American and European American children, but the associations were considerably weaker in African American than in European American children. The researchers attempted to explain the results in terms of cultural meanings (e.g., normality) of harsh or controlling parenting in African-American and European American communities. From a different perspective, however, the results may also reflect different parental attitudes toward children's aggressive behavior.

Parental Attitudes Toward Peer Conflict

Relative to the literature on parental attitudes toward shyness-anxiety, aggression, and self-control, far less information is available about parental attitudes toward peer conflict. Ross and colleagues (1990) analyzed maternal responses to toddlers' peer conflicts and found that mothers intervened frequently and often sided against their own child. The results might be biased because mothers' responses were observed in the presence of the other child's mother. In this study, the ethnicity or cultural background of the sample was not reported. In a study on Colombian parents of third- to eighth-grade children, Chaux (2005) found that parents were actively involved in 14% of the conflicts of their children. Parental involvement in peer conflict comprised mainly of helping children to settle the conflict by repressive means (e.g., threatening or sanctioning those involved children in order to settle) or by becoming a surrogate, thereby supporting one side.

Cultural beliefs and norms about conflict in general may play a role in shaping parental attitudes toward and involvement in peer conflict. For example, Italian adults view peer conflict as a more normative interpersonal experience compared to adults in England, Hong Kong, or Japan (Argyle, Henderson, Bond, Iizuka, & Contarello, 1986). Italian adults engage in lively debates, which may expose children to conversations about conflict situations and socialize them to see different perspectives. Indeed, Italian children are often required to engage in lively debates themselves (Corsaro, 1988). Thus, parental attitudes about interpersonal conflict are expressed in their child-rearing practices that promote children's ability to negotiate on their own in peer conflict situations.

Parental Attitudes Toward Bullying and Victimization

To our knowledge, few cross-cultural comparisons have been conducted to directly examine parental attitudes toward bullying and victimization. However, existing related studies seem to show that parents across cultures vary in their attitudes toward children's bullying. In a survey study of parental attitudes in a sample of over 1000 English primary schoolchildren, Eslea and Smith (2000) found that parents generally expressed sympathy toward victims of bullying and were supportive of antibullying intervention. A large number of parents also endorsed unsympathetic responses, such as encouraging children to stand up for themselves or hit back. Studies assessing children's perceptions of parental beliefs regarding fighting suggest that such perceptions are relevant to children's actual behavior. For example, Orpinas, Murray, and Kelder (1999) measured family influences on fighting among middle school students from an ethnically diverse urban school, with the majority of students being Hispanic. Students' reports of parent-child relationships, parental monitoring, and parental support of fighting were found to be strongly associated with their fighting behaviors. In a study of parents' attitudes toward fighting in an ethnically diverse middle school sample comprised mostly of European American and African-American children, Malek, Chang, and Davis (1998) found that 30% students believed their parents would want them to fight if confronted or insulted, with this belief more prominent among students from lower-income schools. Similarly, in a study with middle school students from predominantly low-income African-American neighborhoods, Cotten and colleagues (1994) found that families' attitudes toward violence were positively correlated with the students' attitudes toward violence.

In a study with mostly high-risk African-American youth admitted to a hospital emergency department for assault-related injuries, Solomon, Bradshaw, Wright, and Cheng (2008) found that beliefs about fighting were prevalent, with 62% parents reporting "anyone who won't fight is going to be picked on even more." Moreover, 78% of youth and 47% parents agreed with the statement "If a student hits me first, my family would want me to hit them back." According to Sawyer, Bradshaw, and O'Brennan (2008), being victimized often stigmatizes African-American youth. This belief, along with the cultural emphasis for males in Western societies to be tough, may explain the high prevalence of retaliatory behavior in this sample.

Finally, parental attitudes and responses toward victimization may differ across cultural or ethnic groups. In a study with 1,495 parents of elementary, middle, and high school students (78.9% identified as White), for example, Waasdorp, Bradshaw, and Jeffrey (2011) found that parents of non-White youth were less likely to report talking with their victimized child. The authors suggested that these ethnic minority parents might believe that the school should address such problems.

Although the literature on parent attitudes toward bullying and victimization is limited, taken together, the

existing studies suggest that parental attitudes are likely to be shaped by cultural norms, which may contribute to differences in ways in which children are socialized in their bullying and victimization experiences. Further cross-cultural research on parental attitudes in this area will be useful for designing culturally effective antibullying programs in school and community settings.

Parental Attitudes Toward Peer Involvement

Parental attitudes toward children's involvement in peer relationships, such as friendship and peer groups, may also reflect specific cultural features in a society. Young and Ferguson (1981) conducted a longitudinal study through interviews comparing Italian children from Palermo and those who had immigrated to Rome and the United States. The researchers found that Palermo parents were more likely than parents from Rome and the United States to display displeasure for children spending free time with friends rather than being at home. Consistent with this finding, researchers have found that parents in Italy tend to be more restrictive of their children's autonomy and peer activities than parents in North America (e.g., Lambert, Hamers, & Frasure-Smith, 1979). It has been suggested that the encouragement of identification with the family among Italians may be accompanied by ambivalence toward extrafamilial peer relationships (Argyle et al., 1986; Attili, 1997).

In a study in four communities in Oslo (Norway), Lincoln, Nebraska (United States), Ankara (Turkey), and Seoul (South Korea), Aukrust and colleagues (2003) examined the parental perceptions and attitudes about their children's friends and peer groups. Although parents in all groups generally believed that close peer relationships were important for their children, parents in some countries seemed to place greater value on peer relationships than those in other countries. Oslo parents highly valued the stability of children's friendships and believed small class sizes and continuity of classroom composition to be helpful for children to maintain stable friendships. In contrast, Lincoln parents were less concerned about the preservation of friendship groups but were instead more concerned about their children's comfort with their teacher and their classroom experience. Seoul parents tended to emphasize academic success and, at the same time, highly regarded their children's sense of belonging with their peers. Finally, Ankara parents tended to believe that their children had difficulties maintaining friendships, perhaps due to the large class sizes in Ankara schools. Thus, parental beliefs and attitudes about children's peer relationships may be related to the organization of socialization settings and practices.

In summary, parental attitudes and associated socialization practices, to a great extent, are indicative of cultural values and requirements of the society. Inquiry into culturally relevant parental attitudes and behaviors, especially in parent-child interactions, is likely to shed light on the role of sociocultural conditions in the development of social-behavioral and psychological problems.

CULTURE, PEER EVALUATION, AND THE REGULATORY FUNCTION OF PEER INTERACTIONS

Peer interactions become an increasingly important socialization context for individual development from childhood to adolescence. During interactions, children interpret and evaluate each other's behaviors and express their attitudes about the behaviors. Swords, Hennessy, and Heary (2011), for example, found that girls appeared to be more accepting than boys of others who displayed behavioral and emotional problems. More important, when children believed that the target child was more responsible for his or her conditions, they were less accepting of the child. Perceived responsibility was a significant predictor of acceptance, especially when the target child was a boy. Nevertheless, like adults' attitudes, peer evaluations of, and responses to, children's behaviors are consistent with the guidance of cultural norms and values that are endorsed in the society, community, and group.

Peer Evaluations

Peer evaluations include understanding, interpretation, and judgment of the behavior that a child displays. Based on the social-cognitive processing of the information, peers may generate and express their responses to the child, which form their attitudes toward the behavior. Cultural norms and values that are adopted in the peer group provide a framework of reference for social evaluations in peer interactions.

Peer Evaluations of Shyness-Inhibition, Social Anxiety, and Unsociability

To investigate cultural differences in peer evaluations, X. Chen and colleagues conducted several studies concerning shy and anxious behavior and peer interactions and relationships in Canadian and Chinese children. In an observational study of peer interactions among

4-year-olds, for example, Chen, DeSouza, Chen, and Wang (2006) found different peer attitudes toward children who displayed shy and reticent behaviors in China and Canada. When shy children in Canada displayed a behavior to initiate social interaction, peers were likely to make negative responses, such as overt refusal, disagreement, and intentional ignoring of the initiation. However, peers tended to respond in a more positive manner in China by showing support and approval and by controlling their negative actions. The results indicated that passive and anxious behaviors that shy children displayed were regarded by peers as incompetent and deviant in Canada but appropriate or even desirable in China, indicating courteousness and a signal of looking for social engagement. In addition, whereas peers were more likely to make forceful and negative voluntary initiations (e.g., verbal teasing) to shy than nonshy children in Canada, peers made similar voluntary initiations to shy and nonshy children in China. Therefore, in their interactions with children who display shy-reticent behaviors, peers are generally unfriendly and unreceptive in Canada but more supportive and cooperative in China.

Cultural norms and values are also reflected in peer attitudes, such as acceptance and rejection. Research findings have shown that shy children seem to experience fewer problems in peer acceptance in societies where assertiveness and self-expression are not highly valued or encouraged. Eisenberg, Pidada, and Liew (2001), for example, found that shyness in Indonesian school-age children was negatively associated with peer nominations of dislike. Chen and colleagues found that shyness was associated with peer rejection in Canada but with peer acceptance in China in the early 1990s when the impact of the massive social and economic reforms in the country was still not evident on individual attitudes and behaviors (e.g., Chen, Rubin, & Sun, 1992). As urban China is changing toward an increasingly competitive market-oriented society with the introduction of more individualistic cultural ideologies, children's shyness is associated with more negative peer attitudes. By the early part of the twenty-first century, as the country became deeply immersed in a market economy, shy children, unlike their counterparts in the early 1990s, were clearly rejected by peers (X. Chen, Cen, Li, & He, 2005; Chen et al., 2011). Interestingly, shyness was positively associated with both peer acceptance and peer rejection in the late 1990s, which seemed to indicate ambivalent attitudes of peers toward shy-inhibited children during a transitional period characterized by mixed traditional Chinese and new Western values.

Heinrichs et al. (2006) studied perceived cultural norms and their relations to social anxiety among youth in multiple societies. The results indicated that youth in collectivistic countries, including Japan, Korea, and Spain, reported higher levels of social anxiety and greater fear of blushing than did youth in individualistic countries, including Australia, Canada, Germany, the Netherlands, and the United States. Moreover, youth in collectivistic, especially East Asian, countries were more accepting of socially reticent behaviors than youth in individualistic countries. High levels of social anxiety and fear of blushing symptoms appeared to be associated with the greater acceptance of reticent behavior at both individual and cultural levels. Heinrichs et al. (2006) argued that cultural norms concerning socially anxious behavior determine, in part, not only the display of the behavior but also social judgments and evaluations of the behavior.

In another study in Western (Australia, Canada, Germany, the Netherlands, and the United States) and East Asian (China, Japan, and Korea) countries, Rapee et al. (2011) presented to adolescents vignettes describing individuals who displayed shy and reserved behaviors or outgoing and socially confident behaviors. The participants were then asked to indicate the extent to which they would expect the individuals in the vignettes to be liked by others and to succeed in their careers. The results showed that the difference in perceived social and career impact between shy and outgoing vignettes was smaller among participants from East Asian countries than from Western countries. Shyness tended to be negatively associated with experienced quality of life for all groups of countries, but the associations were more evident for Western groups than for East Asian groups. These results suggested that participants in Western countries viewed shy behavior as having a more negative impact on social relationships and life adjustment than did their counterparts in East Asia.

In the literature of peer relationships and social behaviors, unsociability or social disinterest, which refers to nonfearful preference for solitary activities, is considered another major aspect of social withdrawal (Asendorpf, 1990; Coplan & Armer, 2007). Unlike shyness, unsociability in children remains relatively understudied, particularly from middle childhood. According to a conceptual model proposed by Asendorpf (1990), whereas shyness-inhibition is derived from an internal conflict of approach and avoidance motivations, unsociability is based on low levels of both approach and avoidance in social settings. Unsociable children do not have a strong desire to play with others, although they may not strongly avoid peer interactions (Coplan et al., 2004). It has been argued that in Western cultures, preference for solitude may be considered

representing an autonomous action of the individual if it is based on personal choice (Coplan & Armer, 2007). Thus, unsociability does not necessarily indicate social incompetence and deviance because personal decision making and self-oriented acts are encouraged in Western societies. Moreover, it has been suggested that engagement in solitary activities may have potential benefits for well-being (Leary et al., 2003; Long & Averill, 2003).

Unsociability or social disinterest is related to more negative social attitudes in more collectivistic cultures that emphasize group affiliation and interpersonal connectedness (Greenfield, Suzuki, & Rothstein-Fisch, 2006). There is great pressure in collectivistic societies on individuals to identify with the group and to function in a group context (Sharabany, 2006). During socialization, children are encouraged to develop a sense of social belonging and integration to the group. Because preference for solitude, including pursuing personal autonomy and independence, does not fit a group orientation, children who prefer solitude and maintain distance from the group are viewed as selfish and deviant (X. Chen & French, 2008). Thus, unsociability is likely to elicit negative peer evaluations. Consistent with this argument, in a sample of children in a rural area of China where traditional values were still well maintained, X. Chen, Wang, and Cao (2011) found that unsociability was positively associated with peer rejection although shyness was associated with peer acceptance. In addition, Coplan, Zheng, Weeks, and Chen (2012) found that children in Canada and China responded differently when they were presented with hypothetical vignettes describing the behaviors of an unsociable figure. Compared to their Canadian counterparts, Chinese children viewed the behaviors of the unsociable child as less intentional, and they characterized the unsociable child as having a greater motivation to play with others. Coplan et al. (2012) argued that given the social pressure to engage in affiliative and collectivistic activities, it was more difficult for Chinese children to believe that any child would display socially disinterested behaviors intentionally. As a result, Chinese children believed that the unsociable peer might still desire to play with others and their socially disinterested behavior might be less intentional.

Peer Evaluations of Aggressive and Antisocial Behaviors

Compared with shy and anxious behaviors, aggressive and antisocial behaviors are associated with negative peer attitudes more consistently across cultures, which is understandable, given that aggression, disruption, and violence are likely to threaten not only the well-being of individuals but also the harmony of the group. Nevertheless, variations have been found across cultures or subcultures in peer attitudes toward these behaviors. In cultures such as that of the Yanomami Indians, where violent behaviors are regarded as socially acceptable or encouraged, children, especially boys, who display these behaviors may be admired as heroes by their peers (Chagnon, 1983). In some central and southern Italian communities, due to social and historical circumstances, aggressive and defiant behaviors may be viewed by children as reflecting social assertiveness (Casiglia et al., 1998; Schneider & Fonzi, 1996). In the United States, aggression is generally discouraged. However, aggressive children and adolescents may obtain support from their peers (e.g., Cairns & Cairns, 1994; Rodkin, Farmer, Pearl, & van Acker, 2000). In peer groups that encourage violence, being able to fight and display aggressive behaviors is related to the acquisition of personal status in the group (Bernburg & Thorlindsson, 2005; K. Graham & Wells, 2003).

Positive evaluations of aggressive and antisocial behaviors in peer groups are illustrated in Dishion and his colleagues' work (e.g., Boislard, Poulina, Kiesner, & Dishion, 2009; Dishion, McCord, & Poulin, 1999). In a study of delinquent behavior, the researchers asked 13- to 14-year-olds to discuss a variety of topics, such as planning a joint activity and solving a social problem, and found that delinquent youth engaged in four times the amount of talk about rule breaking than nondelinquent youth did. Moreover, delinquent youth were likely to display positive reactions to deviant talk, such as laughter and expression of interest, whereas nondelinquent youth often ignored deviant talk. In contrast, delinquent youth were less likely to react positively to normative talk than nondelinquent youth. Dishion et al. (1999) argued that deviant talk seems to be a tool that antisocial and delinquent youth use to formulate, establish, and maintain social support networks. The deviant talk of delinquent adolescents indicates their understanding of (1) the group norm that values rule breaking and other antisocial behaviors, (2) peer expectations of their actions to be in accord with the norm, and (3) the potential damage of violation of the norm on their relationships with others in the group. Positive reactions of adolescents to the talk signify their endorsement of the group norm, which is an indication of their collective attitudes about rule breaking. At the same time, deviant talk is useful for individual members to acquire and enhance their status and peer recognition in the group.

Children's aggressive and antisocial behaviors are generally regarded as more problematic in group-oriented cultures (e.g., X. Chen & French, 2008). In Chinese

schools, for example, these behaviors are strictly prohibited in social interactions. To help children control their aggressive and disruptive behaviors, students are required to engage in public evaluations in which they evaluate each other's behaviors according to school standards. Although aggressive children in China may form groups with peers that exhibit similar behavior (X. Chen, Chang, Liu, & He, 2008), they are likely to be rejected, criticized, and even shamed by others in the larger context (e.g., X. Chen et al., 2005).

In a cross-cultural study of adolescent misconduct, C. Chen, Greenberger, Lester, Dong, and Guo (1998) explored perceptions of peer approval and disapproval of externalizing behaviors in four samples: European Americans, Chinese Americans, Chinese in Taipei, and Chinese in Beijing. Students in junior high schools (grades 7 and 8) reported their peers' attitudes toward their behaviors such as talking back to teacher, doing something dangerous for excitement, stealing, and lying to parents. Students were asked whether their peers would admire or think badly of them if they were to engage in these behaviors, on a 7-point rating scale (e.g., 1 = endorsing none of the misbehaviors; 7 = endorsing all six types of misbehaviors). The results showed that European American adolescents (M = .86) had higher scores on peer approval for the behaviors than did Chinese adolescents in Beijing and Taipei (M = .28 and .28). Chinese American adolescents (M = .51) fell between European Americans and the two Chinese groups. In contrast, Chinese in Beijing and Taipei (M = 4.30 and 3.49) reported a higher level of peer disapproval of the behaviors than did European and Chinese Americans (M = 2.21 and 2.85). Greenberger and colleagues (2000) found similar results in another study conducted with adolescents in different samples in the United States, China, and Korea. In this study, the participants in the United States (M = 2.71 and 1.42) perceived a lower level of negative sanctions against physical aggression toward others and other antisocial behaviors from parents and friends than did Koreans (M = 2.78 and 1.61) and Chinese (M = 2.78 and 1.69), and Koreans perceived friends as less disapproving of the behaviors than did Chinese. Taken together, the findings from these studies clearly show that Chinese and Korean adolescents are less likely than American adolescents to believe that their peers and parents would endorse aggressive and antisocial behaviors.

Peer Evaluations of Conflict Behavior and Bullying

Some studies have been conducted to examine peer evaluations of conflict and bullying and their effects on children's behaviors. In addition to examining similarities and differences between Chinese and Canadian children on social behaviors in limited-resource and potential conflict situations, French et al.'s study (2011) examined how the behaviors were associated with peer attitudes. Upon completion of the behavioral observation of conflict, children were individually interviewed about how much they liked playing with the other children in the group. The analyses revealed a series of cross-country differences in the relations between conflict behaviors and peer evaluations of liking. Specifically, assertive behavior in the attempt to acquire the only toy in the playroom was negatively associated with peer liking and passive behavior, and uninvolvement was positively associated with peer liking in Chinese children; these associations were not significant in Canadian children. Holding control of the toy was positively associated with peer liking and passive behavior was negatively associated with peer liking in Canadian children but not in Chinese children. Thus, the results suggest a very different profile of esteemed behaviors in conflict situations for Chinese and Canadian children. Children who hang back, let others play with the toy, and watch others are liked by their peers in China. By contrast, their peers in Canada accept children who are assertive and successful in attaining control of the resource. The differences in relations between behavior and group member's evaluations of liking among Canadian and Chinese children are striking but consistent with previous findings that socially constrained behaviors, such as modesty, are valued by Chinese children whereas active behaviors in controlling the situations are valued by Western children (e.g., X. Chen, DeSouza, et al., 2006).

Researchers have studied the third-party mediation in children's conflict, which also provides information about peer attitudes. In observational studies conducted by Butovskaya, Verbeek, Ljungberg, and Lunardini (2000) comparing 2- to 7-year-old children in Russia, the United States, Sweden, and Italy, third parties were found to typically support one side rather than to seek a way to settle the conflict. However, Russian children were more likely than children in other countries to try to find a compromise, indicating that peer conflict might be perceived as more disturbing and less tolerable in the Russian culture (Verbeek, Hartup, & Collins, 2000). Butovskaya et al. (2000) found that among 2- and 3-year old children in a multicultural child care center, 30% Moroccan and 37% Antillean children intervened in the conflict, compared to only 17% Dutch children. The authors suggested that collectivistic characteristics,

which promote third-party intervention, might explain the greater tendency of Antillean and Moroccan children to intervene.

Concerning peer attitudes toward bullying, it appears that children who explicitly demonstrate a negative attitude show less bullying behaviors than children who show a positive regard toward bullying (van Goethem, Scholte, & Wiers, 2010), although this association may be moderated by a number of factors. In a study conducted by Pepler and colleagues (1993), approximately half of the children said they would intervene to support victims during bullying episodes. In another study (Rogers & Tisak, 1996), when children were asked how peers ought to respond when witnessing a peer hitting another child, responses varied by age and by the relationship they had with the peer. Although all children believed that the attack should be reported to an authority, older children were more likely to think that the bystander would confront the perpetuator or not respond at all. Moreover, children thought that the bystander would be more likely to respond or intervene if the victim or the perpetuator was a friend rather than an acquaintance. Salmivalli and colleagues (1996) used peer reports to examine bullying among sixth graders in Finland and found that girls tended to align themselves with the victim by telling an adult about the bullying or staying out of the situation, whereas boys tended to incite the bullying. These results point to the role of gender on third-party conflict intervention in childhood.

In short, research findings have indicated different cultural norms and values with regard to children's shyness-inhibition, social anxiety, aggression, conflict, and bullying. These norms and values are manifested in peer attitudes and responses in interactions, which, along with adult socialization attitudes and practices, constitute important social environments for the development of adaptive and maladaptive behaviors.

The Regulatory Function of Culturally Directed Peer Interactions

Whereas culture provides guidance for social evaluations of children's behaviors, social evaluations in interactions, in turn, may serve to regulate children's behaviors and their developmental patterns. Research has indicated that social interaction situations are likely to elicit attention to external demands, which is an important condition for the regulation of behaviors (Duval & Silvia, 2002). Feedback from others in the interaction process may enhance children's awareness of social expectations and the differences between their behaviors and the expectations.

From the contextual-developmental perspective, the regulatory function of social evaluations and responses is an important part of the mediating process of cultural influence on individual development. The process may occur as children attempt to maintain or modify their behaviors or behavioral styles according to culturally based social expectations. The need for social approval, group affiliation, intimate feelings within relationships, and overall social acceptance in larger settings is the main motivational force that directs children to participate in social interactions, attend to social evaluations, and maintain or modify their behaviors according to social expectations. To obtain social affiliation and integration, children need to understand others' attitudes and to maintain their behaviors accordingly. As illustrated in the C. Chen et al. study (1998), the perceptions of peer approval of misconduct were positively associated with antisocial behavior, school misconduct, and deviant behaviors such as cigarette smoking and alcoholic drinking, whereas the perceptions of peer disapproval of misconduct were negatively associated with these behaviors. The patterns of the associations were generally consistent in European American, Chinese American, Taipei Chinese, and Beijing Chinese adolescents.

Regulatory Role of Social Interaction in the Development of Internalizing Behaviors

Little research has been conducted to directly examine how social interaction processes play a role in regulating the development of socioemotional functioning, particularly of an internalizing nature. Nevertheless, the results of several studies suggest that there exists a peer contagion effect on children's and adolescents' socioemotional distress, such as depression, which indicates that peer interactions may enhance or weaken children's internalizing behaviors. Prinstein and his colleagues, for example, studied how the characteristics of friends and peer groups contributed to the development of adolescent depression (Prinstein, 2007; Stevens & Prinstein, 2005). An interesting finding was that youth in socially active groups, such as those identified by the participants as Populars and Jocks, had experienced significant declines in internalizing distress in development. In contrast, youth in groups that were academically oriented, such as the Brains, exhibited increased internalizing distress from childhood to adolescence (Prinstein & La Greca, 2002). Conway, Rancourt, Adelman, Burk, and Prinstein (2011) extended the work by examining depression socialization among adolescents with different status in the peer group. The results indicated that the peer group had stronger effects for adolescents who

were peripheral members of the group, which was likely due to the fact that, compared with nuclear members, peripheral members faced greater pressure to conform to the group norm and thus were more susceptible to peer influence.

Van Zalk, van Zalk, and Kerr (2011) investigated whether adolescent crowds affected individual social anxiety in Sweden. The researchers focused on Radical crowds (Punks and Goths) comprised of adolescents who were shy and socially fearful with extremely eye-catching or shocking appearance (e.g., wearing white face paint, faked bloodstains around the eyes or mouth, or half-shaved long black hair). Adolescents in these crowd groups were believed to create unusual appearance to limit anxiety-arousing social contacts. The distinct striking physical feature of the Radical peer crowd appeared to facilitate the socialization of social anxiety. Through social interaction processes, adolescents in Radical crowds were more susceptible to peer influence than adolescents in the other groups. According to van Zalk et al., group members might strengthen socially anxious behavior of one another by providing empathy and approval in situations that provoke social fear because the behavior is consistent with the group norm.

Finally, in a study of adolescents' suicide attempts in Hong Kong, T. Ho, Leung, Hung, Lee, and Tang (2000) found that suicidal behaviors (ideation, plans, and acts) increased among adolescents with friends who had attempted or completed suicide. As Ho et al. pointed out, although the study could not determine a causal relationship between individual suicidal acts and their friends' suicidal behaviors, the results showed that youth with friends who carried suicidal attempts increased the risk of suicidal behaviors themselves.

Regulatory Role of Social Interaction in the Development of Aggressive and Antisocial Behaviors

The regulatory function of peer interaction has been observed in a number of studies of the development of aggressive, antisocial, and delinquent behaviors (e.g., Lavallee, Bierman, & Nix, 2005; Zakriski, Wright, & Cardoos, 2011). Among them, studies conducted by Dishion and his colleagues (e.g., Dishion et al., 1999; Piehler & Dishion, 2007) concerning deviancy training, delinquency training, or peer contagion processes provided particularly compelling evidence that interaction among youth with externalizing behaviors led to the escalation of the behaviors. The researchers found that peer activities, such as talk about rule breaking and positive reactions to the talk, predicted increase in later substance use, delinquency, violence, and high-risk sexual behavior (e.g., Patterson, Dishion, & Yoerger, 2000; Piehler & Dishion, 2007). As argued by Dishion and Dodge (2005), the grouping of antisocial and delinquent adolescents provides a context that elicits and reinforces their externalizing behaviors.

The salience of the group norm and uniformity of norm-based social evaluations and responses may affect the regulatory effects of peer interactions. Battin, Hill, Abbott, Catalano, and Hawkins (1998), for example, found that gangs with explicit norms and rules exerted greater influence on youth than more informal peer groups. Gang involvement made a unique contribution to the development of criminal behavior beyond the membership of nongang delinquent networks. With a few exceptions (e.g., Mager, Milich, Harris, & Howard, 2005), studies have shown that homogenous groups consisting of similarly antisocial and delinquent youth seem to have particularly evident negative effects; inclusion of prosocial members in the group may reduce adolescents' antisocial behavior (e.g., Dishion et al., 1999; Tremblay, Pagani-Kurtz, Mâsse, Vitaro, & Pihl, 1995). In mixed groups, such as those consisting of aggressive and nonaggressive children, for example, peer interaction may pull the children toward the mean level of members' behavior. Thus, peer interaction may reduce aggression for highly aggressive children but make nonaggressive children more aggressive. Moreover, effects seem to be magnified in either direction for those who are more discrepant from their peers (Boxer, Guerra, Huesmann, & Morales, 2005).

Bernburg and Thorlindsson (2005) examined how cultural values of violence affected youth aggression through the peer group in Iceland. The results indicated that group adherence to violent values and norms predicted aggression through social control beyond individual internalization of the cultural values. Thus, by directing the group processes, such as social control, culture may be involved in individual development of aggressive behavior.

Chen and his colleagues (e.g., X. Chen, Chang, et al., 2003; X. Chen, Chang, et al., 2008) examined how peer group context contributed to individual development in Chinese children. The results indicated that peer groups not only contributed to individual behavior but also affected the significance of individual behaviors for development. Specifically, in groups that functioned on the basis of academic achievement as a major standard, children evaluated each other according to their attitudes and achievement in academic areas. Moreover, group members were sensitive to the feedback from group peers on their academic performance. Within the group, children who performed better on academic subjects were more likely to

receive social and emotional support from others and had more opportunities to learn from others. In groups that did not value academic achievement, however, the common negative attitudes toward academic achievement led to group approval and support for deviant behaviors, such as violation of school rules and disruption of classroom instruction. This group context exacerbated the development of social and behavioral problems of academically poor children and thus placed them at particular risk for maladaptive social development.

Personal and Social Moderators of Regulatory Function of Social Interactions

Various personal and social factors may affect the regulatory function of social interactions. Child age or developmental period may be an important factor that moderates the effects of social interactions. Although the regulatory role of social interaction in human development may be evident from childhood to adolescence, the process of regulation may vary qualitatively and quantitatively across developmental stages. With age, social interactions become more complicated as children are more interested in, and capable of, exploring different lifestyles with others (Brown, 1990). The development of social-cognitive abilities also makes children more competent in understanding social evaluations, integrating various norms and values for group activities, and regulating their behaviors.

In addition to age, children's sensitivity to social evaluations, which includes cognitive and affective activities, such as attention to evaluations of peers, understanding of social cues, and concern about social relationships, has been shown to promote or hinder behaviors that are expected and encouraged by others and to motivate children to be attuned to social environments and actively resolve problems in interactions (Henirch, Blatt, Kuperminc, Zohar, & Leadbeater, 2001; Rudolph & Conley, 2005). Prinstein (2007) studied how individual characteristics, such as social anxiety and global self-worth, and peer characteristics, such as friends' popularity and friendship quality, moderated peer contagion effects on adolescent development of depression. The results indicated that higher levels of social anxiety were associated with adolescents' greater susceptibility to peer contagion, particularly among girls, which was consistent with a previous finding that socially anxious adolescents were particularly likely to conform to the attitudes and behaviors of their peers (Cohen & Prinstein, 2006). Moreover, higher levels of friends' popularity and lower levels of positive friendship quality were associated with greater susceptibility to depressive symptom contagion, suggesting that individuals were more likely to conform to norms that were established by peers of high status and based on more intimate relationships.

Laursen, Hafen, Kerr, and Stattin (2012) found in a sample of secondary school students in Sweden that friends influenced adolescents' alcohol intoxication and delinquent behavior over time, but the influence was moderated by the social status of adolescents in the friendship. Friends shared similar behavioral problems before the friendship was formed, and similarity increased after the friendship began and continued to grow among those who remained friends 1 year later. In stable friendships, the partner who was more accepted by peers exerted greater influence over the less accepted partner. As a result, less accepted adolescents were most vulnerable to behavioral problems when their friends had high initial level of alcohol intoxication and delinquency and at the same time had a relatively higher status among peers.

Peer influence may also be moderated by affective and attitudinal processes in peer interactions, such as mutual responsiveness, understanding of each other's ideas, and shared beliefs and values. Piehler and Dishion (2007) found that deviant talk was associated with escalated levels of antisocial behavior for adolescents who were involved in more mutually responsive and intimate interactions and relationships. Thus, supportive social context facilitated the links between deviant peer activities and the development of antisocial behavior. These findings suggest that intensive interactions may increase the salience of the group norm and uniformity of norm-based social evaluations and responses, which in turn may promote children's commitment to the norms of the group and eventually strengthen the regulatory function of peer interactions.

Cultural Variations in Regulatory Function of Social Interaction

Children's social-evaluative sensitivity may be related to individual past experiences and social-cognitive abilities (Dodge, Coie, & Lynam, 2006; Rudolph & Conley, 2005) as well as sociocultural conditions, such as values of self versus group orientation. In cultures where the view of others is regarded more important than the view of one's self, children may be inclined to attend to others' perceptions of them. Indeed, it has been found that children and adolescents in East Asian societies, such as Japan, display higher levels of social-evaluative sensitivity due to the concern about losing face than in North America (e.g., Dong, Yang, & Ollendick, 1994). Consequently, peer interactions and attitudes may play a more important role in individual development in East Asian societies. Dekovic

et al. (2002) found that participation in peer activities and peer acceptance were associated more strongly with developmental outcomes such as emotional well-being in Japanese than in Dutch adolescents, which, according to the authors, was due to the higher sensitivity of Japanese adolescents to social feedback.

In Western societies, children are expected to develop personal autonomy during social interactions. Children are encouraged to pursue personal interest and gradually develop individuality and self-identity through activities with peers. Thus, peer interactions provide a context for children to understand themselves in relation to others and to experience self-validation (Rubin, Bukowski, et al., 2006; Sullivan, 1953). As children seek independence, they may become dissatisfied with the constraint of social relationships and attempt to maintain a balance between the pursuit of self-interest and social restriction. It has been noticed that there is a trend of loosening of group ties during late adolescence and that children's sense of belongingness declines steadily with age (see Rubin, Bukowski, et al., 2006).

In group-oriented societies, the tension between the pursuit of independence and personal identity and group commitment may be less evident than in Western cultures. Thus, children and adolescents may maintain strong social affiliation and group identification across different developmental periods in these societies. Social relationships are valued mainly according to their socialization functions in helping children learn social standards and in developing socially acceptable behaviors (X. Chen, Kaspar, Zhang, Wang, & Zheng, 2004; Sharabany, 2006). Children and adolescents in China, for example, tend to describe social activities in terms of how well the activities are compatible with social requirements and standards, such as maintaining interpersonal cooperation and collective well-being (X. Chen, Kaspar, et al., 2004). In C. Chen et al.'s study (1998) and Greenberger et al.'s study (2000), perceptions of parents' and friends' negative attitudes toward externalizing behaviors were positively associated with adolescents' display of aggressive and antisocial behaviors and misconduct in the United States, Korean, and Chinese samples. Thus, youth who believed that their parents and friends would respond less negatively to their externalizing behaviors engaged in more externalizing behaviors. Interestingly, after controlling for others' perceived behaviors, attitudes toward adolescents' externalizing behaviors contributed uniquely to the prediction of adolescents' externalizing behaviors in Korean and Chinese samples but not in the U.S. sample (Greenberger et al., 2000). The results suggest that the attitudes of others play a more important role in affecting adolescents' externalizing behaviors in societies that are more group-oriented.

In summary, children's social experiences in peer interactions and relationships are culturally bound, as argued by Stevenson-Hinde (2011). Cultural norms and values provide a basis for social evaluations and responses in peer interactions, which in turn serve to regulate children's adaptive and maladaptive behaviors. The social-evaluative and regulatory processes occur mainly at the group level. Individual characteristics, such as sensitivity to social evaluations and susceptibility to peer influence, may affect the processes through constraining or facilitating group influence. Along with parental socialization practices, culturally directed peer interactions constitute important social contexts in which children and adolescents develop their social, behavioral, and psychological characteristics and problems.

CHILDREN'S PEER EXPERIENCES AND ADAPTIVE AND MALADAPTIVE OUTCOMES: THE ROLE OF CULTURE

According to the contextual-development perspective (X. Chen, 2012), culturally directed evaluation and response processes in social interactions may have pervasive effects on children's adjustment in various domains. Therefore, to understand whether and to what extent children's behaviors are adaptive or maladaptive in a society, it is important to examine their associations with social attitudes and relationships as well as their adjustment outcomes. An in-depth and comprehensive examination of behaviors in a social interaction context from a developmental perspective is critical to grasping their functional meanings. Cultural variations in developmental outcomes of children's behaviors are sometimes described in terms of goodness of fit—the adjustment of children in the society depending on how their behavioral characteristics fit cultural requirements (e.g., García Coll et al., 2000; Lerner & Lerner, 1983). The contextual-development perspective (X. Chen, 2012) stresses the social interaction processes in which social evaluations and responses regulate children's behaviors and their developmental patterns. At the same time, children play an active role through displaying their reactions to social influence and through participating in constructing the social interaction context. The bidirectional coregulatory process, especially in the peer interaction context, is dynamic and active, beyond the mutual fit between the child and the socialization agent.

The contextual-developmental perspective is consistent with the constructivist view (Piaget, 1970; Vygotsky, 1978), asserting that the social challenge or the lack of fit between the child and the context may be a motivational force for children to pursue higher levels of mental and socioemotional functioning.

Shyness-Inhibition, Unsociability, and Adjustment

In the literature, shyness-inhibition, social anxiety, and, broadly, social withdrawal in childhood and adolescence are associated with a variety of later maladaptive outcomes, such as poor family and social relationships, occupational instability, and mental health problems (Caspi, Elder, & Bem, 1988; Clark, Rodgers, Caldwell, Power, & Stansfeld, 2007; Fergusson, Horwood, & Ridder, 2005; Rubin et al., 2009). The findings, however, are based almost entirely on studies with Western children. Findings of relatively recent cross-cultural studies suggest that relations between shyness-inhibition and other aspects of social withdrawal and adjustment outcomes may be different in children in other societies.

In Western, particularly North American, societies, children who display shy-inhibited behavior likely develop social problems, negative self-perceptions of their competence, and other psychological problems, such as loneliness, social dissatisfaction, depression, and emotional disorders (e.g., Coplan et al., 2004). C. E. Schwartz, Snidman, and Kagan (1999) reported that inhibition in early childhood predicted psychopathological symptoms, such as social anxiety in adolescence. Gest (1997) found that childhood inhibition, as indexed by apprehensive and shy acts and initiation of little social interaction during interviews with researchers, predicted less active and less positive social life in adulthood. Moreover, inhibition was associated with later greater emotional distress, particularly in men. In addition, inhibited children were less likely than uninhibited children to establish independence in early adulthood, such as moving out of the home of their family of origin (34% versus 64% respectively). In another longitudinal study, Gest, Sesma, Masten, and Tellegen (2006) found that peer-assessed shy-withdrawn behavior in childhood negatively contributed to the prediction of the quality of social life, as indexed by overall social acceptance, formation of friendships and networks, and romantic relationships, 10 years later. Similarly, Asendorpf, Denissen, and van Aken (2008) and Caspi et al. (1988) found that shy-anxious children, particularly boys, experienced a variety of problems in adulthood, including delay entry into marriage, parenthood, and career. Childhood shyness was also associated with lower occupational achievement and occupational instability in adulthood. These results support the argument that shyness-inhibition represents a risk factor that may lead to psychopathological development in Western societies (Kagan, 1997).

Shy-inhibited and socially anxious behaviors tend to be related to less negative outcomes in less self-oriented and competitive societies. X. Chen, Chen, Li, and Wang (2009) examined relations between early inhibition and social and school outcomes in middle childhood in Chinese children. Data on behavioral inhibition were collected through laboratory observations from a sample of toddlers (X. Chen et al., 1998). Follow-up data were collected 5 years later when the children were 7 years of age from multiple sources, including observations of free-play peer interactions, interviews, teacher ratings, and school records. The results indicated that early childhood inhibition positively predicted later cooperative behavior, peer liking, perceived social integration, positive school attitudes, and school competence. Early inhibition was also negatively associated with later learning problems. Further analyses based on extreme groups (extremely inhibited and uninhibited groups identified using the criteria of the top and bottom 15% and 8% of the distribution) indicated that the associations were due mainly to the differences between highly inhibited children and other children; children who were identified as inhibited in toddlerhood were more competent in social and school performance and had fewer behavioral and learning problems in middle childhood than those identified as average and uninhibited.

X. Chen, Rubin, Li, and Li (1999) found that shyness in middle childhood positively contributed to adolescent social, school, and psychological adjustment in China. In this study, children's shyness was assessed using peer evaluations when the children were 8 and 10 years old. Follow-up data were collected 4 years later on children's leadership, academic achievement, self-perceptions, and behavioral problems, obtained using teacher and parent ratings, self-reports, and school records. It was found that shyness was not associated with later adjustment problems, either externalizing or internalizing. Moreover, shyness was positively associated with indexes of adolescent adjustment, including teacher-assessed competence, leadership, academic achievement, and self-perceptions of competence. Thus, shy-inhibited Chinese children continued to be well adjusted to the social and school environments in adolescence. Nevertheless, as China has shifted toward a competitive, market-oriented society, shy Chinese children, particularly in urban regions, have experienced increased school adjustment problems and socioemotional problems,

such as depression (Chang et al., 2005; X. Chen et al., 2005; X. Chen, Wang, & Wang, 2009).

Relatively less negative outcomes of shyness have been found in other societies compared with findings from U.S. samples (e.g., Caspi et al., 1988). Kerr, Lambert, and Bem (1996), for example, examined the long-term outcomes of shyness in Swedish society, where shy-reserved behavior was perceived as less problematic than in North America. The researchers followed a sample of children born in a suburb of Stockholm in the mid-1950s to adulthood. It was found that although shyness was related to later marriage and parenthood, it did not affect adulthood income, education, or occupational stability as indicated by frequency of job changes among Swedish men. Kerr et al. argued that the social welfare systems in Sweden assured that people did not need to be assertive or competitive to achieve career success. In the study, Swedish shy girls attained lower levels of education than nonshy girls, which, according to the authors, might be due to the fact that similar social support systems were not available for women at that time.

There is little research on adjustment outcomes of unsociability or social disinterest. The results from relatively limited studies, mostly cross-sectional, seem to indicate that unsociability is not necessarily associated with social or emotional problems in Western cultures (e.g., Asendorpf & Meier, 1993; Harrist, Zaia, Bates, Dodge, & Pettit, 1997). Coplan et al. (2004) found that unsociability was related to lower levels of negative emotionality than shyness. Jennings (1975) found that unsociable children did not display evident deficits in social knowledge and social skills. Harrist et al. (1997) reported that unsociable children did not differ from other children in general and were more competent than shy-anxious children on social-information processing tasks. Finally, Coplan and Weeks (2010) reported that unsociable children had more positive school attitudes than other children.

As indicated earlier, unsociability is regarded as more negative in more group-oriented cultures (X. Chen & French, 2008). Thus, one would expect that children's unsociability is associated with, and contributes to, the development of adjustment problems in these cultures. Liu et al. (2015) found in a cross-cultural study that unsociability was more strongly associated with adjustment difficulties, such as peer rejection, academic failure, and loneliness, in China than in Canada. Relative to their counterparts in urban China, unsociable children seemed to experience even more pervasive difficulties in rural areas of China, which may be because group orientation and social affiliation are emphasized to a greater extent in rural than urban areas. Indeed, X. Chen, Wang, et al.'s results (2011) showed that among rural Chinese children, whereas shyness-sensitivity was associated with social and social status, teacher-rated competence, and academic achievement, unsociability was associated with pervasive problems such as school incompetence and depression. The negative evaluations and response that unsociable children receive from peers and adults may be intensive and persistent in rural Chinese society, where personal choice and individual autonomy are highly discouraged. Many rural areas in China are currently undergoing rapid changes toward urbanization and modernization. It will be interesting to investigate how unsociable children respond to the social, economic, and cultural changes, which will further our understanding of the role of changing context in human development.

In short, research findings suggest that shyness-inhibition and social anxiety in some cultures, such as Chinese and Northern European cultures, lead to less maladaptive outcomes than what has been found in North America. In these cultures, shy, inhibited, and anxious children may not experience heightened difficulties in social interactions. Moreover, these children may receive support and assistance from others, which likely enhances their confidence and ability to form social relationships. Participation in social activities, in turn, provides the opportunity for these children to learn skills to behave appropriately in social situations. At the same time, social relationships that they establish may help them develop positive attitudes toward others and the motivation to achieve success in various areas. Unsociability or social disinterest may reflect, to some extent, personal autonomy and independence, which are more valued in Western individualistic cultures than in group-oriented cultures. Therefore, unsociability tends to be associated with more adjustment problems among children in group-oriented than in individualistic societies. Longitudinal research is needed to understand the developmental outcomes of unsociability in both Western and non-Western contexts.

Aggression, Self-Control, and Adjustment

Research in Western societies has shown that aggressive and antisocial behaviors in childhood and adolescence are associated with a number of social and psychological problems, including delinquency, school dropout, and mental health problems (e.g., Dodge et al., 2006; Landford, Malone, Dodge, Pettit, & Bates, 2010; Tremblay, 2010). Longitudinal data have also indicated that early aggression predicts adolescent and adulthood adjustment

problems (e.g., Dodge et al., 2006). Relative to the large number of projects conducted in Western societies, there is little research on the adjustment outcomes of aggressive and other externalizing behaviors in non-Western societies, although these behaviors may be regarded as equally or even more problematic in some of these societies (X. Chen & French, 2008). The extant findings (e.g., X. Chen et al., 1999; Zhou, Lengua, & Wang, 2009) seem to suggest that the developmental outcomes of aggression in non-Western societies are similar to those in Western societies.

Despite generally similar cross-cultural patterns of relations between aggression and adjustment outcomes, some evidence suggests that children who display aggressive behavior in group-oriented cultures report more negative self-perceptions and self-feelings than their counterparts in self-oriented cultures (e.g., X. Chen, He, et al., 2004). In the Western literature, the findings concerning the relations between aggressive behavior and psychological problems are inconsistent. While some researchers found comorbidity of externalizing and internalizing behaviors, particularly in elementary school ages (e.g., M. K. Holt & Espelage, 2007), others failed to find significant relations (e.g., Mercer & DeRosier, 2008; Palmen, Vermande, Deković, & van Aken, 2011). High comorbidity was often found in studies based on data from a single source, such as parent or youth self-report. With data collected from different sources, such relations were considerably weaker or nonsignificant. It has been argued that aggressive children tend to develop biased self-perceptions of social competence (Dodge et al., 2006), perhaps due to their cognitive deficits or social support received from their peers or both (e.g., Rodkin et al., 2000). X. Chen, Zappulla, et al. (2004) found that whereas aggression was not associated with self-perceptions in Brazilian, Chinese, or Italian children, it was significantly and positively associated with perceived social competence in Canadian children. Canadian aggressive children were more likely than their nonaggressive counterparts to report that they were socially competent. As such, it may be understandable that most aggressive children in North America do not experience emotional problems.

In group-oriented Asian societies, such as those of China, Japan, and Korea, children's behaviors are often evaluated by others in public settings. During the public evaluations, children who display aggressive and antisocial behaviors may be criticized and humiliated. It is believed that negative social evaluations, such as shaming, may lead to self-examination, which may facilitate the internalization of rules and the development of social responsibility (Fung, 2006). This evaluation process makes it difficult for aggressive children to develop inflated or biased self-perceptions of their competence. Moreover, the adverse social experience of aggressive children may facilitate the development of psychopathological problems, such as feelings of loneliness and depression. Consistent with this argument, X. Chen, He, et al. (2004) found that aggression was positively associated with loneliness through the mediation of peer relationships in Chinese children but not in Brazilian, Canadian, or Italian children. X. Chen, Liu, et al. (2003) also found that externalizing behaviors in Chinese children negatively predicted teacher-rated social competence, academic achievement, and self-perceptions of self-worth and positively predicted depression 2 years later. Similar results were found in a 4-year longitudinal study in which aggressive behavior predicted teacher-rated incompetence, low social status, and negative self-perceptions of competence in Chinese adolescents (X. Chen et al., 1999).

Crick and her colleagues (e.g., Kawabata, Crick, & Hamaguchi, 2010) examined associations of overt and relational forms of aggression with adjustment problems in U.S. and Japanese elementary school children. The results indicated similar patterns in the two samples: Physical aggression was positively associated with delinquency, and relational aggression was positively associated with depression. However, the associations between relational aggression and depressive symptoms were stronger in Japanese children than in U.S. children. Thus, Japanese children appeared to be more vulnerable than U.S. children to negative interpersonal experiences. Kawabata et al. (2010) argued that relational aggression toward peers is typically associated with interpersonal conflict and stress, which in turn is associated with social-psychological adjustment problems. Relational aggression may be more detrimental to psychological well-being for Japanese children than for American children because interdependence in peer relationships and friendships are highly valued in Asian cultures, which makes children vulnerable to negative relationship experiences. It is also possible that, relative to their counterparts in Western cultures, children who are relationally aggressive in Japan are perceived as more aversive and are more rejected by peers because relational aggression contrasts greatly with the Japanese cultural beliefs and values. Consequently, these children may feel isolated from peer groups and lack a sense of belonging and relatedness.

Consistent with the results from cross-cultural studies concerning the emotional problems of aggressive children, self-control or regulation may be associated differently with adjustment in Western and Asian cultures.

There seem to be robust links between low self-control and aggression among children in the United States (e.g., Eisenberg et al., 2006; Olson et al., 2005). Zhou et al. (2009) reported that low control and high anger-irritability were also associated with high externalizing problems in Chinese children. However, the associations were stronger in Chinese children than in American children. The results suggest that self-control has comprehensive effects on social and behavioral development in Chinese and perhaps other Asian cultures.

The results concerning relations between self-control and emotional adjustment in the Western literature are inconsistent with each other. Several studies conducted with children in the United States indicated that self-control was not associated with emotional problems (Eisenberg et al., 2005; Oosterlaan & Sergeant, 1996). Some studies suggested that self-control tended to be positively associated with emotional problems in North American children (e.g., Murray & Kochanska, 2002), supporting the argument that some emotional problems may result from overcontrol (Weisz, Sigman, Weiss, & Mosk, 1993). Different results have been found in Chinese children. Eisenberg et al. (2007) found that self-control in Chinese children was negatively associated with symptoms of fearfulness and anxiety. Similarly, X. Chen, Zhang, Chen, and Li (2012) found in a longitudinal study in China that self-control as assessed by performance on delay tasks at 2 years of age negatively predicted self-reported loneliness and depression at 11 years of age. Children who have the ability to control their behaviors likely display appropriate characteristics, such as cautiousness and compliance, which are highly valued in group-oriented societies. At the same time, high emphasis on self-control in Chinese culture is likely to create a challenging situation for children who have difficulties maintaining their behaviors according to social conventions and standards. The stressful experience may trigger negative emotions and psychopathological symptoms in these children.

Cheung and Park (2010) conducted a study of anger suppression and depression in Asian American and European American students and found that whereas anger suppression was positively associated with depression in European Americans, the associations were significantly weaker in Asian Americans. Moreover, an interdependent self-construal attenuated the link between anger suppression and depressive symptoms. According to Cheung and Park, suppression serves a self-protective function for individuals holding Western values, whereas for individuals who hold more Asian values, suppression may be conducive to achieving prosocial goals. Anger suppression may be a form of emotion regulation that promotes social engagement and psychological well-being for interdependent individuals.

Peer Conflict and Adjustment

Studies of the relation between peer conflict and adjustment have been mostly descriptive, with a focus mainly on the link between conflict management and socioemotional development and peer relationships (French, Pidada, Denoma, et al., 2005; Murphy & Eisenberg, 2002; D. W. Shantz, 1986). In general, effective problem-solving methods for resolving peer conflict, which are considered a major aspect of social competence, are associated with positive adjustment outcomes. What is considered an effective strategy to address conflict, however, is likely to be dependent on cultural norms.

French, Pidada, Denoma, et al. (2005), for example, found that disengaging from a conflict was negatively associated with teacher ratings of adjustment problems and positively associated with teaching ratings of social preference in Indonesian children but not in U.S. children. In contrast, negotiation in conflict situations tended to be negatively associated with teacher-rated problems and positively with competence in U.S. children. These findings suggest that Indonesian children who disengage from conflict are better adjusted than others in social areas, similar to Chinese children who use passive strategies to address peer conflict (French et al., 2011). In North American cultures, however, children who use assertive methods and negotiation to resolve conflict are more likely than others to achieve social success (e.g., Laursen et al., 2001).

Bullying and Victimization and Adjustment

Bullying has adverse psychological, social, and physical effects on the development of bullies, victims, and bully-victims. Research has shown that victims and bully-victims are more likely than others to experience anxiety, depression, and psychosomatic symptoms (Kaltiala-Heino, Rimpelä, Rantanen, & Rimpelä, 2000; Özdemir & Stattin, 2011) and are likely to be bullied later as adults (Smith, Singer, Hoel, & Cooper, 2003). Bullies tend to develop difficulties in social relationships and substance use in adulthood (Kaltiala-Heino et al., 2000).

Several cross-cultural studies have been conducted to examine the relations between children's engagement in bullying and adjustment outcomes. Overall, both victims and bullies develop social and life adjustment problems, including higher levels of health problems, poorer

emotional adjustment, and poorer school adjustment, compared to youth who are not involved in bullying. The relations between bullying and adjustment problems may also vary across cultures. Nansel et al. (2004) conducted a comparative study of bullying in 25 countries and found that the rate of bully-victims in Sweden was the lowest among all the countries. However, bully-victims in Sweden were more likely to experience problems in their health, emotional well-being, school adjustment, and peer relationships than their counterparts in other countries. Another study by Due and colleagues (2005) comparing 28 countries on health outcomes among victims who were bullied weekly revealed likelihood ranges from 1.83 to 2.11 for physical symptoms (headache, stomachache, backache, dizziness) and 1.67 to 7.47 for psychological symptoms (bad temper, feeling nervous, feeling low, difficulties in getting to sleep, morning tiredness, feeling left out, loneliness, helplessness). Again, the associations between victimization and psychopathological symptoms tended to be stronger in countries with lower levels of bullying. Specifically, Sweden had the lowest prevalence of bullying, but the risk for having five or more symptoms were three- to fourfold higher in Swedish adolescents, compared to adolescents from Lithuania, a country with a higher bullying prevalence rate. The greater risk of children that experience bullying in countries with lower prevalence may be related to the fact that bullying and other peer relationship problems, especially those involving force and aggression, may be perceived as less acceptable and thus trigger greater negative social and emotional reactions among children in these countries.

Researchers have studied adjustment outcomes of bullying experience among youth in the United States with different ethnic and cultural backgrounds. S. G. Graham and Juvonen (2002), for example, examined relations between victimization and psychological adjustment among Hispanic, Asian, and African-American middle-schoolers in the United States. The results indicated that having the reputation as a victim of peer harassment was positively associated with loneliness and low self-esteem, but only in African-American youth. The authors suggested that these results might be due to the deviation of being victimized from the stereotypical perceptions of African American groups.

A study conducted by D. Schwartz and colleagues (2002) highlights the need for a nuanced view of peer victimization in cultural contexts. In this study, South Korean children exhibiting submissive-withdrawn behavior were found to be more likely than others to be victims of peer bullying. The results appear to be consistent with X. Chen, Wang, et al.'s findings (2011) and Liu et al.'s findings (2015) that unsociable and withdrawn children in China experienced social, school, and psychological problems. In another study with South Korean primary school children (Yang, Kim, Kim, Shin, & Yoon, 2006), female bullies reported greater social and behavioral problems than male bullies. A possible explanation is that female bullies feel more uneasy, given that bullying behaviors do not correspond with cultural norms for girls to be quiet, obedient, and self-controlled.

Peer Group Involvement, Friendships, and Adjustment

The relationships that children form with their peers serve as key contexts for shaping social, emotional, and cognitive outcomes (e.g., Brown, 1990; La Greca & Harrison, 2005; Urberg et al., 1997). Research has demonstrated that having friends is associated with better school adjustment and social satisfaction in children, whereas children without friends tend to experience more internalizing problems and poorer social and academic performance (Pedersen, Vitaro, Barker, & Borge, 2007). Research in Western cultures has also illustrated that peer groups serve as a major social resource for fulfilling individual psychological needs, such as the formation of self-identity and the development of positive self-perceptions and self-feelings (e.g., Rubin, Bukowski, et al., 2006; Sullivan, 1953). However, affiliation with deviant peer groups may contribute significantly to individual adjustment problems, such as school dropout, early pregnancy, substance use, and antisocial behavior (e.g., Cairns & Cairns, 1994; Espelage, Holt, & Henkel, 2003; Kiesner et al., 2003; Kindermann et al., 1995).

Despite the scarcity of longitudinal studies examining the effects of peer relationships on adjustment, the existing literature suggests that the function of friendships and peer groups may play different roles in individual development across cultures. In Western societies, support from friends and peer groups may be an important mechanism for children to accomplish the socialization goal of developing confidence and positive views about themselves (Sullivan, 1953). The role of peer relationships in promoting self-perceptions and self-feelings may be less salient in many non-Western cultures, where the development of the self is not considered a major developmental task. Indeed, findings of cross-cultural studies seem to indicate that children's friendship plays a less important role in enhancing perceived self-worth in group-oriented cultures than in Western individualistic cultures. Whereas one of the major reasons for friendship among Western children is that friends make people feel good about themselves, Chinese

and Indonesian children and children with an Arab and Caribbean background do not view the enhancement of self-worth as an important function of peer relationships (X. Chen, Kaspar, et al., 2004; Cho, Sandel, Miller, & Wang, 2005; Dayan, Doyle, & Markiewicz, 2001; French, Pidada, et al., 2005).

In contrast to self-validation, instrumental aid appears to be a more important function of peer relationships of children in many group-oriented cultures (Smart, 1999; Tietjen, 1989). For example, sharing money and protecting friends from harm are important aspects of the friendships of low-income Black and Hispanic adolescents in the United States (Way, 2006). Instrumental assistance has also been documented to be a salient feature of friendships in Asian countries, such as China (X. Chen, Kaspar, et al., 2004), Indonesia (French, Pidada, et al., 2005), South Korea (French et al., 2006), and the Philippines (Hollnsteiner, 1979), and in Latino societies, such as Cuba (Gonzalez et al., 2004) and Costa Rica (DeRosier & Kupersmidt, 1991). In these societies, instrumental assistance may include helping others solve problems and learn social skills. French and colleagues (2006) showed that Indonesian children without friends demonstrated lower levels of academic achievement than children with friends. Similarly, X. Chen, Kaspar, and colleagues (2004) found that Chinese children were more likely to endorse picking friends who would improve social and academic standing. Dekovic and colleagues (2002) found differences between Japanese and Dutch adolescents in the pattern of associations between peer relationships with development. The quality of peer relationships was associated with self-reported well-being more strongly in Japan than in the Netherlands, which might indicate greater emphasis in Japanese culture on interpersonal relationships in the individual development of well-being.

It should be noted that both the definitions and the cultural norms for peer relationships and group affiliation have changed dramatically with the popularity of online social connections and networks. Peer interactions currently take place over a variety of online contexts, including text messaging, e-mailing, instant message, or chatting, and social networking sites such as Facebook. Normative experiences in youth development, such as increased autonomy, identity exploration, or the formation of intimate peer relationships, unfold through these newer technologies (Lenhart, Purcell, Smith, & Zickuhr, 2010).

How the use of these technologies for online communication affects real-world peer relationships and well-being in children and adolescents is an interesting issue for researchers and professionals. In a study with over 1,000 Dutch adolescents, Valkenburg and Peter (2007) found that adolescents spent most of their online communication time with existing friends and that instant messaging with friends significantly predicted friendship quality and well-being. The researchers also found that personal disclosures through instant messaging were positively associated with friendship quality 1 year later. However, other studies reported no significant associations between online communication and real-world friendship quality or well-being (Gross, 2004; Mesch, 2001; Sanders, Field, Diego, & Kaplan, 2000). It is proposed that unexplored moderators or mediators may explain these inconsistent findings (Wang, Jackson, & Zhang, 2011).

How social and cultural circumstances impact the relations between peer relationships facilitated through online communication and adjustment is another interesting question. Online communication and social networking sites could serve different purposes in collectivistic and individualistic cultures. Chau, Cole, Massey, Montoya-Weiss, and O'Keefe (2002), for example, argued that Internet users from Hong Kong tend to view the Internet as a means of social interaction, whereas Americans tend to use the Internet to seek and gain information. Chau and colleagues (2002) found that U.S. students had more individuals in their networks than Korean students and attributed this difference to how relationships are viewed. Consistent with French et al.'s findings on friendship exclusivity (2006), it has been speculated that Koreans utilize social networking sites to obtain social support and develop deeper relationships from existing and committed relationships whereas American students may use social networking sites to acquire or maintain casual relationships (Y. Kim, Sohn, & Choi, 2011).

In studies of international students in the United States, K. H. Kim, Yun, and Yoon (2009) and Ye (2006) found that online social networking helped international students maintain and develop their social support from their networks in the United States and from online ethnic social groups, which in turn helped them reduce their social difficulties and adjust to the new environment quickly. Reich, Subrahmanyam, and Espinoza (2012) examined the use of online communication and its association with adjustment in Latino adolescents. The results, however, showed no differences between Latino and European American adolescents in the frequency of social interactions and adjustment outcomes.

In summary, research findings have indicated that individual behaviors and experiences in peer contexts, such as shyness-inhibition, aggression, conflict, bullying, and group involvement, may be associated differently with

adjustment outcomes in different cultures. The differences in the associations further indicate that culture plays an essential role in determining the functional significance of individual behaviors through shaping social attitudes and social interaction processes.

Peer Relationships and Resilience

Resilience is concerned with the process or phenomenon of positive adaptation in the context of significant risk or adversity (Masten & Powell, 2003; Luthar, Crossman, & Small, 2015). Research on resilience often focuses on protective factors in the development of individuals who experience high levels of risk, such as parental mental illness, family economic hardship and conflict, and neighborhood violence. Protective factors are assets that weaken the adverse effects of risk, such as supportive parenting and effective skills to cope with difficult circumstances (Luthar et al., 2015; Masten, 2014).

It is commonly believed that positive peer relationships, including overall peer acceptance, intimate friendship, and constructive group activities, can serve protective functions for at-risk children (e.g., Rubin et al., 2006). Findings of a number of studies have indicated that negative experiences in the family, such as child abuse and poverty, are associated with psychopathological symptoms, such as low self-esteem, lack of school engagement and achievement, and high peer victimization, but the associations are often weaker or nonsignificant for children who have high-quality friendship and peer networks (e.g., Bolgar, Schwartz, & Kupersmidt, 1998). In a study of negative parenting and adolescent externalizing problems, for example, Lansford, Criss, Pettit, Dodge, and Bates (2003) found that friendship quality and peer group affiliation served as protective factors for adolescents who were exposed to unilateral parental decision making, low supervision, and harsh discipline; positive peer relationships attenuated the associations between aspects of family adversity and externalizing problems.

Cultural norms about children's behaviors and peer relationships may affect the meaning, function, and development of resilience in children and adolescents. According to Ungar (2013), resilience is concerned with a set of processes that serve to help individuals to obtain psychological and social resources in culturally meaningful ways. The social-ecological perspective emphasizes that resilience represents the capacity of both individuals (e.g., children's capacity to seek help) and their environments (e.g., the availability of health resources and assets in the community) to optimize adaptive development. Consistent with this perspective, in the International Resilience Project, a large-scale cross-cultural study, Ungar and colleagues (e.g., Ungar, 2013; Ungar et al., 2007) found that there might be culturally distinct aspects of resilience. More specifically, a series of qualitative and quantitative analyses revealed that youth who were resilient were those who successfully navigated their way through a series of tensions in accessing material resources and in finding appropriate roles in the community. The experience of resilience was determined largely by how youth used different strategies to address the challenges posed by the tensions within social and cultural constraints. Moreover, the impact of aspects of resilience (e.g., affiliation with a religious organization) on children's lives might depend on social and cultural contexts (e.g., the importance of the religion or spirituality in the society) (see Ungar et al., 2007).

Other studies have also provided evidence for the role of social and cultural circumstances in the development of resilience, including the protective force of peer relationships. For example, De Antoni and Koller (2000) showed that Brazilian street children developed relationships with one another, which served as a support when caring adults were unavailable. Similarly, in a study of 3,000 street children in Colombia, Felsman (1989) found that children sought existing social supports, including gang affiliation, when primary physical and emotional needs were not met elsewhere. The studies demonstrate that resilience may develop as a result of the requirements of the particular context and that aspects of resilience may serve particular functions in the context.

CONCLUSIONS, PRACTICAL IMPLICATIONS, AND FUTURE DIRECTIONS

The experience of children and adolescents in the peer context, including social behaviors in interactions with others and relationships established through interactions, has an extensive and lengthy influence on normal and abnormal development (e.g., Rubin et al., 2015). Failure to maintain appropriate behaviors in peer interactions, solve problems in interactions in an effective manner, establish desirable relationships, or obtain supportive group affiliation likely leads to psychopathological outcomes. Yet how children interact with others and form social relationships is constrained by cultural norms and values in the society or community. By guiding social interaction processes and shaping functional and structural features of social relationships, culture exerts a significant impact on individual development in various areas.

In this chapter, we reviewed research findings on cross-cultural variations in the prevalence of major internalizing and externalizing behaviors, such as social anxiety, aggression, conflict, and bullying, that children and adolescents display in the peer settings. We discussed the role of culture in affecting social attitudes and responses toward specific behaviors, which in turn serve to regulate the development of the behaviors and their relations with adjustment outcomes. Based on our review and discussion, it seems reasonable to conclude that adaptive and maladaptive human development is a complex phenomenon that must be understood with cultural factors taken into account (García Coll et al., 2000; Kleinman, 1980; Tamis-LeMonda et al., 2008).

Research on culture, peer relationships, and developmental psychopathology has far-reaching practical implications. As Cicchetti and Toth (2009) indicated, to promote psychological health and well-being of individuals, it is important to translate scientific findings into practical applications. Thus, researchers and professionals should consider how research results concerning cultural contexts for adaptive and maladaptive development help address issues in the diagnosis, prevention, and treatment of problems in culturally relevant and effective manners. For example, the findings on the influence of cultural norms and values on individual behaviors and problems suggest that researchers, policymakers, and clinicians need to be sensitive in assessing and assigning cultural meanings to psychopathological symptoms among children of different backgrounds. To determine the extent to which a specific behavior (e.g., social anxiety and shyness) is normal or abnormal, it is essential to understand how it is defined in the society or community, including (1) how people perceive, evaluate, and respond to the behavior, particularly in the context of social interactions; and (2) how the behavior is associated with concurrent and developmental adjustment outcomes. Thus, obtaining information regarding culturally directed social attitudes about the behavior and its developmental patterns is an integral part of diagnosis. In addition, according to the contextual-developmental perspective (X. Chen, 2012), peer interactions and relationships serve as a crucial group-level mediator in bridging culture and individual development. Therefore, parents, educators, and practitioners should consider the social interaction context when they develop prevention and intervention programs for children and adolescents who display psychopathological problems.

From a multiple-levels-of-analysis perspective, Cicchetti and colleagues (e.g., Cicchetti, 2006; Cicchetti & Blender, 2006; Cicchetti & Toth, 2009) have indicated that biological, psychological, and social-contextual factors may jointly and interactively influence individual normal and abnormal development. For example, there is growing evidence indicating the genetic underpinnings of social relationships and psychopathological functioning (e.g., Kendler et al., 2007). Moreover, a number of studies have demonstrated interactions between gene polymorphisms and environmental conditions (e.g., early parent-child relationships, parenting practices) in predicting developmental outcomes (e.g., Caspi et al., 2002; Hankin, Jenness, Abela, & Smolen, 2011; Sheese, Voelker, Rothbart, & Posner, 2007). However, these studies have been conducted mainly within a Western society. Cultural similarities and differences in the relations of genetic factors to children's peer relationships and adaptive and maladaptive behaviors have not been explored. As argued by Chiao and Ambady (2007) and Miller and Kinsbourne (2012), it will be interesting to investigate genetic influence on social relationships and behaviors in different cultures, which will help us achieve a more complete understanding of gene–environment interactions in human development.

Researchers often use a broad framework, such as collectivism versus individualism or independence versus interdependence, to conceptualize cross-cultural studies, especially in comparing children in Western societies with those in non-Western societies. The broad framework has been criticized from both theoretical and methodological perspectives. Theoretically, it is considered oversimplistic for describing complex cultural systems and for explaining the heterogeneity within a particular culture and differences between cultures that are believed to be collectivist/interdependent or individualist/independent (see X. Chen, French, & Schneider, 2006; Miller, 2002). Methodologically, it is difficult to identify the defining features of individualistic and collectivist cultures and to assess these features. It also appears ineffective and problematic to measure macro-level sociological constructs of collectivism and individualism (Hofstede, 1994), which are defined mainly by political, social, economic, and ideological organizations, using attitudinal scales at the individual level (Oyserman, Coon, & Kemmelmeier, 2002). The relations between societal or group-level cultural orientations and individual values systems and behaviors may not be straightforward.

Despite the criticisms, however, researchers continue to use the framework of collectivism versus individualism or interdependence versus independence to characterize cross-cultural differences in individual attitudes and behaviors. The dimension of collectivism-individualism may be useful in distinguishing cultures that differ in

extreme form (e.g., the United States and some Asian countries). However, it is important for researchers to be aware that the broad framework may have limited value in characterizing different types of collectivist or individualistic cultures and cultures with mixed individualistic and collectivist features.

Research on culture, peer relationships, and developmental psychopathology has relied on direct or indirect comparisons of groups of children and adolescents in different societies or communities. Cross-cultural comparisons can provide interesting findings about similarities and differences between children and adolescents with different backgrounds, which are important for understanding the role of culture in development. However, researchers need to pay attention to various issues in the research processes, such as selecting representative samples in the culture and controlling for potential confounding factors, such as socioeconomic status (Schneider et al., 2006). Moreover, cross-cultural comparisons provide little information about how culture is involved in peer interactions and relationships and individual development. Cultural influence on children's functioning in social settings is highly complex, involving personal and contextual factors at multiple levels. According to the contextual-developmental perspective (X. Chen, 2012), for example, children play an increasingly active role in socialization and development through participating in social interactions in which they construct cultural norms for their activities and mutual evaluations (Corsaro & Nelson, 2003; Edwards et al., 2006). It will be important to investigate how children in different cultures actively engage in the socialization processes.

Self-reports are commonly used in cross-cultural studies of children's behaviors and problems because of relatively low costs for data collection and advantages in data analysis. With young children, parental reports are perhaps the most common, and sometimes the only accessible, method. However, self-report methods have obvious limitations that may undermine valid cross-cultural comparisons; these include culturally specific response biases, the reference group effect, and differences in the understanding of questions or items in measures (e.g., Schneider et al., 2006). Peer evaluation is a reliable method in assessing children's social behaviors and peer relationships (e.g., the Revised Class Play, X. Chen et al., 1992; Masten, Morison, & Pellegrini, 1985); the method is particularly useful for cross-cultural research because it taps insiders' perspectives of children. However, peer evaluation is used with children in schools mainly from third or fourth grade. Moreover, it does not allow for cross-cultural comparisons on group mean scores because peer nomination or rating data typically need to be standardized within the class or grade. In addition, when assessing behaviors that are not apparent in social interactions, such as anxiety, fear, or other internalizing behaviors, it may be difficult for peers to provide accurate and reliable information. Compared with self-reports and peer assessments, observations, in either controlled laboratory or naturalistic settings, can provide more objective information about children's peer interactions and individual behaviors, which allows for more straightforward cross-cultural comparisons. However, conducting observations of children in equivalent conditions, developing culturally sensitive and comparable coding systems, training coders to reliably code data from different cultures, and interpreting the results beyond observed variables are highly challenging tasks for researchers. A strategy for handling many of the methodological difficulties is to use a multimethod approach and integrative analysis, which likely reduces potential biases and errors in data from a single source.

Cross-cultural researchers often study children in non-Western societies by comparing them with children in Western, especially American, societies. Due to globalization and technological development, rapid large-scale social and cultural changes have been occurring around the world, including both Western and non-Western countries. Cultural exchanges and interactions and massive movements of populations have led to the merging and coexistence of diverse value systems (X. Chen, 2015; Tamis-LeMonda et al., 2008), which has made the exposure to different cultures an integral part of the experience of children and adults today. Adapting to a changing environment with mixed and even conflictual social and cultural values may be stressful for youth. However, social and cultural changes also provide opportunities for young people to interact with peers of different backgrounds, which may help them develop competence to function in different circumstances. It will be important to investigate children's and adolescents' peer experiences and adaptive and maladaptive development in the new environment.

Linking Educationally Relevant Behavior and Psychological Processes to Biology 803
REFERENCES 804

A decade ago, a chapter on schools, schooling, and developmental psychopathology appeared in the prior version of this volume (Pianta, 2006). A major aim of that chapter was to articulate pathways for interdisciplinary intersections between education and developmental psychopathology. At that time, the task involved identifying mutual and overlapping interests, presenting a conceptual framework for mapping those interests to scientific questions and programs of study, and reviewing evidence from extant research consistent with the emerging interdisciplinary paradigm. A number of intersecting research programs and topics were described in more detail, and possibilities for further work were identified. In large part, that effort was about describing parameters of schools of interest to developmentalists.

In the time since, the progress made in understanding the intersections between educational structures and processes with developmental processes has been nothing short of astonishing. Developmentalists have much more fully exploited school settings as a means to more fully understand development in context (M. Greenberg & Harris, 2012), while scholarship in education has been transformed

by a combination of funding structures (Institute of Education Sciences [IES], 2013), increasing sophistication of developmental science (Bakermans-Kranenberg & van IJzendoorn, 2011), and policy initiatives that have provided metrics and benchmarks for educational performance and opportunity (Kane, Kerr, & Pianta, 2014). Methodological frameworks and research infrastructure (measures, analytics, funding, professional societies) have enabled a level of engagement between the educational and developmental sciences that was barely conceivable a decade ago. As just one example, a recent report describes results from a longitudinal study of impacts of an elementary-grade, school-based aggression prevention program on high school outcomes as they are moderated by genetic factors (Musci et al., 2013). The promise reflected in that paper pertains not only to better understanding individual heterogeneity of intervention outcomes in terms of gene polymorphisms but to the idea that, through continued deepening of the connections between developmental psychopathology and education, we more fully understand development in context (Blair et al., 2011). The Musci et al. (2013) and other studies (Essex, Armstrong, Burk, Goldsmith, & Boyce, 2011) suggest a promising future for exploration. In short, an array of opportunities has emerged and been explored, and the promise of deepening and extending these connections has been revealed further.

The fundamental premise of this chapter is that realizing the promise of linking developmental psychopathology (methods, models, and understandings) with education science, practice, and policy will require an even greater appreciation and deepening exploitation of schools as contexts for human development (Aber, Brown, Jones, & Roderick, 2010; Allen, Pianta, Gregory, Mikami, & Lun, 2011; Crosnoe et al., 2010). This chapter narrows and presses these possibilities for intersection with some depth, around the particular focus on proximal processes in classrooms related to interactions with teachers. Superficial linkages between the disciplines, in which schools are treated as locations (for data collection, intervention implementation, or recruitment of samples) rather than developmental contexts with their own dynamics and properties worthy of examination in their own right (Seidman & Tseng, 2011; Tseng, 2010), will fail to build on the extant capacity for knowledge generation. Similarly superficial are educationally focused research programs that are not developmentally informed, failing to recognize the deep linkages between academic achievement and development in other domains (Jang, Reeve, & Deci, 2010; S. M. Jones, Brown, Hoglund, & Aber, 2010; Pedersen et al., 2005), for example, or defining students' experiences in school only in terms of the curriculum to which they are exposed or the years of experience of the teacher delivering it (Goldhaber & Hansen, 2010; Harris & Sass, 2011; Sanders & Rivers, 1996). More fully exploiting the intersection of schooling and development remains important for developmental psychopathology precisely because of the role school context dynamics play in shaping the outcome trajectories of children and youth, and perhaps even the adults who also populate these settings (MetLife, 2002; National Center for Education Statistics [NCES], 2014; National Education Association [NEA], 2010). And this intersection is critical for education scientists, practitioners, and policymakers if they hope to fully understand and explain the student outcomes around which most of their efforts are organized.

The bulk of this chapter is devoted to experiences of children and youth in classroom settings and the opportunities they create for development of human capital. Structural elements of schooling—schools set standards and metrics for performance, educators develop and implement policy (Goe, 2007; Loeb, Kalogrides, & Béteille, 2012; Office of Head Start, 2011)—are a focus only insofar as they influence interactions with teachers and thereby shape the level and flow of this form of resources intended to shape development (Kane & Staiger, 2012; La Paro et al., 2009; Sabol, Hong, Pianta, & Burchinal, 2013; Yoshikawa et al., 2015). Proximal process experiences in schools play a meaningful role in organizing development—aspects of identity, competence, relationships, risk, and opportunity all emerge and consolidate in part through experiences in schools (Allen, Kuperminc, Philliber, & Herre, 1994; Bassok & Rorem, 2014; Connell & Wellborn, 1991; Eccles, Wigfield, & Schiefele, 1998; Hughes & Kwok, 2006; O'Connor & McCartney, 2007; Pianta & Allen, 2008; Pianta, Belsky, Houts, & Morrison, 2007; Sullivan & Bal, 2013). For the purposes of this chapter, the specific form of proximal process that is the focus is teacher-student interaction. And although the bulk of the chapter reviews evidence on the nature, quality, and impact of teacher-student interactions as they pertain to development, a section focuses on extending new evidence from the study of teacher-child interaction that reflects developmental psychopathology frameworks for understanding biological mechanisms that intersect with context and experience (Ellis, Boyce, Belsky, Bakermans-Kranenberg, & van IJzendoorn, 2011)—differential susceptibility (Belsky & Pluess, 2013; Ellis et al., 2011), gene–environment interaction (Beach et al., 2014; Musci et al., 2013), and allostatic load (Blair et al., 2011).

The study of schools and schooling, from a developmental psychopathology perspective, may challenge many

prevailing models, methods, and theories of how disorder manifests and develops, in large part because schools present an astonishing level of variation and differentiation in setting-level affordances for adaptations (MET Project, 2010; NCES 2014; Pianta et al., 2007). Drawing from Boyce and Ellis (2005), schools and schooling processes are developmentally relevant in part because they are so dynamic and fluid, they organize experience in ways meaningful for individuals and for groups, and they provide highly differentiated niches for adaptation (Williams, Tolan, Durkee, Francois, & Anderson, 2012). As one example, the richness of peer contexts in schools is just beginning to be understood, in part due to advances in social network analysis (McKown, 2013) that provide a much more nuanced and dynamic understanding of peer microclimates. This understanding of peer relations in schools as consisting of multiple, overlapping, shifting settings, each with unique norms and rituals and structures, has been applied in one way to understand racially related school experiences and outcomes (McKown, 2013; Williams et al., 2012) but also has relevance for appreciating the roles of schools in organizing peer experience, with broader implications for youth development and well-being. For example, the impacts of peer relations, accrued in part in school-based microclimates, can be seen more than a decade later in markers of physical health and functioning in jobs and relationships (Allen et al., 2011).

In terms of teachers' influence on students, a proximal process organized in schools, studies evaluating teacher impacts consistently find that the nature and quality of students' experiences with teachers, teachers' sensitivity, and their calibration to students' developmental needs vary tremendously across grades, teachers, and even within a day with the same teacher (Curby, Grimm, & Pianta, 2010; Jerome, Hamre, & Pianta, 2009; Plank & Condliffe, 2013). This means that any given middle school student may have strikingly different, developmentally relevant experiences with five different teachers each day and across a number of peer settings structured by courses, by where classrooms may be located in a building or how lunchtime is organized or scheduled (NCES, 2014; NICHD ECCRN, 2005). Put another way, schooling affords children and youth a stunning number of social settings (Spilt, Hughes, Wu, & Kwok, 2012; Weinstein, 2002; Zelazo & Lyons, 2012) that each pose developmental challenges and opportunities. This school-centric, multilevel, multisetting dynamism, and the actors, actions, and structures that shape it, is only beginning to be understood and mapped yet has important consequences for better appreciating not only their contributions to development but also the shifting nature of adaptation in context (Baker, Grant, & Morlock, 2008; Pedersen et al., 2005; Rudasill, Reio, Stipanovic, & Taylor, 2010; Weinstein, 2008).

It is also the case that the scientific tools (theories and paradigms, analytics, aims) heretofore brought to bear on schools as settings and on their impacts are somewhat limited with regard to their potential for illuminating the nature and impact of proximal processes. As one trend reflecting this broader pattern, education scientists, shaped by funders' priorities (e.g., IES, 2013), are highly focused on interventions that drive improvements in standardized achievement test scores or on econometric analyses that model impacts of various policies and programs on those same test scores (Glazerman et al., 2011; Goe, 2007; Goldhaber, 2007; Raudenbush & Jean, 2014). This is a limited design for scientific inquiry, constraining attention to narrow outcomes and lacking attention to basic developmental processes and mechanisms influencing those and a range of collateral outcomes that may in fact mediate test score performance. Given this, it may be no surprise that education reform can be criticized for promoting policies and applications that have limited capacity to engage local dynamics and conditions (Aber et al., 2010; Aber, Brown, Jones, Berg, & Torrente, 2011; Weinstein, 2002). Education science, or the study of schools and schooling, could benefit tremendously from the full complement of tools (theories, measurement, scientists) of developmental psychopathology.

In the sections that follow, this chapter tracks progress of research linking schools and schooling with developmental psychopathology with a focus in a domain of proximal processes through which schooling intersects with development—interaction with teachers. Given the predominant focus of education science funders on school achievement outcomes, developmentally informed efforts to expand knowledge regarding teacher-student interactions processes are often promoted by foundations seeking to address knowledge gaps created by federal agencies' priorities for support and by their structuring of the intellectual or practical landscapes.

Major foundations now supplement the portfolio of research support for investigating the nature and impact of students' experiences with teachers in school settings. For over a decade the Wm. T. Grant Foundation has dedicated a major portion of funding to the study of settings that serve children and youth, including families, schools, and out-of-school settings (Seidman & Tseng, 2011; Tseng, 2010; Tseng & Seidman, 2007). These efforts were a direct response to the convergence between the increased understanding and evidence that contexts played a tremendous

role in shaping youth development and the fact that very little was known about their properties and dynamics; therefore, both theory and potential applications relevant to improving youth outcomes were severely limited (Broader, Bolder Approach to Education, 2010; Skiba et al., 2014; Sullivan & Bal, 2013; Weinstein, 2008). The foundation funded efforts to articulate theoretical frameworks for inquiry into settings, basic science of setting measurement and work on implications for application, and a major grants program focused on interventions in which properties of the setting were the outcome of focus (Allen et al., 2011; S. M. Jones, Brown, & Aber, 2008; S. M. Jones et al., 2010; S. M. Jones, Bub, & Raver, 2013).

A recent call for proposals by the Spencer Foundation (2014) explicitly acknowledges this gap in knowledge and in funding. In a major grants program the foundation characterizes as an effort to "reinforce our commitment to intellectually ambitious research, oriented ultimately to improving the practice of education," (p. 3), a call for proposals was issued to specifically address concerns that the last decade of scientific work in education has been singularly focused on intervention impacts on standardized achievement tests. The Spencer call notes that "the popularity of doing research to learn 'what works' has a tendency to squeeze out deeper questions of how, when, for whom, and why an intervention works" (p. 3). The Spencer Request For Applications therefore focuses attention on three types of studies that reflect a developmental and interdisciplinary perspective on questions of significance related to the intersection of schooling experiences, over time, and the emergent outcomes of children, youth, and professional educators. The next excerpt presents this perspective in brief, starting with a description of the types of studies the foundation seeks.

> Studies that focus more or less directly on teaching and learning processes themselves, at the classroom level (or in instructional settings outside classrooms).
>
> Studies that pay attention to the larger policy and institutional environments within which educational transactions take place. Key . . . is attention to the conceptual and empirical links between . . . infrastructure and the actual character of educational practice.
>
> Studies that help develop research tools that can support advancing the kinds of research we have identified here. The development of improved measurement tools, stronger theoretical frameworks and analytical methods. (pp. 3–4)

Foreshadowing the sections to follow, and emerging from the streams of research supported by the mechanisms just described, are studies that now utilize methods and measures, conceptual frameworks, and analytic tools to achieve a focus on the intersection between schooling and development that is far more cross-disciplinary, multilevel, and multisystem than a decade ago. For example, programs of research are beginning to advance understanding of basic mechanisms of influence and coregulation in classrooms between teacher behavior and student learning by sensoring candidate markers across multiple systems that hypothetically coregulate teaching and learning processes (e.g., teacher and student behavior, mood, effort; heart rate, cortisol levels; attention and learning). The result could be a multisystem mapping of classroom process and examination of linkages (causal, leading, lagging) of association and coregulation across multiple levels and domains of candidate behavioral, social, neurological, and physiological processes in the context of actual classroom interactions (e.g., Coan, Schaefer, & Davidson, 2006: Montpetit, Bergeman, Deboek, Tiberio, & Boker, 2010).

Examples of the promise of this work include K. F. Miller's (2011) use of video and eye gaze to track teachers' attention in real-time classroom interactions, experience sampling of teacher emotion and stress (N. Jones & Youngs, 2012), and studies showing impact(s) of feedback on teachers' interactions with students (Allen et al., 2011; Pianta et al., 2014; Pianta, Mashburn, Downer, Hamre, & Justice, 2008), some of which takes place in real time (K. F. Miller, 2011). Importantly, knowledge of the interface between child development and context expanded rapidly when studies of behavioral and psychological variables incorporated measurement and theory of biological, physiological, and neurological processes (see Boyce & Ellis, 2005). It is now possible to study and understand similar processes in classrooms and their relations with teaching and learning. Typical educational research on classrooms is focused primarily on behavioral or psychological variables assessed at fixed time points, providing an extraordinarily limited sample of the actual processes active in classrooms that are likely responsible for mediating or moderating the effects of schooling.

The basic science implications of this work are clear; it would not only map candidate processes and generate hypotheses for theory and further testing but also provide a methodological template for extensions across variations in teachers, students, grade levels, content areas, and other relevant features. Such work also has applied implications. For example, evidence indicates observations of teachers' interactions with students account for a modest but significant proportion of variation in student

learning (e.g., Hamre, Hatfield, Jamil, & Pianta, 2014), and teachers can be coached to improve those behaviors, in turn improving student learning (Allen et al., 2011; Downer, Pianta, et al., 2012; Pianta et al., 2008). These coaching and assessment procedures focus on observed teacher and student behavior. By embedding behavioral foci (e.g., teacher-student interaction and student engagement) within assessment of other coregulating processes (e.g., stress reactivity, emotions, neurological activity, heart rate, movement) during classroom interactions, it may be possible to identify neuropsychological and biobehavioral coregulators of teachers' behavior that could become candidate targets for professional development. Evidence suggests several possible candidate processes (e.g., real-time noticing, self-regulation of emotion and stress) that influence teachers' interactions with students and can be trained as skills (Hamre, Pianta, et al., 2012), while there is a growing body of literature on teachers' mindfulness and contemplative practices demonstrating impacts on a range of biobehavioral mediators of classroom interactions and outcomes (Davidson et al., 2012; Jennings, 2014; Roeser, Skinner, Beers, & Jennings, 2012). And by tracking students' neuropsychological activity in real time, it may become possible to identify links between such activity and teacher behavior and therefore sharpen the focus of behavioral observations of, and interventions for, teacher competence.

In short, emerging methods and approaches in cognitive neuroscience and learning sciences, biobehavioral science, developmental psychology, quantitative and computational methods of analysis, combined with the scientific study of teaching, enable investigators to map a new frontier in this translational sector of knowledge generation and activity linking education and human development. This interdisciplinary, multisystem, multilevel focus on classroom process is increasingly feasible (Coan, Beckes, & Allen, 2013; Essex et al., 2011; Hamre, Downer, Jamil, & Pianta, 2012) and reflects the confluence of education, developmental science, and cognitive neuroscience exploration of causal and coregulating links of social behavior and interpersonal relationships with physiological and neurological systems and associations with learning, mental health, and other developmental outcomes (e.g., Beckes & Coan, in press; Essex et al., 2011; Gazelle, 2006; Mikhail, El-Hayat, Allen, & Coan, 2013; Montpetit et al., 2010). The potential of these new paradigms for furthering the integration of education and developmental psychopathology is evident and could be advanced through the study of teacher-student interactions, at least in the short term.

CONSIDERING THE INTERSECTION OF EDUCATION AND HUMAN DEVELOPMENT

What Are the Key Questions?

Further integration of inquiry in education and developmental psychopathology pivots on questions of common interest to scientists from various disciplines that leverage not only knowledge in respective fields but new knowledge in this integrative domain (e.g., M. Greenberg & Harris, 2012; Kane et al., 2014; Kemeny et al., 2012;). As has been noted on many occasions, one of the foundational studies pressing a developmental orientation to the study of psychopathology, *15,000 hours* (Rutter & Maughan, 2002), was in part a study of school effects and adaptation to school, linking schooling to developmental psychopathology at its inception (see Rutter & Maughan, 2002; Sroufe & Rutter, 1984). Marking progress in the exploration of this connection, Rutter and Maughan (2002) summarized themes in research on schooling and development in the then-20 years since *15,000 hours* with a series of gapsonly partially addressed in the span since their seminal work was published, questions that remain relevant even now, some 35-plus years since the original study. These seven gaps in the knowledge base posed by Rutter and Maughan mapped the landscape of investigation and application for more than a decade and included:

1. the need for hard empirical evidence on factors related to changing failing schools, including attention to contextual features (such as community attitudes), resources (intake mix), teacher recruitment, finances, and leadership;
2. research on peer processes and influences within schools;
3. studying characteristics of schools that matter for social, behavioral, and self-efficacy outcomes;
4. how schools foster connections to the goals of schooling and socialization;
5. how selective and nonselective school systems function to influence child outcomes;
6. how different experiences in schools affect children differently based on their pattern of strengths and limitations, and vice versa; and
7. how and why children respond so differently to the school environment.

In the ensuing years, robust scientific literatures grew around each of these questions and were codified in contemporary reviews (e.g., Aber et al., 2011; Durlak,

Weissberg, Dymnicki, Taylor, & Schelling, 2011; Guerra & Bradshaw, 2008; McKown, 2013; National Council for Accreditation of Teacher Education [NCATE], 2010).

These varying literatures codify four fairly general impressions:

1. Documentation of efforts to change failing schools remains an idiosyncratic enterprise without any strong scientific backing for factors predictive of success or failure (e.g., Rockoff, Jacob, Kane, & Staiger, 2011; Tseng, 2010; Weinstein, 2002).
2. Schools are now well understood not only as settings for development of peer relations; increasing attention is being paid to processes related to shaping of social norms as well as peers' role as mediators of learning (Hughes & Kwok, 2006; McKown, 2013; Mikami, Lerner, & Lun, 2010).
3. Multilevel analysis of school and classroom effects continue to point out that schools, as a setting, are poorly understood in terms of the key characteristics and features that operate through various mediating mechanisms to promote development; while it is widely accepted that schools matter, how they matter separate from classroom or peer influences is much less well understood, and science in this domain of school-level effects is challenging (Ferguson with Hirsch, 2014; Lau & Nie, 2008; Raudenbush & Jean, 2014; Ruzek, Hafen, Hamre, & Pianta, 2014).
4. The science of individual differences in children's response to school settings remains relatively uninformed with respect to integration of advances in developmental science and methods (Beach et al., 2014; Essex et al., 2011; Musci et al., 2013) in part because the individual differences among children and youth are understood and assessed by educators and education scientists too often only in terms of education-defined metrics in single domains. The need for further understanding, on the part of educators and education scientists, of contemporary developmental science and its methods, has been well documented (NCATE, 2010; Rockoff et al., 2011). At the same time, developmentalists need to formulate constructs and measures that align to educationally relevant contexts and processes (Plank & Condliffe, 2013; Sullivan & Bal, 2013) if this knowledge gap is to be closed.

One result of the scientific progress around these questions, and a pathway that could lead to productive knowledge generation and integration, would derive from a reformulation of the linkage between development and education from one limited to focal areas of inquiry as reflected in those questions (i.e., effective schools, peer relations, individual differences) toward a perspective in which inquiry is integrative, process or mechanism focused. As is reflected in the Spencer Foundation request for proposals described earlier, present-day understanding of the relevance of educational settings and processes for developmental psychopathology starts with a description of features that form the affordances present in school settings, which include: actors (teachers, peers, leaders), developmental processes, actions that engage those processes, and aspects of school structure (policy, size, timing, curriculum) that shape those actions. The features of schooling, their determinants, and their interrelations create the functional contours of schooling as a system of proximal process affordances (assets or risks) for human development. One example of incorporating a process orientation is recent scholarship aimed at applied decision making, including large-scale studies of policy metrics used in teacher evaluation (see Harris & Sass, 2011; Kane et al., 2014), which now includes process mediators (such as teacher-student interaction or student motivation) of the links between the structural inputs (e.g., categories of teacher effectiveness) and outcomes (student performance on multiple-choice assessments of state standards) that are typically the primary points of interest.

The Hierarchical Nature of Schooling and School Settings

As a prelude to a more thorough examination of research on teacher-student interaction, it is critical to recognize that schools are multilayered, multilevel settings composed of structural and process features that reciprocally interact to affect child outcomes and adaptation. This organization of school settings has consequences for research aiming to better understand schooling and its connection to human development and makes that work very challenging, one of the reasons why there has been so little rigorous science identifying replicable features of effective schools (Loeb et al., 2012; Rockoff et al., 2011; Weinstein, 2008). The typical starting point for understanding the multilayered nature of schooling is to view it only in terms of a hierarchical (and static) organization or a nesting structure. In this frame, schools are nested within districts or classrooms nested in schools, as if the nesting only was a classification scheme or, even more, a causal structure in which higher-order units (districts) determined the nature of activity in lower-order units (schools and classrooms). This layering of the various levels of schooling process

and structure is intentionally designed as a parameter of influence; financial and regulatory actions at district, state, and federal levels causally influence actions and conditions that affect children and their opportunities. Yet despite this hierarchical administrative and political structure, the evidence is overwhelming of stunning variation in local opportunities that more directly influence development (Goldhaber & Hansen, 2010; McKown, 2013; NICHD ECCRN, 2005; Office of Head Start, 2011; Pianta et al., 2007). Thus, not only is it a challenge to measure and model the multilevel nature of schooling in an effort to understand developmental impacts, sorting the developmentally salient features of actions at various levels from those that appear critical but are perhaps irrelevant remains a particular challenge.

For example, school districts closely attend to regulations related to student-teacher ratios, often referring to ratios as key determinants of students' educational experiences and outcomes. Yet rigorous evaluations of the impact of ratios on student experience and learning indicate few, if any, effects within the range of ratios that encompass nearly every variant present in classrooms across the United States (NICHD ECCRN, 2004). Furthermore, to the extent ratios have any impact on student outcomes, it takes place in the tails of the distribution and is mediated by processes, such as teacher's management of the classroom, which is developmentally and educationally relevant across the entire range of student-teacher ratios. Another example of this distinction between developmentally relevant and irrelevant aspects of the hierarchical nature of education is evident in studies of curricular decisions, implementation, and impacts (Clements & Sarama, 2008; Durlak et al., 2011; Fukkink, 2007). The literature is replete with examples of district-mandated curricula (e.g., in elementary math or in secondary history) that are implemented with such variation at the classroom level so as to not even yield a detectable impact on student learning separate from more generic properties of peers or teachers' instructional style (Mashburn, Downer, Hamre, Justice, & Pianta, 2010).

Nonetheless, the hierarchical nature of schooling can result in substantial changes at the more proximal levels where educationally and developmentally salient experience takes place. School policies and practice, largely regulated by states, are increasingly affected by federal priorities and initiatives, adding a layer of regulation and direct influence that has expanded considerably in the last decade and was virtually nonexistent in decades prior. For example, the Federal Race to the Top (RTTT) competition (Nicholson-Crotty & Staley, 2012) delivered hundreds of millions of dollars to schools, through state-managed programs, for activities focused on federal priorities. More specifically, the federal interests in teacher performance evaluation, and the use of standardized test scores as a metric for evaluation, were a condition of states receiving RTTT funds. Another federal priority, written into requirements for states to receive RTTT funds, was replacement of existing state standards and assessments with implementation of the Common Core standards and assessments. These two federal initiatives, despite intermediary layers of interpretation and implementation, have already proven to be rather potent determinants of opportunity for students (Glazerman et al., 2011; Goldhaber, 2007; Los Angeles Unified School District [LAUSD], n.d.; Nicholson-Crotty & Staley, 2012).

Teacher evaluation policies, reflecting the RTTT emphasis on test scores as determinants of decisions related to tenure and promotion, have induced shifts in the nature of the teacher workforce (Boyd, Grossman, Lanford, Loeb, & Wyckoff, 2009; Goe, 2007; NEA, 2010; Plank & Condliffe, 2013; Ronfeldt, Loeb, & Wyckoff, 2013) and indications of shifts in student performance (Taylor & Tyler, 2012). For example, Wyckoff and colleagues (Loeb, Miller, & Wyckoff, 2014) recently reported on the impacts of changes in teacher tenure policies and practices in New York City. In a longitudinal examination of the causal impact of a tenure policy shift that extended the probationary period and conditioned tenure or additional probation on the basis of teacher performance assessments, Wyckoff et al. reported that such changes led to an increase of ineffective teachers leaving the workforce, an effect particularly noted for Black and Latino students. In effect, these shifts to the teacher tenure law, in part predicated on measurements of teacher performance that included classroom observation of teachers' behaviors with students, led to changes in staffing that were likely to also shift the nature and quality of teacher behaviors toward children.

The Common Core standards, while not yet implemented fully, are a pronounced departure from most existing state standards that define student success (and in turn most school efforts to promote success), which are largely focused on rote recall of facts assessed through group-administered multiple-choice assessment. In contrast, Common Core emphasizes greater conceptual understanding, peer-mediated learning opportunities, application in context, and authentic assessments. Adoption of Common Core and the resulting district- and school-level policies and practices could have a pronounced effect on shaping classroom experiences for students despite the expected variation in implementation locally.

The Dynamics of School Settings

A second feature of schooling is its dynamic quality. Time and change are fundamental to how schools are organized as opportunity structures and are expressed in several forms. Schools themselves are structured to change over time —in aspects such as size of schools or classrooms, curriculum and expectations for student performance, and allocation of staff. One might consider these to be elements programmed into the design of schools to shape experiences and opportunities for students and learning. These programmed features are triggered largely by an operationalization of time as chronologically coded, in terms of age or grade level, for example (Bassok & Rorem, 2014; Mihaly & McCaffrey, 2014). This operationalization creates a sense of dynamics that are fairly predictable: When children reach a certain age they enter kindergarten; when they reach the end of elementary school, they start middle school. In each case, the change is predictable and intentionally shifts the opportunity structure. In addition to these designed dynamics is an assortment of schooling features that are less predictable and are often triggered by aspects of individuals or higher-level systems. For example, annual district budget cycles may determine availability or termination of specific programs, often intended for vulnerable students (e.g., Star, Lynch, & Perova, 2011; Stroub & Richards, 2013), while adaptation and performance of individuals can trigger responses by the school that might completely reshape the opportunity structure for that person (Skiba et al., 2014; Stroub & Richards, 2013; Sullivan & Bal, 2013). This individual-level dynamism might be seen in responses as formal as referrals for special education or other services (Sullivan & Bal, 2013) or informal shifts, such as regrouping with different peers for instructional or social purposes (Cameron, Connor, & Morrison, 2005; McKown, 2013). In short, between predictable dynamics (changes triggered by external forces or responses to individual adaptation) and the microdynamics of everyday interactions and routines (McKown, 2013; Williams et al., 2012), schools are highly dynamic systems in which the opportunity structure might shift radically or ebb and flow with the contours of the day (Curby, Brock, & Hamre, 2013) or week.

The individually triggered dynamics of schooling also operate for school staff, with consequences for students that are both direct and mediated through school-level factors. An exquisite illustration of such dynamism is presented in Ronfeldt, Loeb, and Wyckoff's (2013) analysis of teacher turnover in a large urban school system. It is widely reported that teacher turnover rates are higher than desired (30% annually on average) and costly to districts. Utilizing multiple years of data on student performance, teacher retention, turnover, and transfers, as well as information on teacher performance and other attributes, the Ronfedlt analysis corrects for some methodological challenges in other studies and demonstrates that turnover has negative effects specifically on the most disadvantaged students and schools. These effects are transmitted not only directly to the students being taught by new teachers but are distributed at the school level as newly hired teachers require additional resources. And turnover itself is often a function of both larger social and economic conditions that affect teachers, students, neighborhood, and schools (MetLife, 2002; NEA, 2010; Stroub & Richards, 2013). The primary point is that teacher turnover is an illustration of school dynamics that has consequences for opportunity.

In sum, the multilayered, dynamic nature of schooling creates a structure in which proximal opportunities to influence development are shaped in ways that can be predicted and in turn evaluated under some circumstances for causal influences, while in other cases they provide opportunities to model complex mediating and moderating patterns of association over time. These features of the ecology of schools in turn create opportunities for scientists. With these larger points about the nature of schooling as background, the chapter now turns to a focus on key agents of proximal process in schools and contemporary evidence for their roles in this ecology and its effects on students.

EDUCATIONAL DEMANDS AND OPPORTUNITIES THAT SHAPE STUDENT EXPERIENCE AND OUTCOMES

One way to frame the intersection of schooling and development is to consider the school setting in terms of demand and opportunity (Tseng & Seidman, 2007). And although recent national reports (e.g., Aud et al., 2013; Bassok & Rorem, 2014; LAUSD, n.d.; NCES, 2014) clearly show that academic demands, and some opportunities, have risen considerably in the past decade, they also point to stark inconsistencies between these opportunities and student outcomes, particularly for more vulnerable groups in the population. For example, between 1982 and 2009, the rates of students taking Algebra II coursework rose from 40% to 76%, and steady increases have been reported annually for the percentages of students taking Advanced Placement tests and the number of tests that these student take (NCES, 2014), but such increases largely involve White, upper-income, suburban students. At the same time, performance benchmarks in

the major areas of reading and math remain flat over time for U.S. students with increasing gaps between U.S. students and their international counterparts and among race and income groups of U.S. students. According to the National Assessment of Educational Progress (2015), there were no gains in students' scores in reading and math across the period of 1980 to 2008 or even from 2004 to 2008, a period of considerable effort to improve the rigor and intensity of educational experience and inputs in these areas. Nonetheless, in international assessments from 2009, 15-year-olds in the United States scored in the midrange of the 34 countries of the Organization for Economic Cooperation and Development. This general pattern of results—relatively flat trajectories, modest closing of gaps, midrange performance relative to international peers—is replicated at nearly all grade levels (NCES, 2014). Thus, despite intensive efforts to improve the nature and quality of educational inputs and outcomes, progress as assessed by performance on standardized achievement tests has been minimal or nonexistent. In short, demands have clearly increased for many children while outcomes have not, leading us to question whether what appear to be enriched opportunities for learning and development are being actualized in students' proximal experiences.

In understanding schools in terms of demand and opportunity, Tseng and Seidman (2007), in their description of social settings, emphasized the interpersonal transactions between members within the environment as the most developmentally salient characteristic of a setting,—even stating that interventions would be best served to target such interpersonal interactions (Allen et al., 2011; Seidman & Tseng, 2011). Perhaps not surprisingly to developmentalists, large-scale efforts to decompose variance sources to which various school-relevant outcomes metrics (achievement, dropout rate, disciplinary infractions) could be attributed invariably identify classrooms as the single most important locus of effects, with teachers and peers described as the source of relevant experiences (Goldhaber, 2007; Mihaly & McCaffrey, 2014; Sanders & Horn, 1998; Sanders & Rivers, 1996). For these reasons, any effort to fully understand the impact of schooling and the link between schooling and development will benefit from a primary focus on proximal process in classrooms (Hamre, Pianta, et al., 2013).

Classrooms

Students spend at least one-quarter of their waking hours in schools, most of it in classrooms, and the capacity of these settings to promote developmental learning, on average, is modest at best (Bassok & Rorem, 2014; Hamre, Pianta, et al., 2013; Kane et al., 2014; LAUSD, n.d.). Adolescents routinely describe experiences in classrooms that promote disengagement and alienation, a sense that these settings and the adults responsible for their quality are disconnected from developmental needs of youth (Eccles, Lord, Roeser, Barber, & Hernandez Jozefowicz, 1997; Morin, Maïano, Marsh, Nagengast, & Janosz, 2013; Roseth, Johnson, & Johnson, 2008). In a recent population-level survey of students in Los Angeles secondary schools (LAUSD, n.d.), a little more than half expressed agreement with statements reporting easy access to supportive adults, a feeling of being cared for at school, or receiving helpful feedback from teachers, and although 90% of all students expressed plans to go on to some post–high school education, only 16% of seniors had specific plans to continue their education.

Evidence from national-level observations of American elementary school classrooms shows clearly that the nature and quality of the instructional and social supports actually offered to young students in classrooms is generally low, and even lower for less advantaged students (Kane & Staiger, 2012; MET Project, 2010; NICHD ECCRN, 2005; Pianta et al., 2007). Just to illustrate using some of the results from the NICHD observations of more than 800 classrooms in each of first, third, and fifth grades across more than 23 states, of the opportunities for academic activities and learning to which a typical student is exposed, more than 85% of those opportunities take place in the context of teacher-directed whole-group instruction or individual seatwork, in contrast to small-group work (Pianta et al., 2007). These academic opportunities also have a pronounced focus on performing basic skills, tasks that require a discrete answer that is correct or not rather than eliciting analysis, reasoning, or problem solving around a more ambiguous challenge. Students in these settings have few individual interactions with their teacher. When examining the classroom from the perspective of more global dimensions of teacher-student interaction, the picture produced is of a setting that is mildly positive socially and lacking in cognitive stimulation or active engagement. Teachers' interactions with students were almost devoid of conceptual challenges or abstract information, and students were not engaged in interactions that provided feedback that elicited higher levels of performance. From the student perspective, the picture was one of passive, compliant engagement. And, over time, the likelihood of a student being exposed to a teacher rated in the top third of the sample distributions for quality of their interactions with students (emotional

and instructional features of behavior) was less than 10% (Pianta et al., 2007)

More recently, the Measures of Effective Teaching (MET) Study, funded by the Bill and Melinda Gates Foundation, reported on the nature of experiences across 2 consecutive years in more than 3,000 fourth- to tenth-grade classrooms in four large school districts (Kane & Staiger, 2012; Kane et al., 2014; MET Project, 2010). Using a suite of standardized observation protocols (very similar to those in the NICHD study) that scanned for both general qualities of teachers' interactions toward students and teaching practices relevant to specific content areas (see Kane & Staiger, 2012), the MET findings corroborate the impressions gleaned years earlier from the NICHD Study of Early Child Care and Youth Development observations—classroom learning experiences were largely rote in nature and rarely called for reasoning, problem solving, or analytic skills; instruction was delivered primarily in large groups; content was discrete and isolated rather than made relevant and connected to other knowledge; and students were engaged in very passive ways (Kane & Staiger, 2012; Kane et al., 2014).

Additional work from the MET study and other investigative teams show quite clearly that the kind of instruction observed in these large-scale studies – a narrow focus on decontextualized skills and knowledge—contributes directly to the sense of alienation and disengagement described by youth (Crosnoe et al., 2010; Ferguson with Hirsch, 2014). It should come as no surprise then that engagement in school begins to decline early in adolescence and by entry into high school this decline is so pronounced that half of high school students report that they do not take their school or their studies seriously (e.g., LAUSD, n.d.; NCES, 2014; Wang, Brinkworth, & Eccles, 2012). Not surprisingly, given the developmental salience of active engagement and intrinsic motivation in adolescence, middle and high school youth not only withdraw energy from school but also drop out (S. M. Jones et al., 2008; NCES, 2014).

In sum, at the most macro-level, as schools have ramped up academic demands and focused more intently on skills and knowledge defined by standards and assessed using group-based multiple-choice tests, an argument can be made that the first wave of school reform efforts has not created developmentally salient opportunities for learning (Plank & Condliffe, 2013; Skiba et al., 2014) or teaching (Abenavoli et al., 2013; NEA, 2010). Moreover, as economic stresses have been placed on students, families, and communities over the past decade, the risks associated with poverty have interacted with, and exacerbated, school-based demands (Plank & Condliffe, 2013; Skiba et al., 2014; Weinstein, 2008). Students report increasing levels of stress (NCES, 2014), as do teachers (MetLife, 2002; NEA, 2010), and rates of teachers' use of exclusionary discipline practices (e.g., suspension) have increased dramatically over the past decade, a trend that has been characterized as reflecting notable misalignment between demands on students and educators and resources that are relevant for their success in creating and realizing educational opportunity. Signs of increasing misalignment are notably evident for several groups of students, including African Americans and other students of color, those with mental health or behavioral problems, and those from low-income backgrounds (Skiba et al., 2014; Sullivan & Bal, 2013). Moreover, indications of strain and misalignment are also reflected in educational personnel and structures. Fifty percent of the teaching workforce leaves the profession after 5 years, with the vast majority reporting feeling inadequately trained to respond effectively to students' social needs and behaviors (J. Greenberg, Pomerance, & Walsh, 2011; NEA, 2010). And by some indications roughly 10% of schools in America are chronically failing to engage students in productive learning opportunities (NCES, 2014).

These trends bring to the foreground the gaps in knowledge that would provide a more informed understanding of how schools foster developmentally salient experiences for students and the parameters that shape those experiences toward promotive and preventive opportunities in contrast to risk-exacerbating ones. At present, there is ample evidence that schools play roles that shape development toward competence and toward pathology, with signs that conditions in communities marked by greater economic or social risk, or for students characterized by those risks, are tilting in a negative direction.

The next sections turn to a more detailed and in-depth analysis of scientific progress related to one nexus of education and human development: teacher-student interaction. Within this broad domain of research on a key proximal process in schooling, the focus is on describing these interactions in developmentally salient terms, identifying key points of impact on outcomes for children and youth, and presenting evidence from interventions related to improving their impact.

CONCEPTUALIZING AND MEASURING TEACHER–STUDENT CLASSROOM INTERACTIONS

Analysis of the substantial empirical literature in education policy research focused on identifying teachers' effects

on student performance (i.e., teachers' value-added for student learning gains) leads to the quite clear conclusion that teachers matter for student achievement (Goe, 2007; Kane & Staiger, 2012; Loeb et al., 2012), motivation (Patrick, Anderman, Ryan, Edelin, & Midgley, 2001; Reeve, Jang, Carrell, Jeon, & Barch, 2004; Ruzek, Domina, Duncan, Conley, & Karabenick, 2014; Wang & Holcombe, 2010), and a range of behavioral and social outcomes (S. M. Jones et al., 2010; Pakarinen et al., 2011; Wang et al., 2012). However, in the education policy literature, much of the work on teacher impact or effectiveness relies primarily on administrative data sets that typically are limited in measurement to teacher demographics and student achievement test scores. Thus, most of the teacher-effects studies fail to document the specific teaching behaviors that count for detected impacts on students' outcomes or how those behaviors are organized and produced. Yet description and measurement of teachers' developmentally salient classroom behaviors is one area of considerable progress in research over the last decade, such that some of the conceptual models and accompanying assessments have been integrated into the first wave of teacher performance assessments implemented at scale in districts and states (see Kane et al., 2014). These assessment tools derive from the larger literature on teacher-student interactions showing impacts on social, behavioral, and cognitive development in the early years of schooling and beyond, documented in both experimental and well-controlled quasi-experimental studies (Cameron et al., 2005; Curby et al., 2010; Howes et al., 2008; S. M. Jones et al., 2013; Raver et al., 2011). And although this body of work provides credible support for the value of teacher-child interactions for development, the accrued evidence also outlines a number of pressing questions for further conceptual and empirical investigation.

A cluster of questions for further study is motivated by the lack of consensus on the basic lexicon and classification scheme for describing teacher-student classroom interactions (Hamre et al., 2013). Extending back more than 25 years to Brophy and Good's seminal work (1986) on describing and measuring teachers' classroom interactions, there have been numerous efforts to address this challenge, each with varying degrees of success. Given what one would imagine as the scientific and applied importance of this focus, there has been very little in the way of systematic progress in measurement or understanding. Rather, efforts to describe effective teaching have collectively led to a mostly fragmented understanding: large numbers of small-scale studies; many attempts at description that lack evidence of validity or tools for data collection (Lemov, 2010); challenges in more systematically discerning and measuring the aspects of teacher behavior that are unique to teaching a certain content area (Grossman, Cohen, Ronfeldt, & Brown, 2014; Hill, 2010; van Hover, Hicks, & Cotton, 2012) or grade level (Pianta et al., 2014); or derivations that are specific to data collection methods, such as observation or informant report (Kane et al., 2014; Raudenbush & Jean, 2014; Ruzek, Hafen, Allen, et al., 2014). The descriptive basis for measuring and understanding the effects of teaching on developmental outcomes is both limited and limiting.

Making matters more challenging is the widespread demand for descriptions of effective and ineffective teaching, including schemes that could be used in performance evaluation, accountability, and improvement efforts (see Archer, Kerr, & Pianta, 2014; Glazerman et al., 2011; Harris & Sass, 2011; Rockoff et al., 2011). With nearly every state requiring some form of teacher performance assessment, the portfolio of existing efforts is broad, ranging from district-specific rubrics to widely used approaches that have been applied with precise adherence to standards or, more typically, adapted by local educators (see Archer et al., 2014; Kane & Staiger, 2012). When studies have included various forms of assessing teacher-student interaction, including multiple observation tools (Kane & Staiger, 2012; Staiger & Rockoff, 2010) or combinations of observation and student report (Brock, Nishida, Chiong, Grimm, & Rimm-Kaufman, 2008; Kane et al., 2014; Raudenbush & Jean, 2014), the evidence indicates considerable commonality across clusters of behaviors identified through these forms as readily and reliably detectable and as salient for student learning (Hamre, Pianta, et al., 2013). These behavioral clusters include aspects of teachers' social and emotional behaviors toward students, their practices related to classroom management, and how they deliver instruction (Danielson, 2007; Marzano, 2014). Thus, although operationalized descriptions of the elements of developmentally salient teacher behavior remain fragmented and unstandardized in the sense of a systematic lexicon and lack the precision and structure of a formal classification system, the evidence does suggest possibilities for convergence among the various forms in use. There is tremendous demand for tools that can be used in the evaluation of effective and ineffective teachers (Kane & Staiger, 2012; Rockoff et al., 2011) and that support high-stakes and low-stakes decisions (Archer et al., 2014). However, even though there is, in concept, general agreement on broad clusters of effective teacher behaviors, the scientific work to derive strong assessments has been outstripped by applied demands, and so research has quickly moved

more to a focus on application than on the basic science of description. This is unfortunate because valid and replicable description the teacher behaviors most salient for student learning and development is the linchpin of scientifically derived applications that could meet current and projected demands in practice.

A Framework for Conceptualizing and Measuring Teacher-Student Interactions

As noted, the need to further articulate and validate theoretical frameworks for teaching is exceptionally important and was suggested by Douglas (2009): "Our knowledge of classroom instruction will be well served by studies that build on a common theoretical framework" (p. 519). In a series of theoretical and empirical papers published over the past decade, Pianta, Hamre, and colleagues (Hamre, Hatfield, et al., 2014; Hamre, Pianta, et al., 2013; Pianta & Allen, 2008; Pianta et al., 2007; Pianta, La Paro, & Hamre, 2008) have presented and evaluated one such framework of effective teaching, Teaching Through Interactions (TTI), operationalized through observation, and focusing exclusively on interactions between teachers and students as the proximal process through which teachers influence learning and development. This framework and the empirical work associated with it is presented here as an illustration of a systematic, empirically based effort to describe developmentally salient teacher-student interactions, which can also serve as the basis for contrasting approaches and models.

The TTI framework situates the study of teacher-student interaction within a developmental systems theory framework (Bronfenbrenner & Morris, 1998; Lerner, 2002); interactions are embedded within the dyadic system of teacher-child relationships and involve psychological, behavioral, biological, and cultural processes. Within dyadic relationship systems, interactions reflect behavioral exchanges in which information and experience are transmitted between adult and child through channels that operate bidirectionally and transactionally (Sroufe, 2005). The original version of the TTI framework posited a conceptualization of teacher-student interactions predicated on domains of child development they foster. This developmental-domain approach to conceptualization organized teachers' classroom interactions into three broad domains of support for student development: Emotional Supports, Classroom Organization, and Instructional Supports (Hamre, Pianta, et al., 2013; Pianta et al., 2008) based on their presumptive salience for student development in the areas of social and emotional development, self-regulation and attention, and achievement, respectively. And TTI further defines these three broad domains to encompass and organize sets of increasingly molecular features of interactions that are presumed to be important to students' academic and/or social development and that can be observed in classrooms.

Factor Analytic Examination of the Organization of Teacher-Student Interaction

A considerable body of work on teacher-child interactions draws from the TTI conceptual framework (Hamre, Pianta, et al., 2013) and the observational measure corresponding to this framework, the Classroom Assessment Scoring System (CLASS; Pianta et al., 2008) as applied to age spans that encompass preschool through late adolescence. And although other theoretical frameworks and accompanying assessment tools have been in widespread use in the field (Lemov, 2010; Marzano, 2014), the empirical evidence base surrounding their use and validity is more limited in scope and rigor. Research using the CLASS has provided evidence supporting the TTI three hypothesized broad domains of teacher-child interactions—Emotional Support, Classroom Organization, and Instructional Support —as an empirically sound approach to describing teacher-student interactions in classrooms (Hamre, Pianta, et al., 2013), addressing in part Douglas's (2009) call for a common description. More specifically, results from a confirmatory factor analytic study of CLASS-derived observational data from over 4,000 preschool to fifth-grade U.S. classrooms (Hamre, Pianta, et al., 2013) suggested that the TTI hypothesized 3-factor structure provided better fit to the observed data than 1- or 2-factor solutions. However, analysis of CLASS-based observations in upper elementary and secondary grades (Allen et al., 2011), most notably from the MET sample of more than 3,000 classrooms (Kane & Staiger, 2012), suggests that a more general, single domain reflects a combination of teachers' management and instruction is the best-fitting descriptor of effective teaching. Evidence from students' reports of effective teaching, when examined for factor structure, tends to confirm this more general, single factor as the best-fitting descriptor (Downer, Lopez, et al., 2011; Ferguson with Hirsch, 2014; Kane & Staiger, 2012). Both the general, single-factor structure and the three-domain structure have received support in empirical studies examining predictions to student learning and development (Allen et al., 2011; S. M. Jones et al., 2013; Kane & Staiger, 2012; Lüdtke, Robitzsch, Trautwein, & Kunter, 2009; MET Project, 2010; Pianta et al., 2007; Ruzek, Hafen, Hamre, et al., 2014).

Associations with Student Outcomes

In numerous studies, three domains of teacher-child interactions (emotional, organization, instruction) have been linked to students' social, emotional, regulatory, and cognitive development (see Downer, Sabol, & Hamre, 2010, for review). In general, effect sizes obtained between these ratings of the features of teachers' interactive behaviors and student outcomes such as achievement test scores are small (Brock et al., 2008; Burchinal, Vandergrift, Pianta, & Mashburn, 2010; Mashburn et al., 2008; Pakarinen et al., 2011; Rimm-Kaufman, Curby, Grimm, Nathanson, & Brock, 2009), although larger correlations are detected for students with higher risk profiles (Hamre & Pianta, 2005; McCartney, Dearing, Taylor, & Bub, 2007), or for students' reports of the classroom environment or motivation (Ferguson with Hirsch, 2014). Recent evidence also indicates that children's gains in language and literacy skills when they experience higher-quality teacher-child interactions and instruction are larger at upper levels of the distribution of teacher effectiveness (Burchinal et al., 2010; Hatfield, Burchinal, Pianta, & Sideris, in press), suggesting the greater potency, for some children, of certain teacher behaviors. Evidence also suggests that features of teacher-child interaction support children's executive functioning skills (Weiland & Yoshikawa, 2013) and social and emotional skills (Gormley, Phillips, Newmark, Perper, & Adelstein, 2011). However, as noted, the effect sizes are typically small, and it is quite possible that the small magnitude of the overall association may not be linear. This possibility is supported by limited evidence of a cutoff or differences in magnitude in the association between quality and child outcomes at varying points on the quality distribution, although the study of such cutoffs has yielded inconsistent results (e.g., Burchinal, Kainz, & Cai, 2011, for a review).

A recent meta-analysis of 10 large preschool and child care studies provided evidence of thresholds teacher-child interactions and child outcomes, but such thresholds did not emerge in all analyses (Burchinal et al., 2011). Factors such as the actual threshold levels tested, how thresholds are derived (empirically or on an a priori basis), use of different covariates or measures of quality all seem to influence the likelihood of detecting a threshold. Other studies replicate threshold-related findings with some success and also extend the range of outcomes examined (Burchinal, Sideris, Vernon-Feagans, & Pianta, 2013; Weiland, Ulvestad, Sachs, & Yoshikawa, 2013). For example, Weiland et al. (2013) reported that children showed larger gains in executive functioning skills at higher levels of teacher-child interaction quality, thus suggesting some possible threshold effect.

The consistency or stability of students' exposure to effective teacher-student interactions also appears to be of additional benefit for promoting behavioral development and academic trajectories (Landry, Smith, Swank, Assel, & Vellet, 2001; Sanders & Horn, 1998). At the same time, there is clear evidence that students rarely have the same quality experiences from year to year (La Paro et al., 2009; Pianta et al., 2007). However, most research on consistency of student experiences is conducted on a year-to-year basis, not fully exploring the potential developmental ramifications of variation experienced on a day-to-day or within-day basis (Kern & Clemens, 2007). Recent analysis of observed experiences in early childhood classrooms offers new insights about the importance of within-day variability.

Results from a series of observational studies examining consistency of teacher-child interactions across the preschool day indicate that students do experience variability in these domains of teacher behavior (Curby et al., 2010) and that greater variability is related to poorer developmental outcomes (Brock & Curby, 2014; Curby et al., 2010; Zinsser et al., 2013). For example, variability in emotionally supportive features of teachers' interactions across a day moderated associations between teacher-student relationship quality and students' problem behaviors and social competence (Brock & Curby, 2014). Additionally, Curby, Brock, and Hamre (2013) found that, even after accounting for mean levels of observed features of teacher-student interaction, consistency of interaction quality predicted within-year gains in academic and social outcomes. Similarly, Zinsser and colleagues (2013) found that students were more aggressive in classrooms with inconsistent teachers, even when those teachers provided, on average, high levels of support. And recent studies of students in middle schools, with multiple teachers, demonstrate the consistency in the features of teacher-student interactions, across teachers and within days, accounted for students' levels of problem behavior (LoCasale-Crouch, Jamil, Pianta, Rudasill, & DeCoster, 2013). In sum, it appears that not only the general level of teacher-student interaction quality is a developmentally salient feature of the classroom setting and that consistency in such features can have additional value.

Challenges to Detecting and Interpreting Associations Between Domains of Teacher-Student Interaction and Student Outcomes

Over the course of the last decade of research on teacher-student interactions, using either the CLASS

or the Framework for Teaching (Danielson, 2007) as the tool for observations of classroom teaching, a number of important limitations pertaining to description of teacher-student inter actions have surfaced in factor analytic studies and in studies examining associations with student outcomes. As noted earlier, for both the FFT and CLASS, the best-fitting factor structure across numerous studies (Hamre, Pianta, et al., 2013; Pakarinen et al., 2011) identifies factors reflecting instruction, classroom management, and warmth/support dimensions, although these can vary from study to study and in most studies display less-than-ideal fit indices (Hamre, Pianta, et al., 2013; Mihaly & McCaffrey, 2014; Raab, Dunst, Wilson, & Parkey, 2009; Salminen et al., 2012; Wagner, Göllner, Helmke, Trautwein, & Lüdtke, 2013). However, most studies using the CLASS report very high correlations among the three domains, limiting examination of the extent to which individual domains of interactions are associated with specific domains of children's development (Hamre, Pianta, et al., 2013). Studies using the FFT also indicate factors to be highly correlated, and due to high multicollinearity among domains, researchers sometimes use only one domain of teacher-child interaction at a time (e.g., Pakarinen et al., 2011; Rudasill, Gallagher, & White, 2010), use an overall score (e.g., Jamil, Downer, & Pianta, 2014), or struggle to interpret results when all three domains are in the same model (Mashburn, Downer, Rivers, Brackett, & Martinez, 2014; Rimm-Kaufman et al., 2009). Thus, although possibly a conceptual and empirically satisfying map of classroom interactions, the three broad domains posited by the TTI framework posed a less-than-satisfactory solution for understanding the specific ways in which teachers' interactions with children support development, despite the consistent evidence of teacher-student interaction effects overall.

Therefore, a challenge to better understanding the nature and impact of teacher-student interactions on development has been the specificity of relations between and among domains of such interaction (e.g., social interactions, instructional interactions) and domains of children's development (e.g., peer relationships, language development). Challenges in parsing that association for a clearer understanding of effects are posed by frequently noted associations among features of teachers' behaviors. For example, teachers who are highly sensitive are also often more like to engage in effective language stimulation practices. Within the larger debate about the domain specificity of socialization (Downer et al., 2010; Dunn, 2010; Grusec & Davidov, 2010), Grusec and Davidov (2010) argued against a general socialization factor, "but rather each form of relationship between the object and the agent of socialization serves a different function, involves different rules and mechanisms for effecting behavior change, and facilitates different outcomes" (p. 687), a rather strong statement in support of domain specificity. Dunn (2010) noted that a domain-specific approach may offer conceptual clarity but fails to fully acknowledge the real-world overlap among domains, on both the input (e.g., teacher-child or parent-child interactions) and the outcomes sides, pointing out the lack of empirical support for this strong assertion of domain-specificity.

A Dyadic Systems Model for Conceptualizing Teacher-Student Interaction and Effects

Following from published reports of challenges with regard to identifying associations between the three TTI domains and child outcomes, Hamre, Hatfield, et al. (2014) advanced and evaluated a model for considering both domain-general and domain-specific associations between teacher-child interactions and children's development. In a recent revision to their TTI framework, Hamre, Pianta, and colleagues (2013) argued that there are both generic properties of interactive behavioral exchanges between adults and children as well as properties that are specific to role, intent, and content. This reformulation posits a general dyadic systems-level property of teacher-child interactions, responsive teaching, which is hypothesized to foster development in all domains (social-emotional, behavioral, and cognitive outcomes) because it reflects a property of coregulation that both activates students' attention and engages them in learning opportunities presented at the time. This general feature of dyadic interaction systems is hypothesized to engage the members of the dyad, providing a platform for the features of exchange (behavior, language, information) that have a specific focus or intent. This reformulation argues that there are systems-level properties of interactions that characterize general properties of exchange regardless of the intent or content of those exchanges. In empirical tests of instruments such as CLASS or FFT, in which the focus of observation is on teachers' behavior toward and response to students' cues, this generic factor is assumed to be present in all dimensions of teacher behavior being observed, an assumption confirmed in factor analyses of these instruments, which typically yield a large first factor loading on all dimensions (Kane & Staiger, 2012; MET Project, 2010; Mihaly & McCaffrey, 2014).

Beyond general features of responsivity, it is clear that teacher-student interactions typically also carry an intent,

a focus on learning or on content, that in part reflect desired consequences of that interaction for children's performance. In research on teacher-child interactions, this impact of intent or learning focus has been most clearly demonstrated in relation to interactions that foster early literacy development. For example, interactions in which attention is explicitly paid to the phonological properties of written and spoken language appear necessary for most children to gain these foundational skills in early literacy (see B. M. Phillips, Clancy-Menchetti, & Lonigan, 2008, for review). Such features of teachers' interactions have been conceptualized as distinct from more general responsivity (Justice, Mashburn, Hamre, & Pianta, 2008). Moreover, in the domain of mathematics, Hill (2010) has conceptualized a set of teacher behaviors relevant for math learning that are not captured by general responsivity features. Evidence suggests that these math-specific features indeed are unique to predicting student mathematics learning gains separate from the contributions of more general features (Hill, 2010). Most recently, van Hover and colleagues (2012) conceptualized a set of interactive behaviors displayed by teachers that are unique to teaching in the content areas of history and social studies, behaviors that in turn can be codified and observed reliably. On the basis of this conceptual distinction between features of teacher-student interaction that reflect general properties of dyadic systems (responsive teaching) and features reflecting the intent or learning focus of the interaction, Hamre, Hatfield, et al. (2014) hypothesized that general and domain-specific features reflecting intent and content of interactions should show common and differential associations to outcomes in social and cognitive domains.

Responsivity

At the core of all of the dyadic systems conceptualizations described in TTI are general features of interaction that reflect a dyadic system-level property that is best captured by the construct of responsivity. There is a long history of theory and research describing responsivity as a property of interactions between adults and children, both in the parenting (Bornstein, Tamis-LeMonda, Hahn, & Haynes, 2008; Landry, Taylor, Guttentag, & Smith, 2008) and early childhood education (Howes & Smith, 1995) literatures. *Responsivity* is defined as "prompt, contingent, and appropriate reactions to . . . children" (Bornstein et al., 2008, p. 867). Early work by attachment theorists highlighted the importance of this type of parenting for fostering positive social, emotional, and cognitive development (Bowlby, 1973). However, responsivity, as a construct or dyadic process, transcends a single theoretical approach (Landry et al., 2008), with similar descriptions coming from sociocultural (e.g., Rogoff, 1990) and socialization (e.g., Maccoby & Martin, 1983) researchers. Several other features of responsivity are reflected in various approaches to describing general properties of effective teacher-student interactions, including active engagement, cue detection, and contingent responding (Brophy & Good, 1986; Danielson, 2007; Lemov, 2010).

Teachers are active agents, and the classroom is intentionally designed to foster development. Children learn more when teachers actively and intentionally use their interactions to engage children in classroom experiences. This emphasis on active and intentional engagement is in contrast to approaches that emphasize a more passive role for the teacher (Landry, Anthony, Swank, & Monseque-Bailey, 2009). Thus, elements of active engagement may be present in nearly all features of teacher-child exchanges. Another common element of interactions is cue detection (Linhares & Brum, 2009). Many descriptions of effective teaching mention teachers' recognition of children's cues in moment-to-moment bouts of attending and response. In the educational literature, this phenomenon is sometimes referred to as teacher noticing (e.g., van Es & Sherin, 2002) or with-it-ness (Kounin, Friesen, & Norton, 1966), although these descriptions have tended to focus on the behavioral aspects of cue detection rather than on teachers' abilities to visually detect when children are in need of emotional or cognitive support. And for adults to engage effectively with children, they must not only attend to cues but also respond contingently in back-and-forth exchanges that build on each other to form the functional episodes of attachment and cognitive scaffolding that foster development (Allen et al., 2011; Bodrova & Leong, 2012; Raver et al., 2011; Rimm-Kaufman et al., 2009). The properties of interactive behaviors—cue recognition and accurate interpretation, contingent responses, loops of back-and-forth cycles of calibrated behavior and emotion—collectively define the construct of responsive teaching (Hamre, Pianta, et al. 2013).

Intended Learning Targets

Effective teaching also requires more than being responsive to student cues and activation of engagement and attention; in nearly all instructional or social encounters, teachers have a goal or aim associated with their role and function; this is the aspect of teaching that is often described as intentional or goal directed (Piasta et al., 2012; Urdan & Schoenfelder, 2006; Wasik & Hindman, 2011). The Hamre, Pianta, et al. (2013) formulation posits three more specific aspects of teacher-student interaction that

reflect teachers' intent—motivation-inducing supports, management and routines, and cognitive facilitation—that also are complemented by content-specific behaviors (Hill, 2010; van Hover, Hicks & Cotton, 2012). In the Hamre, Pianta, et al. (2013) formulation, features of teacher-student interaction that are focused on intended learning targets are also hypothesized as distinct from the general elements of responsive teaching.

Thus, aside from interacting in a generally responsive manner that engages students, interactions with teachers must also convey supports that enable students to approach difficult tasks and persist in those tasks toward mastery (Ruzek, Hafen, Allen, et al., 2014; Wang & Holcombe, 2010; Wang et al., 2012;). Therefore, a primary intent of effective teacher-child interactions must be to activate and foster motivational processes. The strategies teachers may use to enhance motivation, informed in part by self-determination theory (Connell & Wellborn, 1991), focus on fostering connection, competence, and autonomy (Allen et al., 2011; Ruzek, Domina, et al., 2014; Ruzek, Hafen, Allen, et al., 2014; Wang & Holcombe, 2010). A second functional intent of teacher-student interaction is to organize and manage activity, time, and attention, with teachers providing very clear expectations to students about behavior, performance, and self-regulation concerning tasks and time in the classroom. Teachers' interactions in this broader area of management and routines have been shown to support the development of self-regulation and executive functioning skills (Cameron et al., 2005; Patrick et al., 2001; Raver et al., 2011; Ursache, Blair, & Raver, 2011). Finally, teachers' exchanges with students should convey information, expand knowledge, and develop cognitive capacities. As noted in an earlier section, classrooms vary considerably in elements of cognitive demands through which teachers intentionally engage students to foster conceptual understanding and reasoning skills (Ferguson with Danielson, 2014). Such stimulation of cognitive processes may occur in the context of general interactions as well as in the context of content-specific instruction. One recent study suggests that science activities in particular may stimulate more cognitively challenging interactions among teachers and children (Cabell et al., 2011). For the most part, evidence routinely points out the low level of cognitive demands and facilitation present in teachers' instruction, a consistent finding across grade levels and resource levels of schools (LAUSD, n.d.; MET Project, 2010; NICHD ECCRN, 2005; Pianta et al., 2007).

Unfortunately, conceptualization and measurement of teacher-student interaction often confound the general properties of interaction with features related to intent and focus. To disentangle this challenge empirically, Hamre, Pianta, et al. (2013) employed a bifactor analytic strategy to explicitly test the revised model describing teacher-student interactions, positing both general and domain-specific features of teacher-student interaction. Bifactor modeling produces independent, uncorrelated factors that can be examined as unique predictors of student outcomes, even when all factors are in the same model (Chen, Hayes, Carver, Laurenceau, & Zhang, 2012). The bifactor model is an approach to dealing with the common situation in which researchers propose a general construct of interest that is hypothesized to include several highly related domains (Chen et al., 2012; Chen, West, & Sousa, 2006).

More specifically, Hamre, Hatfield, et al. (2014) used bifactor modeling to examine the existence of general (i.e., Responsive Teaching) and domain-specific factors (i.e., Motivation-Inducing Supports, Management and Routines, and Cognitive Facilitation) present in teacher-student interactions and hypothetically differential prediction of child outcomes by those factors. They note a*s* a primary rationale the difficulties that arise in analyses with correlated factors such as in the multiple correlated domains of the CLASS or FFT (see MET Project, 2010; Kane & Staiger, 2012). The standard analytic methods (including ANOVA, regression, and logistic regression) test the extent to which each predictor explains variability in the outcome adjusting for other predictors in the model (J. Cohen, Cohen, West, & Aiken, 2003). In these approaches, even moderately correlated predictors are less likely to provide significant results, and when detected, multicollinearity makes these results more difficult to interpret and explain. The bifactor approach allows for a more precise evaluation of general and domain-specific elements of teacher-student interactions.

In the first study to examine teacher-student interactions using the bi-factor approach, Hamre, Hatfield, et al. (2014) drew from live observations of 325 preschool classrooms, comparing bifactor model fit to one-, two-, and three-domain solutions. More importantly, this study further evaluated the bifactor approach (and validity of the reformulated TTI theoretical framework) by examining the extent to which the general factor of responsive teaching as well as the posited domain-specific factors (i.e., motivational support, management and routines, and cognitive facilitation) differentially predict children's executive functioning, social, and early academic development from fall to spring of the preschool year. The authors expected responsive teaching, because of its hypothesized role in promoting student engagement, to

predict growth across all student outcome domains; they also expected domain-specific associations in which more positive student-teacher relationships were predicted by motivational support, students' executive function outcomes by management and routines, and growth in early academic outcomes predicted by cognitive facilitation.

Results from this study provided new insight into the ways in which teachers' interactions with young children in preschool classrooms support growth across a range of developmental domains, suggesting that arguments regarding general or domain-specific approaches to conceptualizing the influence of adults on development (Downer et al., 2010; Dunn, 2010; Grusec & Davidov, 2010) may be oversimplified, with support present for both sides of the argument. In the Hamre, Hatfield, et al. (2014) study, children in classrooms with high levels of responsive teaching, a *general* system-level property of teachers' interactions, demonstrated greater gains across a number of outcome domains, including cognitive, self-regulatory, and relational functioning. Moreover, there was also support for domain specificity in relations between specific features of teacher-child interaction and child outcomes, with teachers' positive management and cognitive stimulation uniquely predicting self-regulation skills and academic performance, respectively, independent of responsive teaching.

This initial empirical support for the reformulated TTI framework suggests a promising direction for further refinement and evaluation of what could be an important advance toward a validated theoretical description of teacher-student interaction as a developmentally salient feature of educational settings (Brown, Jones, LaRusso, & Aber, 2010; Seidman & Tseng, 2011; Tseng & Seidman, 2007). Efforts that use the bifactor analytic strategy to replicate the Hamre, Hatfield, et al. model (2014) suggest some level of support and need for further conceptual refinements. For example, in secondary grades, Hafen and colleagues (in press) have applied the bifactor strategy to the MET data, confirming a general factor that tracks closely to responsive teaching, with a somewhat different set of domain-specific factors than reported in Hamre, Hatfield, et al. (2014), perhaps due to the content-learning focus of secondary schools in contrast to the socialization focus of the early education settings in the Hamre, Hatfield, et al. study. Replication efforts in elementary settings (Downer, Ruzek, Stuhlman, & Hamre, 2014) confirmed the general responsive teaching feature of teacher-student interaction but differed from the early childhood results in terms of domain-specific features (Hamre, Hatfield, et al., 2013).

Students' Perceptions of Teacher-Student Interaction

In addition to the study of teacher-student interaction and classrooms based on observations at the classroom level, there is a large literature that addresses understanding students' unique perceptions of the classroom setting, their individual experiences, and their views of others in that setting, using student self-report methods, a body of work that is integral to understanding proximal processes in classrooms (Fraser & Walberg, 1981; Turner & Meyer, 2000; Weinstein, 1983). This is particularly notable in research on the effects of classroom environments on students' motivation and psychological beliefs, some of which has employed observations to assess instructional climates (e.g., Jang et al., 2010; Patrick et al., 2001; Spearman & Watt, 2013), but most studies utilize student surveys to measure classroom climate or experiences with teachers (Ferguson with Danielson, 2014). This preference for describing teacher-student interaction through measuring student perceptions stems from the view that students' own perspectives are primary determinants of their responses to the classroom as an opportunity setting and therefore the most salient for predicting student-level outcomes (Lüdtke et al., 2009).

A benefit of surveys is that students draw on a deep set of personalized experiences to assess their teacher's instructional practices (Wagner et al., 2013), perspectives that may add unique predictive value in understanding the classroom as a learning environment (Lüdtke et al., 2009; Ruzek, Hafen, Allen, et al., 2014). Conceptualization and measurement of the classroom setting, and in particular teacher-student interaction, from students' individual perspectives also posits general and domain-specific features. For example, surveys measure the overall classroom climate based on multiple students' reports within the same classroom (Marsh et al., 2012) as well as differential student experiences both *within* (Kuklinski & Weinstein, 2001) and *across* classrooms (Oakes, 2005). Moreover, factor analytic evidence confirms a general factor reflecting responsive, engaging teaching as well as specific elements pertaining to management and cognitive demand (Ferguson & Danielson, 2014), suggesting some convergence between student experience and observational data regarding the organization of teacher-student interaction in classrooms.

However, despite these convergences in description, student survey research also reveals additional complexity in classroom processes (Tseng & Seidman, 2007) in that different students in the same classroom disagree about the extent to which their teacher engages in various practices. Significant within-classroom variability in student

reports suggests that surveys of student perceptions do not describe or measure classroom processes in aggregate form (Lüdtke et al., 2008; A. D. Miller & Murdock, 2007;) but actually provide a complementary window on teacher-student interaction, in which observation of teachers' behavior can assess a central tendency or level of resources available (Pianta & Allen, 2008; Pianta et al., 2007), while student surveys capture the salience of individual experiences (Marsh et al., 2012; Wagner et al., 2013; Wang et al., 2012).

In sum, the significance of work to conceptualize and validate models for describing and understanding the developmental salient features of teacher-student interaction is notable, and progress in the past decade has been substantial. As mentioned earlier, the absence of empirically validated models for descriptions of teacher-student interaction and developmentally salient classroom processes leaves the field wide open for opinions, conjecture, and as-yet-to-be tested good ideas (Lemov, 2010) that have a tendency to drive into the popular understanding of teaching and even shape policy (Green, 2014), particularly in the absence of rigorous tests of assumptions (Loveless, 2014). In fact, although as is discussed in sections to follow, there is a growing body of evidence on the improvement of student learning and development as a consequence of interventions that improve teacher-student interaction (Allen et al., 2011; Jennings, Frank, Snowberg, Coccia, & Greenberg, 2013; S. M. Jones et al., 2010, 2013; Kemeny et al., 2012; Pianta et al., 2008, 2013), the need for a lexicon and classification scheme for teaching is critical to scientific and applied progress.

PSYCHOLOGICAL AND CONTEXTUAL FACTORS RELATED TO QUALITIES OF TEACHERS' INTERACTIONS WITH STUDENTS

There are large literatures examining an assortment of psychological (e.g., attitudes, beliefs) and contextual (e.g., school size, principal leadership skills) factors as they are related to elements of teaching. By and large these literatures are composed of correlational, cross-sectional studies, most without strong designs or measurement of confounding factors or strong theoretical bases (Ferguson with Danielson, 2014; Henry et al., 2013; Kane & Staiger, 2012; Tsouloupas, Carson, Matthews, Grawitch, & Barber, 2010.). For these reasons, there are few conclusions to be drawn from the vast majority of this work; however, there are converging indications from studies with a strong basis in cognitive science and in the area of self-regulation and stress management that point to a cluster of psychological attributes that may bear important causal connections to qualities of teacher-student interaction experienced by students.

Teachers' Cue Detection Skills Shape Their Interactions with Students

Threaded throughout theoretical and empirical studies on effective teaching is the premise that teachers' behavior toward students (and hence the proximal processes involved in promoting development) involve mechanisms associated with teachers' psychological processing of the information flow available to them in everyday interactions in classrooms in real time. Presumably, the more accurate teachers' processing of information, the more well calibrated their interactions can be with regard to the individual and collective needs of students. This linkage between information processing theory and teachers' practices in the classroom has a fair level of basis in empirical results in cognitive science, specifically the dual-process model of cognition.

The dual-process model of cognition emphasizes the importance of efficiency of educators' conscious processing of information (see Feldon, 2007); these processes form and rely on comprehensive schemas about effective teacher practices that are not biased by personal perceptions or irrelevant sensory information and can both guide practice efficiently and enable cognitive capacity to focus on information relevant for intentional action in the present moment. For the novice teacher, preparation should lead to schemas based on unbiased, research-based practices (Artino, 2008). For more experienced teachers, experience and professional development might help them actively identify, question, and modify the biased or inappropriate schemas they currently utilize to automatically guide their classroom behavior (Artino, 2008).

Regardless of whether teachers are using effortful or automatic cognitive processing at any given moment, their processing of information needs to be accurate, unbiased, and effective for the particular situation (van Merriënboer, Kirschner, & Kester, 2010). And, in the case of classroom teachers, incoming information should also effectively link to accessible, relevant, and accurate knowledge about learning and development (NCATE, 2010). Efficient processing focuses available cognitive resources on information relevant for effective teaching (germane load) rather than on irrelevant events (extraneous load) that arise in the classroom (Artino, 2008; Feldon, 2007). In addition, processing should take into consideration the

breadth of information available to identify and interpret relevant information, helping the teacher guard against creating faulty, stereotyped responses (Feldon, 2007; Gregory & Weinstein, 2008). As new information is integrated into existing knowledge, chunking, or the creation of a single, comprehensive unit, can help guide behavior. Because chunked data forms one piece of information in working memory terms, the data are processed more efficiently and require less mental effort, thus reducing teachers' cognitive load (Feldon, 2007; van Merriënboer et al., 2010) and presumably their errors in interpreting cues in the classroom information flow.

With this background of applying cognitive load theory, a particularly promising area of research on effective teacher-student interaction focuses on teachers' skills in observing and analyzing others' or their own practices, typically using video as a stimulus (Hamre, Pianta, et al., 2012). Much of the work in this domain of teacher competence has occurred in the context of case studies (Rosaen, Lundeberg, Cooper, Fritzen, & Terpstra, 2008; Tripp & Rich, 2012) or small, informal video viewing groups (Alsawaie & Alghazo, 2010; Borko, Jacobs, Eiteljorg, & Pittman, 2008; Sherin & van Es, 2005; van Es & Sherin, 2002, 2006; van Es, Tunney, Goldsmith, & Seago, 2014) and so relies on small samples and qualitative analysis (Borko et al., 2008; Rosaen et al., 2008; Sherin & Van Es, 2005; Tripp & Rich, 2012; van Es & Sherin, 2008, 2010). Therefore, the evidence base is very descriptive in nature and subject to misinterpretation for various reasons.

However, these and other more rigorous studies do suggest that the psychological processes tapped by video analysis correlate with their behavior in the classroom (Jamil, Sabol, Hamre, & Pianta, 2015; Wiens, Hessberg, LoCasale-Crouch, & DeCoster, 2013). In the one experimental study of teachers' video analysis skills, Hamre and colleagues (2012) demonstrated not only that teachers' observation and video analysis skills can be assessed and variations in teachers' responses quantified but that these skills mediate intervention effects on gains in quality of observed teacher-student interaction and student engagement. More specifically, Hamre, Pianta, et al. (2012) used a random assignment experiment to examine the impact of a course designed to promote knowledge of effective teaching (using the Classroom Assessment Scoring System as a template for description) and teachers' skills in observing specific behavioral examples and indicators of effective teaching using video-tagging software. Teachers in the treatment group were observed postcourse and 1 year later and on each occasion were rated as demonstrating higher levels of instructional support interactions in their classrooms (Hamre, Pianta, et al., 2012). Subsequent analyses indicated that the gains in interaction for the treatment group were attributable to gains in their skills in observing effective interaction in video tagging activities. The importance of teachers' observation skills for supporting effective classroom interaction is also demonstrated in experimental studies of effective coaching with middle and high school teachers showing that teachers' observation skills promote teacher-student interactions and student engagement, and mediate gains in achievement across content areas (Allen et al., 2011). In treatment-on-the-treated designs, preschool teachers' greater exposure to video examples of effective teaching (presumably a means to increase observation skills) has been shown to correlate strongly with improvements in qualities of their interactions with children (Downer, Ruzek, et al., 2014; Pianta et al., 2014).

Another pattern of findings demonstrating the promise of a focus on teachers' cue-detection skills as a facilitator of effectiveness emanate from a set of professional development evaluations in which interventions focused on cue detection in video analysis resulted in increases in teachers' effectiveness as indicated by observed classroom instruction. Santagata (Santagata, Zannoni, & Stigler, 2007; Santagata & Angelici, 2010) reported that when novice teachers learned to apply an observation framework and assessment to three videotaped lessons, improvement was evident not only in their analysis skill but in their observed instruction. In a qualitative study, video analysis of their own teaching using tagging software (MediaNotes) appeared to help teachers focus on specific aspects of their teaching and see progress (Tripp & Rich, 2012), a finding consistent with evidence gleaned from video clubs (Alsawaie & Alghazo, 2010). In an experimental study of 26 middle/high math teacher candidates, those who viewed videos and posted analysis for discussion showed improvement in their instructional interactions, as assessed using a standard observation rubric (Alsawaie & Alghazo, 2010). And Van Es & Sherin (2010), in a small-sample study, showed that fourth-and fifth-grade teachers who met once or twice a month for a year to observe and analyze video of their classroom interactions not only improved analysis skills but also increased effectiveness of observed practice.

In sum, evidence emerging from the growing body of literature on teachers' capacities for accurate identification and interpretation of children's cues suggests the potential importance of competencies in this area of knowledge of and skill in enabling the classroom to function as a social and behavioral context for learning (Borko et al., 2008). The mechanisms involved in teachers' psychological

processing of the information flowing to them in real time from their everyday interactions in classrooms are not well understood and are posited to be mediators of their effectiveness in the classroom, an area for considerable further research, with stronger linkages to cognitive science needed. Presumably, the more accurate teachers' processing of information, the more well calibrated their interactions can be with regard to the individual and collective needs of students. However, this is only one of many hypotheses needing to be tested rigorously. This linkage between information processing theory and teacher-student interactions in the classroom has profound implications for understanding and improving the effectiveness of teachers and is an area of research that could be greatly expanded and linked to cognitive neuroscience.

Teachers' Capacities for Self-Regulation and Stress Management

Perhaps one of the more promising areas of recent investigation related to factors that shape the nature, quality, and developmental impact of teacher-student interactions is research on features of teachers' own personal skills in emotion regulation, self-awareness, and management of stress (Abenavoli et al., 2013; Jennings et al., 2013; Kameny et al., 2012; Roeser et al., 2012). This literature on teachers' personal characteristics, which at one point was largely focused on static personality traits and teacher beliefs, has become far more developmental in nature, both in terms of examining the dynamics of teachers' capacities over time and in the ways in which it is informed by contemporary theories of developmental science that link features of interactive behavior to an array of social, cognitive, emotional, and physiological processes (Roeser et al., 2012). As such, this body of work has opened up a far more comprehensive understanding of the personal and contextual supports for effective teaching (and hence the developmental salience of the classroom for students).

By way of background, accumulating evidence demonstrates a rather direct link between aspects of teachers' mood, stress, and emotional resourcefulness and qualities of the classroom setting (see Roeser et al., 2012, for an overview). In a study using the NICHD Study of Early Child Care and Youth Development data set, Hamre and Pianta (2004) examined associations between child care providers' self-reported depressive symptoms and sensitivity of their behavior toward children, identifying not only a relation between higher levels of depression and less sensitive behavior but specifically a relation between negative mood and harshness of behavior toward children. Other work shows that teachers' negative emotional experience, stress, and lack of efficacy forecast higher rates of student problem behavior (Tsouloupas et al., 2010; Wang et al., 2012) and lower levels of observed emotional support behaviors toward to students in the classroom (Merritt, Wanless, Rimm-Kaufman, Cameron, & Peigh, 2012). Given the apparent importance of teachers' emotional health and well-being for their capacity to engage in effective interactions with students, it is of some concern that so many teachers report high levels of stress; nearly half leave the profession in the first 5 years of teaching, citing stress or burnout as the primary factor (Jalongo & Heider, 2006), and half of the early retirements from teaching are attributed to chronic occupational stress and symptoms of mental or physical health problems (e.g., McCarthy, Lambert, O'Donnell, & Melendres, 2009). In short, the available evidence suggests quite clearly that the capacity for the classroom to enable students' learning and development is considerably eroded by teachers' emotional well-being. Roeser and colleagues (2012) have advanced a comprehensive logic model that suggests a pivotal role for teacher emotional well-being and emotion regulation in mediating the relation between workplace demands and stress, on one hand, and the qualities of their classroom interactions, on the other.

The literature on teacher working conditions, drawn from a range of studies relying on state- or district-wide samples of teachers, confirms the importance of the social nature of the classroom and teachers' emotional states. A recent study by Johnson, Kraft, and Papay (2012) examined a broad range of teacher working conditions in relation to student achievement gains and showed that between-school differences in achievement growth in Massachusetts are in part attributable to teachers' reports of more or less stressful working conditions in schools. Ladd (2009) and Hirsch and Emerick (2006) found evidence that working conditions (defined to include facilities and material resource conditions in addition to task demands, collegiality, and leadership) account for significant between-school variance in student achievement. Johnson, Kraft, and Papay (2012) found that indices of the social conditions of the school as a workplace, including community support, principal leadership, and relationships among teachers, were the working conditions most strongly associated with student achievement gains,.

In an important conceptual shift, Ferguson with Danielson (2014) hypothesized that some working conditions are more directly enabling of teachers' effectiveness in the classroom; more specifically, those conditions that describe social resources and enable motivation are posited

to have greater effects on classroom behavior, in part as a function of emotional well-being and stress, as suggested in the Roeser et al. model (2012). Similarly, after more than a decade of tracking schools in Chicago, Bryk (2010) concluded that classroom learning "depends in large measure on how the school as a social context supports teaching and sustains student engagement" (p. 24). In some education scholarship, these school-level conditions are bundled under school leadership and studied through a lens of effects of school leaders. Consistent with this focus, Robinson, Lloyd, and Rowe (2008) conducted a meta-analysis of 27 peer-reviewed studies examining school leadership with student outcomes. They found that the strongest predictors of achievement were not leadership practices that aimed to inspire teachers but those that were directly supportive of their effectiveness in the classroom, particularly quality of instruction.

Importantly, one mechanism that is posited to mediate the influence of emotional well-being and stress on qualities of teacher-student interaction is teachers' capacity to be flexibly attentive to students' cues during ongoing classroom interaction. These capacities for teachers to read and respond to varying students' behavior, to shift attention across multiple sources of information, and to maintain cognitive flexibility to solve problems and project potential solutions have all been identified as coalescing around a core of self-management skills that enable smooth and effective interactions (see Roeser et al., 2012, for summary). They also are highly consistent with the line of research on teachers' observation and cue-detection skills described earlier. Perhaps not surprisingly, as practitioners and scientists have designed interventions to bolster teachers' emotion-management capacities and counteract the harmful effects of stress, they have turned to the literature of tools related to mindfulness-based stress reduction (MBSR; Mind and Life Education Research Network, 2012) both because of the success of MBSR and related contemplative practices (e.g., yoga) for promoting health and reducing stress-related problems and because these practices are intended to promote awareness, empathy, cognitive flexibility, and capacity to engage socially (Abenavoli et al., 2013; Jennings & Greenberg, 2009; Jennings et al., 2013; Kemeny et al., 2012; Zelazo & Lyons, 2012).

Over the last decade, the role of teachers' emotional well-being in enabling their effective interactions with students has been clearly demonstrated in evaluations of interventions using MBSR and related contemplative practices with teachers (see Abenavoli, et al., 2013; Jennings et al., 2013; Kameny et al., 2012). In a number of randomized controlled trials, training teachers in mindfulness techniques or yoga has resulted in dramatically lower levels of stress and negative mood, increased skills in cue detection and cognitive flexibility, and more positive qualities of interactions with students (Jennings et al., 2013; Kemeny et al., 2012). In a detailed random assignment evaluation of an 8-week (42-hour) meditation-oriented training program, Kameny and colleagues (2012) reported the typical drop in teachers' self-reported stress and negative mood but also showed enhanced performance on direct assessments of emotion recognition, empathy-related cognitions, and an assortment of physiological indicators of lowered stress. Interestingly, a recent report of results from an intervention designed to promote teachers' cue-reading skills in interactions with children with whom they report high levels of conflict and stress demonstrated that teachers exposed to the treatment not only increased the sensitivity of their behavior toward students but also showed drops in cortisol levels (Hatfield & Williford, 2014).

In sum, a body of evidence, increasingly drawn from causal design studies, demonstrates strong linkages between and among the developmentally salient features of teachers' behavior experienced by children (e.g., sensitivity), teachers' skills in reading and interpreting children's behavioral cues, and a cluster of cognitive and self-regulatory mechanisms. The further expansion and deepening of this literature has tremendous promise not only for understanding the determinants of classroom processes that promote learning and development but for training and support of the teacher workforce (MetLife, 2002).

ACTIVATING THE CLASSROOM AS A SETTING FOR DEVELOPMENT

As has been emphasized throughout this chapter, the educational and developmental salience of the classroom setting is in no small part a function of the qualities of teachers' interactions with students. Whether classroom processes are conceptualized in terms of broad domains such as responsivity or more narrow-band practices related to classroom management or language stimulation, or assessed using observation or student self-report, the last decade of research has produced a compelling body of evidence on the nature, value, and determinants of teacher-student interactions. It should come as no surprise, then, that there is also considerable research and development activity related to the design and evaluation of interventions to improve the quality of teacher-student interactions and thereby activate the classroom as a setting that promotes learning and development. The next

sections present evidence for the impact of such treatments on classroom processes and student outcomes, starting in early education settings and extending to high school.

Need for Professional Development Targeting Effective Teacher-Child Interactions

The quality of teachers' interactions with children is a prime target for intervention for several reasons. First, as noted throughout, the nature and quality of teachers' interactions with children are consistently linked with children's development. This is as true within early education and primary grades (Bridges, Justice, Hogan, & Gray, 2012; Curby et al., 2009, 2010; Dickinson & Brady, 2005; Guo, Piasta, Justice, & Kaderavek, 2010; Jackson et al., 2006; McCartney et al., 2007) as it is from late elementary through high school (Allen et al., 2011; Kane et al., 2014). Second, large-sample standardized observations of PK–12 classrooms from across the nation suggest that students at all grade levels and economic backgrounds are likely to experience teacher-child interactions of mediocre to low quality (Justice et al., 2008; Kane & Staiger, 2012; D. Phillips, Gormley, & Lowenstein, 2009), particularly in relation to cognitive demands placed on students' responses and the feedback provided for students to perform analytic and reasoning skills and activities (Kane et al., 2014; Pianta et al., 2007). The limited use and intensity of practices such as offering stimulating conversational language, encouraging conceptual understanding, and providing rich feedback is particularly concerning, given evidence that these features of interaction are consistently linked with children's development of early academic and language skills (Howes et al., 2008; S. M. Jones et al., 2010; Mashburn et al., 2008) and in students' engagement in the upper grades (Allen et al., 2011, 2013; Wang & Holcombe, 2010). And third, assessments of teacher-student interactions increasingly are used as components of states accountability frameworks in early education (Hamre, Goffin, & Kraft-Sayre, 2009; Maxwell & Tout, 2012; Sabol et al., 2013) and in teacher performance accountability assessments in grades K–12 (Kane et al., 2014). Therefore, interventions designed to improve interactions are likely to be of considerable interest and are an opportunity to evaluate mechanisms of influence on salient proximal processes in classrooms and their subsequent impact on students over time.

Not surprisingly, and perhaps as a result of the lackluster impacts of standard-fare professional development (PD) interventions to promote more effective teaching (Early et al., 2007), an emerging trend for PD is to focus on teachers' actual classroom practices and behaviors, using a variety of behavior change techniques, such as coaching, modeling, and rehearsal practice. In support of this shift, meta-analytic findings of effects related to general forms of such interventions suggests that training focused on teacher skills improves both the competency of child care providers ($d = .45$, $SE = 0.10$) and children's outcomes ($d = 0.55$, $SE = 0.30$), and that skills training is most effective when there is a specific behavioral focus (Fukkink, 2007). Other research demonstrates that targeting teacher-child interactions can be effective in producing improvements in their implementation of instructional activities and socio-emotional interventions (Domitrovich et al., 2009; Hsieh, Hemmeter, McCollum, & Ostrosky, 2009; Landry et al., 2009; Powell, Diamond, Burchinal, & Koehler, 2010; Raver et al., 2008). Although the results of both primary studies and meta-analyses point out the value of focusing on teachers' skills in the classroom, the field is only beginning to explore specific features of these PD approaches responsible for impacts and the manipulable features of each treatment (e.g., dosage) that might inform designing uses at scale (Aber et al., 2011).

Coaching and Improvement of Teacher-Student Interaction in Early Education Settings

Sheridan and colleagues (2009) suggested that studies of PD interventions be designed to better understand the dynamic processes underlying intervention effects. Desimone (2009) similarly suggested that studies should attempt to identify the mechanism responsible for any detected effects. Such a focus requires a theory of why a certain input to teachers would produce certain intended outcomes for teachers and children. In formulating one approach to coaching teachers, consistent with the prior discussion on observation and cue-detection skills, it has been hypothesized that change in teachers' interactive behaviors could be improved by building skills in detecting effective teacher-child interactions through video analysis of others' or their own interactions (Downer et al., 2012; Hamre et al., 2012; Toth, Pianta, & Erickson, 2011).

This hypothesis draws from the literature cited earlier, in which the benefits of coaching might arise from the development of observation skills (Feldon, 2007). In complex classroom settings with high information processing demands, teachers' capacities for enacting effective interactions are dependent in part on their skills in detecting moment-to-moment cues within the flow of interaction as it unfolds in real time (Hamre, Downer, & Jamil, & Pianta, 2012), and such skills may also help lower teachers' stress

and emotionally reactive responses to classroom situations (Roeser et al., 2012). This capacity for processing information must be deployed efficiently and used flexibly to guide and respond to local circumstances (Feldon, 2007; Schank, 1997; van Es & Sherin, 2002). The MyTeachingPartner (MTP) coaching model (Allen et al., 2011; Pianta et al., 2008) was designed specifically to focus teachers' attention on and analysis of moment-to-moment interaction cycles and build observation skills by engaging in guided analysis of video clips of their own interactions and access to exemplars of positive or effective indicators in the form of annotated video clips.

In the first evaluation of MTP coaching, teachers assigned to coaching showed more positive growth across a number of teacher-child interaction features, with effect sizes (*d*) ranging from .77 to .97 (Pianta et al., 2008). And for teachers in classrooms in which the majority of the children's family income fell below federal poverty guidelines, coaching had a stronger effect on improvements in both emotional and instructional features of teacher-student interaction than was the case in the entire sample. A series of follow-up studies using the original pre-K MTP sample examined features of access, use, and engagement of teachers with the website and coaching as well as impacts on child outcomes (Downer, Kraft-Sayre, & Pianta, 2009; Hamre et al., 2010; Mashburn et al., 2010; Pianta et al., 2013). One follow-up showed that early career teachers who spent more time watching themselves on video also showed greater improvements increased growth in interactions (Pianta, Mashburn, Downer, Hamre, & Justice, 2008). With regard to impacts on child outcomes, for children in classrooms in which teachers received coaching, greater gains were observed for literacy skills and vocabulary, and they demonstrated lower levels of problem behavior (Downer, Jamil, Maier, & Pianta, 2011; Downer, Pianta, et al., 2014; Hamre et al., 2010; Mashburn et al., 2010). Overall, these results from that initial MTP evaluation suggested that exposure to structured viewing of teacher-student interaction, using video, was a particularly helpful feature of professional development for improving interaction and children's learning, confirming the hypothesis of the importance of teacher observation skills,

As part of the National Center for Research in Early Childhood Education (NCRECE) program of research on professional development and preschool quality, MTP coaching was the focus of a more recent and larger-scale experimental evaluation. The NCRECE study of MTP enrolled nearly 500 teachers in preschool programs for 4-year-olds from 10 sites across the country, randomly assigned to MTP coaching implemented by local coaches or a "business as usual" control group. In the intent-to-treat evaluation of MTP as implemented in the NCRECE study, coaching produced substantial positive impacts on teachers' instructionally focused interactions with children (Downer et al., 2012). Teachers receiving coaching were observed to use more strategies that facilitate children's higher-order thinking skills, provide more intensive and frequent feedback, and support children's language development, with effect sizes (*d*) ranging from .51 to .69. Moreover, during the year in which teachers received coaching, children in classrooms in which teachers received coaching were observed to exhibit more multiword language behavior than children in control classrooms, while in the subsequent postcoaching year, children whose teachers had received coaching demonstrated higher levels of inhibitory control in direct assessments. However, treatment effects were not detected for directly assessed literacy or language skills, unlike the prior study of MTP coaching.

Controlled experimental evaluations of other forms of coaching focused on teacher-student interactions in early education settings confirm quite clearly that interactions are highly sensitive to feedback from coaches and to models of effective behavior with children (Bierman et al., 2008; Domitrovich et al., 2009; Landry et al., 2009). Moreover, many of these studies also demonstrate that when teachers are provided with feedback and modeling on behaviors related to a targeted instructional activity or child outcome, not only are there impacts on interaction, but there are also effects detected for improved child outcomes, whether academic or behavioral in nature (Allen et al., 2011; Mashburn et al., 2013; Neuman & Cunningham, 2009; Reeve et al., 2004; Powell et al., 2010; Reyes, Brackett, Rivers, White, & Salovey, 2012). Collectively, these results confirm a causal role for teacher-child interaction and children's learning and development (particularly in the context of targeted behaviors or curricular activities) and also demonstrate the surprising sensitivity and responsiveness to intervention and feedback of developmentally salient features of teacher-student interaction. Finally, the suggestion that impacts on teacher behavior and in turn on student outcomes may in part be a function of increases in teachers' knowledge of and skill in observing interactions suggests a pathway forward for further research on mechanisms of impact and increased efficiency of interventions.

Coaching and Improvement of Teacher-Student Interaction in the Upper Grades

As children age through the grade levels, they become increasingly responsible for organizing their own responses

to the opportunities provided in the classroom setting (Allen et al., 1994; Connell & Wellborn, 1991; Deci & Ryan, 1985; Pianta & Allen, 2008). In contrast to the younger grades, in which direct inputs from teachers' instruction related to knowledge and skill development are critical for promoting children's learning and social gains (Bierman et al., 2008; Domitrovich et al., 2009; Piasta et al., 2012), in the middle and secondary grades, the value of the classroom setting for promoting learning is increasingly a function of promoting students' experiences of autonomy, their interpretation of the material to be learned as relevant, and the integration of peer relations in the process of learning (Allen et al., 1994; Wang et al., 2012; Wang & Holcombe, 2010). Thus, interventions that promote teachers' influence in this process must be tailored to acknowledge the manner in which teacher-student interactions can facilitate students sense of autonomy and relevance of the material and recruit the influence of peers.

Teacher-Student Interactions and Peer Relations

Particularly at the secondary level, teachers perceive their primary function as imparting academic content rather than facilitating good social relationships with peers (Barber & Olsen, 2004). Teachers' behaviors toward students should theoretically relate to students' behaviors toward one another in that classroom (S. M. Jones et al., 2008); however, empirical tests of this relation are limited. Literature involving elementary school youth suggests that teachers promote students' good peer interactions in the classroom by having warm relationships with students and using instructional practices that sensitively engage students. Effects of teachers' interactions with students on peer-peer interactions may be due to a modeling effect for peers to follow in their treatment of each other (Mikami, Lerner, & Lun, 2010). In fact, in experiments (White, Jones, & Sherman, 1998) and in naturalistic designs (Hughes, Cavell, & Wilson, 2001), peers increased in their personal liking of a target child who is praised by the teacher. Peer perceptions that a teacher had a good relationship with a child also predicts subsequent increases in their acceptance of that child (Hughes & Kwok, 2006). And when teachers are observed to exhibit warm relationships with students, social conversation among peers increases (Rimm-Kaufman, La Paro, Downer, & Pianta, 2005).

It is also the case that instructional practices that sensitively engage students also promote positive classroom peer interactions, not only through modeling but also by conveying that all students are valued, thereby diminishing a social hierarchy (E. G. Cohen & Lotan, 1995; Mikami et al., 2010). Early elementary school teachers' practices that cater to students' diverse learning needs (Donohue, Perry, & Weinstein, 2003) as well as those that dismantle academic status hierarchies (Mikami, Griggs, Reuland, & Gregory, 2012) each predicted students having better peer relationships over the course of a school year. And the widespread practice of cooperative learning—mostly though interventions that engage all students across diverse academic backgrounds in particular academic activities—has been associated in meta-analysis with children's positive interactions with peers (Roseth et al., 2008). And in a middle school sample, Mikami, Boucher, and Humphreys (2005) found that training teachers in a cooperative learning intervention improved student self-report of positive peer relationships in the classroom.

The role of classroom experiences in promoting positive peer relations may be particularly important in adolescence, as features of classroom experience with peers is apparent in links from peer relations in middle school to verbal aggression, antisocial behavior, and greater anxiety into the 20s (Allen, Chango, et al., 2012; Chango, McElhaney, Allen, Schad, & Marston, 2012; Szwedo, Mikami, & Allen, 2012). Teenagers' experiences of peer rejection, which can heighten vulnerability to anxiety and depression, can be reduced in classrooms in which teachers are sensitive and supportive. (Chango, et al., 2012). When examined together, the combination of observed autonomy and connection with peers in early adolescence provides the strongest prediction of global adjustment in early adulthood. The importance of teachers' roles as facilitators of peer relations through their interactions in the classroom setting, often clash with their views of their roles as managers (MetLife, 2011) or with school-level pressures for test-score outcomes as part of accountability frameworks (Clotfelter, Ladd, & Vigdor, 2007), creating a potential misalignment between teachers' and students' aims in secondary education that is confirmed in student reports of the classroom (LAUSD, n.d.) and in observations (Kane et al., 2014). In one random-assignment study of coaching teachers focused on improving interactions, Mikami et al. (2011) noted that a substantial side benefit of improved behavior of teachers toward students was a rise in positive interactions noted among peers.

Interaction-Focused Coaching and Student Academic Achievement

Allen et al. (2011) designed an approach to coaching teachers in secondary grades that specifically focuses on enabling autonomy, increasing relevance, and integrating peers as resources for teaching and learning in the context of improving the overall nature and quality of

teacher-student interactions. This coaching program did not target instruction or knowledge in specific content areas but rather focused on enhancing the motivational and instructional qualities of teachers' ongoing, daily interactions with students in a manner that applied to teachers across a range of content areas. The first experimental evaluation indicated significant promise at the secondary grade level. In a randomized controlled design across several rural and small-town school districts, coaching focused on interactions with students yielded 9-percentile-point gains in end-of-year standardized achievement tests classes relative to control classes (Allen et al., 2011). Coaching significantly improved teachers' sensitivity toward students and behavioral indications of their understanding and awareness of students' perspectives, as well as greater use of instructional strategies focused on conceptual understanding and analysis rather than performance of rote activities. Interestingly, results suggest that the impact detected on student outcomes was mediated in part by higher levels of student motivation and engagement (Allen et al., 2011).

However, this initial study had several important limitations. The largest limitation was significant attrition (with 33% of teachers dropping out postrandomization). Other limitations to the generalizability of the study included implementation with a primarily rural population of schools, teachers, and students, which may not be comparable to the challenges facing large urban school districts (Provasnik, Kewal, Ramani, et al., 2007). Equally importantly, the initial version of the program (a 1-year, relatively intensive intervention, requiring rapid ramp-up) was not optimally suited to the structure and needs of most schools, in which teachers take time to form trusting relationships with coaches and have relatively little time during their school week to devote to training activities. Perhaps reflecting this, effects detected on student achievement from the initial intervention study were seen only in the year following completion of the intervention rather than during the intervention itself (Allen et al., 2011), suggesting a relatively gradual uptake process.

The need for replication of initially promising programs, especially of challenging interventions implemented in complex systems, has been long and widely recognized (Forman et al., 2013), so further work evaluated this interaction-focused coaching model in an urban setting with primarily high school students (Allen et al., 2012). Two notable modifications to the original coaching program were made. First, the coaching program was decreased in intensity, such that the average teacher participated in five to six coaching cycles per year (as compared to 10 to 12 cycles targeted in the original intervention). At the same time, the intervention was extended to take place over a 2-year period instead of a 1-year period. This allowed more time for teachers to form relationships with their coaches and also allowed coaching to extend across two different classrooms of students for each teacher across the 2 successive years. This more distributed approach to coaching was considered more suitable to the needs and demands of a large, stressed, urban school district serving a high proportion of students in poverty. Evaluation of this modified interaction-focused coaching model demonstrated clear and significant benefits, this time during the first year of treatment, on students' state standardized test scores as well as a range of indicators of observed and student-reported engagement (Allen et al., 2012).

Of considerable importance in these two controlled evaluations of interaction-focused coaching on secondary students' performance on state achievement tests was not only the increase in the quality of teacher-student interactions and the nearly 10-percentile-point benefit attributed to coaching, but that achievement gains were equal in magnitude across content areas (i.e., math, language arts, science, history). That is, coaching teachers to improve features of interaction not specific to any content or learning target caused increases in achievement equally across all four different content domains taught in secondary school classrooms. Features of teacher-student interactions changed through coaching—regard for students' perspectives, conceptually focused instruction—were developmentally salient for students learning a broad array of information, suggesting perhaps that teachers' knowledge of adolescent development and skills in interacting with adolescents are at least as important to the developmental value of the classroom as is their knowledge of the content they are teaching (NCATE, 2010; NEA, 2010).

Interaction-Focused Coaching and Racial Disparities in Discipline

Persistent disparities in school discipline have been documented for a range of groups including males, academically underperforming students, low-income students, and students who qualify for special education services (e.g., Losen & Orfield, 2002; Skiba et al., 2014; Sullivan & Bal, 2013; Weinstein, 2002). Whereas each of these group trends is important to consider on its own, a phenomenon that cuts across groups is of special concern. Namely, African-American students within all of the groups receive a disproportionate number of discipline sanctions. Said differently, being African American places a student at risk for receiving a discipline sanction in school no matter

his or her gender, socioeconomic status, special education placement, or achievement level (Skiba et al., 2014).

In most middle and high school classrooms, teachers typically have the right to send a student out of their classroom by issuing a disciplinary referral to an administrator. These are commonplace practices; in one study that reported 2,000 referrals issued in a single semester in a school with 3,000 students, 70% of these referrals were issued to African-American students, who comprised 38% of the student body (Gregory, Nygreen, & Moran, 2006); disproportionality in out-of-school suspensions can be explained by the disproportionality in these classroom-initiated referrals (Skiba et al., 2014). In the case of special education referral and placement, disproportionality is evident throughout the grades and is identified most closely with what are termed *high-incidence disabilities*, which include learning disabilities as well as emotional or behavioral problems that interfere with learning (Sullivan & Bal, 2013). For both disciplinary infractions and high-incidence special education classification, teacher referral is a critical, if not necessary, factor in determination.

Three strands of research suggest the importance of understanding teachers' actions in the context of the classroom as a setting for proximal processes when examining disparities in disciplinary actions or special education referrals. First, a differential behavior hypothesis asserts that African-American students have higher rates of misconduct than other groups and would, therefore, be referred more often. Studies have not found support for this hypothesis based on minimal differences in student self-reported behavior, perhaps best exemplified in a nationally representative sample showing few and generally small differences in self-reported unsafe behavior across racial groups compared to the racial discrepancy in discipline sanctions (Dinkes, Cataldi, & Lin-Kelly, 2007; Gregory & Weinstein, 2008). Second, accruing evidence shows that students are issued referrals for reasons in which an adult interprets a behavior as misconduct; Gregory and Weinstein (2008) found that African-American students were more likely than White students to be referred for reasons related to perceived defiance, such as inappropriate language, insubordination, and an unwillingness to cooperate. In a recent, longitudinal study with school records from across Texas school districts, more than three-quarters of African Americans were issued sanctions for discretionary reasons (76.7%) compared to less than half of White students (47.9%; Fabelo et al., 2011), even when racial groups were equally represented in mandatory removal from schools for serious violations (e.g., illegal use of a firearm). And when accounting for a range of risk factors associated with discipline, multivariate analyses showed that African-American students were more likely than White students to receive a discretionary discipline sanction but less likely to receive a mandatory one (Fabelo et al., 2011). A third line of research on adults' interpretation shows that African-American students receive harsher sanctions for perceived misbehavior compared to White students. Even after controlling for their own ratings of student behavior, teachers tend to issue discipline referrals more to African-American than White students (Bradshaw, Mitchell, O'Brennan, & Leaf, 2010; Horner, Fireman, & Wang, 2010), and African-American students are more likely to be issued out-of-school suspension for their first infraction (Fabelo et al., 2011).

Consistent with the larger body of research on the value of teacher-student interaction in fostering a classroom setting conducive to student learning and development, interventions that improve teacher-student interactions are also effective in eliminating the racial discipline gap. For example, Gregory et al. (2014) reported an evaluation of the Allen et al. (2011) coaching that focused on teachers' providing clear routines, fair implementation of rules, and proactive monitoring of behavior and that fostered respectful relationships that recognized students' needs for autonomy, leadership, relevancy, and peer interactions. After the first year of the intervention, coaching improved teachers' interactions with students, as noted earlier, and also reduced levels of disciplinary referrals for all students and lowered the odds that African-American students were referred for disciplinary reasons. Gregory and colleagues then followed those teachers into the subsequent year to examine effects with a new group of students. Analyses took into account student (e.g., gender, achievement), teacher (e.g., race, years of teaching experience), and classroom (% African American) factors, showing that teachers who received coaching used fewer disciplinary referrals overall and especially with African American students. African-American students in the control-teacher classrooms were over two times more likely to be issued a referral compared to non–African American students, a disparity that was significantly reduced for teachers receiving coaching that focused on increasing the value of their interactions with students.

Disaggregating Components of Coaching and Their Impacts on Teacher-Student Interaction

As described, interventions that directly target teacher-child interactions can be effective in producing improvements across a range of practices, both instructional and social (Domitrovich et al., 2009, 2012; Hsieh et al., 2009;

Landry et al., 2009; Powell et al., 2010; Raver et al., 2008). Yet for the most part, investigators are only beginning to explore mechanisms responsible for impacts (aside from the focus on interactions and promotion of labeling and observation skills) and the manipulable features of treatment (e.g., dosage etc.) that might inform designing uses at scale. To the extent that interaction skills-focused coaching appears to have some empirical basis as effective, studies that have evaluated effects of coaching on teachers typically have examined dosage as a feature of fidelity, with results demonstrating the importance of dosage but providing little in terms of effective levels or thresholds. In one example, Landry et al. (2009) varied dosage of a coaching intervention to reveal that greater dosage was important for elevating skills of teachers who were less well trained. In another, Ramey and Ramey (2008) reported that dosage was a key moderator of treatment effects in large-scale professional development efforts. An unanswered question in the coaching literature is the minimal dosage of specific components of coaching needed to effect change in teacher practice as well as the upper thresholds for dosage after which more training has diminishing returns.

In a follow-up study to evaluations of interaction-focused coaching reported earlier for early childhood education teachers (Downer, Ruzek, et al., 2014), a series of treatment-on-the-treated analyses examined associations of dosage of exposure to coaching components (feedback, video) with qualities of their interactions and, further, the extent to which the amount of exposure to feedback or videos with a focus on a certain domain of interaction would relate to increases in quality of their interaction in that domain and not to other areas of interaction.

Coaching usually takes place in cycles of engagement between teacher and coach (Sheridan et al., 2009), which typically include some form of feedback and coaching input. Results of analyses indicated that all three domains of teacher-child interaction that were the focus of the coaching program (instructional, emotional, organizational) were sensitive to dosage of exposure in terms of number(s) of coaching cycles to which the teacher was exposed (Pianta et al., 2014). However, improvements in teachers' instructional and organizational behaviors were associated with increases in the number of coaching cycles only up to a point; after roughly seven cycles, increases in organizational support leveled off, while the same pattern was observed for instructional support after twice as many cycles. Teachers' emotionally supportive behaviors increased steadily with an increasing number of cycles.

Findings that more coaching cycles tend to result in greater change over time are consistent with prior results (Pianta, Mashburn, et al., 2008) and evaluations of other coaching models in preschool programs (Landry et al., 2009; Powell et al., (2010) as well as the literature on mental health consultation (Domitrovich et al., 2012; Durlak et al., 2011). The results suggesting that a teacher's behavior may not change appreciably after a certain quantity of coaching have not been reported in other studies. If this type of curvilinear association were to be replicated, an important aim for further research could be to determine the reasons for this effect; this may suggest a need for better timing and pacing of coaching inputs to teachers so that learning can be consolidated before additional progress can be made, or it may be a sign of some ceiling effect on teacher progress related to teachers' own personal histories or characteristics.

In terms of the specific components of coaching, hypotheses were supported regarding the importance of focused feedback or watching video exemplars, both intended to promote observation and analytic skills, but in different ways for different domains of interaction. Feedback that called teachers' attention on their own instructionally focused interactions or that requested teachers' observation and analysis of their instruction was related to observed increases in all areas interaction in the classroom. Apparently, teachers' exposure to feedback focused on instructional behaviors had a broad-spectrum impact, contributing as well to improvements in emotionally supportive behaviors and classroom management. It may be true that the learning that makes it possible to change instruction (e.g., seeing and understanding feedback loops, stimulating language and conversation) transfers into other areas of interaction rather easily. Interestingly, Piasta et al. (2012) reported that this sort of cross-domain transfer effect, when teachers learn a new skill in one area of classroom interaction and improvements are seen in a wide variety of other areas, may occur under conditions in which the phenotypic skill change may in fact be the consequence of acquiring proficiency in a competence (such as observation) that supports multiple skills. If there is some broad-spectrum effect, this would suggest that one possible way to make coaching, which is often described as an expensive and inefficient intervention (Kane & Staiger, 2012), more efficient might be to focus coaching dosage more exclusively on instructional behaviors.

Summary of Coaching Impacts on Teacher-Student Interaction

The findings reported herein describing the impact of coaching focused on teacher-student interactions show

the widespread benefits of such interventions. Although primarily describing evaluations of a particular model of coaching, the consistency of results across samples and across grade levels aligns well with other rigorous evaluations of other coaching models focused on teacher-student interaction. Across all these models, the core components of each treatment approach involved providing teachers with feedback (e.g., information, video, probes for analysis) from a coach, based on that coach's observation of the teachers' actual interactions with students in their classroom. This feedback takes place in periodic cycles across an academic year or even longer. Some models include additional didactic components (Bierman et al., 2008; Piasta et al., 2012) and more or less emphasis on behavior related to a specific content area of instruction, classroom management, or curriculum (e.g., Clements & Sarama, 2008). The variation across models is substantial in terms of the specificity and concentration of feedback on interactions, in terms of dosage and cycles of feedback, and in replicability and standardization of the coaching model. Given the now-almost-ubiquitous use of coaching as a means of improving teacher performance, rigorous studies of replicable and scalable coaching models, and the components responsible for impact, have a critical role to play in efforts to promote student learning and development. Given this context, the experimental studies on interaction-focused coaching suggest a number of tentative summary points for further empirical examination.

Clearly, providing teachers with structured, focused feedback on their interactions with students leads to improvement in a range of features, including sensitivity and responsiveness as well as aspects of cognitive stimulation. The regularity with which coaching produces changes in features of teacher-student interaction suggests how malleable these interactions can be and how responsive to a range of contextual supports. These features of interaction, in short, are apparently not a function of some matrix of fixed personality traits but rather properties of a rather dynamic system of contextual and personal factors. A second tentative conclusion concerns the impacts of improved teacher-student interactions on student outcomes. The evidence from the early childhood literature indicates greater impact on proximal outcomes, such as self-regulation and observed language skills, while for secondary students, improving teacher-student interactions appears consistently related to academic and behavioral gains. In short, there does appear to be some empirical support for the contention that teacher-student interactions have broad-spectrum value for student learning and development. However, such conclusions have to be tested against far more rigorous standards for domain generality and domain specificity, on both the interactions and the outcomes sides of the equation. Further decomposition of coaching components and examination of dose-response effects, while promising, have yielded only suggestive results indicating the potency of feedback for teachers that calls attention to key features of interactions, again confirming indications of the importance of observation skills and cue detection as mediators of interaction quality.

Overall, it is apparent that this key proximal process, teacher-student interaction, has considerable salience for development and can be shaped by structured inputs that increase its value for deflecting developmental trajectories toward more positive outcomes. Given this larger conclusion related to the linkage between education and developmental processes relevant for adaptation, the chapter concludes in the next section by examining larger trends that will shape this literature, and its promise, in the coming years.

FUTURE DIRECTIONS: DEEPENING KNOWLEDGE ON THE LINKS BETWEEN CLASSROOM PROCESSES AND DEVELOPMENT OF CHILDREN AND YOUTH

This chapter has focused on the value of classroom processes for the development of children and youth, in particular features of teacher-student interaction as a core mechanism for transmitting that value, in the larger context of understanding the intersection between education and human development. A decade or more of basic descriptive studies, research on the correlates and determinants of interaction quality, and controlled evaluations of interventions to promote the quality and impact of teacher-student interactions have led to pronounced gains in knowledge. Gaps exist in all these domains—description, determinants, and intervention. The extent to which another decade of research yields substantial gains in knowledge will depend in part on three larger trends affecting the nature and quality of science in this area: funding for research on classroom processes; establishing and supporting programmatic the developmental science of applied practice; and harnessing the scientific and applied potential of studying biological processes as they relate to classroom processes and educational outcomes.

Funding Science at the Intersection of Education and Human Development

In the past decade, a considerable investment of largely federal research and development funds has been distributed to a range of scientific activities at the intersection of education and human development. Given the source of these funds in the Department of Education's Institute of Education Sciences, the Department of Health and Human Services' National Institutes of Health, and the National Science Foundation, the focus of activities on producing evidence for policies, programs, and practices that improve educational and developmental outcomes for children and youth is not surprising. Scanning recent reports from these agencies (e.g., IES, 2013) as well as policy documents that are used to align funds to aims (NCES, 2014) reveals notable concerns in the extent to which the investments of research funds have delivered improved outcomes for children and youth.

NIH, IES, and NSF all adhere to a pipeline conceptualization of inquiry as moving from basic description and exploration, through development of interventions, to early-stage efficacy evaluations, and on to larger-scale evaluations of more widespread implementations at a population level (IES, 2013). In each agency, the aim is to produce knowledge, in the form of theory or technique, that is relevant to improving the outcomes of, in this case, children and youth. Schools and schooling factor differently into the design of these agencies portfolios in a way that shapes the resulting research products. For example, within various branches of NIH, school contexts and schooling processes are involved largely as sites for treatment delivery or as locations from which to collect data, all in the service of addressing health or mental health outcomes typically conceptualized and assessed as somewhat static properties of individuals. In the NIH branches, relevant outcomes include diagnosis and assessment of psychopathology, socio-emotional, or behavioral disturbances as presented in nosologies or in continuous form, relevant health outcomes (e.g., drug abuse), and to a lesser or secondary extent attainment or achievement. Funding mechanisms are often disorder-driven and focused on isolating cause and effect in highly controlled trials.

In IES, schools are the locus of inquiry, inputs, and outcomes. Not surprisingly, in nearly all IES calls for proposals, the outcome or aim of the scientific activity to be funded is an outcome assessed in school-age children and youth, most often operationalized as performance on standardized tests. In many ways, IES funding is yoked to the standardized end-of-year assessments of state standards. In IES and NSF, performance on learning and achievement-related assessments is considered the primary aim of nearly all scientific work, with social and behavioral conditions or outcomes viewed as secondary (IES, 2013). For example, of the more than a dozen topical areas that are the focus of IES funding, a handful concern social or behavioral outcomes and only one focuses on the "social and behavioral context for learning."

Two fundamental concerns arise from this analysis and are relevant for the present discussion. First, there are tremendous gaps in integration at the level of child and youth outcomes. That is, research activities tend be organized around studying or producing outcomes in the achievement *or* socio-emotional domains; consequently, this may lead to distortions in the knowledge base regarding how performance in various domains of development may be linked (and may also be a key to intervention success). This is a particular risk with the IES portfolio, which has an almost uniform focus on standardized achievement assessments as the defined target of research. However, the NIH-related portfolio shows increasing signs of fragmenting in this way as well. With recent indications that school-based interventions that have strong value for youth's social and emotional experiences of classrooms produce gains in achievement (Aber et al., 2011; Allen et al., 1994, 2011; Domitrovich et al., 2012; Durlak et al., 2011) and that school attainment based on achievement appears to be one of a set of leading indicators of problem behavior trajectories (NCES, 2014; Office of Head Start, 2011; Pedersen et al., 2005; Rudasill et al., 2010), it may be important for funding agencies to more explicitly and intentionally broaden and balance the ways in which outcomes for children and youth are included and prioritized in their funding mechanisms and aims.

A second and perhaps more important gap is the lack of a basic science focus, in any funding agency, on the processes and mechanisms of school settings as a focus of study in their own right. In other words, there is little or no funding available for science that aims to understand the fundamental mechanisms related to schooling processes as the actual outcome of a research activity. If, as suggested throughout this chapter and in scores of policy documents, teachers' behaviors with students cause student performance to improve (however weakly or indirectly), it would appear that the basic science devoted to describing, producing, and improving such behaviors would be a top priority of funding agencies. This is not the case. At present, there are virtually no federally supported research mechanisms that promote rigorous basic science in teacher preparation, even when almost a half

million new teachers enter the workforce each year from university-based teacher preparation programs (Harris & Sass, 2011; Henry, Kershaw, Smith, & Zulli, 2012; Loeb et al., 2012; NEA, 2010; Ronfeldt, 2012) and large state agencies are tasked with certification, accreditation, and standards monitoring for this workforce sector.

Moreover, there are no funding mechanisms and hence no extant studies that track teachers longitudinally, either from selection into the profession and through training or throughout various points in their careers. This is the case despite the fact that teaching is the single largest professional group in the United States; teachers leave the profession at a very high rate (at considerable economic costs and at some costs to students and schools); and factors such as burnout, fatigue, and job-related health and mental health concerns are listed among the more frequent reasons for leaving (Bauer et al., 2006; Jennings & Greenberg, 2009; MetLife, 2002). Moreover, we know very little about the development of teachers' competence in the classroom, what skills can be trained or the conditions under which skills are enhanced or eroded over time, or the personal and contextual forces in teachers' lives that are involved. Given recent and consistent evidence that interventions focused on teachers' own personal well-being (such as mindfulness or other contemplative practices) have pronounced benefits on their well-being, on qualities of their practices in the classroom, and on outcomes for the children they teach (Bauer et al., 2006; Jamil et al., 2014; Jennings et al., 2013) this knowledge gap is remarkable yet may be a significant impediment to the very aims of funding agencies to support research activities that improve the lives of children and youth.

THE DEVELOPMENTAL SCIENCE OF APPLIED PRACTICE IN SCHOOLS

Any discussion of schools, schooling, and education at some point becomes filtered through a lens of application—how knowledge or technique can be applied in practice in real-world settings like classrooms or can drive policies in ways that more effectively or efficiently shape those practices or intended outcomes (Aber et al., 2011; Harris & Sass, 2011; Rockoff et al., 2011). Unfortunately, as well described by Aber et al. (2011) in a recent paper outlining the conditions through which the study of schooling and human development can be enabled, the dichotomization of research and practice remains a major conceptual and pragmatic impediment to constructing programs of research relevant to both knowledge generation and its application to solve social problems. Given the architecture of funding mechanisms outlined earlier, with one major source aimed at discovery and another at application and impact, it should come as no surprise that much of research at the intersection of education and human development is dismissed by practitioners or policymakers as irrelevant for reasons related to either their lack of attention to the realities of school settings and therefore lacking in practical utility (see Aber et al., 2011) or their being black box impact studies (randomized controlled trials or econometrics) that are high on methodological rigor and technique but insufficiently descriptive of the processes and mechanisms responsible for the impacts being evaluated or detected (Taylor & Tyler, 2012).

Historically, the linkage between research and practice has often been addressed by efforts or paradigms that shape the output or translation/dissemination of investigations (Tseng, 2010). The assumption of many of these efforts is that the best way to overcome the dichotomization of research and practice is for investigators to report findings in formats and venues relevant to practitioners or for practitioners to select from proven-effective models and implement them with fidelity. These two, admittedly oversimplified, patterns of linkage are exemplified by the kind of brief reports often used to disseminate findings or resources, such as the What Works Clearinghouse (http://ies.ed.gov/ncee/wwc/default.aspx). In both patterns, there is an underlying assumption that evidence is revealed under highly controlled circumstances that in fact reduce relevance or understanding of the role of the school setting in the associations or impacts being examined and that the act of making evidence relevant for applied purposes is one of translation of such evidence (Aber et al., 2010). Put another way, these links are bridges, not integrations, the end result of which is typically a somewhat limited and constrained understanding of impacts and a growing number of proven-effective treatments that glance off the complex social systems for which they were intended to solve problems. Or, as might be argued by economists or policymakers, the social returns on investments in research and development related to school-based interventions has been staggering low, despite ubiquitous evidence of impact (Durlak et al., 2011). In large part, very little has changed in the past decade to overcome the dichotomization of research and practice. The field continues to be challenged by implementation in clinical trial research: Interventions developed for application in schools routinely suffer from challenges with fidelity of implementation in evaluation trials, even when the intervention development process has been sensitive to the challenges of school

settings (Aber et al., 2011; Berkel, Mauricio, Schoenfelder, & Sandler, 2011; Sabol et al., 2013; Tseng, 2010). The research-practice dichotomy also comes to the fore in a different but related context: that of scale-up of interventions proven effective in evaluation trials (Berkel et al., 2011).

The field of implementation science, with its aim of studying the translation of interventions from efficacy studies to application at scale, focuses on conditions enabling high levels of implementation fidelity and quality in the delivery of treatments in settings (Halle, Metz, & Martinez-Beck, 2013; Tseng, 2010). This relatively recent effort to conceptualize and rigorously study the conditions under which impacts of successful treatments erode or maintain when the treatment is turned over to large number of new implementers is a critical advance in breaking down barriers between science and practice (Dane & Schneider, 1998; Neuman & Cunningham, 2009; Resnicow et al., 1992; Taggart, Bush, Zuckerman, & Theiss, 1990). By and large, the results of this effort have centered on conditions of treatments and of settings that determine the fidelity with which an intervention can be applied by practitioners in the field. As the knowledge base of intervention science builds, it is increasingly apparent that even basic concepts of fidelity, in which the prescribed set of procedures that determine treatment success developed in the controlled laboratory setting are relevant to field settings and personnel, are being called into question because they assume a more unidirectional relation between the lab and the field (Aber et al., 2011).

The question of how best to make research more useful to practitioners in schools is not new (e.g., National Research Council, 2002). Recent attention to this topic has focused on the conceptualization of the linkage between evidence and application and has made explicit the need to measure and study these processes in their own right (Tseng, 2010). Tseng (2010) focused on communication between researcher and practitioner as the basis for the disconnect, arguing that the research community needs a better understanding of how practitioners define, acquire, interpret, and use research. In education science, there is increasing recognition that strides in evaluating the impacts of education policies and interventions that improve outcomes for students have not been matched to the use or adoption of proven-effective approaches. For example, the What Works Clearinghouse lists over 400 studies that meet the highest scientific standards for research and that show evidence of efficacy for the intervention being evaluated (http://ies.ed.gov/ncee/wwc/default.aspx). Other organizations (Coalition for Evidence-Based Practice, www.coalition4evidence.org) also maintain lists of school-based interventions tested as effective. In a decade or more of knowledge generation with regard to effective programs and practices, there have been virtually no positive improvements in mental health, behavioral, or academic outcomes in school (NCES, 2014). Is it possible that knowledge generation (research) is disconnected from the realities experienced by children and youth in school settings and the work of professionals in these settings in ways that simply prevent the flow of information and value?

Aber and colleagues (2011) took a different approach to the questions of application, dissemination, and translation, in effect reconceptualizing both the relationship between the scientist and practitioner as well as the relationship between the laboratory and the field. In so doing, they provided a new frame for work in the research-practice dialectic at the intersection of "mental health prevention meeting education reform" (p. 411), drawing from more than a decade of experience in developing, implementing, and evaluating a universal, school-based preventive intervention focused on literacy and socio-emotional competencies in middle childhood (Aber et al., 2011; Brown et al., 2010; S. M. Jones et al., 2008, 2010). Working in New York City, this team drew the focus of their intervention development and evaluation from national (NCES, 2014) and city-level (Hoven et al., 2005; see Aber et al., 2011) reports of the prevalence of emotional and behavioral disorders to substantiate the need for delivering intervention supports at a population level. Their focus on schools as the place for intervention was admittedly driven by the convenience of reaching population-level scale (Aber et al., 2010) through working in schools as a setting. What this team then realized was the need to fundamentally reorganize their approach to development and implementation of mental health supports, shifting from a focus on program application to a deliberate, cyclical process of integrating theory with conditions in settings.

In their reflection on a decade of this work, Aber et al. (2011) outlined three dimensions operating at the intersection of research and practice that they believe shift the nature of this linkage from bridge or translation to one carrying more of an integrative stance. Importantly, the overriding feature of these dimensions is a scientifically derived theory of practice. Consistent with the primary focus of this chapter on schools as social settings (Seidman & Tseng, 2011; Tseng & Seidman, 2007), Aber et al. (2011) emphasized that their starting point for their version of translational research is practice. Invited by a partner who was at the time deeply and programmatically embedded in the schools with a focus on conflict resolution, the research

team devoted an initial period of time to forming a deep and comprehensive understanding and articulation of a logic model for the practice(s) they wished to further refine and evaluate. This focus on actor, actions, and structures in the social setting of the school enabled not only the refinement of the intervention but also the specification of key constructs and assessments that could be the focus of research (Aber, Brown, Chaudry, Jones, & Samples, 1996). Importantly, though, this team explicitly acknowledged the dialectic dynamic of research and practice and so drew from validated developmental and intervention sciences theory to shape the views and understanding of practice as articulated by practitioners. For example, a teacher's practice intended to reduce student aggression that involves contingent responding to student misbehavior with a set of consequences might be understood by practitioners as informed by and consistent with operant conditioning learning theory, whereas it could also be interpreted from the developmental lens of attachment theory or motivation theory, which might alter understanding of the meaning and consequences of that practice in the social setting of the classroom. This dialectic, in which practice is understood and examined through a series of varying lenses, when engaged in over time, enables the derivation of what Aber et al. (2011) called a "mutually fitting program intervention theory and developmental/contextual theory" (p. 412).

This effort to develop a scientifically based theory of practice can have profound influences on the thinking of practitioners working daily in classroom and school settings (Aber et al., 2010; Roderick, 2014). Often working in isolation and focused narrowly on daily circumstances and conditions, practitioners develop local theories of their work, which can often fail to reflect advances in knowledge in relevant domains. Thus, local actions, such as daily practices in classroom settings, become governed by a set of beliefs, schema, and routines that may become increasingly idiosyncratic, constraining, and isolated from new knowledge. As Roderick (2014) observed, cycles of practice-focused engagement with researchers introduces new elements into the local theories that develop around practice, foster contradictions and questions around operating assumptions, and create a higher-order dialogue and meta-framework in which everyday practices of educators, conditions of settings, theories of youth development, and intervention protocols are mutually informative and integrated.

This iterative, programmatic, and explicit embrace of bidirectionality and dialectical dynamics, evolving over time in the context of repeated engagement of researcher (organized around standardization) and practitioner (organized around situational nuance), organizes into its own social system capable of producing an emergent organizing principle that is then realized in the behavior and methods of scientists and practitioners. This is the "mutually fitting program intervention theory and developmental/contextual theory" that Aber et al. (2011) described, with the emphasis on mutuality and fit at the research-practice nexus in which understanding and action align over time. To be clear, this emergent principle is not a translation, extension, application; it is not a bridging device; rather, it is an integration that transcends and includes the research-practice dichotomy and reflects a new domain of knowledge. This is not dissimilar to a recent conceptualization in implementation science proposed by Berkel et al. (2011) that focuses on transformation and calibration taking place through high levels of engagement between facilitators of an intervention and participants. Fundamentally, what these authors (Aber et al. 2011; Berkel et al., 2011; Roderick, 2014) and a host of others describe is the growing irrelevance of constructs such as dissemination or translation, which presuppose knowledge generation as primarily emanating from scholarship taking place in relatively controlled conditions. Rather, they point to an emergent knowledge generated through structured engagement that brings rigorous, systematic, theoretically informed inquiry to problems of practice *and* problems of theory. What is suggested by this work is that these emergent forms of knowledge are a different and perhaps uniquely important source of information about human development. Knowledge of and immersion in the school setting are therefore indispensable.

INDIVIDUALIZATION OF CLASSROOM PROCESS EFFECTS ON TEACHERS AND STUDENTS: BIOLOGICAL SENSITIVITY TO EXPERIENCE

A common point of considerable interest to education scientists, educators, and developmental scientists with an interest in psychopathology is how to best account for range and variation across individuals in any number of key outcomes. Although much activity in this broad domain is centered on characterization of groups demonstrating various outcomes or processes in common, there is equally as much, if not more, attention devoted to understanding individual variation and how to respond to individuals through professional practice.

In the past decade, developmental science has brought new understanding to the problem of individual differences and the forces that shape them. This in part

has been the result of a set of conceptual advances for understanding biological mechanisms that intersect with context and experience—differential susceptibility and biological sensitivity to context (Bakermans-Kranenburg & van IJzendoorn, 2011; Belsky & Pluess, 2013; Boyce et al., 2006), gene–environment interaction (Musci et al., 2013; Beach et al., 2014), and allostatic load (Blair et al., 2011). In each case, the theoretical advance incorporates individual biological makeup and individual experience to explain individual differences in outcomes. Powerful advances in assessment of individual genotype(s) and associated physiological mechanisms have been linked to relevant experiences with some known association with individual differences in outcomes (Beach et al., 2014; Musci et al., 2013).

Boyce and Ellis (2005) first used the term *biological sensitivity to context* to describe one such cluster of mechanisms responsible for individual differences, at the time focused on understanding effects of child rearing. In the Boyce and Ellis model, genetics determines an individual's susceptibility to environmental influence, largely through stress response systems. Greater stress exposure upregulates reactivity to create vigilance in response to threat, while nurturing experiences also upregulate stress response, resulting in vigilance that produces exploratory behavior and greater social resources. Thus, highly susceptible organisms respond differentially to variation in settings, producing differences in developmental outcome. Belsky (2005) and colleagues (Belsky & Pleuss, 2009) also advanced evidence for differential susceptibility to experience as a means of explaining why some individuals exposed to known risk factors perform better than average on certain developmental outcomes while the majority of their peers perform worse. This finding has been captured as for better *and* for worse as a way of more fully explaining why some highly reactive children develop problems while others appear to function at higher-than-typical levels.

Evidence in support of these sensitivity-susceptibility arguments has grown considerably in the last decade and advanced exponentially with increased knowledge of the genome and methods for collecting genomic and physiological data. For the most part, the concepts have been tested and confirmed with parenting as the context of interest; that is, studies have consistently supported these models when examining outcomes for highly reactive children reared in supportive or negative parenting relationships. In this literature, biological risk is increasingly measured in terms of dopamine-related genes (Bakermans-Kronenburg & van IJzendoorn, 2011), while literature also suggests that genes involving serotonin transfer and uptake may also lead to the for-better-and-for-worse pattern (Beach et al., 2014). Bakersman-Kronenburg and van IJzendoorn (2011) reported results of a meta-analysis of susceptibility/sensitivity studies involving dopamine-related genes, finding confirmation of poor outcomes in adverse settings and more positive than average outcomes among children reared in nurturing settings.

Emerging evidence suggests that classroom settings, and teacher-child relationships, are contexts that influence development consistent with this susceptibility or sensitivity to context frame. For example, Essex and colleagues (2011) showed the for-better-and-for-worse pattern of results for children demonstrating high physiological and behavioral reactivity in first grade when examined for mental health symptoms in adolescence; reactive students with more positive teacher-child relationships performed better than expected while their counterparts with negative teacher-child relationships fared much more poorly.

Two Forces that Will Shape Research in the Next Decade

This chapter has focused on one set of processes related to the intersection of educational experiences in schools and developmental psychopathology: interactions between teachers and students. As has been outlined throughout, there is a strong conceptual case to be made for the study of teacher-student interaction to function as a pathway for developing theory and strong science that fosters improved understanding of the conditions under which development of children and youth are influenced (intentionally and otherwise) by experiences in schools. Studies on the nature, determinants, and consequences of teacher-student interaction, and the production of more effective interactions all begin to fill gaps in various relevant literatures. And yet, at the same time scientific work is proceeding, the pressures to apply any available knowledge or tools is unprecedented and often outpaces the production capacity of any research program. The demand for knowledge and application is at once a tremendous challenge to science and an opportunity, if identified and harnessed strategically. Aber and colleagues' (2011) work on socio-emotional learning programs is an example of the benefits that can be gained, scientifically and in the application of knowledge to pressing problems, when joint interests are identified early and take a primary role in defining and conducting research in the field that is both scientifically rigorous and has strong applied value. This concluding section takes the prior discussion of future directions in research funding, the science of applied practice, and new knowledge to be gained through study of biological processes in classroom

interactions and contextualizes it within the opportunity structure for scientific work in the schools.

Teacher Performance Evaluation

At the most macro-level context, consider that as states seek to implement education reforms, assessment and evaluation of teacher performance as a vehicle for driving continued growth and improvement is top of mind for school district superintendents, school principals, teachers, union leaders, and state or federal policymakers. This is a tremendous opportunity not only for establishing important links between science and application; the advent of large-scale data collection on teacher performance affords the opportunity for investing strategically in capacity to analyze these data for purposes of better understanding teacher efforts on developmental and learning outcomes and to complement existing data collection with protocols that advance the next frontier of understanding, including intervention protocols or biometrics.

There is no shortage of need for evidence as teacher performance evaluation gets applied on a widespread basis, with interests weighing in on all sides—unions seeking to protect members from undue harm; reformers advancing a good argument for the need to use metrics as levers for workforce development and improvement; teachers pressing for fair and reliable systems and meaningful feedback and support; and parents and members of the public wanting better schools for all students (Kane et al., 2014). Assessment of teacher performance—particularly teachers' classroom behaviors that cause increases in students' knowledge and skills—is not only a driving force in educational reform but a context in which the scientific study of teacher-student interaction can play an enormous role and in which strong developmentally oriented science can be designed and conducted.

In this context, in which assessment plays such a prominent role, both for purposes of evaluation and more important for purposes of improvement, it is tremendously important that evidence guides development, uses, and decision making. Widely reported analyses of the most common teacher assessment methods practiced for decades (principal drive-by observations and ratings; hiring interviews and selection procedures; tenure reviews, etc.) all led to the same conclusion:— There is virtually no connection between these tests and student learning and development, teachers' own professional development, or incentives to improve. In fact, teacher performance assessment and its uses, as typically practiced in the field or in teacher preparation, until very recently had no basis in evidence (Kane et al., 2014; Rockoff et al., 2011; Staiger & Rockoff, 2010). With a wave of federal funding, many states began to tie data on teacher education graduates to data on K–12 student learning; and many developed multimethod approaches for measuring teachers' performance, including data from observation, state standards tests, and student surveys, among others. Moreover, many states are now in the process of implementing Common Core standards, with plans to assess the attainment of students' higher-order learning, teamwork skills, and application of knowledge. States are now in the process of implementing new standards for evaluating teachers and teacher preparation programs in light of Common Core. The infrastructure for collecting data both on teacher performance (including behavior) and student learning (including some aspects of social and cognitive skills) will soon exist at very large scale and will be linked to resources and initiatives designed to drive improvements in these broad domains (Glazerman et al., 2011).

There are big and meaningful questions driving teacher performance assessment (Goldhaber, 2007; Rockoff et al., 2011; Staiger & Rockoff, 2010): What methods can be used to select or hire an effective teacher? What data are useful sources of feedback for teacher improvement? What experiences in preparation or professional development cause teachers' performance and student development to improve? Although most studies of these early-stage performance assessments have been important in laying a foundation for inquiry into teacher effects on student development, most fail to articulate specific processes or instructional practices that may lead to student learning and other positive classroom and student outcomes.

Linking Educationally Relevant Behavior and Psychological Processes to Biology

Despite increasing use of biometrics in developmental science and the transformation of theories human behavior to now incorporate biological processes in nearly every formulation of basic mechanisms of influence and coregulation, the penetration of measures or theories in education has been minimal at most. We know virtually nothing about intersections among multiple systems that presumably would be involved in coregulation of teaching and learning processes (e.g., teacher and student behavior, mood, effort; eye gaze, vocal tone, heart rate, cortisol levels, neurophysiological activity; attention and learning). This is the case even though there are multiple examples of links between biology and behavioral science from the

literatures on parenting and peer relations (e.g., Coan et al., 2006: Montpetit et al., 2010).

Developmental psychopathology advanced rapidly when studies of behavioral and psychological variables incorporated measurement and theory of biological, physiological, and neurological processes (see Boyce & Ellis, 2005; Essex et al., 2011). It is now possible to study and understand similar processes in classrooms and their relations with teaching and learning. A host of questions concerning causal mechanisms, individualization of effects, and aggregation of effects over time could be informed by more integrative scientific work. Moreover, the nature and dynamics of schooling—the way that inputs are structured and delivered, the timing of changes in social and instructional contexts, the hierarchical forces involved—all introduce sources of variation that could be of interest in further understanding the coregulation of biology and behavioral development. In short, building a stronger infrastructure and scientific architecture for the integration of biological measurement and theoretical perspectives into the study of schooling would likely catalyze interdisciplinary science on the intersection of education and human development.

Integrating biometrics and biologically informed theory into the study of teaching and learning in classrooms has considerable applied implications. Existing metrics and tools are inefficient, resulting in empirical findings that suggest promise but are also possibly quite incomplete—teachers' interactions with students account for only a modest level of variation in student learning (e.g., Hamre et al., 2013), and although teachers can trained to improve those behaviors, thereby improving student learning (Allen et al., 2011; Bierman et al., 2008; Downer, Pianta, et al., 2014; S. M. Jones et al., 2013; Pianta et al., 2008), the interventions are expensive, time-consuming, and blunt in terms of precision of impact. Embedding behavioral foci (e.g., teacher-student interaction and student engagement) within assessment of other coregulating processes (e.g., stress reactivity, emotions, neurological activity, heart rate, movement) during classroom interactions could help identify mediating mechanisms and assessments that drive efficiencies in identifying the most important teacher (and student) behaviors on which to focus attention. In turn, these behaviors or their coregulators (e.g., heart rate) could become candidate targets for interventions or more widespread training through teacher preparation. This type of integration could yield more precise targeting of observations and professional development to focus on teacher behaviors most potent for student engagement and learning.

In conclusion, it is highly plausible to conceive of a field in which the methods of cognitive neuroscience, biological science, developmental psychology, computational analytics, and education science become further integrated and organized around a focus on teacher-student interaction and student learning. It is equally plausible that the new knowledge and tools developed by this scientific integration would scale into applications at a very rapid pace, with considerable potential to accelerate inquiry and application. These advances set the stage for future interdisciplinary integrations that will shape research on classroom process for decades to come.

INTRODUCTION

Prevention Science

The overarching objective of prevention science involves intervening in the course of development to reduce the emergence of maladaptation or psychopathology. Although the ultimate goal of prevention involves altering the developmental course for individuals who are at risk for maladaptation to foster positive outcomes and reduce future problems (Durlak, 1997), prevention trials also possess important implications for informing developmental theory. Specifically, understanding the processes that can right the course of development can inform our understanding of the operation of risk and protective factors in normative development (Cicchetti & Toth, 1991, 1992; Kellam & Rebok, 1992). It then follows that although ideally theory should provide the foundation for the development of preventive interventions, once delivered, the outcomes of preventive interventions should also link directly back to developmental theory (Ialongo et al., 2006).

From its inception, developmental psychopathology has embraced the importance of facilitating the development, delivery, and evaluation of theoretically informed prevention and intervention initiatives (Cicchetti, 1999; Cicchetti & Toth, 2009; Toth, Pianta, & Erickson, 2011). This investment emanates from the discipline's core conceptualization of normative and atypical development as a continuum, thereby forgoing the need for discrete (and

Research conducted at MHFC was supported by the Administration for Children, Youth, and Families, the National Institute of Mental Health (MH54643; MH076928; MH45027), the Spunk Fund, Inc., Monroe County Department of Human Services, and the United Way of Greater Rochester. We thank our colleagues, Dante Cicchetti, Jody Todd Manly, and Fred Rogosch; their input over many years has contributed to the formulation of many of the ideas presented in this chapter. We also thank the children, families, therapists, and research assistants without whom the work discussed herein would not be possible. Finally, we greatly appreciate the editorial assistance provided by Carol Marcy.

all-too-often arbitrary) categorical classifications of mental illness. Moreover, leaders in the field of developmental psychopathology have consistently maintained that they are as interested in understanding how some individuals at risk for psychopathology maintain positive adaptation as they are in understanding contributors to the emergence of maladaptation and mental disorders (Sroufe & Rutter, 1984). Given these core tenets, it is quite understandable why developmental psychopathology has been at the forefront of progress in the field of prevention science.

The magnitude and pervasiveness of mental disorders highlight the criticality of implementing initiatives to prevent the personal and societal costs associated with mental illness. According to the World Health Organization (2003), 450 million individuals worldwide are affected by mental or behavioral problems at any given time. In the United States, an estimated 40.3% of adolescents and 26.2% of adults suffer from a diagnosable mental disorder annually (Kessler, Chiu, Demler, & Walters, 2005; Kessler et al., 2012). Moreover, 3.1 million American youth aged 12 to 17 (12.7% of the U.S. population aged 12–17 in 2012) and 34.1 million American adults (14.5% of the U.S. population aged 18 or older) received mental health treatment or counseling in the past year (Substance Abuse and Mental Health Services Administration, 2013).

In this chapter, we invoke a developmental psychopathology perspective to guide our discussion of the current state of prevention science. Rather than providing a comprehensive review of the field of prevention, we examine developments that have occurred since the publication of the prior volume of *Developmental Psychopathology* (Cicchetti & Cohen, 2006). After reviewing programmatic preventive initiatives that are consistent with goals articulated by Ialongo and colleagues (2006), we direct our attention to conceptual and methodological considerations in the field of prevention science. We then discuss translational research and the importance of dissemination of efficacious interventions. We conclude by proffering recommendations for future directions for prevention science in the next decade.

Contributions of Developmental Psychopathology to Prevention Science

In an article marking the twenty-fifth anniversary of the journal *Development and Psychopathology*, Alan Sroufe (2013) reflected on the achievements of developmental psychopathology. He noted that the volume of descriptive work on psychopathology has been remarkable, highlighting advances in our understanding of the antecedents and correlates of behavior problems, neurophysiological correlates of maladaptation, and research on brain development and gene–environment (G×E) interactions. Sroufe also stated that our knowledge about the developmental course and the role of predictors of problems during different periods of life has greatly increased. The latter progress is particularly important as it confirms a premise of developmental psychopathology—namely, that understanding the developmental course is more important than listing symptoms alone (Sroufe, 2013). However, despite these remarkable advances, Sroufe also cautioned that we have much more to learn about how psychopathology develops. This point is integrally related to how best to facilitate advances in the area of prevention science. It is clear that understanding how psychopathology develops and not simply relying on categorical diagnostic classification systems will poise us to better target early precursors of future maladaptation into our prevention strategies.

Toward this goal, and in describing "a path forward," Sroufe (2013) suggested an approach that diverges from a search for correlates of categorical disorders. Rather, "the path would be one in which we begin with early patterns of adaptation, trace their courses and manifestations in different phases of development, and document when and how they may be manifest in disorder" (p. 1221). In further elaborating on this conceptualization, Sroufe described key capacities that consistently have been found to undergird the core of healthy or unhealthy psychological development. These include: (1) the capacity for stable emotional connection with others; (2) internalization of standards of conduct; and (3) attainment of flexible self-regulation. Interestingly, the salience of these constructs is readily observable in multiple current diagnostic classification systems of mental disorders. Importantly, focusing on core capacities rather than diagnostic categorizations of disorders may help to circumvent the myriad of problems associated with the comorbidity of disorders. By fully understanding these core capacities, their development, and how they may become diverted onto maladaptive pathways, it will be increasingly possible to design prevention strategies with these issues as the target of intervention. Of course, such a paradigm shift possesses implications for policies regarding what constitutes reimbursable services, an issue that would need to be resolved before adopting this approach.

Definitional Perspectives on Prevention

To begin our examination of the current state of prevention science, it is first important to define terminology.

The original prevention classification schemata was developed by the Commission on Chronic Illness in 1957 and included the now commonly recognized terms of primary, secondary, and tertiary prevention (Durlak, 1997; Mrazek & Haggerty, 1994). In this classification system, the term *primary prevention* referred to an intervention delivered to a normative population who do not evidence any disease to decrease the occurrence of disorder or illness. Secondary prevention programs were designed to decrease the prevalence or rates of established disorders or diseases; as such, these programs were targeted at individuals at higher risk for developing disorders. Tertiary prevention was directed at reducing or eliminating the duration or consequences of a disorder or illness. This original classification system failed to articulate the relationship between mechanisms linking the causes of diseases to outcomes or the occurrence of the disease. Moreover, the roots of this original classification system were based largely on infectious diseases with a biological origin and were consequently less useful when considering conditions that did not have a clear biological manifestation (Foxcroft, 2013).

Over time, a more sophisticated understanding of the complexity associated with the relations between risk and protective factors and health outcomes, variations in developmental pathways, and empirical strategies to test these relations emerged (Ialongo et al., 2006). In 1994, the U.S. Institute of Medicine (IOM) adopted the prevention classification system originally proposed by Gordon (Gordon, 1983; IOM, 1994). In their report, the IOM rejected the notions of primary and secondary prevention and opted for universal, selective, and indicated prevention descriptors. According to this system, universal preventions are delivered broadly to the general public. Selective preventions are provided to individuals who are considered to be at increased risk of developing a disorder. Indicated prevention, most similar to actual treatment provision, is targeted at individuals who have exhibited early symptoms of disorder or who have biological markers indicating a predisposition to a disorder.

Most recently, the IOM reviewed the definition and classification of prevention in a report on preventing mental, emotional, and behavioral disorders in young people (National Research Council [NRC] & IOM, 2009). After considering alternative approaches to the classification of prevention, including the original conceptualizations of primary and secondary prevention, as well as identifying at-risk individuals through genomic analysis, the report endorsed the 1994 IOM system (universal, selective, and indicated prevention) as the preferred system for classifying prevention initiatives prior to the emergence of disorders.

SELECTIVE REVIEW OF PROGRAMMATIC PREVENTIVE INTERVENTIONS

At the start of the twenty-first century, Ialongo and colleagues (2006) highlighted several areas requiring the attention of preventive intervention scientists in the field, including a need for randomized controlled trials (RCTs) with long-term follow-ups, investigations of mediators and moderators, and integration of psychological and biological assessments. A paucity of RCTs, the gold standard of treatment evaluation, was found in the evaluation of preventive interventions when the last edition of this text was published. In the last 10 years, a multitude of RCTs of preventive intervention programs have been conducted, resulting in a greater understanding of which programs are effective for preventing the development of a wide range of psychopathology. Additionally, long-term follow-ups have become more common, with some studies including 12-month follow-ups and beyond as part of the evaluation of preventive interventions. Studies also have increasingly tested moderators of intervention efficacy, including a handful that have examined genetic moderators, to allow for a better understanding of who is most likely to benefit from particular preventive programs. Furthermore, preventive intervention RCTs have increasingly evaluated hypothesized mechanisms of intervention change, another point of needed improvement noted by Ialongo and colleagues. However, despite advances that have occurred since the 2006 chapter, the issues highlighted by Ialongo and colleagues remain among the most pressing in the field of prevention science. In fact, emerging work in the biological/genetic arenas has raised more issues and highlighted the complexity inherent in understanding mechanisms contributing to the efficacy of prevention strategies. Toward this goal, the identification of mediators of intervention efficacy must be accelerated.

Attention to mediators of intervention efficacy is paramount for several reasons. First, an understanding of how an intervention works allows for the most potent factors to be identified and potentially built into the subsequent provisions of the prevention program. Second, preventive interventions, by design, offer an opportunity to understand the basic processes of development (Cicchetti & Toth, 2009; Ialongo et al., 2006), and mediators of treatment efficacy highlight developmental pathways, which can then inform basic research in developmental science. These advances in basic science, promoted by an understanding of intervention mediators, can then be used to further progress in the field of prevention science through translational research, thus completing the prevention research

cycle (Gunnar, Fisher, & the Early Experience, Stress, and Prevention Network, 2006; Ialongo et al., 2006).

Next we highlight some of the key preventive intervention studies published since the last edition of *Developmental Psychopathology*. This text is not intended to be an extensive and complete review of all RCTs published in the preventive intervention literature in the last 10 years. Rather, we primarily emphasize cohesive programs of research that have responded to the goals for the field set forth by Ialongo et al. (2006), including utilizing multiple levels of analysis in study design and examining sustained effects, mediators, and moderators of intervention efficacy. To begin our review, we discuss strategies targeted at the prevention of specific disorders or those directed toward individuals confronted with high-risk conditions. Our focus on disorders is not meant to suggest that we favor reliance on categorical diagnostic classification systems but rather reflects the approach generally taken in the extant literature to date.

Internalizing Disorders

Several programs of research have focused on preventing the further development of internalizing symptoms, most notably depression, in youth. Many of these preventive intervention programs have targeted preadolescents and adolescents, given the increased rates of depression, particularly for females, observed throughout the adolescent developmental period (Hankin et al., 1998; Lewinsohn et al., 1994). Several recent meta-analyses have confirmed positive but small effect sizes for preventive interventions for depression (Merry et al., 2012; Stice, Shaw, Bohon, Marti, & Rohde, 2009). Stice and colleagues (2009) established that larger effect sizes were found for intervention programs that focused on high-risk participants and older adolescents as well as those using samples with a greater portion of females and individuals from ethnic minority groups. Interventions that were brief (but include homework) and were delivered by professional interventionists rather than by paraprofessionals or schools also produced larger effects (Stice et al., 2009). Studies included in this meta-analysis were coded as to whether they contained cognitive change, behavioral activation, problem solving, or social skill content, and it was hypothesized that programs including these content areas also would have larger effect sizes; however, program content was not found to be related to effect size in this meta-analysis (Stice et al., 2009).

One well-studied example of the cognitive-behavioral approach to prevention is the Penn Resiliency Program (PRP), which aims to change negative explanatory thinking styles and decrease depressive symptoms. It was designed for youth (typically ages 10–14) as a short-term, school-based program to be administered in groups. This program was initially evaluated in the context of efficacy studies, with results suggesting preventive effects on depressive symptoms up to 2 years later (e.g., Gillham, Reivich, Jaycox, & Seligman, 1995). More recent work with PRP has yielded varied results in the application of PRP in both school and primary care settings. In a school-based RCT, PRP was compared to two control conditions, the Penn Enhancement Program (matched in frequency and duration to PRP to control for the nonspecifics of the active condition without focusing on cognitive-behavioral and social problem-solving skills) and a no-intervention control condition. A total of 697 middle school children (many with elevated depressive symptoms, but excluding those meeting criteria for major depressive disorder) from three schools were randomized to one of the three conditions. Children who received PRP had reduced depressive symptoms over the follow-up period compared to children in both control conditions; however, this result was found in only two of the three schools involved in the trial (Gillham et al., 2007). In an RCT conducted in a primary care setting with early adolescents with elevated depressive symptoms, no overall prevention effect was found for PRP on depressive disorders (Gillham, Hamilton, Freres, Patton, & Gallop, 2006). A meta-analysis of 17 controlled evaluations of the effect of PRP (including those conducted in both school and nonschool settings) on depressive symptoms found an overall small but significant effect size for PRP in reducing depressive symptoms compared to no-intervention control conditions (Brunwasser, Gillham, & Kim, 2009). Limited data were available to examine PRP compared to active control conditions, and available data showed no advantage of PRP on reducing depression symptoms compared to active controls (Brunwasser et al., 2009). Gender, group leader characteristics (i.e., research team leader versus community leader), and baseline level of depressive symptoms were all examined as moderators. Results suggested that none of these moderators explained a significant amount of heterogeneity; moderation effects may have been difficult to detect as only 17 studies were included in the meta-analysis (see Brunwasser et al., 2009, for more details). Overall, results from studies evaluating the utility of PRP are mixed, with PRP developers noting reduced and/or inconsistent intervention effects when moving along the continuum from efficacy studies to real-world application (Gillham et al., 2007).

The Positive Thoughts and Action preventive intervention is another program that focuses on applying traditional cognitive-behavioral strategies to stressors typically encountered during the pre- and early—adolescent period. In a school-based RCT for adolescents, those randomized to receive the Positive Thoughts and Action program (versus a supportive therapy) reported greater decreases in depressive symptoms and improvements in self-esteem (McCarty, Violette, Duong, Crz, & McCauley, 2013). Notably, improvements on measures of interpersonal relationships were not found for the students receiving the cognitive-behavioral preventive intervention (McCarty et al., 2013).

Other preventive interventions for depression during the adolescent period have focused on interpersonal relationships and communication in recognition of the increased importance of relationships during this developmental period. A program originally developed to target substance abuse, the Iowa Strengthening Families Program (ISFP), has more recently been evaluated with regard to its impact on internalizing symptom trajectories for adolescents (Trudeau, Spoth, Randall, & Azevedo, 2007). ISFP is a universal relational intervention that focuses on familial relationships. It is delivered in group format over the course of 7 weeks when children are in the sixth grade via concurrent parent and child training sessions followed by joint 1-hour family sessions, where skills learned in the separate sessions are practiced. Videotapes of family interactions are used to convey key concepts of ISFP. Trudeau and colleagues (2007) evaluated internalizing symptom development through twelfth grade for 238 sixth graders receiving ISFP compared to 208 children from families in a minimal contact condition. Internalizing symptom growth rate was slower for adolescents in the ISFP condition compared to those in the control condition (Trudeau et al., 2007).

Other preventive interventions have used the framework of interpersonal psychotherapy (IPT) to focus on relational patterns and communication strategies more broadly as a way to decrease depressive symptoms. IPT addresses the interpersonal aspects of depression, focusing specifically on disputes with close others, grief, role transitions, and interpersonal sensitivities (S. Stuart & Robertson, 2003; Weissman, Markowitz, & Klerman, 2000). Importantly, it has been adapted specifically for use with adolescents (Mufson et al., 1994; Mufson, Weissman, Moreau, & Garfinkle, 1999). An indicated preventive intervention RCT compared IPT-Adolescent Skills Training (IPT-AST), administered in group format in schools, to school counseling as needed, provided by the school guidance counselor or social worker. Forty-one students in grades 7 to 10 were randomized to the two conditions; those who received IPT-AST had fewer depressive symptoms at postintervention 3-month and 6-month follow-up compared to the students who received school counseling (Young, Mufson, & Davies, 2006). Additionally, mother-child conflict was reduced in the IPT-AST group compared to the school counseling group and emerged as a moderator of intervention effects, such that adolescents receiving IPT-AST with high baseline mother-child conflict evidenced greater decreases in depressive symptoms than adolescents with high baseline mother-child conflict in the school counseling condition (Young, Gallop, & Mufson, 2009). This moderation finding is consistent with the explicit focus on relationships in IPT and highlights the utility of this intervention for adolescents with elevated depressive symptoms and mother-child conflict. A second study by this research group compared IPT-AST to school counseling for 57 adolescents in the ninth and tenth grades; again, adolescents in the IPT-AST condition had fewer depressive symptoms compared to those in the school counseling at postintervention; however, there were no significant differences between the two groups at 12-month follow-up (Young, Mufson, & Gallop, 2010). An RCT for 380 high school students compared a brief cognitive-behavioral-based preventive intervention to a brief IPT-AST intervention (Horowitz, Garber, Ciesla, Young & Mufson, 2007). A third group of students was randomized to a control condition. Students in both active school-based intervention conditions had lower levels of depressive symptoms at the end of the intervention, and the largest differences between intervention and control groups were seen in adolescents with the highest levels of baseline depressive symptoms. The intervention effect of cognitive-behavioral treatment, but not IPT-AST, was partially mediated by attributional style. Surprisingly, however, differences in level of depressive symptoms between intervention and control adolescents were not maintained at 6-month follow-up. Findings suggest that two effective interventions can operate through different pathways yet impact the same outcome variable, highlighting the need for inclusion of postulated mediators in preventive intervention RCTs to better understand how and why interventions are successful. This study identified baseline severity as a moderator of intervention efficacy, thus identifying the group most likely to benefit from this intervention. Finally, although immediate improvement in symptoms occurred, benefits were not maintained at 6-month follow-up, similar to the findings of Young et al. (2010) in which the benefits of IPT-AST compared to

school counseling did not emerge at 12-month follow-up. Because the fields of developmental psychopathology and prevention science aspire to promote long-term adaptive development, continued efforts to develop and evaluate sustained intervention efforts are needed.

A large-scale indicated preventive RCT for adolescent depression utilizing the IPT model is currently under way at Mt. Hope Family Center, University of Rochester, in Rochester, NY. This study is building on previous preventive intervention research as well as treatment trials utilizing IPT-A for depression to target developing depressive syndromes in 13- to 15-year-old adolescent girls from disadvantaged backgrounds, half of whom have a history of maltreatment. The multilevel study design includes a 1-year and an 18-month follow-up to assess the stability of hypothesized intervention gains as well as the assessment of hypothesized mechanisms at multiple time points to allow for mediational analyses. Cortisol and genetic samples also are being collected at multiple time points as part of the preventive intervention to assess multiple levels of functioning at which the intervention may be efficacious. This innovative design will allow for changes in these biological indicators to be assessed in relation to social and psychological measures over the course of the study; additionally it will allow for gene × intervention analyses to be conducted. Examining the efficacy of an IPT-based preventive intervention in this population is critical, given the increased rates of depressive symptoms in children with maltreatment histories (Kaufman & Charney, 2001; Toth, Manly, & Cicchetti, 1992) as well as the crucial need for interventions that target the maladaptive relational representations and patterns that often develop in individuals with histories of maltreatment (Cicchetti & Toth, 2006a; Toth, Cicchetti, Macfie, Maughan, & VanMeenan, 2000). Moreover, Heim and Binder (2012) have found differential responses to treatment in depressed adults with and without histories of child maltreatment, thereby highlighting the implications of this line of research for prevention and intervention. The work is very promising, given results from a recent RCT study of IPT for young socioeconomically disadvantaged racially and ethnically diverse depressed mothers, many with a history of interpersonal trauma (Toth et al., 2013). Results from this study indicated that IPT was effective for reducing symptoms of depression in this population (Toth et al., 2013). Thus, these results suggest that IPT is well suited for treating depression in women from disadvantaged socioeconomic backgrounds and may be an acceptable and effective approach to preventing the development of depression syndromes in this high-risk population.

Two recent meta-analyses examined the effectiveness of anxiety prevention programs for children and adolescents. Overall small but significant effects were found on the reduction of anxiety symptoms, with mixed evidence regarding larger effect sizes for selected and indicated programs (Fisak, Richard & Mann, 2011; Teubert & Pinquart, 2011). The FRIENDS program, a cognitive-behavioral preventive intervention for child anxiety, was identified as being commonly used, and programs using the FRIENDS manual evidenced significantly larger effects compared to those that had not used the FRIENDS manual (Fisak et al., 2011). In a universal preventive intervention for child anxiety utilizing the FRIENDS program, a large sample of 9- to 10-year-olds and 14- to 16-year-olds were randomized to the active intervention or a monitoring control condition; randomization occurred at the school level. and the intervention was delivered in the school setting (Barrett, Lock, & Farrell, 2005). The intervention was tailored to each of the two age groups and consisted of 10 weekly group sessions for the children, followed by two booster sessions conducted 1 and 3 months after the 10-week intervention. Parents of children in the intervention condition received four, 2-hour parent workshops. At postintervention assessment, no differences were found between the intervention and monitoring groups regarding anxiety symptom reduction; however, at 12-month follow-up, children in the intervention group demonstrated greater reductions in anxiety than those in the monitoring group (Barrett et al., 2005). Overall, children in the 9- to 10-year-old sample showed initially higher levels of anxiety and greater reductions in anxiety symptoms at postassessment compared to those in the 14- to 16-year-old group, suggesting that younger children may be an important target for anxiety preventive intervention efforts. Accordingly, Fun FRIENDS is a developmentally appropriate derivation of the FRIENDS intervention for 4- to 7-year-olds, which includes teachers and parents to promote child skill development. Fun FRIENDS was compared to another active intervention condition (a social and emotional skill program based on cognitive-behavioral therapy) and a waitlist control group for a group of 488 4- to 7-year-olds. Randomization occurred at the school level. Children in the Fun FRIENDS condition and the other active intervention condition showed greater gains in social and emotional competence and reductions in symptoms compared to the waitlist control group; notably, children in the Fun FRIENDS group evidenced greater improvements at postintervention and 12-month follow-up (Anticich, Barrett, Silverman, Lacherez, & Gillies, 2013). Consistent with a developmental psychopathology framework, it is

critical for preventive interventions to be tailored to the developmental level of the recipients and for prevention science to continue to examine the developmental window during which provision of a preventive intervention is most likely to promote optimal development.

Parental Depression and Anxiety

Children of parents with depression and anxiety disorders are a group especially at risk for the development of internalizing symptoms. More specifically, children of depressed parents are at increased risk for behavior problems, insecure attachment, and diagnoses of depression, anxiety, and other psychiatric disorders later in life (Beardslee, Gladstone, & O'Connor, 2011; Hammen & Brennan, 2003; Silk, Shaw, Forbes, Lane, & Kovacs, 2006; Toth, Rogosch, Manly, & Cicchetti, 2006; Weissman et al., 2006). Accordingly, this has been an important focus area for preventive intervention research, with notable progress evident over the last decade. A recent meta-analysis concluded that preventive interventions for children of parents with mental illness significantly decrease offspring internalizing symptoms as well as incidence of developing the same mental disorder of the diagnosed parent (Siegenthaler, Munder, & Egger, 2012). Toth and colleagues used a relational intervention, Child-parent psychotherapy (CPP), to promote secure attachment in the offspring of mothers who had a major depressive disorder (Toth et al., 2006). CPP, grounded in the work of Selma Fraiberg, focuses on the mother-child relationship and promotes the caregiver's understanding of how her own experiences being parented may be impacting her current relationship with her child and the way that she parents (Lieberman & Van Horn, 2008). In the study, 130 depressed mothers and their toddlers were randomized to either CPP or a treatment-as-usual comparison group. Consistent with a developmental psychopathology perspective of understanding the continuum between normal and abnormal development, a nonpsychiatric group of mothers and their infants was recruited for comparison purposes. At postintervention, toddlers in the CPP condition had higher rates of secure attachment compared to those in the intervention comparison group as well as compared to the offspring of a nondepressed comparison group (Toth et al., 2006). Thus, CPP was successful at promoting a healthy course of development for at-risk toddlers of mothers with depression in this preventive intervention.

Research in developmental psychopathology has consistently been dedicated to examining the generalizability of findings developed on middle-class, primarily Caucasian samples to underserved, racially/ethnically and economically diverse populations. Accordingly, the findings from the preventive intervention by Toth and colleagues (2006) have been used to develop a similar preventive intervention program for socioeconomically disadvantaged depressed women from diverse backgrounds and their infants. Toth and colleagues (2013) recently published the first study from this RCT, supporting the efficacy of IPT for reducing depression in mothers in this sample. This multilevel investigation also examined possible genetic moderators of treatment outcome with results indicating that changes in depressive symptoms over time depended on both intervention group (IPT versus enhanced community standard) and genotypic variation in corticotropin releasing hormone receptor 1 (CRHR1) and the linked polymorphic region of the serotonin transporter gene (5-HTTLPR; Cicchetti, Toth, & Handley, 2015). Importantly, IPT as an indicated treatment for maternal depression was simultaneously being examined as a selective preventive intervention for the 12-month-old infants of the mothers in the Toth et al. (2006) study, considered at risk due to exposure to maternal depression. Data from this study are being examined to determine the efficacy of IPT for maternal depression at enhancing the socio-emotional development of offspring as well as the utility of combining CPP and IPT for preventing the sequelae associated with maternal depression, including insecure and disorganized attachment.

Cognitive-behavioral interventions also have been utilized for interventions with children of depressed parents. Beardslee, Wright, Gladstone, and Forbes (2007) examined the long-term effects of two family-based preventive interventions utilizing a cognitive framework for offspring of depressed parents. A clinician-facilitated intervention was designed to increase family understanding of depression and build family support networks during approximately seven sessions plus refresher meetings or calls at 6- to 9-month intervals (family meetings as well as separate session with parents and children were used) and was compared to a lecture intervention in which parents attended two meetings and received similar psychoeducation about depression and its impact on families. However, the information was not connected to the individual family's experience, and children were not included in this very brief lecture-based intervention. Participants in the study included 105 families in which at least one parent had a mood disorder and at least one child was not depressed and fell between ages 8 and 15 at the start of the study. Four and half years after the initial intervention, families were assessed to examine the long-term effects of both preventive interventions on family functioning. Children in both

groups experienced decreases from baseline internalizing symptoms, with no advantage of either intervention group. Parental changes in attitudes and illness-related behaviors were sustained and greater in the clinician group, as was children's understanding of parental mood disorder. The demonstration of long-term sustained change 4.5 years after the initial intervention is an important strength of this program of research and suggests the utility of short-term interventions, specifically for school-age and adolescent offspring of depressed parents.

Compas and colleagues (2009, 2010, 2011) also have developed a brief cognitive-behavioral intervention designed for children in the 9- to 15-year age range with a depressed parent. The focus of this 12-session intervention is on providing cognitive-behavioral skills to enhance parenting and promote child coping skills in a small family-group format (Compas et al., 2009). Twelve months after the initiation of the intervention, children in the active condition had fewer depressive and other internalizing symptoms compared to those in the provision of written information control group; marginally significant effects were found for child externalizing symptoms (Compas et al., 2009). When Compas and colleagues (2010) examined mediators of 12-month outcomes, they found that increases in use of coping strategies, such as acceptance, positive thinking, and distraction, as well as positive parenting (praising child, scheduling enjoyable activities with the child), accounted for a significant portion of the intervention effect. Children in the cognitive-behavioral condition also had lower rates of major depressive disorder compared to children in the control cognition at 24-month follow-up (Compas et al., 2011). The 24-month follow-up and examination of efficacy mediators of this RCT for parental depression are important strengths of this program of research and are consistent with the goals set forth by Ialongo and colleagues (2006).

The Coping and Promoting Strength is another program based largely on cognitive-behavioral strategies to prevent psychopathology in children at risk due to parental mental illness. Ginsburg (2009) recruited 40 families in which a parent had an anxiety disorder diagnosed with the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (*DSM-IV*), and the child (ages 7–12) did not meet criteria for an anxiety disorder. Twenty families were randomized to the active preventive intervention and the other 20 to a waiting list control group. The program aimed to teach children specific skills, such as problem solving, provide psychoeducation about anxiety, address maladaptive cognitions, and reduce parental overprotection and modeling of anxiety symptoms. The program was also informed by a family-based intervention for offspring of depressed parents; thus another goal of the Coping and Promoting Strength program was improving communication within the family (Ginsburg, 2009). Families received 6 to 8 weekly 60-minute sessions, followed by 3 monthly booster sessions. A year after this brief intervention, none of the children in the active condition met criteria for an anxiety disorder; in comparison, 30% of the children in the waitlist group had developed an anxiety disorder. Despite these impressive findings, the sample size was very small in this study, and more research is needed on preventive interventions for children of parents with an anxiety disorder.

Externalizing Disorders

A large number of RCTs evaluating preventive interventions for child and adolescent externalizing behaviors have emerged in the last decade. The behaviors targeted include childhood disruptive behaviors and violent and substance-abusing behaviors in older children, adolescents, and young adults. One well-studied preventive intervention program in this line of research is Fast Track, a multicomponent intervention focused on at-risk children. A sample of 891 children from schools in four geographic regions was selected during kindergarten for inclusion in the study due to elevated externalizing symptoms. Of the children in the study, 76% scored in the clinical range for externalizing symptoms on the Child Behavior Checklist. Families were randomized to either Fast Track or a control condition. Services were provided over a 10-year span, which started in first grade and included components designed to address risk factors in the classroom, peer relationships, family risk factors, and the communication between families and school, tailored to each age group (see Conduct Problems Prevention Research Group, 2010, for details on specific intervention components in elementary and middle school). The efficacy of Fast Track has been demonstrated for promoting prosocial child development during elementary school (Conduct Problems Prevention Research Group, 1999, 2002, 2004, 2007). More recently, research on Fast Track has examined its impact on child socio-emotional development during the middle school years. When children were assessed in seventh grade, positive intervention effects were found only for children's parent-reported hyperactive behaviors and self-reported delinquent behaviors; there was no reduction in parent-rated oppositional-aggressive scores (Conduct Problems Prevention Research Group, 2010). There was also no reduction in parent-rated oppositional-aggressive

scores in eighth grade, and children in Fast Track reported being more likely to have a deviant best friend in eighth grade. These findings are in contrast to the positive intervention findings reported at the end of elementary school (Conduct Problems Prevention Research Group, 2004). However, when initial risk level was considered as a moderator of Fast Track effects, those in the highest risk group receiving the Fast Track intervention showed lower rates of externalizing disorders when assessed not only in third grade but also in sixth, ninth, and twelfth grades (Conduct Problems Prevention Research Group, 2011), suggesting the importance of subgroup analyses to more fully understand intervention effects. Dodge, Godwin, and the Conduct Problems Prevention Research Group (2013) found that the mechanism by which Fast Track reduced antisocial behavior after ninth grade was through altering patterns of social information processing, including reducing hostile-attribution bias, devaluing aggression, and increasing competency in responding to social problems. The research on Fast Track highlights the critical need to conduct long-term evaluations of preventive interventions, to examine intervention effects during multiple developmental stages, and to consider the impact of moderating variables, such as initial risk level.

The Incredible Years is another well-researched example of an intervention approach to prevent the development of oppositional defiant disorder and conduct disorder in young children. The program was originally developed to treat clinic-referred children (Webster-Stratton & Hammond, 1997; Webster-Stratton & Reid, 2003; Webster-Stratton, Reid, & Hammond, 2001, 2004); however, more recently the components of Incredible Years have been adapted for use as preventive interventions. An RCT was used to examine the efficacy of teacher training and a teacher-administered component of the Incredible Years curriculum, Dinosaur School (Webster-Stratton, Reid, & Stoolmiller, 2008) which is based on cognitive social learning theory and basic research on children with social and emotional disturbances and developed for children ages 3 to 7 (Webster-Stratton & Reid, 2004). Elementary schools (focused on children in kindergarten and first-grade classrooms) and Head Start programs were identified based on high rates of poverty and then randomized to receive either the Incredible Years curriculum or a control condition. Findings supported significant improvements in the classroom management strategies of teachers in the intervention condition and significant improvements in self-regulation, conduct problems, and social competence in children in the intervention condition (Webster-Stratton et al., 2008). The greatest improvements were observed for children in classrooms assessed to have a higher risk level at baseline, again suggesting that level of initial risk can be an important moderator of intervention effects.

The parenting component of the Incredible Years also has been adapted for use as a preventive intervention (Webster-Stratton, 1998). In a recent RCT, preschool-age siblings of youth with delinquency adjudication histories ($n = 92$) were randomly assigned to either the active intervention based on the Incredible Years curriculum, involving both child social competence group sessions and parenting competence group sessions in addition to home visits, or a control condition, involving monthly telephone calls (Brotman et al., 2008). The intervention resulted in differences in observed child aggression during parent-child interactions but not in parent reported aggression. Improvements in parenting practices also were observed for the intervention group, and these were sustained at 16-month follow-up (Brotman et al., 2008). In an effort to incorporate biological outcome assessments, critical for understanding the multiple levels at which a preventive intervention may successfully promote adaptive development, cortisol regulation also was examined after this preventive intervention (Brotman et al., 2007). Salivary cortisol samples were collected pre- and postintervention from both groups before and after exposure to a socially challenging situation. Children in the active intervention group evidenced an increase in cortisol levels in response to anticipation of the social challenge from pre- to postintervention, and this pattern is similar to what would be expected in typically developing low-risk children (Brotman et al., 2007). This effect was not observed for the preschoolers in the control condition. This study highlights the need to examine biological changes in response to preventive intervention to more fully understand the multifaceted ways in which preventive intervention rights the course of development for at-risk children. Finally, more recent work within this program of research has been directed toward identifying ways to successfully disseminate the Incredible Years curriculum into the community more broadly while maintaining fidelity to the model (e.g., Taylor et al., 2008; Webster-Stratton & Herman, 2010).

Triple P—Positive Parenting Program is another well-studied parent training program with solid evidence for the prevention and treatment of externalizing behavior problems (de Graaf, Speetjens, Smit, de Wolff, & Taveechio, 2008; Sanders, Kirby, Tellegen, & Day, 2014; Sanders, Markie-Dadds, & Turner, 2003). Triple P was developed in Australia and has a unique structure that recognizes the varying levels of support appropriate for

different families based on need and preferences for the type, intensity, and modality of assistance. It targets parents of children birth to age 12 and consists of five levels of increasing strength: a universal population-level media strategy for all parents, two levels of brief primary care consultations for mild behavior problems, and two intensive parent training and family interventions for children at risk for severe behavior problems (Sanders et al., 2003). The modality of delivery is flexible, including face-to-face, group, telephone-assisted, and self-directed formats, to meet the requirements of individual families and settings. The multilevel program and flexible format are optimal characteristics for prevention efforts as they allow the program to be disseminated broadly in the community and reach families that may otherwise be reluctant or unable to access programs through standard entry points. Triple P emphasizes parents' capacity for self-regulation of parenting behaviors. It aims to prevent externalizing behaviors by providing parents the knowledge, skills, and confidence to utilize positive parenting practices and promote nurturing and nonviolent environments for children (Sanders et al., 2003).

A variety of derivative programs of Triple P have been developed to target specific populations (Sanders et al., 2003). For example, Stepping Stones Triple P has been adapted at all five levels for parents of children with developmental disabilities, given the increased risk for behavior problems in this population (Tellegen & Sanders, 2013). Level 5 of Triple P also has been enhanced for parents at risk for child maltreatment (Pathways Triple P) and includes content on anger management and other behavioral strategies to improve a parent's ability to cope with raising children. Other variants include Teen Triple P (for parents of teens ages 12–16), Workplace Triple P (delivered through workplaces as an employee assistance strategy), Lifestyle Triple P (for parents of obese and overweight children), and Indigenous Triple P (a version for Aboriginal parents), among others.

A recent meta-analysis of Triple P (Sanders et al., 2014) and its adaptations has found medium intervention effects for children's behavioral outcomes ($d = 0.47$), parenting practices ($d = 0.58$), and parent satisfaction and efficacy ($d = 0.52$). Small to medium effects were seen for parent adjustment ($d = 0.34$) and parental relationship ($d = 0.25$). Fifteen moderator variables were examined across outcomes, and nearly all were a significant moderator for at least one of the outcomes. However, none consistently moderated across all outcomes. After controlling for other moderators, only study power (greater or less than 35 in smallest group), study approach (i.e., universal, targeted, treatment), Triple P level, and the severity of initial child problems uniquely moderated one or more of the outcomes. In addition to the body of work evaluating program levels, formats, and adaptations (see de Graaf et al., 2008; Sanders, Markie-Dadds & Turner, 2003; Sanders et al., 2014), Triple P has undergone large-scale population trials to evaluate the efficacy of the multilevel system at reducing behavior problems or child maltreatment across communities. The first trial (Sanders, 2008) targeted all parents of children ages 4 to 7 in 10 catchment areas in Brisbane, Australia. Relative to matched communities in Sydney and Melbourne, a random sample of households ($N = 3{,}000$) demonstrated significantly greater reductions in emotional and behavioral problems 2 years postintervention. Parents in intervention communities also reported greater reductions in depression, parenting stress, and coercive parenting practices. Prinz and colleagues (2009) randomly assigned 18 counties in South Carolina, US, to receive Triple P or care as usual. Following intervention, Triple P counties had lower rates of maltreatment and placements in out-of-home care. These studies on Triple P represent a coherent program of research suggesting the utility of the program for promoting adaptive child and parent functioning for several populations. Its unique flexibility of intensity and modality, as well as its proven portability into the community with long-term sustained effects, make it an exemplary model of preventive interventions for children at risk for externalizing behaviors. However, more work is needed to better understand moderators of treatment efficacy.

The Good Behavior Game (GBG; Dolan, Turkkan, Werthamer-Larsson, & Kellam, 1989; van der Sar & Goudswaard, 2001) is another preventive intervention aimed at the reduction of externalizing behaviors in children. It is a universal, school-based program designed to promote prosocial behaviors and prevent disruptive behavior. Consistent with the aims set forth by Ialongo et al. (2006), recent research on this preventive intervention has aimed to understand the long-term effects of the GBG as well as mechanisms by which it works. Witvliet, van Lier, Cuijpers, and Koot (2009) examined mechanisms of efficacy of an RCT for the GBG that was initiated in 2004. In the study, 758 children were randomly assigned to the GBG or a control condition, and the group-based intervention took place in first and second grade. The 2-year intervention successfully reduced child externalizing behaviors, specifically for boys enrolled in the study (Witvliet et al., 2009). Increases in peer acceptance were found to partially mediate the reduction in externalizing symptoms for boys (Witvliet et al., 2009). Another RCT

of the GBG found that it successfully reduced aggressive behavior, but only for children who initially showed a low level of on-task behavior, highlighting their high-risk status (Leflot, van Lier, Onghena, & Colpin, 2013). These effects were mediated by reductions in peer rejection (Leflot et al., 2013). Results from this set of studies underscore the importance of examining moderators of treatment effects so as not to conclude that an intervention is ineffective when it is, in fact, effective for a subset of the sample receiving it. Results also suggest that the GBG intervention works through one of its initially postulated mechanisms of action, that is, improving youth social relations.

Consistent with a developmental psychopathology approach to examining multiple levels of a system in the context of a preventive intervention, Leflot, van Lier, Onghena, and Colpin (2010) and colleagues examined teacher behaviors rather than child-centered variables as a mediator of the efficacy of the GBG. They found that improvements in teacher classroom management strategies (i.e., using fewer negative remarks) predicted fewer talking out behaviors, which then predicted reductions in oppositional behavior in the children receiving the GBG intervention (Leflot et al., 2010). Accordingly, this program of research also highlights the importance of examining multiple mediators of efficacy that take into consideration the myriad levels at which a preventive intervention can operate (e.g., child, teacher, system).

Another area of research on the GBG over the last 10 years has aimed to understand its utility at preventing a wide range of externalizing behaviors and disorders in young adults. One strategy to address potential variability in participant response to intervention effects, informed by a developmental psychopathology approach and called for by Ialongo et al. (2006), is to account for potential interactions between individual developmental trajectories and intervention effects. This can be done using growth mixture modeling (Muthén et al., 2002). Petras and colleagues (2008) used general growth mixture models to examine trajectories of youth, ages 19 to 21, who had been enrolled in the GBG during first and second grade. Children in the study were identified as having one of three aggressive and disruptive behavior trajectories from first through seventh grade: persistent high, escalating medium, stable low. Findings supported reductions in rates of antisocial personality disorder and violent and criminal behavior for male GBG participants in the persistent high trajectory (Petras et al., 2008). Other studies of outcomes approximately 10 years after GBG intervention found reductions in substance abuse disorders and smoking and antisocial personality disorder (Kellam et al., 2008) and service utilization for behavioral, emotional, and substance-related problems (Poduska et al., 2008) specifically for males who had been in the highest risk group in first grade. This program of research again exemplifies the importance of including moderators and person-centered analyses in follow-up research to identify the groups of participants most likely to benefit from a preventive intervention over time.

Another high-risk externalizing behavior, often associated with myriad comorbidities, involves alcohol and other substance abuse among teens. A prime example of a cohesive program of preventive intervention research for teen substance abuse is the Strong African American Families Program (SAAF). SAAF is a universal preventive intervention that targets alcohol use among rural African American teens (Brody et al., 2004; Murry & Brody, 2004), informed by several earlier validated interventions for families, such as the Strong Families Program (Spoth, Redmond, Shin, & Azevedo, 2004). We focus on SAAF, given its consistency with the aims of developmental psychopathology to develop preventive interventions that demonstrate utility with diverse, often underserved, populations. Additionally, this intervention also was developed out of a program of basic developmental research with rural African American families that elucidated ways in which parenting practices impact adolescent alcohol use (e.g., Brody, Flor, Hollett-Wright, & McCoy, 1998; Brody, Ge, Katz, & Arias, 2000; Brody, Murry, Kim, & Brown, 2002; Wills, Gibbons, Gerrard, & Brody, 2000; Wills, Gibbons, Gerrard, Murry, & Brody, 2003). This strategy of translating basic research into intervention and using it as a test of developmental theory is closely in line with the tenets of developmental psychopathology.

Brody, Murry, Kogan, et al. (2006) conducted an RCT of SAAF that examined both its long-term effects as well as potential mediators of efficacy, which were tied back to the conceptual theories from which the intervention was derived. In the study, 332 families were assigned to either a 7-week family skills training program (SAAF) or the control condition when offspring were 11 years of age. Highlighting the cultural sensitivity of this study, randomization occurred at the county level, acknowledging the close-knit and widespread familial ties of the population targeted. Additionally, data collection occurred in the home, conducted by African American research assistants (Brody, Murry, Kogan, et al., 2006). The intervention was administered both at the individual (child, parent) level as well as the level of the parent-child dyad each week of the intervention, and youth were followed 29 months after baseline assessment. Adolescents who had been

in the intervention condition were less likely to initiate alcohol use, and for those who did use alcohol, their rate of increase over time was slower based on latent growth modeling results (Brody, Murry, Kogan, et al., 2006). Mediational results confirmed the mechanism of action on which the intervention was based, namely, the SAAF intervention reduced alcohol use through the development of youth protective factors, including a goal-oriented future orientation and more vigilant parenting (Brody, Murry, Kogan, et al., 2006). Positive changes in parenting in the intervention condition also were linked with improvements in the parent-child relationship and youth self-control at postintervention (Brody et al., 2005) as well as at 65-month follow-up (Murry, McNair, Myers, Chen, & Brody, 2013). Similar to findings reviewed earlier from the GBG, findings from SAAF indicated an impact on other risk behaviors besides substance use, including reduced sexual risk behaviors at longitudinal follow-up when participants were 17 years of age (Murry et al., 2011; Murry et al., 2013). These studies demonstrate that targeting the prevention of a single risk factor early in development or during a critical risk phase can have a positive cascade, subsequently preventing multiple risky behaviors and disorders.

Brody and colleagues (2009, 2014) also investigated gene × intervention effects for the SAAF intervention. They examined the dopamine receptor-4 gene (DRD4) alleles that have 7 or more repeats as a potential moderator of the efficacy of SAAF adapted for teens (SAAF-T) on preventing adolescent substance abuse (Brody et al., 2014). They found that male participants in the control condition with at least 1 allele of DRD4 who were randomly assigned to the control condition were more likely to use substances over the course of the study compared to participants with at least 1 allele of DRD4 with 7 or more repeats who received the SAAF-T intervention. Males in the control condition with at least 1 allele of DRD4 were also more likely to use substances over the course of the study compared to adolescents in either the control or intervention groups who carried 2 alleles of DRD4 with 6 or less repeats (i.e., neither DRD4 allele had 7 or more repeats). Thus, results support DRD4 as a moderator of treatment efficacy and identify the group, male carriers of at least 1 allele of DRD4 with 7 or more repeats, as potentially most in need of preventive intervention in this population. Similarly, Brody and colleagues (2009) found that participants in an RCT of SAAF who were assigned to the control condition and carried a genetic risk, defined as a variable-nucleotide repeat polymorphism in the promoter region of gene SLC6A4, were more likely to display an increase in risk behaviors over the course of the study compared to those at genetic risk who were assigned to SAAF.

Child Maltreatment

Children who have experienced maltreatment are especially at risk for a variety of internalizing and externalizing symptoms. Child maltreatment represents an egregious failure of the caregiving environment to meet children's basic needs for safety and security. When children are exposed to these conditions, they are at risk for maladaptation in multiple psychological, biological, and relational domains of functioning (Cicchetti & Manly, 2001; Cicchetti & Valentino, 2006). As development is cumulative, maltreatment often results in negative cascades wherein early failures to resolve stage-salient issues lead to subsequent maladaptation (Masten & Cicchetti, 2010). Accordingly, ideal preventive interventions for child maltreatment are administered early in development, thereby promoting a healthy developmental trajectory from a young age. Given that a large percentage of maltreated children are abused or neglected by a primary caregiver, preventive interventions that focus on parenting and the relationship between child and caregiver are of utmost importance (Toth & Gravener, 2012).

An exemplary preventive intervention for child maltreatment was conducted by Cicchetti, Rogosch, and Toth (2006), who compared two active prevention strategies in an RCT for 1-year-old infants in maltreating families and their mothers. Basic research on attachment security in children who have been maltreated suggests that a large majority develop a disorganized attachment (Cicchetti & Barnett, 1991; Cicchetti et al., 2006a), increasing the likelihood of subsequent failures to navigate stage-salient issues of development (Sroufe, 2005) and clearly suggesting the need for relationally based preventive interventions with this population (Toth, Pianta, & Erickson, 2011). Using findings from basic science as a guide, one of the interventions chosen for this RCT was CPP (described earlier), which focuses on the relationship between primary caregiver and child. A psychoeducational parenting intervention (PPI) was chosen as the second active intervention for comparison, given clear deficits in basic parenting skills found in maltreating parents. Socioeconomically disadvantaged mothers and their infants ($n = 137$) were randomly assigned to one of the two treatment conditions or a community standard (CS) group that received treatment as usual. Additionally, a sample of mother-child dyads also with low socioeconomic status (SES) but without a history of maltreatment was recruited as a normative comparison

(NC; $n = 52$). The inclusion of this normative group allowed for basic comparisons on study variables between maltreated and nonmaltreated infants, consistent with the aim of developmental psychopathology to understand the continuum between normal and abnormal development. Moreover, the inclusion of the normative group enabled the determination of whether provision of the preventive intervention could result in promoting functioning in the maltreatment group receiving intervention that is comparable to that seen in nonmaltreated infants. Prior to intervention, significantly higher rates of disorganized attachment were observed in the maltreated compared to the nonmaltreated infants (Cicchetti et al., 2006). Several differences also were noted between the mothers in the maltreating group compared to the nonmaltreating group, including higher rates of self-reported maltreatment in their own childhoods and maladaptive parenting attitudes in the mothers in the maltreatment group. This group of mothers also reported less family support and evidenced less maternal sensitivity. Both active interventions were administered weekly in the home over a 1-year period. Postintervention, children who were in the CPP and PPI conditions, as well as those in the NC group, differed significantly from the CS group on attachment classifications. Although disorganized attachment continued to predominate in the children in the CS group, this was no longer the case for children in the CPP and PPI conditions. Additionally, less than 2% of the children in the CS group moved from an insecure to a secure attachment from pre- to posttreatment, in contrast to more than half of the toddlers in the CPP and PPI groups who developed a secure attachment over the course of the intervention. Somewhat surprisingly and contrary to expectations, infants in the CPP group did not evidence greater attachment security than those whose mothers received PPI. No evidence was found for treatment mediators, despite the sound theoretical choice of each of these interventions and hypothesized pathways through which they are believed to operate. These results suggest that early in development, the provision of a good-enough intervention, even if it is not targeted at improving attachment, may be efficacious in doing so. However, it remained unclear whether these results would be sustained over time.

Importantly, attachment security in the four groups was examined 12 months after the completion of the intervention. Children in the CPP condition had higher rates of secure attachment and lower rates of insecure attachment than those in the PPI or CS groups (Stronach, Toth, Rogosch, & Cicchetti, 2013). The CPP group and the NC groups did not differ from each other, meaning that 12 months after preventive intervention, children who had received the relational intervention continued to be more likely to evidence a secure attachment with their mothers and at rates comparable to those observed in the nonmaltreated group of children. Children in dyads that had received the PPI did not continue to evidence benefits regarding increased attachment security. The findings from this study highlight the importance of longitudinal follow-ups, consistent with recommendations that such follow-ups are necessary to fully understand the impact of preventive interventions (Ialongo et al., 2006). These results suggest that for sustained change in attachment security in maltreated children to occur, a theoretically informed intervention directed specifically at the attachment relationship, such as CPP, is more efficacious than a PPI.

An important next step in preventive intervention science involves the integration of biological and psychological processes in the evaluation of preventive interventions, with increasing recognition that experience can impact biology (Cicchetti & Gunnar, 2008; Ialongo et al., 2006). Basic research with maltreated children has suggested the negative impact of early adverse care on the development of the hypothalamic-pituitary-adrenal (HPA) axis; this research has necessitated an evaluation of changes in HPA axis functioning postintervention to more fully understand the impact of psychosocial intervention on biological processes in this population (Bruce, Gunnar, Pears, & Fisher, 2013; Cicchetti & Gunnar, 2008). Cicchetti, Rogosch, Toth, and Sturge-Apple (2011b) offered an example of this integration in a study that examined cortisol regulation in response to the above-described preventive intervention for maltreated infants and their mothers. Morning cortisol was collected from offspring in maltreating families ($n = 91$) and from those in the nonmaltreated group ($n = 52$) at baseline, midintervention, postintervention, and 1-year follow-up, when offspring were approximately 38 months of age. No group differences in morning cortisol existed at baseline between the maltreated and nonmaltreated infants. Latent growth curve analyses were used to examine similarities and differences in cortisol regulation over time among the nonmaltreated, community standard, and combined (CPP, PPI) maltreated intervention group over the 25-month period. Children in the maltreated community standard comparison condition experienced declines in morning cortisol over the course of the intervention, whereas the trajectory of morning cortisol for the intervention group over time remained statistically indistinguishable from the trajectory of morning cortisol for the nonmaltreated

comparison group of children. These results underscore the potential of psychosocial interventions to affect biological processes in maltreated children, diverting their developmental course toward a more positive trajectory via multiple levels of functioning. In an effort to understand whether the impact of this preventive intervention on child attachment security was impacted by genotype, Cicchetti, Rogosch, and Toth (2011a) also examined the moderating effects of polymorphisms of the serotonin transporter and dopamine D4 receptor genes on the efficacy of the previously described RCT. Genetic variation did not moderate the efficacy of the intervention on improving attachment security, suggesting that the experience of maltreatment may be so powerful that it overrides the effects of genetics and that maltreated children may benefit from intervention regardless of genetic vulnerability.

Notably, CPP also has been evaluated by another research group and found to be an efficacious intervention for improving behavioral problems and trauma symptoms in preschool children exposed to domestic violence (Lieberman, Ghosh Ippen, & Van Horn, 2006; Lieberman, Van Horn, & Ghosh Ippen, 2005).

The Nurse-Family Partnership (NFP) is another early intervention designed to prevent child maltreatment and promote adaptive functioning and subsequent development in young, economically disadvantaged mothers and their offspring (Olds, 2006). NFP provides services for low-income, first-time mothers during pregnancy and continuing through the child's second birthday. Nurses provide in-home intervention to promote health behavior during pregnancy, facilitate the development of supportive relationship between new mothers and friends and family, link mothers with other needed resources, promote sensitive and competent caregiving behaviors, plan future pregnancies, and complete their education and/or find work (see Olds, 2006, for more details). Mixed evidence has been found for the effects of NFP on incidence of maltreatment and emergency room visits among young children (e.g., Matone, O'Reilly, Luan, Localio, & Rubin, 2012; Olds, Henderson, Chamberlin, & Tatelbaum, 1986; Olds, Henderson, & Kitzman, 1994). More recent efforts to understand the impact of NFP on timing of maltreatment reports found that after age 5, children in dyads receiving NFP compared to those in a comparison group (which included screenings and referrals as needed) had fewer first child protective services reports up through age 15; the effect was more pronounced in an identified high-risk subgroup and for neglect compared to any abuse onset (Zielinski, Eckenrode, & Olds, 2009). Results again highlight the importance of conducting long-term evaluations and identifying potential moderators to more fully understand the effects of preventive intervention programs.

Other preventive interventions for children who have been maltreated have focused on children placed in out-of-home care. Attachment and Biobehavioral Catch-up (ABC) is a preventive intervention that was designed for infant, toddler, and preschool-age maltreated children in the foster care system. Ten conjoint foster parent-child sessions are used to promote the caregiver's ability to create an environment in which the child feels nurtured and loved, even when the caregiver feels pushed away; to work with the caregiver on personal issues that may be arising in the context of caring for the foster child and reduce frightening behaviors on the part of the parent; and to develop a highly controllable interpersonal environment so children can begin to learn to regulate their emotions and behaviors (Dozier, 2003; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008). Preliminary results from an RCT comparing ABC to a time-matched educational control condition found that foster children in the ABC condition evidenced fewer avoiding behaviors when distressed compared to children in the control condition (Dozier et al., 2009). The impact of ABC on HPA axis functioning also has been examined to provide a better understanding of the multiple domains in which ABC may be advantageous to maltreated children. Consistent with hypotheses regarding this preventive intervention, children who received ABC were found to be able to regulate HPA axis functioning better than children in a control condition postintervention (Dozier et al., 2008). Notably, ABC has also been adapted for use with biological parents at risk for neglecting their infant and toddler-age children. Children in parent-child dyads receiving ABC were found to have lower rates of disorganized attachment and higher rates of secure attachment compared to those in an educational control condition (Bernard et al., 2012), suggesting that effective programs developed for out-of-home placements may also be utilized with appropriate amendments with biological parent-child dyads.

The Early Intervention Foster Care Program, more recently termed Multidimensional Treatment Foster Care for Preschoolers (MTFC-P), focuses on improving placement success specifically for preschool children in the foster care system (Fisher, Burraston, & Pears, 2005). MTFC-P is a family-based intervention that works with foster children, foster parents, and permanent placement resources over a 6- to 9-month period. It involves intensive training for foster parents prior to child placement, consultation and support for foster parents during placement,

weekly therapeutic play groups for children, and services to bridge the transition to a permanent placement (Fisher, Stoolmiller, Gunnar, & Burraston, 2007). This intervention has been shown to be effective at reducing the number of failed placements for children in foster care relative to the comparison condition (Fisher, Burraston, & Pears, 2005). More recent research on MTFC-P has included biological and physiological measures of intervention efficacy. An RCT for young maltreated children who were randomly assigned to either MTFC-P or foster care as usual found that children receiving MTFC-P evidenced improvements in cortisol regulation (Fisher et al., 2007). Additionally, children who received MTFC-P were found to be more responsive to performance feedback errors when using an electrophysiological measure of response monitoring compared to those who received treatment as usual and comparable to nonmaltreated peers (Bruce, McDermott, Fisher, & Fox, 2009).

Consistent with a developmental psychopathology perspective, the needs of children in out-of-home care are likely to differ depending on the child's developmental stage. ABC and MTFC-P both focus on young children in out-of-home placements; alternatively, Fostering Healthy Futures (FHF) is a child-focused preventive intervention designed for preadolescent children (ages 9–11) that has been found to have effects on placement stability and permanence (Taussig, Culhane, & Hettleman, 2007; Taussig, Culhane, Garrido, & Knudtson, 2012). FHF is a 30-week program for preadolescent youth in out-of-home care that involves weekly child skills groups and individual mentoring by graduate students in social work or psychology. FHF was designed to promote child well-being by identifying and addressing mental health issues, preventing adolescent risk behaviors, and promoting competence (Taussig et al., 2007). The initial RCT of FHF ($n = 156$) revealed significantly better outcomes on a multi-informant factor score of mental health functioning for youth randomized to the FHF preventive intervention relative to youth in the assessment-only condition 6 months postintervention (Taussig & Culhane, 2010). The more positive mental health outcomes associated with FHF likely contribute to better placement stability and permanency found for intervention youth, especially for those initially placed in nonrelative foster care. Specifically, after controlling for baseline behavior problems, youth initially placed in nonrelative foster care who participated in FHF had 44% fewer placement changes, were 82% less likely to be placed in residential treatment, and were five times more likely to have attained permanency 1-year postintervention than control youth in nonrelative foster care at baseline (Taussig et al., 2012). This study was particularly rigorous in that it integrated data from interviews with children and caregivers, social histories completed by caseworkers, legal petitions filed in the dependency and neglect court that led to out-of-home placement, and statewide administrative case and placement records. Longitudinal follow-up of this sample is currently under way through young adulthood.

Taken together, these studies suggest that psychosocial preventive interventions administered to at-risk or maltreated infants and children and their biological or foster parents can have a sustained impact on child functioning, placement success, and biological processes in the child. Expanding the scope of assessments administered in preventive intervention RCTs to include biological measures provides additional evidence for the importance of preventive interventions for correcting the course of development for at-risk children.

Child Trauma

In a historical climate marred by national and international terrorist acts, war, highly publicized school shootings, domestic violence, and natural disasters occurring in densely populated areas, there is a vital need for the evaluation of preventive interventions geared toward preventing posttraumatic stress disorder (PTSD) and other negative sequelae associated with exposure, both direct and vicarious, to traumatic events. In fact, it is estimated that about 14% of children and adolescents experience a disaster by age 16 (Becker-Blease, Turner, & Finkelhor, 2010), and yet few RCTs have been conducted in this area. This is likely in part due to the numerous ethical, logistical, and methodological challenges associated with research in the context of large-scale catastrophic events (Masten & Osofsky, 2010). And yet the need for evidence-based services in these situations is paramount. For example, in the 2 years following Hurricane Katrina, more than 40% of 7,258 children (grades 4–12) from affected areas met the National Child Traumatic Stress Network cutoff for referral to mental health services (Osofsky, Osofsky, Kronenberg, Brennan, & Hansel, 2009). In the last decade, the Psychological First Aid (PFA) approach has been developed in collaboration between the National Child Traumatic Stress Network and the National Center for PTSD. PFA interventions are grouped into eight core actions:

1. Initiate compassionate contact.
2. Enhance feelings of safety and comfort.

3. Gather information to identify immediate needs and concerns.
4. Provide practical assistance.
5. Connect individuals with social supports.
6. Provide psychoeducation about stress and coping.
7. Link families with appropriate community services to be utilized now and/or in the future.
8. Provide educational handouts (Vernberg et al., 2008).

These core actions are grounded in the five basic principles for facilitating positive adaptation after a traumatic event, principles that have received empirical support (Hobfoll et al., 2007). Tools have also been developed to facilitate the development of an evidence base for PFA (Vernberg et al., 2008). There is a growing consensus that this is the approach of choice for children and adults in the aftermath of disasters (Watson, Brymer, & Bonanno, 2011); yet without empirical evidence, many questions remain regarding the application of PFA with children and adolescents immediately postdisaster (La Greca & Silverman, 2009).

Other empirical research on preventive interventions for disaster exposure has been limited. An RCT comparing a universal, teacher-administered resilience-focused intervention to a control condition found that the active intervention effectively prepared children in fourth and fifth grade for mass trauma in Israel (Wolmer, Hamiel, & Laor, 2011). A school-based preventive intervention also was found to reduce PTSD symptoms compared to a waitlist control group for second- to sixth-grade children exposed to a terrorist attack in Israel (Berger, Pat-Horenczyk, & Gelkopf, 2007). In contrast, an early intervention for child (ages 7–18) survivors of car accidents found no advantage for children receiving a psychological debriefing intervention compared to no intervention (Stallard et al., 2006).

In summary, despite research highlighting the criticality of providing adequate supports following the occurrence of traumatic events (Kronenberg et al., 2010), there continues to be a dearth of studies designed to assess preventive intervention in the aftermath of mass trauma (Foa et al., 2005), and many of the existing preventive interventions for trauma exposure have not employed an experimental RCT design (see Peltonen & Punamaki, 2010, for a review), which makes firm conclusions about the efficacy of these preventive interventions difficult to ascertain. Importantly, previous research indicating the iatrogenic effects of universal intervention immediately after exposure to a traumatic event in adults (Lilienfeld, 2007) underscores the need to carefully evaluate postdisaster preventive interventions for children and adolescents.

Parental Divorce

Offspring of divorced parents are also at risk for maladaptive development (Afifi, Boman, Fleisher, & Sareen, 2009; Amato, 2001; Pedro-Carroll, 2005) and have been the recipients of preventive interventions to ameliorate the course of development. The New Beginnings Program (NBP) for youth (ages 9–12) and their mothers is one such program that was developed from basic research on risk and protective factors for children of divorced parents. The NBP has been found to be effective for this population (Wolchik et al., 2000, 2002), and more recent research has examined the long-term effects of this preventive intervention and putative mediators of treatment efficacy. NBP involves both mother and child intervention components. Offspring who received NBP were found to have fewer internalizing and externalizing symptoms, mental health diagnoses and other risk factors, and greater academic achievement and self-esteem compared to youth in a literature control condition 6 years after the intervention concluded (Wolchik, Sandler, Weiss, & Winslow, 2007). Zhou and colleagues (2008) tested putative mediators of 6-year longitudinal effects, both to better understand the pathways through which intervention effected change and, equally important, to test the causal inferences regarding how divorce leads to the development of psychopathology. Improvements in the mother-child relationship were found to mediate NBP effects on offspring mental health for those who were at high risk for maladjustment at baseline. Results suggest the importance of the mother-child relationship as a protective factor for high-risk youth who experience parental divorce and highlight the continued need to study the caregiver-child relationship over the course of development.

Another recent study of the NBP intervention moved beyond mediational models toward examining developmental cascade effects of intervention on child adaptation (McClain et al., 2010). Developmental cascade models recognize the dynamic interplay between adaptive (or maladaptive) changes over the course of development. Using this framework, support was found for a model in which improvements in the mother-child relationship were followed by related decreases in child internalizing symptoms, subsequently related to increases in youth self-esteem and decreases in internalizing disorder symptoms in adolescence (McClain et al., 2010). This program of research has been strengthened by a 15-year follow-up on the effects of

NBP, which indicated that the active intervention reduces the occurrence of internalizing disorders for youth and substance-related disorders for male youth (Wolchik et al., 2013). Taken together, these findings support the utility of NBP for improving the developmental trajectory for youth of divorced parents and also provide a detailed and developmentally informed understanding of how the intervention works both in the short and the long term.

Summary

Just as there are many pathways to risk over the course of childhood and adolescence, so are there many pathways to health, exemplifying one of the core concepts in developmental psychopathology, equifinality (Cicchetti & Rogosch, 1996). Since the turn of the century, researchers have made great strides using the gold standard RCT design to evaluate preventive interventions for at-risk children and families, many developed out of relational (e.g., Bernard et al., 2012; Cicchetti et al., 2006; Horowitz et al., 2007; Toth et al., 2006) or cognitive-behavioral approaches (e.g., Compas et al., 2009; Gillham et al., 2007; McCarty et al., 2012) and grounded in basic developmental science (Toth, Pianta, & Erickson, 2011). Follow-ups 1 year and beyond have become more common (e.g., Barrett et al., 2005; Compas et al., 2011; Conduct Problems Prevention Research Group, 2011; Kellam et al., 2008; Murry et al., 2013; Stronach et al., 2013), allowing the field to identify which interventions have lasting positive impacts on developmental trajectories and are therefore most important to disseminate. Progress has been made on the identification of mediators (e.g., Compas et al., 2010; Horowitz et al., 2007; Leflot et al., 2010; Witvliet et al., 2009; Zhou et al., 2008) of treatment efficacy. Genetic and other biological assessments have increasingly been incorporated into preventive intervention trials (e.g., Brody et al., 2009, 2011; Cicchetti et al., 2011a; Cicchetti et al., 2011b; Dozier et al., 2008), although much more is necessary on this frontier, which is likely to shape the future of preventive intervention research. An overview of meta-analyses of preventive interventions conducted in the last two decades suggests overall small to medium effect sizes (Sandler et al., 2014). Importantly, this review also highlighted the heterogeneity of effects in a majority of the meta-analyses reviewed and identified possible sources for future research to investigate (Sandler et al., 2014). And so, in the midst of progress comes the acknowledgment that we still have far to go to ameliorate the negative course of development for the many children and families at risk for psychopathology.

CURRENT DIRECTIONS IN CONCEPTUALIZING COMPLEXITY

As evidenced in the previous section, the field of prevention science has achieved significant gains over the last decade. The developmental psychopathology perspective has paved the way for many of these gains through its advancement of a unifying conceptual framework and emphasis on multidisciplinary and translational research (Cicchetti & Toth, 2009; Rutter, 2013; Toth et al., 2011). However, as advances in theory and methodology are made, new directions and challenges arise. One of the major challenges facing the field is how to conceptualize and evaluate preventive interventions in the context of increased complexity. This section focuses on current directions in the field to advance our ability to capture the complexity of mechanistic processes and outcomes involved in preventive interventions. We first discuss the importance of rich theoretical models in designing and evaluating preventive interventions. We present an assessment of advances and limitations in measuring intervention effects at multiple levels of analysis (e.g., genetic, neuroimaging, psychosocial) and in multiple ecological contexts (e.g., individual, interpersonal, cultural). To conclude this section, we highlight recent thinking on developmental cascade models, models that aim to integrate multiple risk and protective processes in examining preventive intervention effects longitudinally.

Theoretical Foundations

Intervention targets in prevention science are inherently complex. Preventive interventions aim to alter developmental and adaptive processes that typically occur at multiple levels within complex social, biological, and environmental systems (Cicchetti & Toth, in press; Lich, Ginexi, Osgood, & Mabry, 2013). Individuals within systems also present with their own unique mix of genetic, biological, and psychological strengths and weaknesses and history of prior experiences that influence the probability of intervention efficacy (Lich et al., 2013). Conceptualizing how an intervention alters individual and systems-level factors and their transactions is not an easy task. Given the complexity of intervention targets, multiple mechanisms are likely involved in most preventive interventions. As illustrated in the selected review of programs just presented, a wide variety of efficacious preventive interventions currently exist. Our challenge in the field is to move beyond establishing efficacy and to focus on closely aligning preventive interventions with theory to delineate the underlying mechanisms by which interventions work

and to identify subgroups for which interventions are more or less effective.

Both the design and evaluation of preventive interventions need to be more theory-driven than is currently the norm (Cicchetti & Toth, 2009; Ialongo et al., 2006). The general theoretical rationale for selecting a given approach for an intervention target is usually clearly specified. However, the hypothesized mediating mechanisms of the intervention program must also be clearly delineated and grounded in theory to adequately evaluate the theorized process by which the intervention program exerts its effects. Moreover, subgroups for which interventions are expected to be more or less effective also must be specified a priori (Bloom & Michalopoulos, 2013; Fairchild & MacKinnon, 2014). Finally, consideration of theorized mediating mechanisms and subgroup analyses must be couched within a broader developmental systems perspective that emphasizes the importance of moving beyond additive or interaction models to conceptualizing dynamic reciprocal, bidirectional, and co-acting processes in our models (Lich et al., 2013; Marshall, 2013). Ideally, detailed conceptual models reflecting these dynamic processes across levels of analysis (e.g., biological, cognitive, behavioral) and ecological contexts should be constructed prior to designing or selecting intervention components. The model can then guide the development or selection of the preventive intervention components to accomplish the hypothesized underlying mechanisms and determine which measures are most appropriate to evaluate the efficacy of the intervention on these processes. Finally, researchers should determine the appropriate trial design (e.g., comparison group, level of randomization) and statistical methodologies to answer target research questions. Thinking through the conceptual model while also delineating statistical models can help researchers identify assumptions and limitations of statistical results in the context of the more complex conceptual model as well as examine feasibility issues with regard to statistical analyses and power estimates.

Multiple Levels of Analysis

Consistent with the developmental psychopathology perspective, and as just illustrated, an increasing number of empirical studies are incorporating multiple levels of analysis to understand complex developmental processes, which has resulted in theoretical advances (Cicchetti & Gunnar, 2008). The multiple-levels-of analysis approach improves on the definition of mental health problems as brain disorders and suggests that they can be better conceptualized in a more dynamic fashion that reflects the probabilistic, bidirectional, and transactional interplay among genetic, neurobiological, social, psychological, and environmental influences across the life course (Cicchetti & Toth, 2009; Cicchetti & Toth, in press; Toth, Gravener-Davis, Guild, & Cicchetti, 2013). As discussed, intervention design needs to be informed by these theories. Researchers also need to routinely incorporate measures at multiple levels of analysis in intervention trials to more fully capture and evaluate intervention effects and mechanistic processes consistent with theory. The methods and technology to assess various levels of analysis are continuing to evolve, which allow for more effective and efficient measurement of phenomena. However, the field has not yet made optimal use of these technological advances. This section highlights our evolving understanding and methodology, with a particular emphasis on biological levels of analysis.

At present, most evaluations of preventive interventions continue to involve theories, experimental designs, and measurement batteries that have been dominated by processes at the psychosocial and behavioral levels of analysis. Historically, trials of preventive interventions conducted with children and adolescents have paid minimal attention to neurobiological and physiological systems in their evaluations of treatment efficacy (Cicchetti & Gunnar, 2008). The neglect of biological levels of analysis in evaluations of preventive intervention efficacy may be in part due to beliefs that biological systems are more static and less malleable to intervention (Cicchetti & Gunnar, 2008; Ialongo et al., 2006). However, research is increasingly demonstrating that interventions can alter physiological structures and functions relating to the behavior of interest (e.g., Beauregard, 2009; Dozier et al., 2008; Fisher et al., 2007; Linden, 2006). Moreover, genetic moderation of intervention efficacy is increasingly being elucidated (Brody et al., 2009, 2013; Cicchetti, Toth, & Handley, 2015). Over the last decade, several important articles and special issues in prominent journals (e.g., Belsky & van IJzendoorn, 2015; Beauchaine, Neuhaus, Brenner, & Gatzke-Kopp, 2008) have called for increased emphasis on biological levels of analysis, especially in the area of genetics and G×E interactions.

The biological level of analysis has already provided some important directions in designing preventive interventions. Research has demonstrated that biological vulnerabilities can give rise to broad classes of homotypic comorbidity (e.g., multiple externalizing disorders in an individual, such as conduct disorder and substance abuse) and heterotypic comorbidity (e.g., co-occurrence of internalizing and externalizing disorders, such as anxiety and

attention-deficit/hyperactivity disorder; Beauchaine et al., 2008; Riosa, McArthur, & Preyde, 2011). For example, dysfunction in the mesolimbic dopamine system has been found to be a core neural substrate of risk for all or most externalizing behaviors (Beauchaine et al., 2008). Given common biological risks, preventive interventions should not focus on single disorders but rather address risk for psychopathology across internalizing and externalizing spectra that lie in homotypically continuous pathways (Beauchaine et al., 2008). For example, preventive interventions for conduct disorder ideally should include modules for substance abuse prevention even if substance use has not been initiated. Heterotypic comorbidity also should be assessed and explicitly addressed in preventive interventions (Beauchaine et al., 2008). A recent meta-analysis demonstrated that interventions can have medium to large effects on comorbid disorders, although larger effects are generally found for homotypic (ES $d = 1.18$) than heterotypic ($d = 0.54$) comorbidity, especially when interventions are directed at specific disorders (Riosa et al., 2011).

One of the most frequently stated rationales for focusing on biological systems in the context of preventive interventions is the possibility of elucidating markers of biological vulnerability for the purpose of identifying those at highest risk and therefore in greatest need of intervention (Beauchaine et al., 2008; Ialongo et al., 2006). The concept of differential susceptibility has gained momentum over the last decade, emphasizing individual differences in susceptibility to environmental influence based on biological markers (e.g., genotype, reactivity to stress, endophenotype; Belsky & Pleuss, 2009; Ellis & Boyce, 2011). Extended to preventive intervention, this theory provides a rationale for why some individuals may be more (or less) responsive to an intervention than others. Utilizing multiple levels of assessment is important in preventive interventions to more fully understand who is most at risk and most in need of preventive intervention. Importantly, differential susceptibility theory recognizes that biology can function as either a risk or a protective factor and that it is equally important to understand both ends of this continuum (Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Belsky & Pluess, 2009; Ellis & Boyce, 2011). Current theory suggests that individuals scoring high on a given biological susceptibility marker may be more vulnerable to both positive and negative environmental contexts (Ellis & Boyce, 2011). Based on this understanding, it is plausible that those susceptible individuals in greatest need of intervention based on prior exposure to negative environmental contexts may also be the most responsive to interventions providing more favorable environments. A number of preventive interventions have demonstrated stronger effects for individuals at highest risk (e.g., Conduct Problems Prevention Research Group, 2011; Horowitz et al., 2007; Leflot et al., 2013; Petras et al., 2008; Stice et al., 2009; Webster-Stratton et al., 2008), which is consistent with this idea. Importantly, research on differential susceptibility has generally been conducted with Caucasian populations (van IJzendoorn, Belsky, & Bakermans-Kranenburg, 2012), thereby calling into question whether similar results would be obtained with more heterogeneous populations. Moreover, few studies have directly investigated differential susceptibility as a possible mechanism for this pattern of results. Consistent with capitalizing on RCTs to test theory, researchers should investigate biological measures as moderators of intervention response and examine the way preventive interventions may alter biology (Beauchaine et al., 2008; Belsky & van IJzendoorn, 2015; Ialongo et al., 2006).

The next subsections discuss four main domains of biological inquiry represented in the field of developmental psychopathology that are ripe for furthering our understanding of differential susceptibility and intervention effects at multiple levels of analysis. These four domains include genetics, endophenotypes, neuroimaging, and reactivity to stress.

Genetics

With the completion of the Human Genome Project in 2003, considerable enthusiasm and efforts have been invested over the last decade in identifying gene variants and molecular mechanisms involved in psychopathology. To date, the results from such efforts have yielded more questions than answers. More traditional approaches in behavioral genetics using twin and adoption designs have found considerable heritability across nearly all psychological traits, with estimates most often ranging from 40% to 60% (DeYoung & Clark, 2012). Heritability estimates of mental disorders, such as schizophrenia (70%–80%) and major depression (40%), are also quite substantial (DeYoung & Clark, 2012). Given these substantial heritability estimates, many researchers expected to be able to identify the specific genes associated with mental disorders relatively easily once it became possible to examine the entire human genome. However, the expectation that simple, direct paths from gene to disorder would be found has not been realized for complex mental disorders. Few linkage studies detect genes, many genome-wide association studies fail replication, and the few genetic effects that are replicated account for only a small amount of variance

(Kendler, 2011; Moffitt, Caspi, & Rutter, 2006). One explanation for these results is that most genes contributing to psychopathology are incompletely penetrant, meaning that individuals may not develop the disorder despite having the allele(s) associated with the condition. Incomplete penetrance can lead to small effects, multiple effects, effects that vary with genetic background or environmental exposure, and effects that vary over time and developmental level (Johnson, 2012). A focus on main effect associations between gene and disorder may also contribute to the small percentage of genetic variance accounted for in disorders. Gene × environment (G×E) interactions sometimes explain more variance in outcome than main effects (Beauchaine et al., 2008). For example, marked gene effects are commonly found within environmentally exposed subgroups (G×E interaction) when virtually no relationship exists between gene and outcome (main effect; Cicchetti, Rogosch, Sturge-Apple, & Toth, 2010; Moffitt et al., 2006). Considering these findings, it may be possible that some multifactorial disorders might result from relatively few genes whose effect sizes are conditional on exposure to specific environmental experiences rather than resulting from many genes of small effect (Moffitt et al., 2006). Explicitly measuring and modeling environmental factors in basic research and preventive intervention trials will be important in evaluating this possibility.

The slow progress in elucidating genetic contributions to psychopathology should not be a deterrent against incorporating genetics into the conceptualization and measurement of outcomes in preventive intervention trials. Research over the last decade has only emphasized the complexity of psychopathology and the importance of multiple levels of analysis in evaluating vulnerability to and protection against psychopathology. For example, several important contributions of gene variants on psychopathology would have been missed if environmental factors had not been considered and explicitly modeled (Moffitt et al., 2006). The molecular mechanisms from gene to protein to phenotype are complex and multifaceted. Multiple types of genetic information can be assessed, which may contribute to our understanding of psychopathology and its prevention. At the level of deoxyribonucleic acid (DNA), sequence variants can be examined ranging from single nucleotide bases to the full DNA sequence. Structural variation in the human genome can also take many forms, including long insertions, deletions, or inversions. Regulatory elements that control the process of DNA transcription (first step in gene expression: DNA → ribonucleic acid [RNA]) are receiving increasing attention given their role in determining which genes are expressed. The rapid growth in the area of epigenetics over the last decade has provided a deeper understanding of the molecular processes likely involved in some environmental impacts on gene expression. Various aspects of gene-environment interplay are also gaining considerable attention and show promise for furthering our understanding of trajectories of psychopathology and understanding who is most likely to benefit from which preventive interventions. Molecular mechanisms also can be examined at the level of RNA and gene products (i.e., proteins, enzymes, neurotransmitters), although this area has received less attention. This section discusses the potential advantages as well as challenges of incorporating measures of gene-environment interplay and epigenetics into preventive intervention trials since these mechanisms show the most promise in advancing our understanding of genetic effects in prevention.

Most complex human behavior arises from a combination of multiple interacting genetic and environmental influences (NRC & IOM, 2009). A single genetic variant or environmental risk factor will rarely be necessary or sufficient to produce a disorder (Beauchaine et al., 2008; NRC & IOM, 2009). For this reason, most researchers in the field of developmental psychopathology are focusing their efforts on understanding the interplay between genes and environment. The investigation of gene-environment interplay is a natural progression for prevention scientists since a main focus of prevention involves altering the environment or how a person interacts with the environment. Understanding how genetic variation increases vulnerability or resilience will improve underlying developmental theories and has the potential to lead to the development and delivery of more efficient and effective preventive interventions. Moreover, the identification of genetic moderation of intervention outcome has important implications for ascertaining which individuals are most likely to derive benefit from a given intervention (Cicchetti & Toth, 2015).

There are multiple types of gene-environment interplay. The most commonly recognized form is the G×E interaction. G×E occurs when two causal factors (i.e., genetic variant, environmental exposure) contribute to an outcome in the same individual, but neither factor is sufficient in itself to produce the outcome alone (Moffitt et al., 2006; Uher, 2011). The effect of each factor depends on the presence or absence of the other. Results from studies of G×E are relevant for preventive interventions since, by definition, altering either of the interacting factors (i.e., changing the environment of a person with the vulnerable genotype) can prevent the occurrence of the problem (Uher, 2011). In the future with sufficient research

evidence, it might be advantageous and cost effective to target interventions to individuals with previously identified vulnerable genotypes. Although G×E investigations are conceptually relevant for preventive interventions, detecting G×E statistically is contingent on the scale of measurement, the statistical model applied, the distribution of genetic variants and environmental exposures in the test population, and statistical power (Uher, 2011).

A number of concerns regarding G×E research have been raised. These include low replication rates, inflated Type I error, small sample sizes to detect interactions, improper handling of potential confounders, and publication bias (Duncan & Keller, 2011; Duncan, Pollastri, & Smoller, 2014; Keller, 2014). Recommendations also have been advanced that include prioritizing replication attempts, reporting all statistical tests conducted, adapting more stringent thresholds for statistical significance, and including covariate by environment and covariate by gene interaction terms in the same model as the G×E of interest (Duncan et al., 2014; Keller, 2014). In an effort to increase methodological rigor, Moffitt and colleagues (2006) provide a useful systematic stepwise approach for the study of G×E interactions.

As highlighted in the review of advances over the last decade, G×E analyses are beginning to be incorporated into prevention trials to examine moderators of intervention effects. Because RCTs are true experiments, they complement and extend findings from nonexperimental G×E investigations and have greater power to detect effects compared to correlational studies (Howe, Beach, & Brody, 2010). However, a number of challenges involved in incorporating genetic measurement in full-scale trials may pose difficulties to implementation. The most significant barriers include substantial costs of genetic assays and the sample size required to detect effects. One proposed alternative, or preliminary step, to conducting G×E investigations in full-scale RCTs is the use of microtrials (Howe et al., 2010). Microtrials are randomized experiments testing the effects of relatively brief and focused environmental manipulations (e.g., specific program components) designed to alter risk and protective mechanisms but not to bring about full prevention effects in distal outcomes. Microtrials can serve as a bridge between laboratory or nonexperimental studies and full-scale trials and provide efficient and cost-effective tests of whether and under what circumstances a risk or protective factor is a suitable candidate for targeting in larger-scale trials. In the context of G×E, participants would be genotyped, and analyses could determine if the effect of the environmental risk or protective factor on outcome is moderated by genetic variation. There will also likely be greater profit in studying how gene-environment combinations shape specific risk or protective mechanisms than searching for genetic main effect or G×E explanations for distal clinical outcomes (Howe et al., 2010). The malleability of risk or protective mechanisms also may vary by genotype, suggesting that interventions may need to be flexible to have maximal benefit.

Gene–environment correlation (rGE) is another important type of gene-environment interplay that is often overlooked or mistaken for G×E. A rGE occurs when a person's genotype influences, or is associated with, his or her exposure to environmental risk (Jaffee, 2011; Knafo & Jaffee, 2013; Moffitt et al., 2006). In rGE, the genetic effect operates through an indirect route by affecting some behaviors (e.g., personality traits) that in turn relate to or bring about the environmental risk and related outcome. There are three types of rGE: passive, evocative, and active (Jaffee, 2011; Knafo & Jaffee, 2013). Passive rGE refers to the association between the genotype a child inherits from parents and the environment in which he or she is raised. For example, the correlation between maltreatment and increased child aggression may reflect the transmission of antisocial behavior from the parents, which is moderately heritable. In evocative rGE, partially heritable traits or behaviors evoke reactions from others in the environment. For example, an introverted child may appear aloof to peers who in turn make fewer social overtures toward the child. In active rGE, individuals actively select or create environments that are in line with their genetic propensities, such as in the case where youth high in sensation seeking affiliate with drug-abusing peers. rGEs can be erroneously interpreted as G×E if careful experimental studies are not conducted. RCTs of preventive interventions are an ethical alternative to allow for relatively strong causal inferences and can help distinguish among rGE, G×E, and gene–gene interactions (i.e., epistasis) (Uher, 2011).

The rapidly advancing field of epigenetics is making it clear that DNA is not the static entity that it was once thought to be (Mill, 2011; NRC & IOM, 2009). Epigenetic processes play a dynamic role in regulating gene expression and are responsive to the environment (Bick et al., 2012; Mill, 2011; Roth, 2013). Epigenetic regulation of gene expression occurs independently of DNA sequence and operates primarily through changes in DNA methylation and chromatin structure (Mill, 2011; Roth, 2013). Chromatin is the term used to describe the DNA-protein complex that forms to package DNA into a smaller volume, prevent damage, and regulate expression and replication functions. For example, chromatin packaging

can be altered by a change in methylation to allow regulatory proteins to more easily access promoter regions in the DNA to facilitate gene expression. These processes can be reversible, such that methylation and chromatin folding can be reversed and promoter regions may become less accessible again. Although epigenetic changes can be reversed, they are often long lasting across the course of development; some can even be transmitted across generations (Roth, 2013). Epigenetic mechanisms may also shed light on the limited associations between gene mutations or predisposing polymorphisms and disorders. Even genes that do not carry mutations or increase risk of disease can be rendered harmful if they are not expressed in the appropriate amount in the correct type of cell at the correct time in development (Mill, 2011).

Research is accumulating in humans and animal models on a broad range of environmental exposures across the life span that are associated with epigenetic variation (Bick et al., 2012; Champagne, 2010; Monk, Spicer, & Champagne, 2012; Roth, 2013). For example, several epigenetic mechanisms have been proposed linking prenatal exposure to maternal stress and early infant outcomes (Monk et al., 2012; Roth, 2013). Changes in DNA methylation have also been documented in response to prenatal exposure to cigarettes or alcohol (Haycock, 2009; Knopic, Maccani, Francazio, & McGeary, 2012). Postnatal environmental exposures, such as the quality of mother and child interactions, may also lead to shifts in developmental trajectories (for better or worse) via epigenetic pathways. Research on early adversity, such as child maltreatment, stressful separations from caregivers, and living in impoverished environments, has found differential methylation patterns in human and animal models (Bick et al., 2012; Monk et al., 2012; Roth, 2013). Methylation patterns have also been linked to specific patterns of HPA axis activity, immune response, and physical and mental health outcomes (Bick et al., 2012; Roth, 2013). Aberrant patterns of methylation have been noted in a number of psychiatric disorders, including schizophrenia, PTSD, and mood disorders (Roth, 2013). These findings highlight ripe areas for future investigation that will advance our understanding of how biological processes respond to the environment and influence developmental trajectories.

Epigenetic mechanisms may be a realistic target for intervention due to their reversibility. Epigenetically informed preventive interventions can include methylation assays in their measurement batteries to evaluate the effects of the interventions on these mechanisms and refine theory. Methylation assays can be conducted genome-wide or at the level of specific regions of candidate genes with known functional properties, such as the glucocorticoid receptor gene (Bick et al., 2012). Tremblay (2008) provides several illustrative examples of study designs that incorporate the epigenetic level of measurement. For example, pregnant women who smoke could be randomly assigned to a preventive intervention aimed at smoking cessation and improving child outcomes in development and behavior. A reasonable hypothesis based on animal and human research demonstrating altered methylation could postulate that smoking during pregnancy has negative epigenetic effects on brain development that could lead to problems with self-regulation and aggression in the offspring's early childhood. An RCT of the program could test whether the program leads to changes in methylation at specific candidate genes, birth outcomes, and cognitive and behavioral development in the child across experimental and control groups. Epigenetics is a relatively new area of investigation, and prevention scientists are just beginning to consider epigenetic mechanisms within the context of understanding the efficacy of interventions on complex outcomes. We anticipate the next decade will bring forth growth in this area.

Endophenotypes

One of the critiques of the current nosology of psychopathology is that diagnostic categories (e.g., *DSM*) are not grounded in biology (Vrieze, Iacono, & McGue, 2012). Equifinality (multiple mechanisms can lead to the same phenotype) leads to considerable heterogeneity within diagnostic classifications, and symptoms overlap across disorders. These issues likely contribute to the difficulty in identifying disorder specific genetic variants. In an effort to address the complexity of linking genetic variation to psychopathology, researchers are attempting to identify endophenotypes, which are narrowly defined behaviors, characteristics, or biological markers that can be objectively quantified and correlate with specific disorders or phenotypes (NRC & IOM, 2009). Endophenotypes are heritable and share genetic variance with the clinical disorder but are etiologically less complex and less subjective to quantify (Iacono & Malone, 2011; Lenzenweger, 2013). Because endophenotypes are heritable, once established, they can be utilized to identify individuals at risk, which can facilitate the evaluation of preventive interventions and risk and protective factors on disorder trajectories. An example of an endophenotype is the amplitude of the P300 response of the visual event-related potential in substance use disorders. There is ample evidence that a reduced P300 amplitude is associated with the development of substance use disorders and related externalizing

psychopathology (Iacono & Malone, 2011). Prevention researchers could prospectively direct interventions toward individuals positive for a specific endophenotype and could study the mechanisms by which the intervention introduces protective factors to prevent the onset of the condition. The inclusion of identified endophenotypes in investigations of preventive interventions may also provide greater insight into the biological and genetic underpinnings of psychopathology. The limited research on endophenotypes for some specific disorders makes this approach difficult to implement. Additional basic research may be needed prior to incorporating endophenotypes into prevention evaluations.

Neuroimaging

Interest in the effects of preventive interventions on brain structure and function is growing. This interest is fueled by the recognition that the brain is plastic and can change in response to internal (e.g., physiological responses to stress, molecular cascades) and external (e.g., learning opportunities, environmental exposures) experiences (Whitten, 2013). Brain plasticity is complex and can occur on multiple levels, including molecular changes, cellular alterations, shaping of neuronal structures and interconnections, and reorganization of functions (Whitten, 2013). Researchers now understand that not only does behavior change when the brain changes but that behavior can induce further brain plasticity through feedback mechanisms (Whitten, 2013). Efficacious preventive interventions may be conceptualized as a method of inducing experience-dependent plasticity to divert maladaptation and promote resilient functioning (Cicchetti & Toth, 2009). Incorporating neuroimaging methodologies into trials of preventive interventions provides various avenues with which to visualize brain structure and function and further understand the complex interplay among brain, genes, environment, and behavior.

Neuroimaging techniques can be utilized in several ways in preventive intervention research. For example, neuroimaging endophenotypes may help identify individuals at risk for a disorder and an optimal population to target interventions (Clark et al., 2013; Glahn, Thompson, & Blangero, 2007). As discussed, such endophenotypes might yield causal links in the mechanisms underlying psychopathology and resilience and refine existing theories. Neuroimaging indicators also may demonstrate effects of preventive interventions (Clark et al., 2013). A number of treatment studies have demonstrated significant intervention effects on neuroimaging indicators, especially using functional magnetic resonance imaging (fMRI) (Beauregard, 2009; Linden, 2006; Porto et al., 2009). Neuroimaging indicators could also predict which individuals are most likely to respond favorably to interventions and serve as a marker of differential susceptibility. For example, alterations or delays in cerebral maturation or functioning might predict poorer response to intervention and could potentially lead to the use of neuroimaging to identify individuals who require more intensive or alternate prevention approaches (Clark et al., 2013).

There are several commonly utilized neuroimaging methods to assess structural and functional aspects of the brain. Structural MRI can be utilized to examine cerebral macrostructure, such as volumes (e.g., whole cerebrum, lobes, subcortical structures, delineated regions of interest), white/gray matter distributions, and cortical thickness among other novel applications. Previously, researchers manually traced structures or regions of interest for quantification, but now automatic cortical parcellation methods (e.g., Freesurfer; Desikan et al. 2006) are more commonly used. Automated methods have many advantages, including being more efficient, less labor intensive, and less costly. They also lead to reduced rater bias and error and require less training. Diffusion tensor imaging is another structural imaging technique that provides data on white matter microstructure and integrity by quantifying water diffusion. White matter integrity can be examined through several approaches, including specified regions of interest (e.g., corpus callosum), whole-brain voxel-based morphometry, and tractography. Voxel-based morphometry statistically compares integrity values for each voxel (smallest unit of imaging visualization, comparable to pixel in photography) to identify local patterns across individuals. Tractography uses three-dimensional modeling to represent the integrity of white matter tracts in the brain. The values per tract can be compared across groups to investigate structural connectivity. fMRI techniques examine brain activity typically during tasks designed to elicit specific mental functions. fMRI indicators are likely to be more sensitive to intervention effects compared to structural analyses. Structural and functional approaches can also be combined and can be collected sequentially in the same scanner.

The challenges associated with utilization of neuroimaging methods have likely hindered many investigators from incorporating them in prevention trials. The collection and analysis of imaging data can easily reach $1,000 per subject, which may be cost-prohibitive for many prevention trials. Access to appropriate scanner hardware and staff expertise also can be limiting factors, and scheduling participants can be complicated as multiple researchers and

clinicians typically share equipment. Recruitment of individuals also can be problematic if people have irremovable metal objects, have fears or problems with small spaces, or have difficulty remaining still for extended periods of time. However, despite these challenges, utilization of brain imaging techniques in evaluating the efficacy of preventive interventions holds considerable promise for advancing the field.

Stress/Allostatic Load

Preventive interventions often target individuals who have experienced considerable adversity or stress in their lives. Products of the physiological stress response, such as the steroid hormone cortisol, are important biological indicators that are useful complements to an individual's subjective response in understanding the development of psychopathology and response to intervention. Researchers have reformulated their conceptualization of the physiological stress response from a process called homeostasis to a model of allostasis (Ganzel & Morris, 2011). Homeostasis is the process of maintaining and reestablishing initial conditions of a system when it is perturbed. In allostasis, an individual accommodates to a current stressor by adjusting homeostatic set points to maintain internal stability rather than trying to return to the original homeostatic balance (Ganzel & Morris, 2011). Allostatic accommodation is a dynamic process. However, these same processes that help the body adapt to stress in the short term can lead to maladaptive functioning when overused or managed ineffectively, such as when an individual is confronted with a major stressor or sustained periods of stress (Cicchetti, 2011; Doom & Gunnar, 2013; Ganzel & Morris, 2011). The wear and tear on the body from this maladaptive process is called allostatic load.

Understanding the brain's role in allostasis can inform the design and timing of preventive interventions. Measurement of allostatic load most often occurs by assaying cortisol. However, the HPA axis and its product cortisol are peripheral sites in allostasis. The brain is the central mediator of allostasis and is therefore likely to be one of the first sites to show allostatic load (Ganzel & Morris, 2011). The brain regions most highly involved in allostasis include circuits related to emotion processing and executive control, such as portions of the amygdala, anterior cingulate, orbitofrontal cortex, hippocampus, and basal ganglia. These brain regions may be affected differently depending on the developmental stage(s) during which the stressor(s) occurs. Brain regions develop and mature at different rates, and stressors can lead to very different patterns of physiological wear and tear based on the onset and duration of stress relative to periods of greater or lesser vulnerability. Stress during especially vulnerable or sensitive periods of development can also impact later brain maturation by altering the neural systems on which later development is based. The brain circuits involved in allostasis and their associated functions are prime targets for preventive interventions aimed at ameliorating maladaptive stress responses and promoting resilience. Implementing preventive interventions during the developmental stages when these neural circuits are most plastic and amenable to change is likely to have the biggest impact. Consistent with this hypothesis, researchers have demonstrated that preventive interventions can normalize cortisol patterns for young children with histories of maltreatment (Cicchetti et al., 2011b; Dozier et al., 2006; Fisher et al., 2007), suggesting positive intervention effects on allostasis. Future research with individuals at various developmental stages and experiencing a range of stressful experiences will provide important information on the plasticity of these brain regions to intervention across the life span.

Multiple Ecological Levels

Bronfenbrenner's social ecological model (1979) has been one of the most widely referenced and instrumental models within developmental psychopathology. It has encouraged researchers to go beyond individual processes to consider a broader set of social and contextual factors (Causadias, 2013; Spencer & Swanson, 2013). Within Bronfenbrenner's model, the microsystem is considered the immediate physical and interpersonal surroundings of the individual (e.g., family, school), and the mesosystem encompasses the interactions between microsystems. The exosystem involves social structures and institutions (e.g., neighborhood, government, and social service agencies), and the macrosystem represents the culture, history, and laws of the broader society in which an individual lives. Although some factors at multiple ecological levels are generally considered in conceptualizing the design of preventive interventions, the actual measurement of these factors is not yet used to its full advantage in intervention trials. In this section, we discuss challenges and current directions in measuring risk and protective factors at multiple ecological levels as well as highlight efforts to integrate analyses across multiple levels via the concept of developmental cascades.

Microsystems and Mesosystems

Many preventive interventions are designed to target factors at the micro- and mesosystems level to facilitate

change for an individual. However, measurement and analysis at these levels are often cursory at best or inferred from individual outcomes. Many studies that include measures at the microsystem level examine a single construct in isolation as a moderator of intervention efficacy. Occasionally a study examines the relative influences of multiple microsystems (e.g., Multisite Violence Prevention Project, 2012), but higher-level interactions or more complex modeling are rarely undertaken. More innovative measures and analytic approaches are needed to better capture influences at these levels.

Social network analysis is an innovative method that can model interpersonal systems and their possible influences on individuals within the system (Gest, Osgood, Feinberg, Bierman, & Moody, 2011). Unlike other approaches, social network analysis accounts for the interdependencies of social interactions and network data. Two approaches to examining social network data are most relevant for prevention science: the structural patterns of social ties and the behavioral dynamics of social networks. Structural patterns of social ties can be examined by having individuals belonging to a system (e.g., school, group, office) nominate others based on a social characteristic (i.e., friendship, whom they look up to). Social patterns can then be visualized using specialized software and summarized by variables such as the density of connectedness, reciprocity of nominations, and presence of hierarchical relationships, among others. Social network analysis can also be utilized to examine the behavioral dynamics of social networks. For example, social norms favoring a behavior can be inferred from the frequency of individuals displaying the behavior who are nominated by others. Individuals who are selected frequently and have high centrality in the network are likely to have a strong influence on behavioral norms (Gest et al., 2011).

Social network analysis may be a particularly relevant technique for preventive interventions delivered within schools or other existing social groups. Often these types of programs aim to modify the social dynamics through either explicit (e.g., social skills curriculum, modify school culture) or implicit (e.g., altering behavioral norms) approaches (Gest et al., 2011). Social network analysis could be utilized to study whether preventive interventions lead to changes in the patterns or behavioral dynamics of individuals in the system (e.g., reduce peer rejection, positive peer models increase influence). Although there are many benefits of social network analyses in understanding social dynamics, this method is difficult to apply when the researcher is not working within a system (e.g., schools, organizations, groups) and does not have access to other individuals who interact socially with participants (i.e., for nomination purposes).

Exosystems and Macrosystems

Influences of the exosystem and macrosystem have received limited attention in the design and evaluation of preventive intervention (Causadias, 2013; DiClemente, Salazar, & Crosby, 2007; El-Bassel, Calderia, Ruglass, & Gilbert, 2009). Researchers recognize the strong influences that factors such as neighborhood violence, distrust in social institutions, and cultural norms can have on individuals' developmental trajectories. However, operationalizing and measuring these factors in meaningful ways can be difficult. These factors also tend to be considered more distal determinants of outcomes when compared to other factors in the micro- and mesosystems that are viewed as more proximal to adaptation and maladaptation. With limited resources and power to detect complex effects, exo- and macrosystem variables often receive less priority and attention in their roles in prevention.

The last decade has witnessed increased attention to the role of culture in developmental psychopathology, and new models are emerging that question the appropriateness of conceptualizing culture solely within the macrosystem (Causadias, 2013; Spencer & Swanson, 2013). Culture is commonly defined as the integrated constellation of practices (e.g., competences, ideas, norms, scripts, tools, rules, goals, institutions) that is socially constructed, transmitted, and constantly renegotiated by the community and its members (Causadias, 2013; Kitayama & Uskul, 2011). This definition focuses on the social-level aspects of culture. Causadias aptly argues that culture also functions on the individual level. Culture serves as an organizing influence on development and is a normative process. Early socialization leads to the progressive consolidation of a cultural self, which is subject to change and continuity over time. By considering culture only as part of a broader distal context, as is common in investigations based on Bronfenbrenner's model, the proximal influences of social-level culture factors and an individual's cultural developmental trajectory may be neglected (Causadias, 2013). Alternate models have been proposed that conceptualize the pervasiveness of culture throughout systems (Juang, Syed, Cookston, Wang, & Kim, 2012; Spencer & Swanson, 2013). For example, Juang and colleagues (2012) viewed culture as central and exerting its influence on the levels of self, family, and value systems. Spencer's phenomenological variant of ecological systems theory (Spencer, Dupree, & Hartmann, 1997; Spencer & Swanson, 2013) focuses on the dynamic and bidirectional processes between individuals' perceptions of

their environment and development and views culture as ingrained in multiple levels of context. Within this model, individuals are viewed as engaging "in a life course process of unavoidable stage specific appraisal processes, series of environmental challenges (e.g., risks and stress) that are linked to diverse sociocultural contexts (e.g., expectations, attitudes, cultural beliefs and assumptions), and normative developmental tasks" (Spencer et al., 1997, p. 820). These alternate models represent important contributions to the field and provide useful guidance for incorporating a more nuanced and accurate modeling of cultural processes in prevention. Efforts should be undertaken to continue to evaluate and test such models.

Advances in conceptualizing culture highlight the need for multilevel assessment of individual and social levels of cultural processes. At the individual level, an appropriate multi-informant approach could include self-reports (e.g., cultural identity, acculturation), naturalistic observations, behavioral Q-sort methods or checklists, and qualitative methods (Causadias, 2013). Assessing cultural cognitions and behaviors is advantageous, as what individuals think is not always consistent with how they behave. Unfortunately, culture is often cursorily assessed in terms of racial or ethnic group identity. It is unrealistic for researchers to expect that existing instruments will adequately capture an individual's cultural self. For this reason, qualitative and mixed-methods studies may provide particularly useful insights into the influences of culture, since they allow participants to expand on their responses and elaborate the specific and local processes unique to their experiences. Measuring culture longitudinally is also important since continuity and discontinuity are expected in the process of cultural development (Causadias, 2013).

The measurement of social-level culture is more difficult and complex. Some studies have employed self-reports to examine social-level culture, but these reports are often inadequate to capture the intricacies involved in social processes. Disciplines such as anthropology, sociology, and political sciences have strong traditions in measuring complex social processes, such as culture. However, theoretical models and methodologies from these disciplines are quite distinct from those often used in prevention science, which makes integration or multidisciplinary approaches challenging. Measuring social-level cultural variables in preventive interventions represents an area for needed growth over the next decade.

Although additional work is necessary to measure culture at multiple ecological levels, researchers are increasingly considering the influences of culture in the design or adaptation of preventive interventions. The 2010 census data indicated that more than half of the 27.3 million increase in the U.S. population between 2000 and 2010 was attributed to the growth of the Hispanic population (Humes, Jones, & Ramirez, 2011), underscoring the need for the provision of culturally sensitive preventive interventions in the United States. Consistent with this change in the population composition, there has been an emphasis since the turn of the century on examining the feasibility and efficacy of adapting and applying preventive interventions to diverse cultural groups (e.g., D'Angelo et al., 2009; Dumas, Arriaga, Begle, & Longoria, 2010; Martinez & Eddy, 2005; Toth et al., 2013) as well as identifying variables that predict the retention of racially and ethnically diverse participants in preventive intervention trials (e.g., Coatsworth, Duncan, Pantin, & Szapocznik, 2006a, 2006b). Importantly, several of the interventions described in this chapter have been applied to, adapted or developed for diverse populations, including CPP, IPT, Fast Track, SAAF, and PRP. However, more systematic programs of research are needed on this topic as cultural adaptations of mainstream interventions do not always yield positive results (Kumpfer, Alvarado, Smith, & Bellamy, 2002). Barrera, Castro, and Steiker (2011) offered four approaches to the development of preventive interventions with diverse cultural groups. The first is through application of evidence-based preventive interventions to diverse cultural groups, in which cultural adaptations are not specifically made. The second approach takes the first a step further, and specific cultural adaptations of evidence-based interventions are made. In the next approach, consumers play a key role in the development of culturally sensitive interventions initiated by an investigator, so that the intervention is based around the culture rather than having surface-level changes made, as in the second approach (Barrera et al., 2011). The final approach is both community initiated and implemented. Given the increasingly diverse U.S. population, we advocate that new interventions should be culturally informed from inception and include diverse samples in initial efficacy studies, consistent with Barrera and colleagues' third-level approach. Accordingly, collaborations with community stakeholders during the development stage and long-term investment in nurturing community relations are paramount. Such efforts should include long-term implementation of interventions in the communities that play a role in intervention development and evaluation.

Developmental Cascades

Conceptualizing and evaluating models with risk and protective factors at multiple levels of analysis and multiple

ecological levels across a system is complex and challenging. The concept of developmental cascades can provide prevention researchers with a theoretically oriented guide with which to integrate the effects of risk and protective factors within and across levels. The term developmental cascades refers to the cumulative consequences of the many interactions and transactions occurring in developing systems that result in spreading effects across levels, among domains at the same level, and across different systems or generations (Masten & Cicchetti, 2010). Cascade models may be particularly relevant for understanding the development and prevention of psychopathology, given that many forms of psychopathology have complex, multifactor etiologies that accumulate over time. Rather than focusing solely on effects on isolated risk and protective factors, preventive interventions can be conceptualized as interrupting negative or promoting positive developmental cascades (Masten & Cicchetti, 2010). Cascades emphasize the continuity in development and can aid researchers in conceptualizing how interventions can be most optimally developed to promote reorganization of person-context systems (Cox, Mills-Koonce, Propper, & Gariepy, 2010). Early person-context systems affect the possibility of later reorganization, and intervention developers need to consider which strategies are likely to promote reorganization and at what point in development they would be most effective.

Developmental cascade models are inherently more complex than the basic mechanistic models focusing on one or a few risk or protective factors that are most commonly examined in the context of preventive interventions. Researchers utilizing cascade models face a number of challenges (Cox et al., 2010; Masten & Cicchetti, 2010). Cascade models require longitudinal data with repeated assessment of multiple domains or levels of function over time. These types of data require not only a significant investment of research funds and participants' time but also they can be difficult and time-consuming to collect. Missing data and subject retention also are major challenges. Multilevel data often involve domains in which a single investigator does not have expertise. Thus, such complex models typically require multidisciplinary collaborations. Without additional expertise, researchers may not conceptualize or include critical processes that involve phenomena at other levels (e.g., neighborhood, community, and cultural levels). Complex statistical approaches are also typically required to analyze multilevel longitudinal data. Other challenges include being able to demonstrate cascade effects. For example, if continuity and covariance of key measures are not controlled, it is difficult to establish if there is a unique effect on one domain on another over time (Cox et al., 2010; Masten & Cicchetti, 2010). A cascade effect also can be obscured by close waves of data collection, which may result in high correlations among variables (Masten & Cicchetti, 2010). Since cascades are inherently longitudinal, newly emerging domains of function (e.g., executive functioning) or organization can emerge, which can be difficult to link with prior functioning. Despite these challenges, Masten and Cicchetti concluded that "the most convincing evidence of a cascade effect will be based on experiments with random assignment to intervention that are designed to produce a particular cascade sequence" (p. 493).

Summary

As basic research has advanced our understanding of the complex interplay of multilevel risk and protective factors contributing to adaptive and maladaptive trajectories across the life span, prevention researchers have grappled with how to integrate and translate these findings into efficacious interventions. Conceptualizing the complexity involved in preventing complex and multidetermined phenomena is quite challenging. The developmental psychopathology perspective has directed researchers to consider the interplay of risk and protective factors at multiple ecological levels and to analyze effects at multiple levels of analysis. Initiatives derived from the developmental psychopathology perspective have led to important contributions to our understanding of the mechanisms involved in prevention. Given theoretical and methodological advances, the field is poised to continue to progress in this direction. Over the last decade, the biological levels of analysis, particularly genetic methods, have been gaining attention in the field. Prevention scientists have increased their use of biological measures in rigorous RCTs of intervention programs, but these investigations remain in the minority. Costs associated with the incorporation of biological levels of analyses into RCTs and the need for expertise that may not be easily accessible to prevention researchers continue to pose challenges to the conduct of multilevel RCTs. Researchers would benefit from a greater emphasis on the biological bases of behavior and genetics during their training. In addition to a likely increase in the number of investigations incorporating the biological level of analysis, such training would enable researchers to better understand and communicate results and would facilitate more effective multidisciplinary collaborations.

Preventive interventions are often focused at the individual level in terms of design and evaluation (DiClemente

et al., 2007). Broadening the design of interventions to target multiple ecological levels may lead to more lasting behavioral change (DiClemente et al., 2007; El-Bassel et al., 2009). The field will also benefit from an increase in RCTs that incorporate more complex modeling of multiple ecological levels and their transactions. The concept of developmental cascades may prove particularly useful in this regard. With these efforts to conceptualize and evaluate preventive interventions in the context of greater complexity come practical challenges. For example, researchers will need to strike a balance between assessing a large number of multilevel constructs and developing an assessment battery that is feasible and acceptable to participants. Multidisciplinary investigations also can be quite costly both in terms of personnel and materials. Larger samples are often needed to utilize complex modeling approaches or to detect effects at certain levels of analysis. Despite these challenges, it is imperative that such initiatives be undertaken and that increasingly sophisticated methodologies be incorporated into RCTs if the field of prevention science is to keep pace with basic research advances being made in understanding the origins and course of psychopathology.

METHODOLOGICAL CONSIDERATIONS AND CHALLENGES

In this section, we consider challenges and advances in translating developmental theory into preventive interventions as well as highlight areas for continued growth. Specifically, we begin with a discussion of challenges and new directions in the design of intervention trials. We also address conceptualizing and refining measurement of intervention outcomes and processes. Topics include how intervention success is operationalized and strategies for optimizing measurement. Complexities and recent developments in methods for evaluating intervention trials are also critically reviewed, including discussions of assessing how interventions work (mediation analyses) and for whom they are most effective (subgroup analyses) as well as systems science, person-centered methods, and qualitative analyses. The final theme encompasses complications associated with implementing and evaluating preventive interventions, such as noncompliance, selection bias, informant discrepancies, sample size, and power issues.

Designing Trials to Test Theory

Unfortunately, many evaluations of preventive interventions are inadequately designed to test theory, and many of our traditional analytic tools are not well engineered to handle the type of theoretical complexity involved in systems (Ialongo et al., 2006; Lich et al., 2013; Marshall, 2013). The interplay of preventive interventions and developmental theory can and should be bidirectional (Ialongo et al., 2006; Toth et al., 2011). Well-designed scientific evaluations of preventive interventions can test theory in an experimental design, which may otherwise not be possible to determine causality. For example, researchers obviously cannot randomly assign which families maltreat their children, but they can randomly assign families at high risk for maltreatment to a preventive intervention designed to alter relational processes and can then determine whether the hypothesized mechanisms of action of the intervention are effective at preventing maltreatment in these families relative to families randomized to a comparison group. As a true experiment in modifying the developmental course, preventive interventions can provide insight into the etiology and processes involved in psychopathology and can subsequently affirm, challenge, or refine existing developmental theory (Cicchetti & Toth, 2009). The benefit of well-designed preventive intervention trials is likely to lead to more rapid advances in our knowledge of etiology and change processes more quickly than has been garnered through traditional longitudinal studies (Tremblay, 2008).

Although RCTs are the gold standard design with which to test the efficacy and underlying mechanisms of a preventive intervention, establishing pre-intervention equivalence of conditions is necessary to draw inferences about the causality of intervention effects. Randomization ensures that systematic differences do not exist between conditions on measured or unobserved variables and that group differences are due to chance alone. Significant group differences due to chance are less likely to occur as sample size increases. Depending on the intervention and research question, randomization can occur at the individual or the cluster level.

Cluster randomization is often used in preventive intervention designs when programs are implemented within systems such as schools, communities, or organizations. Cluster randomization results in multilevel data with individuals nested within clusters. A primary advantage of cluster-randomized designs is that contamination between intervention and control groups is limited since clusters are less likely to associate with other clusters. A disadvantage of cluster randomization is establishing baseline equivalence of groups (Graham et al., 2013; Vuchinich, Flay, Aber, & Bickman, 2012). Random assignment is likely to work to produce pretest equivalence only when a sufficiently large number of units are assigned to each

group. Cluster randomization typically results in a relatively small number of clusters available for randomization, which increases the likelihood that pre-intervention equivalence will not be achieved. Several approaches have been suggested to reduce the likelihood of this problem (Graham et al., 2013). Simple matching strategies can be used to increase comparability across groups. Although this strategy achieves comparability on variables used for matching, it does not necessarily lead to equivalence on variables not included. In addition, simple matching violates randomization and is typically viewed as less rigorous. Stratified random sampling is another option in which clusters are stratified on one or more variables and then randomly assigned within strata. Pre-intervention equivalence is more likely to occur on variables involved in stratification, but equivalence on unmeasured variables is also likely within a certain probability. Graham and colleagues (2013) advocated an approach to further increase the likelihood of pre-intervention equivalence, which involves creating a single stratifying composite based on multiple relevant variables. For example, in a comparative cluster-randomized trial of the rural adaptation versus the original version of the Keeping It Real program in the prevention of substance use in adolescents, the researchers created a composite score for each school based on seven school-level variables. They also had access to school-wide drug use data for some schools and applied missing data procedures to estimate scores to include this variable in the stratifying composite. This approach greatly enhanced the pre-intervention equivalence of groups.

Another important consideration in designing trials to adequately test preventive interventions is determining the optimal comparison condition(s). In the simplest form, a fairly homogenous sample is selected from a well-defined population of interest; half are randomly assigned to receive the preventive intervention, and the other half are assigned to a no-intervention condition. However, a no-intervention comparison condition is not always possible or preferable due to ethical constraints and the nature of the research questions. Comparing the efficacy of two interventions with different underlying theoretical mechanisms is a powerful design, although more complex. For example, in the previously described intervention for infants in maltreating families, the two active interventions differed with respect to their underlying conceptualizations (attachment theory versus parent skills training). This study demonstrates the benefits of including another group that differs from trial participants on risk level for the target behavior to allow further tests of theory (Stronach, Toth, Rogosch, & Cicchetti, 2013). Utilization of an enhanced treatment-as-usual condition, wherein individuals do not receive the evidence-based intervention but rather are assisted in accessing typically available services, also addresses ethical concerns related to withholding treatment.

Studies employing adaptive interventions are also beginning to emerge in the literature and show great promise in achieving more tailored and cost-effective preventive interventions. Adaptive interventions recognize that people vary in the intensity of intervention needed to prevent a given problem. For example, an RCT to prevent child maltreatment in economically disadvantaged mothers who had their first child before age 21 is currently under way at Mt. Hope Family Center (Paradis et al., 2013). The Building Healthy Children program offers an array of evidence-based services that are delivered in accord with need. All mothers receive outreach to assist with basic needs as well as the Parents as Teachers program (Wagner & Spiker, 2001) to provide parent skills training and developmental guidance; CPP to foster secure attachment and interpersonal psychotherapy for depression are provided if these are areas of need. Although appealing from a clinical perspective, adaptive interventions can be particularly challenging to analyze since individuals are receiving different levels or combinations of interventions.

An optimal design strategy that addresses these challenges is the Sequential Multiple Assignment Randomized Trial (SMART; Almirall, Compton, Gunlicks-Stoessel, Duan, & Murphy, 2012; Collins, Murphy, & Bierman, 2004; Dawson & Lavori, 2012; Murphy, 2005; Lei et al., 2012). In a SMART design, there is a separate stage for each critical decision involved in the adaptive intervention. At each stage, all participants are randomized to a treatment option. This approach tests multiple adaptive interventions within the same trial and allows researchers to identify tailoring variables (e.g., early signs of nonresponse, environment or social characteristics) and develop decision rules based on empirical data rather than a priori decisions. SMART also can provide data on the optimal sequence of intervention components or strategies. Almirall and colleagues (2012) offer a useful illustration of employing a SMART design to a pilot study to inform a large-scale SMART intervention.

The duration of longitudinal follow-ups, although improving, continues to be a challenge in the field of prevention science. Many preventive interventions target risk and protective processes early in development to prevent later adverse outcomes in adolescence and adulthood. However, many trials are not continued long enough

to fully evaluate prevention effects through the targeted developmental window. Thus, we may have good evidence that a program increases positive adaptation for the child or family over the short term (usually 6 months to 1 year), but we often do not know whether these effects are sustained and if they alter the course of later developmental processes. Some notable programs, such as Fast Track (Dodge & Goodwin, 2013), the Perry Preschool Program (Parks, 2000), the NFP (Olds et al., 1997), and the NBP (Wolchik et al., 2013) have successfully followed samples from childhood through adulthood. Most prevention scientists recognize the value of long-term longitudinal follow-ups, but many barriers exist that interfere with their successful completion. One such barrier is obtaining adequate funding to conduct long-term follow-ups. Sample retention also can be difficult, especially with high-risk, mobile populations. For some selective and indicated interventions, ethical constraints may limit researchers' ability to follow the comparison group long term without provision of services. Without this comparison group, it is difficult to determine if the intervention had an effect over time (i.e., no change in the intervention group versus increase in symptoms in the control group; both groups have similar decrease/increase in symptoms).

Refining Measurement

Another important challenge in prevention research pertains to how to best conceptualize the measurement of preventive intervention success. This issue is becoming increasingly complicated as preventive interventions tend to be more comprehensive, multilevel, and multicomponent. Several questions are important to consider: What is the most important indicator of efficacy given the goals of the preventive intervention, and what is the best way to measure it? Should outcomes be assessed in terms of diagnosis, level of functioning, or overall quality of life? Who is the focus of outcome measurement (e.g., parent, child, teacher)? Unfortunately, there are no easy answers to these critical questions. Many important outcomes can be measured only indirectly (e.g., internal states in a child), and exclusive reliance on these types of measures may fail to do justice to complex cognitive, behavioral, and physiological processes (Fonagy, Target, Cottrell, Phillips, & Kurtz, 2002). Some other constructs are inherently unmeasurable or poorly defined (e.g., childhood quality of life). Even for those constructs that can be measured directly and reasonably well, inconsistencies across reporters are common and can be difficult to interpret (De Los Reyes, Thomas, Goodman, & Kundey, 2013).

Preventive interventions largely focus on preventing the onset or reducing the severity of a target problem, and thus it is not surprising that most trials focus on quantifying results at the diagnostic or symptom level (e.g., presence/severity of depression, incarceration rates, teen pregnancy). Numerous instruments (both categorical and dimensional) are readily available with adequate psychometric properties with which to assess intervention success at the diagnostic/symptom level. However, as discussed earlier in this chapter, symptoms alone are not the sole or even most important criterion of intervention effectiveness for an individual. For example, parents may report minimal decline in child behavioral symptoms following a preventive intervention but may experience a greater sense of parenting self-efficacy, reduced stress, and higher social support, which may be more meaningful in terms of their overall functioning. Another problem is that reports of symptomatology can vary by reporter, which results in interpretation difficulties. It is common for reports of child functioning to differ between teachers and parents, with parent but not teacher report most often suggesting intervention efficacy. Interpretation in this scenario can become particularly problematic when parents are involved in the intervention program.

An individual's level of adaptation is conceptually a more relevant indicator of intervention success than the presence of the problem or level of symptoms as it takes into account an individual's overall level of functioning across domains. For example, Masten, Burt, and Coatsworth (2006) described a number of developmental tasks in the definition of competence for various developmental stages. Adolescent competence, for instance, includes: (1) attending and behaving appropriately at school; (2) completing a course of secondary schooling; (3) getting along with peers in school; (4) maintaining close friendships; and (5) obeying the laws of the society. However, measuring the level of adaptation can be difficult in practice. Although there are adequate measures of some aspects of adaptation, measures of overall adaptation (e.g., Children's Global Assessment Scale) often have poor inter-rater reliability and may differ substantially depending on the expertise of the evaluator (Fonagy et al., 2002; Lundh, Kowalski, Sundberg, Gumpert, & Landén, 2010). One reason overall measures of adaptation may be so poor is that unevenness across dimensions of adaptation is common, and summarizing across these domains can be subjective (Fonagy et al., 2002). Some research suggests that this unevenness is particularly characteristic of clinical populations and may be a risk factor for later pathology (Fonagy et al., 2002). Multidimensional measurement of

adaptation may be preferable conceptually, although it can be difficult to integrate in analyses practically.

An important outcome measurement that is receiving increasing attention is the underlying mechanism, or mediational process, by which the intervention exerted change. Consistent with the discussion of theoretical foundations, an adequate demonstration of efficacy should include a measurable change in the theorized underlying mechanisms (MacKinnon, 2008). The transactional level of measurement is also relevant in assessing intervention efficacy. Contextual influences on an individual's functioning include parents, family relationships, characteristics of the community and the school or workplace, as well as more general cultural factors (Fonagy et al., 2002). Many preventive interventions aim for change at the level of transactional processes. However, these changes are not always directly assessed and are instead inferred from a decrease or delayed onset of the target problem in the intervention group. Both mechanistic and transactional levels of measurement require a greater sophistication in trial design and statistical analysis, as discussed previously.

A developmental psychopathology perspective (Cicchetti & Toth, 2008; Fonagy et al., 2002) highlights the criticality that the evaluation of intervention efficacy should occur in diverse developmental domains (i.e., diagnosis, level of adaptation, mechanism, transactional, psychological, social, psychophysiological). Beyond the theoretical benefit of understanding the interrelationship of these domains of functioning within the context of the intervention, outcome evaluation within multiple domains reduces the likelihood that the overall impact of a preventive intervention will be erroneously identified as effective or ineffective based on a single domain or measure. However, interpretation can become quite difficult when effects are found on some measures but not on others, especially when there are multiple measures of the same construct. Researchers invested in designing and evaluating interventions need to be especially cautious about overemphasizing significant effects and downplaying nonsignificant ones in these cases. Many researchers have grappled with how to integrate outcome data across measures and domains, but no agreed-on methods are routinely used.

Observational measures are appealing to researchers in terms of being able to measure behavior in more naturalistic settings. Synder and colleagues (2006) argued that behavioral observation may be an especially powerful tool for evaluating the training of the intervention agent (or individual responsible for delivering the intervention), the delivery of the intervention by the agent, and the response of the participant to the intervention. However, observational measures are subject to multiple sources of error that can reduce reliability. Specifically, error sources may be attributable to stable or temporary characteristics of the rater, setting, or interactions between the setting and observed individual(s) (Mashburn, Downer, Rivers, Brackett, & Martinez, 2013; Synder et al., 2006). Understanding these sources of error and adopting data collection procedures that reduce them can improve the reliability of the measure and precision of intervention effects estimated. In an innovative study, Mashburn and colleagues (2013) explicitly modeled and tested various sources of measurement error and compared how various data collection procedures affected power and study costs. Specifically, guided by generalizability theory, they utilized pilot data from an observational measure of teacher-student interactions called the Classroom Assessment Scoring System (CLASS) to optimize the most reliable and cost-effective scenario for measurement in the full-scale study. After quantifying seven sources of error variance, they compared nine scenarios with varying data collection parameters known to affect reliability in the study context, including the number of raters who observed each occasion, the number of days each classroom was observed, and the number of occasions ratings were made each day. Reliability estimates across the nine scenarios ranged from 0.44 to 0.89. Power calculations also were undertaken to illustrate the number of schools needed to achieve a given level of power based on reliability scenarios. The implications of reliability for study costs were especially illuminating, with cost estimates ranging from $4,896 (reliability = 0.48, 102 schools, 3 classrooms per school, 1 day, 2 occasions per day, 1 rater per occasion) to $49,152 (reliability = 0.84, 64 schools, 3 classrooms per school, 4 separate days, 2 occasions per day, 4 raters per occasion). However, the cost savings associated with the lower reliability scenario were greatly surpassed by increased costs associated with the higher intervention costs due to the number of schools needed to achieve adequate power, resulting in a 33% greater total cost than the scenario with greater data collection costs. Considering all of these factors prior to implementing an efficacy study can help researchers optimize measurement and power to detect effects and balance trade-offs among costs.

Evaluating Intervention Trials

The field is evolving from focusing on omnibus pre-post intervention effects to gaining a more nuanced understanding of how interventions work (mediation analyses), whom they work for (subgroup analyses), and whether they

work the same way for different subgroups (moderation of the mediated effect). Moreover, questions such as when interventions are most effective (developmental timing) and how long effects last are also gaining much-deserved consideration. Of these approaches, subgroup analyses have garnered the greatest attention over the last decade (Farrell, Henry, & Bettencourt, 2013; Ialongo et al., 2006; Supplee, Kelly, MacKinnon, & Barofsky, 2013).

Subgroup Analyses

Subgroup analyses aim to answer the question "What works for whom?" Subgroups can be differentiated by baseline status on a host of variables ranging from relatively straightforward ones (i.e., gender, age, geographic region) to complex ones (i.e., risk status, combinations of characteristics; Bloom & Michalopoulos, 2013). Researchers often rely on subgroup analyses to unpack significant main effects of the intervention program or investigate possible sources for nonsignificant main effects (Supplee et al., 2013). These analyses allow prevention scientists to explore whether a program was more or less effective for a portion of the target population. The results of such analyses are critical for understanding the generalizability of findings. For example, it is important to know if interventions are effective for a broad range of groups or if effects are more circumscribed to specific subgroups of the population. One common moderator of preventive intervention effects is baseline pre-intervention functioning. A number of well-designed preventive interventions have shown individuals with poorer functioning at baseline benefited more from the preventive intervention compared to individuals with more adaptive baseline functioning (e.g., Fritz et al., 2005; Gonzales et al., 2012; Wilson, Lipsey, & Derzon, 2003; Wolchik et al., 2000).

Subgroup analyses are also very useful for informing policy and implementation decisions. Resources are limited, and subgroup findings can help guide policymakers in selecting interventions most effective for the target population. Results from subgroup analyses can also guide the development of new interventions and provide directions for adapting or modifying existing programs to better meet the needs of specific subgroups (Fairchild & MacKinnon, 2014; Farrell et al., 2013). Given the potential benefits of subgroup analyses for understanding generalizability and guiding funding and public policy decisions, the Society for Prevention Science incorporated guidelines for examining the consistency of intervention effects across subgroups into its Standards of Evidence for Identifying Effective Interventions (Flay et al., 2005). These standards recommend that researchers conduct subgroup analyses on heterogenous samples with respect to variables such as age, gender, race/ethnicity, and risk levels (Farrell et al., 2013; Flay et al., 2005). Routine examination of subgroup effects on these variables across adequately designed trials would facilitate comparisons among preventive interventions and inform policy decisions.

Although investigating subgroups can serve several important functions, appropriately conducting subgroup analyses is not without significant methodological challenges (Fairchild & MacKinnon, 2014; Lanza & Rhoades, 2013; Supplee et al., 2013; Wang & Ware, 2013). One of the major challenges inherent to subgroup analyses is that researchers often consider them secondary or exploratory and test for moderation only when the overall main effects of the intervention do not reach statistical significance. This approach can lead to biases and misleading findings when studies are not optimally designed to conduct tests of moderation (Bloom & Michalopoulos, 2013; Rothman, 2013). Placing the emphasis on confirming a priori hypotheses about intervention moderators versus conducting exploratory post hoc analyses reduces bias and strengthens the rigor of the study. Ideally, researchers should plan for subgroup analyses during the initial conception and design of the study, thus ensuring adequate measurement and statistical power to detect interaction effects (Bloom & Michalopoulous, 2013; Fairchild et al., 2014; Farrell et al., 2013; Rothman, 2013; Supplee et al., 2013; Wang & Ware, 2013).

Greater incorporation of theory into intervention designs also will likely expand the types of moderators examined in subgroup analyses. For example, the majority of subgroup effects examined in the literature focus on individual demographic differences and baseline levels of the target behavior (Bloom & Michalopoulous, 2013; Farrell et al., 2013). The use of social-ecological theory and intervention logic models in developing a priori hypotheses about subgroup differences may highlight the influence of broader contextual factors (e.g., school factors, community violence, cultural norms, poverty) on intervention outcomes than is usually considered. Qualitative research studies are also valuable sources for generating hypotheses about possible subgroup moderators. As discussed later in this section, researchers also can focus on the interplay between mediators and moderators, which can provide a framework that can facilitate integration of evidence across multiple moderating factors (Rothman, 2013).

By considering potential moderators of treatment during the design of the study, researchers can guide their sampling and randomization plans to ensure sufficient representation of the hypothesized subgroups within the

overall sample (Bloom & Michalopoulos, 2013; Fairchild & MacKinnon, 2014; Farrell et al., 2013; Wang & Ware, 2013). Stratified randomization of treatment assignments may be an optimal approach to achieve this goal (Wang & Ware, 2013). Restricted range on a selected moderator is another problem that can be addressed by considering subgroup analyses during the design phase of the intervention study (Farrell et al., 2013). In addition to ensuring sufficient numbers of individuals per subgroup, researchers can consider strategies to sample individuals across a broader range of the moderator and also ensure that measures of the moderator allow for sufficient assessment of the construct.

As mentioned, another important design element when planning subgroup analyses is ensuring adequate statistical power to detect interactive effects. Because small effect sizes are common in social sciences, the power to detect interaction effects is often low. Many intervention trials are statistically underpowered to detect subgroup effects, which may be a consequence of not considering subgroup analyses in the design of the study as well as funding, resource, and time constraints (Brown et al., 2013; Supplee et al., 2013; Wang & Ware, 2013). Most researchers utilize power analyses to determine the sample size needed to detect intervention main effects. However, at least four times the sample size is needed to detect the same size effect in a moderation analysis (Wang & Ware, 2013). It is not uncommon for the magnitude of interaction effects to be even smaller than main effects, which reduces power even further (Wang & Ware, 2013). Unequal sample sizes per subgroup, a common problem for prevention scientists, can exacerbate the challenge of insufficient statistical power. Designing studies using stratified randomization can help address this challenge by creating subgroups of similar sizes. Since funding, resource, and time constraints restrict the size of most trials, it is in researchers' best interests to prioritize confirmatory tests with adequate power to detect subgroup effects based on theoretical rationale, prior empirical support, and policy importance (Supplee et al., 2013).

Data aggregation approaches are one way to address limited power to detect subgroup effects. For example, meta-analysis can be an effective tool to compare treatment effects in different subgroups, even if these subgroups appear in separate studies (Borenstein & Higgins, 2013). In the case where subgroups can be adequately examined in individual studies, meta-analysis still provides added benefit by yielding a more precise estimate of the intervention effect in each subgroup (and of the difference in effects) than any single study. In addition, confidence intervals around each subgroup mean provide additional context, such as the range within which the true mean falls and the size of the overlap in effects between groups. One challenge in utilizing meta-analysis is that subgroup analyses are often inadequately reported in the literature (Bloom & Michalopoulos, 2013; Farrell et al., 2013; Supplee et al., 2013; Wang & Ware, 2013). Including a theoretical rationale for the moderation tests as well as adding details regarding whether tests were hypothesized or investigated post hoc would help address this issue. Additionally, studies with adequate power to detect interaction effects should include results of both significant and nonsignificant interaction effects and total number of comparisons tested. Finally, requirements by journal reviewers and editors that these details be included in manuscripts for publication also would be useful.

In addition to meta-analysis, Brown and colleagues (2013) highlighted two other approaches that combine data sets to allow for more powerful subgroup analyses. In the integrative data analysis strategy, researchers assemble all individual data into one data set and use trial as the highest level in a multilevel modeling framework. Multilevel growth mixture modeling can be used to calibrate change across trials with different follow-up times. A major procedural challenge with this strategy is obtaining data from other researchers, which can lead to bias when others are unwilling or unable to share. The parallel analysis strategy avoids this complication by allowing researchers to conduct analyses on their own data, but it requires researchers to use standardized analysis protocols. Results are then synthesized across data sets. The availability of large-scale data repositories, such as LONGSCAN (Runyan et al., 2011), that allow researchers to pose questions that can be addressed helps to alleviate this problem.

Subgroup analyses often result in multiple comparisons, which present an additional methodological challenge to prevention scientists. Several possible approaches to dealing with this pervasive problem are proffered. Researchers can specify a small number of theoretically driven confirmatory tests and use family-wise error rate corrections (Bloom & Michalopoulos, 2013; Wang & Ware, 2013). Wang and Ware (2013) also recommended using approaches that control the false discovery rate for exploratory analyses (see also Schochet, 2008).

Latent class analysis (Collins & Lanza, 2010) is a person-centered approach that offers prevention scientists an alternative to traditional subgroup analyses. Person-centered approaches are consistent with the developmental psychopathology perspective, which stresses the importance of studying individual adaptation and maladaptation from a holistic-interactionist viewpoint

(Sterba & Bauer, 2010). Latent class analysis is a mixture model that can be used to identify unobserved latent classes of individuals with similar characteristics and to explore differential preventive intervention effects within each class. Latent class analysis may also be especially useful for researchers faced with complex subgroup questions that involve multiple moderators. Moreover, it represents an approach that addresses the challenges of high Type I error rates and low statistical power of which more traditional approaches to subgroup analyses are so often vulnerable (Lanza & Rhoades, 2013).

Mediation Analyses

Mediation analyses examine a third variable that explains the way two other variables are related. In prevention science, this generally involves an examination of the intervening variable that explains, at least in part, how the preventive intervention affected change in the outcome. As described by MacKinnon (2008), mediation analyses are critical to the evaluation of preventive interventions for a number of reasons. First and foremost, a test of mediation uncovers how the intervention achieved its effects. Second, a test of mediation allows for the investigation of whether the intervention affected the desired underlying process as the intervention designers hypothesized. Finally, lack of support for an intervention effect on the theorized mediator, and likewise lack of support for a mediator effect on an outcome, can inform intervention design by suggesting either that the measurement of the mediator and/or outcome was inadequate or that the program itself did not function as anticipated.

Within the overarching goal of mediation analysis for prevention science—namely to identify how the intervention affected change in the outcome—there are two primary theoretical components. Action theory describes how the intervention intends to affect the hypothesized mediator or intervening variable, and conceptual theory describes how the hypothesized mediator affects the outcome (MacKinnon, 2008). Both action and conceptual theory are critical because they require the researcher to ground all aspects of the preventive intervention in theory. The researcher must have a guiding theoretical framework for how the intervention can manipulate the mediator as well as a guiding theoretical framework for how the mediator subsequently will effect change in the targeted outcome.

Significant advances in statistical approaches to evaluate mediating mechanisms have been proposed over the last decade. Traditionally, causal step models (R. M. Baron & Kenny, 1986; Judd & Kenny, 1981) were the gold standard evidence of mediation. However, more recent methodological advances support the product of the coefficients method as the most flexible method because it has higher statistical power in most situations and because it is easily applied to more complex statistical models (Fairchild & MacKinnon, 2014; Fritz & MacKinnon, 2007; MacKinnon, 2008; MacKinnon, Lockwood, Hoffman, West, & Sheets, 2002). As detailed in MacKinnon (2008), because the distribution of the product of regression coefficients is not normally distributed, methods such as asymmetric or bootstrapped confidence intervals are recommended for null hypothesis significance testing. In addition, reporting effect sizes for the individual paths within the mediation model and the effect size of the mediated effect is an important complement to significance testing, as it allows researchers to understand the magnitude or meaningfulness of the effects within the mediation model (see MacKinnon, 2008, for information on various effect size measures).

As is the case with subgroup analyses in prevention science, statistical power represents a methodological challenge with mediation analyses. Fritz and MacKinnon (2007) provided a useful reference for researchers interested in determining the sample size required for adequate statistical power in the case of a single-mediator model. Moreover, Thoemmes and colleagues (2010) described methods for power analyses in the case of more complex mediational designs, such as multiple mediators, mediation with latent variables, and moderated mediation. Finally, given the realities of funding and resource constraints common among preventive interventions, it is worth noting that a number of recommendations have been advanced for maximizing statistical power without increasing sample size. These include adding additional predictors to the model that explain additional variance in the mediator or outcome and blocking (see Fritz, Cox, & MacKinnon, 2013, for details).

Just as the evidence-based intervention movement in the late 1990s highlighted the need and provided direction for empirical investigations of the efficacy of intervention programs (Chambless & Hollon, 1998; Chambless & Ollendick, 2001; Chambless et al., 1998), the field now emphasizes the theoretical mechanisms underlying preventive interventions. Multiple organizations (e.g., the Substance Abuse and Mental Health Services Administration's National Registry of Evidenced-Based Programs and Practices [http://www.nrepp.samhsa.gov], the California Evidence-Based Clearinghouse for Child Welfare [http://www.cebc4cw.org], the Promising Practices Network [http://www.promisingpractices.net]) routinely catalog the empirical support for the efficacy of preventive

interventions and provide useful databases for researchers, clinicians, policymakers, and consumers to evaluate existing programs. Review criteria of these organizations could be augmented to more rigorously evaluate the evidence on the underlying theory of programs. David and Montgomery (2011) have proposed one such framework for establishing an intervention as empirically based that emphasizes the need to not only evaluate the efficacy of the intervention package but also to demonstrate the efficacy of the theory underlying the intervention package (i.e., mechanism of action). The system includes nine categories that are defined by two factors (theory, intervention package) and three levels of evidence for each factor (empirically well supported, equivocal data, strong contradictory evidence). This system provides a useful framework for prevention scientists. If adopted by organizations and funding bodies, it likely would encourage researchers to place greater emphasis on evaluating mediating mechanisms underlying preventive interventions.

Simultaneous Analysis of Mediation and Moderation

Although mediation and moderation analyses provide useful information in their own right, simultaneous modeling is more consistent with the developmental psychopathology perspective (Fairchild & MacKinnon, 2009). Simultaneous modeling allows for the study of more varied and complex hypotheses that are often more relevant to real-world settings and can answer these questions: (1) Do intervention mechanisms vary for different subgroups of participants (moderated mediation)? and (2) Can a mediation effect explain an apparent interaction effect in data (mediation of moderator effect)? Statistical approaches for addressing these complex questions have been advanced. Interested readers are encouraged to consult these sources for additional information (Edwards & Lambert, 2007; Fairchild & MacKinnon, 2009, 2014; Tein, Sandler, MacKinnon, & Wolchik, 2004).

Like many statistical techniques modeling higher-level associations among multiple variables, simultaneous modeling of mediation and moderation effects is limited by power considerations. For example, assuming an interaction effect accounts for about 1% to 3% of the variance, the overall sample size needed to detect a large effect would be between 500 and 1,000 individuals (Fairchild & MacKinnon, 2009). This sample size is untenable for the majority of prevention trials, particularly those that are delivered individually rather than in group formats. Researchers can facilitate power through alternate means such as applying different Type 1 and Type 2 criterion levels, using extreme groups designs to increase between-group and decrease within-group variation, deliver a stronger manipulation, or reduce error variance by focusing on the reliability of measures. Other limitations of simultaneous modeling include the number of assumptions, difficulties in interpretation when multiple effects are present, and inclusion of more than two time points of data collection in an analysis. Continued statistical advances may reduce the impact of some of these limitations.

Systems Science

The utilization of mediation and moderation models represents progress in our efforts to evaluate the complexity of preventive intervention effects. However, even simultaneous modeling of a mediation and moderation effect typically captures only one aspect of a complex interplay of factors and assumes directionality. Systems science refers to a number of analytic methods that are used to uncover the dynamic behavior of complex systems (Lich et al., 2013). Because developmental systems science espouses a more holistic-interactionistic perspective, the emphasis is on the dynamic interrelations between individuals and their ecology (Urban, Osgood, & Mabry, 2011). For this reason, systems science approaches have been suggested as possible tools to complement multivariate statistical modeling by guiding conceptualization and evaluation of complex developmental phenomena (Lich et al., 2013; Marshall, 2013). Conceptually, relational developmental systems theory is a good fit for the complex interplay of factors across multiple ecological levels involved in prevention and is consistent with a developmental psychopathology perspective. Systems approaches require multilevel conceptualization and measurement, which is a key tenet of developmental psychopathology (Marshall, 2013; Cicchetti, 2008; Cicchetti & Curtis, 2007; Cicchetti & Toth, 2009). However, the application of analytic methods consistent with developmental systems theory is not yet embraced within mainstream prevention or developmental science (Lich et al., 2013; Marshall, 2013; Van Geert, 2012). Training in systems science and analytic methods are not typically included in graduate curricula in clinical psychology programs, and few intervention studies have utilized these methods to date. Various systems analytic methods are applicable across the prevention science research cycle and can complement traditional analytic approaches (Lich et al., 2013). Several relevant examples include social network analysis, systems dynamics, and agent-based modeling.

Social network analysis, which is described earlier in the section titled "Multiple Ecological Levels," allows researchers to examine the structure and function of

interrelationships among individuals or groups. It can readily integrate with and expand on traditional methods and is gradually being adopted by researchers in the field. In systems dynamics methods, mathematical equations are written to quantify the relationships among components of the system under study. Parameter values are drawn from data sources or extant literature or are estimated when not available. After calibration and testing of the model, simulations are conducted to assess for changes over time. Such models may be helpful in understanding and interpreting intervention effects in the broader system context. Agent-based modeling, also referred to as agent-based computational demography and agent-based computational economics, offers researchers a rich quantitative methodology to explore how system components contribute to multilevel phenomena. In this approach, probabilistic rules are programmed into a computer model specifying how agents (e.g., individual, groups) behave, interact, or adapt. Agent-based models can be used to understand and interpret results of preventive intervention trials and evaluate outcome measures based on simulations (Lich et al., 2013; Urban et al., 2011). Systems approaches have a good conceptual fit and hold promise for increasing our ability to capture and understand the complexity of multilevel systems in prevention, but greater visibility of these approaches are needed in training programs and in the published literature. Since these approaches are not currently mainstream in prevention science and many require advanced mathematical or computer modeling skills, multidisciplinary collaborations will be necessary to undertake these approaches.

Person-Centered Methodologies

A person-centered approach focuses on a study of the person as a whole by emphasizing patterns of individual characteristics (Bergman & Magnusson, 1997). Person-centered approaches are consistent with the developmental psychopathology perspective and developmental systems theory, which emphasize individual adaptation and maladaptation from a holistic-interactionist perspective (Marshall, 2013; Sterba & Bauer, 2010). Earlier we briefly described the utility of latent class analysis (Collins & Lanza, 2010) as a novel approach. We now turn our attention to person-centered approaches more broadly and discuss their importance to evaluating preventive interventions.

The majority of investigations of preventive interventions to date have utilized variable-centered analytic approaches to test intervention effects and mechanisms. Variable-centered approaches can provide important insights about how theorized variables and constructs relate to one another in the intervention model. However, this approach tends to summarize individuals' experiences on a given characteristic in isolation from contextual factors unique to individuals. Person-centered theory assumes development involves complex interactions that are at least in part unique and specific to the individual. Rather than reducing developmental processes to component variables, person-centered theory emphasizes patterns across variables. Individual differences exist in developmental processes, and a small number of frequently observed patterns typically emerge at a more global level. A variety of person-centered methods exist, including less restrictive variable-oriented methods (e.g., latent growth curve modeling), classification methods (e.g., longitudinal cluster analysis, latent class growth modeling, latent Markov modeling), hybrid classification methods (e.g., latent growth mixture modeling, mixed latent Markov modeling), and single-subject methods (e.g., P-technique factor analysis, dynamic factor analysis) (Sterba & Bauer, 2010). Unfortunately, many researchers, even those who utilize person-centered methods, underappreciate person-centered theory and the assumptions and statistical vulnerabilities of the different person-centered methods (Sterba & Bauer, 2010). Because no single methodology can adequately test all tenets of person-centered theory, researchers must consider the trade-offs associated with each approach in the context of their research hypotheses.

Qualitative Analyses

Qualitative methodologies often are undervalued and therefore underutilized in prevention science. However, they have the potential to assess and evaluate complexity in greater depth. Prevention researchers may miss important insights by relying solely on quantitative methods. Studies using mixed methods designs that combine quantitative and qualitative methods can provide a broader and deeper understanding and corroboration of study outcomes relative to either method alone (Zhang & Watanabe-Galloway, 2013). Quantitative research methods aim to quantify and demonstrate a change in outcomes, whereas qualitative research methods can answer in depth how and why change occurs or does not occur. An advantage of using mixed methods designs is that quantitative data can yield generalizable results, and qualitative data can provide extensive insights (Zhang & Watanabe-Galloway, 2013). Mixed methods research includes concurrent and sequential designs. Concurrent designs enable researchers to compare open-ended qualitative data with close-ended quantitative data to determine if the two data sets provide

similar, different, or contradictory information about a research question (Zhang & Watanabe-Galloway, 2013). Qualitative assessment can be easily nested within a quantitative intervention trial. Alternately, data can be collected sequentially so that one component informs the other. For example, Petrenko and colleagues conducted pre-intervention qualitative research to inform the development of an intervention for children with fetal alcohol spectrum disorders (FASD) to prevent secondary conditions (e.g., mental health problems, trouble with the law, substance use) common in this population. Qualitative studies included an evaluation of systems barriers contributing to secondary conditions in this population and an investigation of perceived needs and preferences for intervention programming from the perspectives of parents of children with FASD and service providers in the targeted communities (Petrenko, Tahir, Mahoney, & Chin, 2014a, b). These studies address gaps in the existing literature and lead to refinements in early conceptualizations of the intervention program. The preventive intervention program developed from this research, called Families on Track, is currently being tested in a small-scale mixed methods RCT at Mt. Hope Family Center. Pre-intervention qualitative research, such as that highlighted here, can also aid researchers in developing relevant and culturally appropriate interventions that are acceptable to the target population. Qualitative methods are also often used following a quantitative intervention trial to further explain a pattern of unexpected numerical results.

There are three main approaches to mixing qualitative and quantitative data for analysis: (1) the two types of data are analyzed separately, and the results are integrated at the interpretation stage; (2) the two data sets are linked, and one approach builds on the findings of the other; or (3) analysis of one data type is embedded within the other (e.g., transforming qualitative themes into numbers and comparing with quantitative results) (Zhang & Watanabe-Galloway, 2013). One of the most significant challenges for mixed methods designs is overcoming common misunderstandings about the rigor of qualitative methods and the lack of adequate training in these methods in most research training programs (Liamputtong, 2009). Rigor is equally important in qualitative and quantitative research, but distinctive procedures are used to assess it within each method (Liamputtong, 2009; Zhang & Watanabe-Galloway, 2013). Mixed methods research often takes more time, can be more costly, and requires a more extensive skill set (either individually or across the research team) than qualitative or quantitative methods alone. The article length limitations in many journals may be a barrier for the publication of mixed methods research.

Implementation Challenges

The realities of implementing and analyzing the effects of preventive interventions pose a number of challenges for researchers. Randomization is not always possible, given ethical and practical constraints, and even when it is possible, selection bias still can occur. Participant noncompliance and attrition are expected in most prevention trials but complicate statistical analyses. Informant discrepancies are also problematic in analysis and interpretation. To have adequate power to reliably detect effects, many of the innovative methodologies and statistical approaches used to account for increased complexity or deal with real-world complications require large samples. Large samples are prohibitive in many cases due to funding or other resource limitations and the ability to access enough participants who meet study criteria. Each of these challenges is discussed in detail along with recommended strategies to manage it when possible.

Selection Bias

Randomized controlled trials are the gold standard for establishing the efficacy of preventive interventions. However, randomization is not always possible or appropriate. For example, randomization may not be ethical or acceptable with certain populations or in given institutions or agencies. For some selective or indicated interventions that target specific populations, randomization may fail to produce baseline equivalence of groups, especially for small or heterogeneous samples (Blair, 2004). In these cases, a nonexperimental design may be preferable. Nonexperimental studies can also be useful in program evaluation, especially in community-based disseminations of programs where less control is possible (Hill, Rosenman, Tennekoon, & Mandal, 2013). However, selection effects pose problems for both internal and external validity in nonexperimental studies. Sources of selection bias include both self-selection into the program and differential dropout. Methods based on the counterfactual model (also known as Rubin's causal model or the potential outcomes model) can aid researchers in statistically correcting for selection bias (Hill et al., 2013). These methods include propensity score matching, the Heckman two-step approach, and full information maximum likelihood based on a bivariate probit model and its trivariate generalization. In propensity score matching, a

nonexperimental control group is constructed (e.g., from a supplemental data set or separate control sample) to be equivalent to the treatment group by matching participants on a composite index (propensity score) derived from a set of explanatory variables presumed to be relevant to the outcome. In the Heckman two-step approach, the probability of selection for each individual is modeled (step 1), and the error term (reflecting both random error and the effect of unobserved variables driving selection) from this step is modeled in the outcome equation as a proxy for unobserved selection variables (step 2). The third approach involves jointly estimating three sequential equations predicting participation (eligible members attend a program or not), completion (having chosen to attend, participants complete program or not), and outcome (having completed the program, participants show positive change or not), respectively, following a preventive intervention (Hill et al., 2013). Counterfactual models permit researchers to evaluate interventions in uncontrolled settings and maintain some confidence in the internal validity of inferences.

Although the methods just described can adjust for observed confounding, unobserved confounding continues to be problematic (Liu, Kuramoto, & Stuart, 2013). Sensitivity analyses can be utilized with counterfactual methods to help increase confidence in the results from nonexperimental designs (Liu et al., 2013). There are two main approaches to sensitivity analyses. In the first approach, which is often used with matching procedures (i.e., propensity score), researchers determine the point at which intervention effects become nonsignificant (Liu et al., 2013). In the second approach, certain specifications are utilized to quantify the unobserved confounder (e.g., by modeling the relationship of observed confounders with intervention status or outcome under conditions specified by the researcher), which is then used to adjust the estimate of the intervention effect, providing an associated confidence interval. This latter group of simulation methods produces sensitivity results that do not change as a function of sample size since adjustments are not calculated directly from actual sample data (Liu et al., 2013).

Selection bias is not limited to nonexperimental trials. As mentioned, selection bias can occur in RCTs when a systematic difference arises as a result of variation in intervention compliance, quality of implementation, or attrition (McGowan et al., 2010). Unfortunately, study design features, such as random assignment, are insufficient to control for selection bias that occurs after the start of an intervention (McGowan et al., 2010). Investigations of implementation, such as dose response, therapeutic process, and fidelity, are particularly vulnerable to selection biases. McGowan and colleagues (2010) illustrated the significant effects of selection bias on effect estimates through presentation of dose response analyses from the Fast Track study and several data simulations. They demonstrated that even with very small or small levels of confounding, selection biases can lead to an increase in Type I errors (detecting an effect when there is not one). A small amount of confounding can also obscure a small true effect size and often underestimates a medium effect due to significant power reductions. Researchers can consider several strategies to deal with selection bias in experimental studies. Several alternate study design options are possible if researchers are specifically interested in examining implementation factors vulnerable to selection bias (McGowan et al., 2010). For example, participants can be randomly assigned to levels of intervention dosage to determine the thresholds of participation necessary to achieve specific outcomes. Without randomization of dose, researchers cannot be certain confounding has been ameliorated and can only use sensitivity analyses or bounding methods to assess the magnitude of potential bias. Factorial designs are another option for researchers who are interested in the impact of one part of a multicomponent intervention (e.g., peer pairing within the larger Fast Track project). Most studies consider selection biases post hoc. In these cases, statistical use of covariates can sometimes be beneficial, depending on the level of confounding and appropriate selection and collection of covariates. Controlling for pretreatment covariates can help lessen the effects for very small and small confounding, but it is generally ineffective with confounding that is larger or when there is no relation between the covariate and unobserved confounder (McGowan et al., 2010). Researchers should consider including variables in their study designs that have been found in previous studies to relate to motivation, participation in intervention, and adherence to intervention protocols and to predict response to intervention. These variables may be useful in evaluating selection bias and its effects on outcome evaluation. For example, Brody, Murry, Kogan, et al. (2006) found that youth unconventionality and ratio of adults to children in the household were predictors of inconsistent participation in the SAAF preventive intervention. The frequency of potential covariate measurement is also important to consider in the design phase. Researchers may also consider assessing selection bias through some of the sensitivity and bounding approaches (e.g., propensity score matching, Heckman two-step estimator) mentioned in more detail previously in the chapter.

Noncompliance

One of the most significant problems facing intervention trials is participant noncompliance. Noncompliance with randomization and intervention protocols is a reality for almost all trials and can influence the reliability and validity of conclusions, depending on the extent of the problem. Noncompliance is potentially a greater problem for prevention trials relative to treatment studies, since individuals are not generally experiencing serious problems or actively seeking treatment, and other more pressing life demands may outweigh their motivation or abilities to engage in an intervention to prevent possible future problems (Gross & Fogg, 2004; E. A. Stuart, Perry, Le, & Ialongo, 2008; Toth et al., 2013). Noncompliance includes several factors, including mobility processes that determine who remains in the trial at each time point, the extent of compliance with the intervention, and the actual intervention effects for those who complied. Unfortunately, these processes cannot be easily separated after data collection (Vuchinich et al., 2012). The effects of noncompliance are likely to be greatest for interventions that take longer to deliver, have larger samples, and involve more at-risk, mobile individuals. For example, in the context of school preventive interventions, student mobility can be quite large, especially within large urban schools (Vuchinich et al., 2012). Given that mobility is associated with multiple risk factors (e.g., poverty, adverse childhood experiences; Dong et al., 2005; Gasper, DeLuca, & Estacion, 2010), more mobile students (either entering or leaving a given school) may be at higher risk than the average student, resulting in biased intervention effects and poor generalization when data from these students is not captured. From a design perspective, researchers can develop recruitment and retention protocols to facilitate compliance (E. A. Stuart et al., 2008; Vuchinich et al., 2012). For example, researchers can maintain regular contact with participants and obtain contact information of others who will likely know about the participant's whereabouts if contact is lost. Person finding services or online sites can also be useful. Reducing barriers to participation, such as child care, transportation, and the setting and timing of research visits, can facilitate participation. Adequate compensation or incentives also can be helpful in retaining participants. Strategies such as these have been routinely implemented into RCTs conducted at Mt. Hope Family Center.

E. A. Stuart and colleagues (2008) outlined five statistical approaches for dealing with noncompliance. The first approach, commonly referred to as the intent-to-treat (ITT) approach, ignores noncompliance and compares participants who were randomly assigned to the treatment versus control conditions regardless of their actual compliance with their assigned conditions. Another approach involves examining different levels of participation on outcome within the treatment group only. In an as-treated analysis, individuals who did not comply with the intervention are excluded from analyses. However, this approach may lead to biased estimates because it compares the effect of completing the treatment versus all controls, including those who may not have complied if given the option. The as-treated approach also loses the benefits of random assignment. Alternately, researchers can control for the level of participation as a predictor of outcome. However, this approach also leads to biased results for reasons similar to the as-treated approach since controls do not have the option of participating, and some may be very different from noncompliers in the treatment group who receive the same score on the predictor variable. Instrumental variable approaches, which include the complier average causal effect (CACE), represent an additional approach. CACE improves on these alternate approaches by estimating the proportion of controls who would have complied with the intervention if they had been offered it and then comparing this subgroup to those participants who actually complied with the intervention.

Considering all five approaches, only ITT and CACE can make causal interpretations, and both are reasonable depending on the goal of analysis (Ialongo et al., 2006; E. A. Stuart et al., 2008; Vuchinich et al., 2012). Some researchers may be interested in testing whether offering an intervention attains results, regardless of program uptake. Thus, ITT tests causal effects due to group assignment. However, as levels of noncompliance increase, true treatment effects are likely to be obscured. Especially in cases with moderate to high levels of noncompliance, it is important to determine whether the intervention was effective for those who actually complied with it. CACE considers intervention compliance as an uncontrolled factor and estimates the average intervention effect for compliers. CACE estimates are usually larger than those from ITT. The utilization of CACE helps transport findings from RCTs to real-world settings, where noncompliance is common. Although ITT analyses continue to represent the dominant approach in the field, CACE has been increasingly used to evaluate preventive intervention outcomes, including in RCTs intended for depressed mothers with young children (Toth et al., 2013), children of substance-abusing parents, (Stanger, Ryan, Fu, & Budney, 2011), health risk behaviors (Stormshak et al., 2011), academic achievement

(Stormshak, Connell, & Dishion, 2009), and child problem behaviors (Dishion et al., 2013). To facilitate CACE analyses, researchers are advised to measure baseline characteristics believed to affect participation rates. In addition, it is important to draw on theory to determine what constitutes full participation when determining cut points for operationalizing compliance for analyses (E. A. Stuart et al., 2008).

Although compliance with randomization and intervention completion is more heavily regulated by professionals and institutions in cluster-randomized studies than when randomization occurs at the individual level, noncompliance continues to be a significant problem and an additional layer of complexity in analyses (Vuchinich et al., 2012). Vuchinich and colleagues (2012) emphasized a systematic consideration across two factors when considering noncompliance in cluster-randomized designs: (1) whether the analysis is at the person or cluster level, and (2) whether ITT or noncompliance (i.e., CACE) analyses will be utilized. A person-focused ITT analysis is appropriate when researchers want to estimate the impact of intervention assignment on individuals when it is implemented in real-world conditions including mobility. In this scenario, researchers attempt to follow all participants even if they move and do not include late entrants (i.e., people who move into the cluster and may receive part of the intervention but were not a part of the initial randomization). In person-focused noncompliance analyses, researchers estimate the impact of the intervention on participants who complied with it to receive adequate dosage. Only compliers are followed; dropouts and late entrants are not included in analyses. In contrast to person-focused approaches, cluster-focused analyses measure the rates of the problem for the cluster as a whole, not the rate of the problem for individuals who were at one time members of the cluster. Cluster-focused ITT analyses examine the impact of intervention assignment on clusters of participants. Since analysis focuses on the randomization of the overall cluster (not the specific individuals), individual participants that drop out are not followed (initial data still used), but late entrants are added. Cluster-focused noncompliance answers the question regarding the impact of the intervention on clusters that complied with it. Only clusters that remain in the trial or in which the trial was fully implemented are included. This systematic approach highlights the importance of collecting data on compliance at both person and cluster levels (Vuchinich et al., 2012). Collecting data on covariates that predict missingness, late entrants, dropouts, and compliers allows researchers to evaluate whether there are significant differences between intervention and control clusters (Vuchinich et al., 2012).

Noncompliance and missing data on outcomes often co-occur. Fortunately, advances in statistical modeling can accommodate both noncompliance and missing data outcomes to estimate causal treatment effects. The association between noncompliance and missing data status for the control condition is unknown, and therefore assumptions must be made. Jo and colleagues (2010) demonstrated how to apply CACE under various missing-data assumptions. To understand the assumptions being made, it is useful to consider four types of participants: (1) compliers—complete the group assignment given; (2) never-takers—do not participate regardless of group assignment; (3) always-takers—find a way to get the intervention regardless of group assignment; and (4) defiers —do the opposite of what is assigned. Under the first assumption, data are assumed to be missing at random, and the response rate is considered the same across compliance classes. In the response exclusion restriction, the response rate is allowed to vary for the compliers but is not allowed to vary across assignment arms for the never-takers. The stable complier response examines the opposite assumption and allows the missing-data indicator to be freely estimated for the never-taker class but fixed at zero for the complier class. In all three cases, it is common to assume that defiers and always-takers are not given access to the intervention; therefore, their effects are held at zero. Jo and colleagues acknowledged that it is rare to have more confidence in one of these assumptions over others. Even when the relative plausibility of these assumptions is known, it is still difficult to predict the performance of CACE estimators, given that bias mechanisms can be quite complex when both noncompliance and missing data are being estimated. Thus, the authors recommended reporting the range of effects across all three assumptions.

Informant Discrepancies

Although researchers recognize the value of collecting data from multiple informants, the field has shown limited growth in understanding and meaningfully interpreting informant discrepancies over the last 25 years (De Los Reyes, 2013). Because results of controlled trials often point to inconsistencies across reporters with regards to intervention effects (De Los Reyes & Kazdin, 2009), this issue is critical to prevention science. Even though researchers frequently emphasize the value of multi-informant assessment approaches, in practice it is common to interpret and methodologically and/or statistically manage discrepancies

as measurement error (De Los Reyes, Thomas, Goodman, & Kundey, 2013).

Seminal work by Achenbach and colleagues (1987) on informant discrepancies demonstrated that (1) different reports of the same behavior show low to moderate correspondence across reporters; (2) reports of children in the same setting correlate more highly than those of children in different settings; (3) reports of children correspond more than those adolescents; and (4) reports of externalizing behaviors are more highly correlated than reports of internalizing behavior. Some advances have been made in terms of theory and statistical modeling (e.g., Kraemer, 2003); however, models of informant discrepancies and empirical data supporting their utility in interpretation are needed before discrepancies should be viewed as meaningful (De Los Reyes, 2013). The theoretical model with the greatest support for understanding informant discrepancies proposes that individuals vary systematically in the behaviors being expressed and informants vary in their perspectives on the observed behavior (De Los Reyes, 2013). While this model is intuitive, limited direct empirical tests of it have been conducted. The research support for this model is limited to assessments of children's behavior that is directly observable (e.g., externalizing behavior) and examination of discrepancies between persons who fundamentally differ in the context in which they observe the child (e.g., parents and teachers). More research is needed to validate this model and establish that informant discrepancies are meaningful contextual expressions of behaviors. Systematic investigation is also needed to study how researchers and practitioners use informant discrepancies when making decisions about research designs, interpretation, and patient care (De Los Reyes, 2013).

De Los Reyes and colleagues (2013) recently advanced the Operations Triad Model as a guide for researchers handling multi-informant reports. This model encourages researchers to propose a priori hypotheses regarding whether findings across informants will converge or diverge. In the case of hypothesized divergence, it is recommended that researchers posit a priori whether divergence will be the result of measurement error or meaningful variation. Moreover, in the case of anticipated convergence, the Operations Triad Model suggests that researchers create a priori thresholds for defining convergence. If the threshold is not met, researchers are encouraged to conduct post hoc analyses to determine whether measurement error accounts for the discrepancy, in which case compensating operations (i.e., statistical and/or methodological techniques) may be conducted to compensate for the lack of convergence).

Additional general recommendations for researchers include providing informants with more specific instructions (e.g., define labels such as *often* in more concrete terms; provide decision rules) and collect information about the settings in which the behaviors being rated occur (De Los Reyes, 2013). Setting information could help identify whether discrepancies are related to variability of behavioral expression across settings and may contribute to knowledge about which treatments are effective in which settings.

Sample Size and Power Issues

As discussed throughout this chapter, sample size and resulting statistical power issues are likely among the greatest challenges for researchers designing and evaluating preventive interventions from a developmental psychopathology perspective. In previous sections we described challenges related to sample size and power with respect to specific quantitative methodologies (i.e., subgroup analyses, mediation, moderated mediation). In this section we direct our attention to other methodologies designed specifically for preventive interventions that target specific risk populations or disorders with relatively low prevalence. For example, individuals with FASD are at high risk for secondary conditions, such as mental health problems, trouble with the law, and substance abuse (Streissguth et al., 2004). Preventive interventions delivered during early childhood might be able to prevent the onset or severity of many of the secondary conditions. Although the prevalence of FASD is estimated at 2% to 5%, it often goes undiagnosed, and the population can be difficult to recruit due to various barriers (May et al., 2004; Petrenko et al., 2014). Only large multisite studies would be able to accrue an adequate sample to begin to evaluate some of the complexity involved. Unfortunately, multisite studies are very costly and involve additional challenges in coordination and maintenance of fidelity across sites.

Funding and resource limitations can also impact the power researchers can achieve to detect intervention effects and test theory with a given sample. Interventions with a longer duration or with more intensive or costly resource allocation (e.g., interventionist time, higher-skilled personnel, costly program materials) typically result in smaller samples, unless researchers are able to secure larger or longitudinal program grants or multiple funding sources, use existing delivery mechanisms (e.g., incorporating curricula into schools), or establish sustainable partnerships within the community. Such intervention costs can also be prohibitive for innovative studies being conducted, particularly for multisite evaluations. For example, costs

associated with the provision of intervention, in conjunction with the costs of implementing the research protocol, can exceed what is allowed by existing grant funding caps. Research assessment batteries are also limited by funding realities, which puts a strain on the types of questions and theoretical mechanisms that can be addressed. Incorporating multiple levels of analysis, especially at the biological level, can be very expensive and often relies on additional consultants or personnel from other disciplines, which further increases costs. As mentioned, securing funding for longitudinal follow-up evaluations can be particularly difficult, especially in the current competitive funding climate.

Many of the innovative methodologies and statistical approaches discussed earlier that are used to account for increased complexity or deal with real-world complications require large samples to have adequate power to reliably detect effects. There are few options for researchers who are limited to smaller samples. Intensive within-person designs are viable strategies, which have been underutilized in prevention science (Ridenour, Pineo, Maldonado Molina, & Lich, 2013; Sterba & Bauer, 2010). For example, rigorous idiographic studies can be used to test programs for low-prevalence outcomes, examine the efficacy of selective/indicated programs, provide pilot data for larger trials, or understand differential response to programs (Ridenour et al., 2013). Some idiographic designs include multiple waves of baseline data collection for modeling of pre-intervention variability of characteristics. This approach assumes that pre-intervention variability may be predictive of response to intervention rather than treating psychological characteristics as invariant, fixed-effects traits, as is typically done in the majority of single-baseline pre-post statistical analyses (Ridenour et al., 2013). Collecting data intensively on smaller samples allows researchers to overcome the extensive cost that would be involved with multiple-wave baseline data collection in larger studies. Idiographic statistical methods vary in how intervention effects are estimated, the method used to account for serial dependency, and how nonintervention variables (e.g., covariates) are modeled (Ridenour et al., 2013). Examples of idiographic designs include time series analysis (e.g., autoregressive moving average, mixed model trajectory analysis, and P-technique). A discussion of these techniques is beyond the scope of this chapter; interested readers are referred to referenced citations for more details. These approaches exclusively capture intra-individual etiological process and can define these processes multivariately, unlike many of the larger sample approaches, which are limited to univariate processes without more complicated analytic extensions (e.g., parallel process extensions).

Summary

In this section, we discussed the challenges and complexities inherent to preventive intervention methodology and described strategies for addressing these issues and continuing to advance the field. First and foremost, prevention scientists must ground their interventions in theory. Theoretical considerations are needed at all levels and aspects of the intervention, including the overall guiding theoretical framework, the mediating mechanisms, and the subgroup analyses. RCTs continue to be the gold standard for preventive intervention design and new exciting methodologies such as SMART (Almirall et al., 2012; Collins et al., 2004; Dawson & Lavori, 2012; Murphy, 2005; Lei et al., 2012) are now available that allow researchers to develop adaptive or individually tailored interventions to improve intervention outcomes. Person-centered approaches and qualitative methods each offer unique and important contributions to prevention science as they provide opportunities for examining individuals as a whole and in greater depth. Moreover, prevention researchers must strive to move beyond the reliance solely on symptomatology to evaluate outcomes and consider richer conceptualizations of intervention success, such as levels of adaptation, transactional measurements, diverse developmental domains, and observational methods. Finally, prevention science is not without significant challenges. The realities of funding and resource constraints and participant noncompliance, to name only a few, often require researchers to employ innovative methods to appropriately evaluate their intervention. However, the far-ranging impact of prevention for overall societal benefit warrants intensified effort and resources.

TRANSLATIONAL RESEARCH

From Research to Practice

In recent years, the term translational research has become increasingly common, although a consensus on its exact meaning has been slower to emerge (Cicchetti & Toth, 2006a; Gunnar & Cicchetti, 2009). In general, the term pertains to the bench-to-bedside goal of utilizing knowledge gained from basic science to develop and evaluate new treatments (Insel, 2009; Zerhouni, 2005). However, this definition, derived from a medical model, can fail to capture the goals of prevention science with respect to

psychosocial interventions. Importantly, the availability of research-derived interventions does not ensure that they will be accessible to those individuals most in need. Therefore, a second area of translational research pertains to improving access to evidence-based treatments (Sung et al., 2003; Woolf, 2008). Advances in the behavioral and social sciences and in the neurosciences, molecular biology, and genomics have positioned the field of prevention science to develop, evaluate, and disseminate empirically supported prevention and intervention strategies (Toth, Manly, & Nilsen, 2008). Consistent with one of the central tenets of developmental psychopathology, translational research also emphasizes the bidirectional nature of clinical and research endeavors (Cicchetti & Toth, 1998, 2006a; Rutter & Sroufe, 2000).

A key consideration in the conduct of translational research involves making a determination as to when a sufficiently large corpus of evidence exists to warrant broad access to and dissemination of an evidence-based intervention. Understandably, developers of intervention models want to ensure that the integrity of their models is maintained. However, if interventions are not made more widely accessible once a corpus of evidence supports their efficacy, a number of concerns arise. First, failure to share treatment manuals with other professionals who are interested in providing and evaluating the treatment does not allow for independent replication of the positive research outcomes. Because one of the widely accepted components of attaining the classification of an evidence-based intervention involves replication by independent researchers who were not involved with the development of the model, this is a significant problem that, unfortunately, is not widely recognized by individuals in the policy arena. Second, insistence on controlling a model that has been found to be efficacious limits its accessibility and also reduces the likelihood that the model will be evaluated in diverse geographical venues and with heterogeneous populations (Cicchetti & Toth, 2015).

That being said, it also is important that models that have been found to be efficacious are not adopted by individuals who have not been trained adequately in the conceptual underpinnings and delivery of the model. The establishment of training criteria and credentialing standards is critical to the dissemination of evidence-based models. It is highly unlikely that simply reading a treatment manual or completing an online course, in the absence of personally delivered didactics and supervision, will result in the attainment of adequate skills to provide an intervention consistent with standards adhered to by model developers.

Discussions of translational research lead directly to considerations related to the social policy arena. The personal and economic burden of mental illness highlights the importance of utilizing information derived from research to inform policy initiatives. However, despite what should be an almost seamless integration of research, practice, and social policy, reciprocally beneficial interactions among these arenas have been difficult to achieve (Toth & Cicchetti, 2006). Shonkoff (2000) addressed impediments to this integration, stating that whereas scientists are trained to raise questions and to be guided by facts, policymakers are more prone to be governed by political and economic forces. Service providers are more similar to policymakers as they are often faced with situations that require immediate action before empirical data are available to inform specific intervention strategies. In reflecting on this tension, Shonkoff (2000) stated: "Science is focused on *what we do not know*. Social policy and the delivery of health and human services are focused on *what we should do*" (p. 182, emphasis in original). Even when data are available to inform intervention strategies, the realities of heavy clinical caseloads and lack of access to easily understood empirical information by clinicians and policy advocates may limit the likelihood of clinicians and policy advocates adopting evidence-based interventions.

Increasingly, calls have been made for the utilization of science to guide policymaking and funding decisions (J. Baron & Haskins, 2011; Haskins & Baron, 2011). Unfortunately, even when evidence exists that programs are ineffective, political forces may make it difficult to eliminate funding for these programs and redirect the funding toward those that are evidence-based (J. Baron & Sawhill, 2010). In a compelling essay, Haskins and Baron (2011) argued that better population-level outcomes in education, crime reduction, and child well-being would occur if policy and funding decisions were made based on evidence of what works.

It is unlikely that anyone invested in promoting the welfare of children would disagree with the importance of attaining the above-stated objectives. Therefore, it can be difficult to understand why the synergy among research, practice, and social policy has been so difficult to realize. A number of issues need to be considered when evaluating the schisms that remain, including allocation of resources and the willingness of communities to adopt evidence-based models of intervention. In this regard, it is important that efficacious models be evaluated with diverse populations, thereby increasing the receptivity to uptake in diverse communities.

Although there has been increased recognition of the importance of supporting evidence-based social programs, political forces that operate do not always act in accord with this goal. The decisions of policymakers are governed by myriad issues, including program cost, input from constituents, the position of party leaders, public opinion, pressure from lobbyists, and their own political philosophies. Politically favored programs often are held intact or allocated increased resources (Barlow, 2010). At times, scientific evidence that identifies iatrogenic effects of programs is ignored (Lilienfeld, 2005). Unfortunately, even programs with strong scientific support are not equally effective for all individuals. Despite decades of research dedicated to evaluating programs designed to foster positive outcomes for children faced with economic and familial disadvantage, the overall effect sizes for programs found to be effective remain within the small to moderate range (Shonkoff & Fisher, 2013). Moreover, some evidence-based models, although shown to be effective for a designated population, address only a small percentage of individuals in need. For example, although the outcomes for the NFP home visitation program have been shown to be effective in a number of important arenas, such as improving parental caregiving and child health and preventing child abuse and neglect (Kitzman et al., 1997; Olds, Henderson, & Kitzman, 1994), it limits enrollment to first-time mothers who are identified during their first trimester of pregnancy. Because many young mothers living in poverty do not seek prenatal care, these inclusion criteria result in the ineligibility of significant numbers of very high-risk mothers. Therefore, although efforts to increase the availability of evidence-based programs are needed, it would be premature to conclude that resources should be directed only toward those programs that have been supported by rigorous evaluation. Rather, programs that have been found to be ineffective should be eliminated, but the investment in newly developed promising programs is equally important (Cicchetti & Toth, 2015).

When trying to ascertain how best to disseminate evidence-based interventions into community settings, possible impediments for program uptake need to be considered. In general, the evidence base for programs is derived from university-based randomized control trials. Although these approaches reflect the gold standard in the field, they are not without challenges with respect to dissemination into community settings (Sternberg, 2006; Toth & Manly, 2011). RCTs are conducted under very controlled settings and involve utilization of strict inclusion and exclusion criteria for participants that are quite different from those present in individuals seeking mental health care in community settings. Unfortunately, and not surprisingly, when such programs are disseminated into community settings, not only do they yield low rates of utilization with respect to individuals eligible for such services, but they also tend to be less effective due to issues such as lower-credentialed and less experienced providers, lack of supervision, and failure to ensure fidelity of implementation (Dodge & Mandel, 2012). This problem has been referred to as the scale-up penalty and estimated at 50% (Welsh, Sullivan, & Olds, 2010). Moreover, some changes implemented during dissemination may not always lead to the intended positive outcome, resulting in considerable variation in the effectiveness of programs initially provided as part of RCTs and subsequently exported to community settings (Weisz & Jensen, 1999). The way an intervention is conceptualized also is very likely to contribute to whether a community is invested in providing it and adhering to its fidelity (Dodge, 2008). Therefore, to promote community uptake and to achieve impact at the population level, it is critical to consider the ultimate goal of exportation from the initial conceptualization of an RCT. Lessening restrictions on the inclusion/exclusion of participants, for example, ultimately might increase the likelihood that the intervention can be disseminated more effectively (Toth, Pianta, & Erickson, 2011). Regardless, despite best efforts to ensure effective implementation of an evidence-based model in community settings, it is critical that evidence on fidelity of implementation and outcomes within a given community be generated. For this reason, some advocate that legislation should provide a mandate for ongoing evaluation of budgets for federally funded programs once evidence-based models have been disseminated to communities (Haskins & Baron, 2011).

Cross-disciplinary and community collaborations also are keys to facilitating the translation of well-controlled efficacy research into the community (Saul et al., 2008; Spoth, Clair, Greenberg, Redmond, & Shin, 2007; Toth & Gravener, 2012). Illustrative of this point, a university-community partnership has been developed between Mt. Hope Family Center, the Monroe County Department of Human Services, and the United Way of Greater Rochester, NY, to disseminate CPP as well as other evidence-based preventions to a group of at-risk young mothers with few socioeconomic resources (see Toth & Gravener, 2012, for more details). Through this program, Building Healthy Children (described earlier), over 700 young women have been recruited and enrolled through pediatric medical clinics. They were randomly assigned to the active preventive intervention condition or an enhanced care-as-usual condition. A multilevel

of analysis measurement battery was used, including assessments of emotional and behavioral functioning and genetics. Importantly, a high percentage of eligible women were willing to participate in the study and complete the research battery, and the retention rate after enrollment has been over 80%. This result suggests the feasibility of implementing CPP in the community and the need to identify factors that promoted engagement in this study to inform future research. Preliminary analyses have yielded promising results, including decreases in depressive symptoms and higher rates of well child care and immunizations in program participants (Paradis et al., 2013). The Building Healthy Children program exemplifies the bridge between efficacy research and dissemination and demonstrates that the development and maintenance of strong community collaborations allow for more professionals to be trained on evidence-based preventive interventions and more individuals to receive these much-needed programs.

Other strategies for wider dissemination also have been called for, such as disruptive innovation as a way to find inexpensive and simpler means to reach a greater number of individuals at risk for mental illness (Rotheram-Borus et al., 2012). One of the suggestions of this model is to find delivery formats that have the capacity to reach a broader population, such as via utilization of technology and media strategies. Computerized interventions with the current generation of children and adolescents, many immersed in technology from a young age (Vandewater et al., 2007), have the potential benefit of connecting with vulnerable youth in an arena in which they feel comfortable and competent. Several studies have tested an Internet/computer delivery format with positive results for preventing depressive symptoms (Van Voorhees et al., 2009), sexual risk behaviors (Lightfoot, Comulada, & Stover, 2007), and attitudes toward drug use (Williams, Griffin, Macaulay, West, & Gronewold, 2005). Webster-Stratton and colleagues (2010) have also explored a hybrid computer-based and face-to-face adaptation of the Incredible Years program in a small study with reported success, denoting an area for further research. Technology-based and hybrid interventions are a promising frontier for prevention program dissemination, given their ease of use for the current generation, potential low-cost delivery, and ability to reach rural communities with less access to specialized intervention. However, it is critical that technological solutions for broader dissemination of interventions do not neglect those most in need, many of whom may have limited or no access to technology.

As innovative solutions for dissemination are being explored, primary care offers a setting in which a large number of individuals can be reached for the delivery of brief and universal preventive interventions. One advantage of primary care settings over schools is that parents often accompany their children to pediatric appointments and thus are more readily available to participate in the interventions than they may be in the school setting. A primary prevention program developed to prevent child abuse as well as parent-child conflict in Iranian families was administered in a primary care setting, and results supported improvements in parenting and reductions in parent-child conflict compared to a control condition (Oveisi et al., 2010). The primary care setting also provides an opportunity for screenings for secondary or indicated interventions (Berkovits, O'Brien, Carter, & Eyberg, 2010) as well as a setting for disseminating indicated preventive interventions (Gillham et al., 2006, described earlier). Importantly, as child mental health treatment is increasingly provided in primary care medical settings (Olfson, Blanco, Wang, Laje, & Correll, 2014), it will be increasingly important to determine the portability of effective preventive interventions to the primary care setting to reach the widest population of children, adolescents, and families at risk for the development of psychopathology.

Cost Benefit Analyses

An important consideration in evaluating the merits of prevention initiatives ultimately relates to cost benefit analyses. Such analyses can be challenging, as the very nature of prevention involves assessing development and adaptive or maladaptive functioning over time. Such longitudinal follow-up of prevention programs can be cost prohibitive. Moreover, individuals allocating dollars to prevention most typically want to see positive results on their watch rather than hearing about future benefits that will accrue many years later. However, at a time when limited funding necessitates difficult funding decisions to be made by policymakers outside of the field of preventive science, cost-benefit analyses are more important than ever and were cited as an area for improvement in the prior edition of this text (Ialongo et al., 2006). Although such analyses are not yet routinely reported in preventive intervention RCTs and much more work is still needed, there has been some progress in this domain. The cost-effectiveness of a cognitive-behavioral intervention for adolescents at risk for depression was assessed in an RCT comparing the active intervention to care as usual (Lynch et al., 2005). Analyses using quality-adjusted life years and depression-free days suggested that the intervention was cost-effective at $1,632 per participant, although it was noted that no other studies

reporting costs of preventive interventions for teen depression were available for comparison. A cost-benefit analysis of the Communities that Care prevention system, aimed at adolescent health and behavior problems at the community level, found a return of over $5,000 per youth involved in the study (Kuklinski, Briney, Hawkins, & Catalano, 2012). These benefits were found to be largely due to preventing delinquency. Cost-effective preventive interventions for child anxiety (Simon, Dirksen, & Bogels, 2013) and late-life anxiety and depression (van't Veer-Tazelaar et al., 2010) also have been identified. Notably, many of the studies that have evaluated cost-effectiveness for preventive interventions have employed different methods of assessment, making it challenging to compare results across studies. A more coherent program of research widely used in Australia is the Assessing Cost-Effectiveness (ACE) approach (Carter et al., 2009; Mihalopoulos, Vos, Pirkis, & Carter, 2011). One of the major strengths of this approach is the use of a standardized unit, disability-adjusted life years to assist in conducting cost-benefit analysis. The use of a standardized unit, such as disability-adjusted life years or quality-adjusted life years, allows for comparisons between interventions as well as across studies. Disability-adjusted life years take into account years that one loses due to premature morbidity as well as the number of years one lives with a disability (Mihalopoulos et al., 2011). ACE-Prevention is a large-scale study that was undertaken in Australia to evaluate preventive interventions for mental illness with the goal of providing feedback to policymakers (see Mihalopoulos, Vos, Pirkis, Smit, & Carter, 2011, for more details regarding findings). A coordinated large-scale investigation of the cost-effectiveness of preventive interventions commonly used in the United States is an important direction for further exploration.

FUTURE DIRECTIONS AND RECOMMENDATIONS

As articulated in this chapter, the last decade has heralded significant advances in the identification of efficacious interventions for individuals at risk for maladaptation and psychopathology. Moreover, progress has been made in identifying mechanisms whereby efficacious interventions operate to bring about positive change. However, despite progress, much work remains if we are to have an armamentarium of interventions that not only yield large effect sizes in intervention trials but also are effective across a range of diverse populations. Although we have made recommendations throughout this chapter, we conclude by highlighting future directions that we consider integral to continuing the positive evolution of prevention science.

Perhaps first and foremost, increased attention to the theoretical foundations underlying the development and evaluation of preventive interventions is needed. To date, social learning theory and attachment theory have been two of the most widely recognized theoretical frameworks utilized to guide the development of interventions. However, even in interventions guided by these theoretical models, the processes through which positive change emerges has been more difficult to ascertain. By fully considering the components inherent in various theoretical perspectives when designing and evaluating interventions, the likelihood of identifying mechanisms of change will be increased.

Related to this point, basic research on the processes involved with the development of psychopathology needs to be continued and expanded on so that this knowledge can be incorporated into the design and evaluation of interventions. Historically, far too much emphasis has been directed toward categorical diagnoses as intervention outcome indices. Unfortunately, while understandable, such approaches have hindered the elucidation of mediators of intervention efficacy. Rather than continuing to focus on diagnoses, we endorse Sroufe's (2013) recommendation that key capacities of positive adaptation that cut across diagnostic categories be examined. Such an approach is consistent with a developmental psychopathology perspective and holds considerable promise for providing a more comprehensive roadmap of areas of focus in the design and evaluation of preventive interventions.

Additionally, studies of resilience in individuals at risk for the emergence of psychopathology hold considerable promise for informing the development of interventions. Because resilience is a dynamic developmental process, it is critical that short- and long-term longitudinal studies on the determinants of resilient functioning are conducted in the future. Transitional turning points (Rutter, 2012) provide opportunities and challenges for individuals to remain on a positive trajectory despite ongoing adversity, to bounce back from a decline in functioning, to persist on a maladaptive trajectory, or to exhibit a decline in functioning from positive functioning (Cicchetti & Rogosch, 1997). In the conduct of longitudinal investigations, resilience should be conceptualized as a multidomain, multidimensional construct. Because changes in one domain of competent functioning can cascade to affect other developmental domains over time (Cicchetti & Tucker, 1994; Masten & Cicchetti, 2010), a longitudinal multiple-levels-of-analysis approach to investigating

resilient functioning will help to ensure that resilience processes are examined in a thorough and developmentally appropriate fashion. Findings from examinations of resilience hold considerable potential for informing prevention and intervention initiatives. When indicators of resilience are identified, they can be incorporated into the development of RCTs. The conduct of longitudinal investigations of resilience will be particularly important in ensuring that interventions are timed, guided, and implemented as closely as possible to the identification of deviations from adaptive functioning.

To obtain a more comprehensive understanding not only of contributors to the emergence of maladaptation and psychopathology but also to mechanisms of change in intervention studies, we need to increase the conduct of multilevel investigations that integrate biological and psychological indices. Although such investigations are costly and require cross-disciplinary expertise, such initiatives will be seminal to advancing the field of prevention science in the next decade. Multidisciplinary collaborations have been advocated by developmental psychopathologists since the inception of the field, and the recognition by federal funding agencies that multiple principal investigators may contribute equally to the conduct of such research has been helpful in advancing the conduct of multilevel studies. However, the field of prevention science remains in its infancy with respect to such initiatives, and we strongly advocate for increased momentum in this area. As advanced statistical methods available for the analysis of longitudinal and complex intervention trials have burgeoned, incorporation of individuals with requisite expertise in these methods on RCTs also emerges as an important direction for collaboration.

In the next decade, increased attention also needs to be directed toward developmental issues in the design, provision, and evaluation of interventions. Despite repeated calls for such research (Toth & Cicchetti, 1999; Toth et al., 2011), comprehensive studies of issues such as the identification of developmental windows during which the provision of a preventive intervention are most likely to affect optimal development have been slow to emerge. Relatedly, when an individual has experienced a significant stressor or a traumatic event, it remains unclear at what point the provision of intervention is most likely to be effective in alleviating future negative sequelae. Although certainly challenging studies to design and implement, attention to issues of developmental timing of intervention and its relation to outcome are of paramount importance.

Increasingly, research has demonstrated that subgroups of individuals may be more likely to derive benefit from a given intervention. In particular, an emerging body of research suggests that individuals at highest risk may benefit the most. Such findings highlight the importance of conducting screenings to identify individuals at particularly high risk. It may not be that more is always better for everyone. Given cost considerations, it behooves prevention scientists to continue to ascertain "what works best for whom."

Although RCTs with racially and ethnically diverse populations are increasing, much more attention needs to be directed toward ensuring that our knowledge base of efficacious interventions is not limited to middle-class Caucasian populations. Not only has basic research with clinical populations been biased toward reliance on groups with minimal diversity (Nezu, 2011), but studies of intervention efficacy also have suffered from this limitation. Unfortunately, when efforts are made to export efficacious interventions into community contexts, the absence of studies that have included racially and ethnically diverse individuals may limit community uptake, thereby reducing the availability of proven interventions to individuals in need. The paucity of racial and ethnic diversity also has begun to emerge in the conduct of investigations of G×E and differential susceptibility (Van IJzendoorn et al., 2012; however, see Brody et al., 2014, and Cicchetti et al., 2015, for exceptions). Because emergent G×E research has begun to identify differential responsivity to positive and negative contexts, attention to genetic moderation of response to intervention assumes critical importance in relation to heterogeneous groups of individuals.

Related to this point, as our knowledge on the genetic moderation of intervention responsivity increases, we need to identify and/or develop interventions for those individuals who have been found to be less likely to derive benefit from extant interventions. Although some might argue that we currently possess a sufficient corpus of interventions that have been found to be efficacious and that therefore efforts should be directed toward dissemination and scaling up such interventions, we believe that ultimately such an approach is ill-advised. Rather, we advocate for increased dissemination of proven interventions for those most likely to benefit from them as well as increased attention to the development of interventions for individuals who have not been found to derive as much benefit from existing models.

In addition to ensuring that efficacious interventions are available for diverse groups of individuals, we also strongly call for increased efforts to disseminate efficacious interventions into community settings. Rural areas and communities not geographically accessible to benefiting from the developments and trainings provided

by universities continue to be less likely to have access to evidence-based interventions. Unfortunately, individuals in these often isolated communities may be experiencing very high risk contexts and, as such, may be most in need of proven strategies to prevent negative outcomes. Developers of evidence-based models must increase the availability of efficacious interventions more broadly. In this regard, dissemination efforts such as those initiated by the National Child Traumatic Stress Network (www.nctsn.org) are to be lauded.

Throughout this chapter, we have discussed advances, as well as challenges, associated with the availability of increasingly sophisticated methodological and technological strategies. The incorporation of such methodologies into the design and evaluation of interventions offers exciting opportunities for advancing prevention science and for promoting the availability of efficacious models of intervention to vulnerable populations. However, in conjunction with our enthusiasm for such innovative methods and technologies, we offer a cautionary note. Utilization of these advanced strategies must be grounded in a solid theoretical foundation if their potential is to be realized. It is possible to allow technology to outpace sound science, and, ultimately, the absence of a foundational conceptualization will only obfuscate important advances in knowledge and dissemination of effective interventions.

In closing, we are inspired by the progress that has occurred over the last decade with respect to the development, evaluation, and availability of interventions for populations at risk for the development of psychopathology. However, far from resting on past achievements, new frontiers with respect to the conduct of multilevel investigations, longitudinal assessments, and increased incorporation of solid theoretical and developmentally informed foundations into the design and evaluation of interventions beckon those prepared to face the challenges inherent in the conduct of prevention science. It is our hope that the ideas proffered in this chapter will help to foster such advances in the decades ahead.

WHY CULTURAL ADAPTATION IN DEVELOPMENTAL PSYCHOPATHOLOGY

This third edition of *Developmental Psychopathology* is the first to include a chapter focused on the cultural adaptation of evidence-based interventions (EBIs), a topic that represents a point of convergence for many of the core values and goals of the field. Whereas the overarching goal of developmental psychopathology is to elucidate the interplay among the biological, psychological, and social-contextual aspects of normal and abnormal development, the ultimate goal is to inform intervention strategies to promote resilience and prevent or ameliorate dysfunctional outcomes and disorder across the life span (Cicchetti & Hinshaw, 2002; Cicchetti & Toth, 1992). Infusion of cultural factors into EBIs is consistent with the fundamental tenet of developmental psychopathology that maturational, experiential, and cultural aspects of development are inseparably coalesced in ontogeny (Cicchetti, 1990). To the extent this produces differences in the existence, patterning, or impact of risk and protective processes for distinct subcultural groups, modifications to intervention programs and protocols may be needed to provide the best means of reducing psychopathology for these groups. Cultural adaptation has been defined as "the systematic modification of an evidence-based intervention or intervention protocol to consider language, culture, and context in such a way that it is compatible with the client's cultural patterns, meanings, and values"

(Bernal, Jimenez-Chafey, & Domenech Rodríguez, 2009, p. 362). Introduction of this topic in the current volume is well timed with respect to several disciplinary advances in developmental, cultural, clinical, public health, and prevention science and specifically with respect to research on cultural adaptation that has evolved over the past three decades to become a systematic and rigorous field of study in its own right (Barrera, Castro, & Holleran Steiker, 2011; Bernal & Domenech-Rodríguez, 2012; Castro, Barrera, & Holleran Steiker, 2010; Lau, 2006).

This chapter reviews the historical context and challenges that have given rise to this field, the methods and models used to address these challenges, and exemplars of culturally adapted interventions for children and adolescents. Although interventions to address the needs of vulnerable youth exist on a continuum from those that seek primarily to promote health and positive development for whole populations to those targeted at individuals with severe disorders (Weisz, Sandler, Durlak, & Anton, 2005), our presentation of exemplars broadly encompasses the preventive end of the spectrum that addresses risk before it has evolved into debilitating forms of psychopathology, including *universal* prevention approaches that address risk factors in general populations, *selective* preventive interventions that target those segments of the population with greater than normal risk of developing a disorder, and *indicated* approaches that focus on subgroups exhibiting early signs or symptoms of developing a disorder (Mrazek & Haggerty, 1994). The specific goals of the chapter are to: (1) articulate the issues and challenges that have shaped current approaches to cultural adaptation of EBIs; (2) review approaches and models for designing cultural adaptations of EBIs, including frameworks for deciding when, what, and how adaptations should be made; (3) present exemplars of cultural adaptations of EBIs targeting a range of social, emotional, behavioral, and health outcomes; and (4) summarize strengths, limitations, and future directions for the field.

DEFINITION OF CULTURE

Culture is a complex construct that describes the characteristics of a particular group of people, defined by everything from language, religion, cuisine, social habits, music, and arts. A distinct group of people (a tribe, an ethnic group, professional organization, a nation) can be described as "having a culture," meaning that its members share a collective system of values, beliefs, expectations, and norms, including traditions and customs, as well as sharing established social networks and standards of conduct that define them as a cultural group (Betancourt & Lopez, 1993). Although culture can be conceptualized at multiple levels to apply to more universal characteristics of the human experience to narrower conceptualization of the lifeways and worldviews of specific cultural groups and subgroups (Muñoz & Mendelson, 2005), the majority of prior research on cultural adaptation equates culture with ethnicity and race; consistent with this trend, our review of exemplars will focus on adaptations for distinct ethnocultural groups. However, as noted by many scholars (e.g., Castro et al., 2010; B. D. M. Wilson & Miller, 2003), the tendency to equate cultural adaptation with adaptation for specific ethnocultural groups may be misguided in some cases because there are numerous other potential sources of mismatch between an EBI and potential consumers that may be more relevant (Reyno & McGrath, 2006). For example, among the many adaptations of parent training (PT) interventions that have been conducted for distinct ethnocultural groups, a few researchers have adapted PT interventions in ways that transcend ethnicity and race to address issues of low socioeconomic status (SES) (e.g., Brotman, Gouley, Klein, Castellanos, & Pine, 2003).

A focus on ethnicity per se is further complicated by considerable heterogeneity that exists within racial and ethnic groups. In the United States, the four major ethnic groups (Latinos/Hispanics, African American, Asian Americans, Native Americans) collectively comprise approximately 37% of the total population, and they range in size from about 1 million for Native Americans to over 52 million for Hispanics/Latinos (U.S. Census Bureau, 2010). Within each of these broad groups, there exist many homogenous subcultural groups based on factors such as nationality, SES, religious background, immigration history, and generational status (Castro, Barrera, & Martinez, 2004). Asian Americans as an ethnic minority group, for example, are quite heterogeneous with over 20 subgroups (e.g., Chinese, Japanese, Filipino, Korean, Vietnamese, Laotian, Cambodian, etc.), each made unique by linguistic, cultural, and sociodemographic backgrounds and immigration histories in the United States (Sue & Morishima, 1982). Diversity among these Asian subgroups has been associated with a variety of differences in mental health service need, utilization, and outcome. Many scholars advocate population segmentation (Balcazar, Castro, & Krull, 1995), the identification and targeting of subgroups based on the intersection of these cultural dimensions, to avoid ethnic gloss (Trimble, 1995) in planning an intervention. However, opposing arguments counter that the adaptation of interventions for increasingly smaller segments

of the population is not feasible given the number of treatments, disorders, developmental stages, and a host of other factors that would generate a matrix impossible to manage (Kazdin, 2008). Moreover, many interventions ultimately will be delivered in multicultural settings and for populations that are changing on cultural dimensions. Alternative models proposed to address this issue have included adaptive approaches (Collins, Murphy, & Bierman, 2004) that provide opportunities for dynamic sizing (Sue, 2006) or tailoring (Zayas, Bellamy, & Proctor, 2012) of culture-specific program elements on a case-by-case basis (McCabe, Yeh, Garland, Lau, & Chavez, 2005; Pina, Villalta, & Zerr, 2009). In most cases, however, clarity regarding one's conceptualization of "culture," including the theoretical rationale or empirical evidence for expecting cultural differences among subcultural groups or between individuals within a distinct subgroup, is often lacking to support such nuanced models.

HISTORICAL CONTEXT OF CULTURAL ADAPTATION RESEARCH

Cultural adaptation takes the position that, to be effective, interventions must be responsive to the cultural practices and worldviews of the subcultural groups for whom these interventions are intended (Resnicow, Soler, Braithwaite, Ahluwalia, & Butler, 2000). Although this view has gained significant traction over the years as the diversity of the U. S. population has expanded exponentially, this point continues to be a matter of significant debate with strong arguments still voiced about the wisdom, necessity, and feasibility of this position (Elliot & Mihalic, 2004; Kazdin, 2008; Ortiz & Del Vecchio, 2013). Objections notwithstanding, cultural adaptation has emerged as an active research area in response to several key developments across disciplines grappling with the role of culture in the provision of behavioral, psychological, and health interventions for diverse populations (Barrera, Castro, Strycker, & Toobert, 2013; Bernal & Domenech Rodríguez, 2012).

Historically, the broader debate about the cultural relevance of psychology to ethnically diverse populations has been a fundamental driving force**.** The cultural movement in psychology, including the emergence of cross-cultural, multicultural, ethnicity, culture, and race studies over the past three decades, challenged the universality of contemporary theories and raised awareness regarding the lack of representation of ethnic minority populations and the lack of attention given to culturally relevant processes in both basic and intervention research (Betancourt & Lopez, 1993; Markus & Kitayama, 1991; Sue, 1998). In developmental science, seminal papers highlighted the importance of testing integrative, ecologically, and culturally valid models that could better account for unique cultural experiences of ethnic minority children and families and the role of culture in shaping or altering normal and abnormal development (García Coll, et al., 1996; Szapocznik & Kurtines, 1993). Several scholars in intervention sciences (e.g., McGoldrick & Giordano, 1996; Rogler, Malgady, Constantino, & Blumenthal, 1987; Sue, 1998) argued that the majority of science-based interventions, while characterized as universal, are often validated on and influenced by the values and interests of urban or suburban, White, middle-class samples. Consequently, EBIs may not be relevant for addressing issues confronting differing subgroups, including racial-ethnic minority and rural White populations. Even more serious assertions have been expressed that interventions developed without respect for diversity might be used, intentionally or not, to inculcate values, beliefs, and norms of the dominant culture with the result of devaluing, dismissing, replacing, or even eliminating the culture and language of origin (Comas Díaz, 2006; Gone, 2004). Short of such colonialistic concerns, yet still troubling, was mounting evidence of massive health disparities between European American and American ethnic minorities (U.S. Department of Health and Human Services, 2001) coupled with data showing minority populations lack access, enroll at lower rates, and are more likely to drop out of interventions that might reduce these disparities (Smedley, Stith, & Nelson, 2003). Beginning in the 1990s, these developments and other awareness-raising efforts paved the way to policy changes regarding inclusion of cultural minorities in funded research (National Institutes of Health, 1994) and a growing imperative to provide culturally relevant interventions and services for these populations (U. S. Department of Health and Human Services, 2010). Although ethnic minority groups remain underrepresented in clinical trials and published research (Ortiz & Del Vecchio, 2013; Wendler et al., 2006), particularly in top-tier journals (Hartmann, Kim, Kim,et al., 2014), the number and quality of culturally informed developmental studies and interventions trials has increased steadily since the early 1990s.

A second major influence, beginning in the 1990s, was the emphasis on empirically validated interventions as the gold standard for professional practice (Chambless & Hollon, 1998) and a prerequisite for broad diffusion of prevention and health promotion programs (Flay et al., 2005). On the basis of established criteria for EBIs to receive the label of "efficacious" or "effective," special initiatives

and governing bodies across public health service sectors were charged with the task of creating registries to identify and catalog EBIs ready for public dissemination (e.g., the National Registry of Evidence-Based Prevention Programs and Practices; the Collaborative for Academic, Social, and Emotional Learning, the Blueprints Violence Prevention Initiative, the What Works Clearinghouse). By prioritizing programs with established evidence, the majority of which had been validated initially without representation or attention to cultural diversity, the cultural adaptation agenda was solidified. During the past decade and a half, increasing attention has been given to adapting EBIs for use with ethnic, cultural, and racial minority groups who were not part of the original intervention development process. The ascendancy of EBIs and standards of evidence also resulted in a high premium being placed on fidelity of implementation, often as detailed in program manuals (Addis & Cardemil, 2006), and the belief that program effects are best attained under strict adherence to the intervention's procedures as designed and validated (Elliot & Mihalic, 2004). Thus, the fundamental fidelity-adaptation dilemma, which consists of a "dialectic involving arguments favoring fidelity in the delivery of an EBI as designed versus arguments favoring the need for adaptations to reconcile intervention-consumer mismatches in accord with the needs and preferences of a subcultural group" (Castro et al., 2004, p. 221), became the core challenge for this emerging field.

Significant developments in prevention science over the past three decades have also been important in shaping the cultural adaptation agenda. Because the goal of prevention, even more so than treatment, is to maximize public health access and achieve population-level impact (Spoth et al., 2013), ensuring relevance to diverse populations has long been a central concern. A 2009 report on prevention of child social, emotional, and behavioral disorders summarized an impressive body of evidence demonstrating that, when carefully implemented, prevention and health promotion programs can prevent a wide range of health problems, promote positive development, and achieve economic benefits (National Research Council and Institute of Medicine, 2009). As summarized in this report, numerous randomized trials have shown that these types of interventions have had significant, long-term effects in reducing unhealthy eating, physical inactivity, alcohol, tobacco and other drug abuse, teen pregnancy, school failure, delinquent behavior, and violence as well as other mental, emotional, behavioral, and physical health problems. However, this same report also summarized studies showing that a relatively small percentage of these interventions actually are implemented by community-based program delivery systems (e.g., public schools, health care facilities, social service agencies). This report thus underscored a significant problem and an important shift in emphasis, already under way in the field, toward greater focus on effectiveness and implementation studies and a push toward broader community diffusion of EBIs. Distinctions between *efficacy* and *effectiveness* are important for the field of cultural adaptation. Whereas efficacy measures how well an intervention works when tested within the controlled conditions under which it was designed, effectiveness measures how well the intervention works in an applied real-world setting (Flay et al., 2005). The shift in emphasis toward evaluating the evidence of effectiveness studies to determine what preventive programs work, for whom, and under what circumstances is greatly needed to move the field forward in launching successful population-based prevention strategies (Brown, Berndt, Brinales, Zong, & Bhagwat, 2000). Further, a rigorous evaluation of broad dissemination and implementation has important implications for the future of research on cultural adaptation. Moving EBIs into widespread, population-level diffusion requires attention to cultural diversity yet also puts a high priority on adaptation to meet the needs of the local community as well as the service settings in which interventions are delivered (Brownson, Colditz, & Proctor, 2012). Such integration of cultural adaptation and implementation science ultimately will be needed to meet the challenge of reducing racial and ethnic disparities in health (Cabassa & Baumann, 2013).

A final, emergent historical force likely to shape future research on cultural adaptation is the spread of evidence-based practice throughout the world. Countries across the globe are increasingly implementing interventions developed in other countries to address their own public health problems. This trend has already resulted in the wide adoption of EBIs and a growing number of controlled trials of imported and culturally adapted EBIs. The government of Norway implemented a countrywide dissemination of the Parent Management Training–Oregon Model (Forgatch, 1994; Patterson, Reid, & Dishion, 1992) and multisystemic therapy (MST; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998) to target youth behavior problems (Ogden, Amlund-Hagen, Askeland, & Christensen, 2009). The Swedish National Board of Health and Welfare (2011; cited in Ferrer-Wreder, Sundell, & Mansoory, 2012)) reported that, in the last 10 years, imported EBIs comprised over 40% of the total number of social and behavioral interventions tested in Sweden. A recent review of randomized trials narrowly focused

on parent training (PT) interventions to reduce family violence in low- to middle-income countries (Knerr, Gardner, & Cluver, 2013) identified trials spanning 9 countries (Brazil, Chile, China, Ethiopia, Iran, Jamaica, Pakistan, South Africa, and Turkey); given the strict criteria for inclusion in this study of randomized trials, the actual practice of international implementation is likely to be even more extensive.

Although the majority of imported EBIs are based on interventions initially developed in the United States, programs such as the Olweus Bullying Program developed in Norway (Schroeder et al., 2012) and the Triple P parenting intervention from Australia (Sanders, 2012) are examples of programs successfully transported to the United States and several other countries. Thus, the proliferation of interventions crossing international boundaries is well under way, and many of the same debates are taking place about the need to adapt interventions for international diffusion, with some experts cautioning against the trend for global dissemination without careful attention to cultural adaptation (Bernal & Scharró-del-Rio, 2001) and others challenging the assumption that such adaptations are necessary (Knerr et al., 2013). Noting some examples of imported EBIs that have failed to show expected benefits, Ferrer-Wreder, Sundell, and Mansoory (2012) recently advocated systematic, theory-driven international adaptation studies to give researchers an improved ability to empirically test degrees of intervention adaptation in relation to intervention effectiveness and thereby improve the field's ability to learn from both its successes and failures. Their approach draws on models that primarily have been used for domestic adaptations, yet also highlights additional challenges for the future of cultural adaptation as a global endeavor.

Propelled by these historical forces and attempts to address the underlying tensions and controversies they have engendered, cultural adaptation of EBIs has evolved over the past three decades into a well-defined area of study that now spans multiple disciplinary boundaries. The number of interventions that have been adapted and evaluated has grown and, in the process, systematic, data-driven, consumer-sensitive processes have been established for determining if EBIs should be adapted, how they should be adapted, and the results of those adaptations on engagement and intervention efficacy and effectiveness (Barrera et al., 2013). We summarize these developments in the next section, then follow with a summary of exemplars of culturally adapted EBIs that target a range of child and adolescent psychological, behavioral, and health problems.

THE RATIONALE FOR CULTURAL ADAPTATION: GUIDELINES TOWARD A MORE SYSTEMATIC AND TARGETED APPROACH

In 2006, Lau proposed a compelling framework for identifying circumstances that would justify a cultural adaptation of an EBI. This thoughtful discussion articulated a balanced perspective on cultural adaptation, assuming its importance yet also allowing there are likely to be interventions and conditions for which it is not warranted. For example, prominent examples exist of non-adapted preventive interventions, including some of the most widely disseminated programs in the field, that have demonstrated efficacy in trials with large numbers of ethnic and racial minorities (e.g., MST; Henggeler et al., 1998) or when specifically applied to distinct ethnocultural groups in the United States (e.g., Nurse Family Partnerships; Olds et al., 1997). Lau's Selective and Directed Treatment Adaptation Framework (SDTAF) advocated a theory- and data-driven approach for determining if an EBI should be culturally adapted and, if so, which intervention elements might be altered.

The "selective" dimension of this framework recommended cultural adaptations should be pursued only when evidence suggests that delivering a standard treatment would result in a high probability of failure. Some scholars suggest adaptations should not be made to interventions until the original version has been implemented and problems have arisen (Kumpfer, Pinyuchon, de Melo, & Whiteside, 2008). Sanders (2012) argued for a deployment-focused model of adaptation that privileges the responses from participants who may be in a better position to gauge the acceptability of an intervention, as reliance on the perceptions of professionals serving ethnic minority communities may result in filtering by "cultural gatekeepers" who hold views on cultural acceptability that may differ from intended recipients (Lau, 2012; Morawska et al., 2011). The "directed" part of the Lau's framework addresses the question of what to adapt, indicating that adaptations to content or procedures should be pursued only when evidence suggests such modifications are needed. This framework was additionally important for highlighting that adaptations directed at attracting and engaging distinct ethnocultural groups are equally important as those directed at improving intervention outcomes.

Lau's framework prompted dialogue among cultural adaptation scholars that led to significant changes in the conceptualization of cultural adaptation. In a response to Lau (2006), Barrera and Castro (2006) elaborated on

the conditions in which an adaptation would be justified, which they organized into four categories: (1) ineffective engagement, such as poor recruitment, retention, program attendance, or participation in intervention activities; (2) unique risk or resilience factors underlying the intervention target (e.g., discrimination experiences), or that function differently across cultural groups; (3) unique symptoms of a common disorder; and (4) poor intervention efficacy for a particular subcultural group. Other models of cultural adaptation to be discussed later have since incorporated these suggestions by placing a high priority on initial data gathering as a way to determine whether and what to adapt. However, despite these aspirational frameworks, it has been rare for such systematic decisions to be articulated in the cultural adaptation literature. EBI adaptations often have been conducted without first demonstrating diminished engagement or benefit, and often without theory or evidence about unique risk and resilience factors guiding adaptation efforts.

THE CONTENT OF CULTURAL ADAPTATION: SURFACE STRUCTURE, DEEP STRUCTURE, AND CORE COMPONENTS

Focusing on the content of cultural adaptations, Bernal, Bonilla, and Bellido (1995) were among the first to identify the intervention elements that may require adaptation to increase ecological validity or congruence between the client's ethnic and linguistic context and the cultural properties embedded in an intervention. The Ecological Validity Model identified eight dimensions in which intervention adaptations are likely to be made. Some of these dimensions are more likely to involve adaptations to specific aspects of the intervention itself (e.g., language, metaphors, content, concepts, goals, and context), while others are more relevant to the intervention's implementation support structures (e.g., persons and methods). Resnicow, Soler, Braithwaite, Ahluwalia, and Butler et al. (2000) also focused on the content of cultural adaptation, describing aspects of the program, protocol, or delivery system that might require adaptation; they introduced the influential distinction between *surface structure* and *deep structure* adaptations. In their words, "Surface structure establishes feasibility, whereas deep structure determines program impact" (p. 274). Surface structure adaptations typically involve change in an original EBI's materials or activities that address observable and superficial aspects of a target population's culture, such as language, music, foods, clothing, and other observable aspects. An intervention's deep structure involves the processes related to the problem of interest and is more likely to involve the theory-based mediators of the intervention that are thought to affect therapeutic change mechanisms or outcomes.

There is wide agreement that surface structure changes are not only permissible but often necessary to convey respect and achieve "cultural attunement," a term coined by Falicov (2009) to refer to additions to EBIs that are intended to boost engagement and retention of subcultural groups in treatment. Providing services in clients' native language, including familiar cultural traditions and teaching methods (e.g., storytelling, games), and utilizing individuals of color as educational facilitators are examples of features that might attract subcultural groups into treatment and increase their sustained participation. Surface structure changes are also important to maximize comprehension (e.g., understandable content that is matched to the linguistic, educational, and/or developmental needs of the consumer group), motivation (e.g., content that is interesting and important to this group), and cultural relevance (content and materials that are applicable to participants' everyday lives), as described by Castro et al. (2004).

Advisability of deep structure change is a matter of debate among adaptation experts. The reluctance to make deep adaptations is related to the belief that there are features of a program that should not be changed because they reflect the core components or the internal change processes of the intervention responsible for program effects (Falicov, 2009). However, the boundaries of deep structure are not always clear and are generally a matter for program developers to define. Evidence from mediation studies that aim to identify core components (MacKinnon, Fairchild, & Fritz, 2007) can provide guidance, but tests of mediation are not always available nor do they include all components that program developers might include in their definition of the program's core components. For example, in the cultural adaptation of the New Beginnings Program for divorcing parents that was conducted to prepare for an effectiveness trial in family courts (Wolchik et al., 2009), mediation analyses identified specific parenting strategies to retain because they accounted for both immediate and sustained program effects (Tein, Sandler, MacKinnon, & Wolchik, 2004; Zhou, Sandler, Millsap, Wolchik, & Dawson-McClure, 2008), but, in addition, program experts identified intervention processes (e.g., home practice assignments and review) as additional aspects of what they considered to be "core components" to be preserved in the adaptation process. Kumpfer et al.

(2008) drew a strong line at making changes to program components, the timing, and the overall structure of the Strengthening Families Program (SFP) when adapting it for international dissemination. They defined these as deep structure adaptations based on experiences and evidence from effectiveness studies of SFP with American ethnic subgroups that showed diminished effects when such adaptations were made (Kumpfer, Alvarado, Smith & Bellamy, 2002).

A second major class of adaptation involves the introduction of novel or augmented intervention content to target risk factors for youth psychopathology that fall outside the foci of the original EBI. In this way, interventionists targeting culturally diverse populations supplement intervention content to address ecological risk and protective factors pertinent to specific cultural communities (e.g., Coard, Wallace, Stevenson, & Brotman, 2004; Lau, Fung, Ho, Kiu, & Gudiño, 2011; C. R. Martinez & Eddy, 2005). Intervention development studies that draw from existing EBIs but infuse additional elements in which culture is a primary consideration sometimes favor the term *culturally informed* (Falicov, 2009) or *culturally tailored* (Bernal & Domenech Rodríguez, 2012) over *cultural adaptation*. Bernal and Domenech Rodríguez (2012) highlighted that incorporation of cultural dimensions such as interdependence, spirituality, relational views of self, and particular worldviews into an intervention can serve goals of supporting the culture and language of origin and the development and maintenance of cultural values, both of which are empowerment strategies. These added elements may not necessarily change core components but can enrich program effects in ways that are specific to the struggles, needs, and strengths of distinct ethnocultural groups. Even the Kumpfer et al. model (2008), which drew a hard line against deep structure change, did not tacitly prohibit augmented content so long as core components are not displaced. When cultural augmentation occurs, clear documentation of added components and inclusion of measures to assess change on these cultural components can facilitate understanding of whether, how, and to what extent they contribute to intervention outcomes, yet these types of analyses are rare in the literature (Castro et al., 2010)

The admonition against changing core components in the process of cultural adaptation is based on the assumption that the theory of change involved is universally relevant and powerful. To the extent that these assumptions are not accurate, more extensive modifications may be needed. Castro et al. (2004) described a continuum among interventions that incorporate cultural elements that varies between the extremes of making minor surface structure alterations to an original EBI to the complete rejection of the EBI in favor of a novel, culturally grounded approach; the latter falls outside the boundaries of what some scholars would define as "culturally adapted." Unlike cultural adaptations that begin with an established EBI and then work to integrate cultural elements that increase relevance and fit for subcultural groups, culturally grounded approaches begin with an assessment of need obtained from members of a particular subcultural group who then participate actively in developing the intervention from the ground up (McKay et al., 2004). The latter approach is based in models of community-based participatory research (CBPR; Minkler & Wallerstein, 2003) and is contrasted with the traditional Prevention Research Cycle, which includes a series of stages that begins, instead, with (a) basic research typically conducted in a university setting to identify a disorder's risk and protective factors, then continues to (b) the design of an intervention that changes modifiable risk and protective factors, (c) empirical trials of the intervention to determine efficacy and to inform intervention modifications, (d) effectiveness trials to assess generalizability to real-world applications, and (e) large-scale intervention dissemination (Mrazek & Haggerty, 1994). Interventions based on the CBPR framework have gained in popularity recently, partly in response to problems that university-based EBIs developed in the Prevention Research Cycle tradition have encountered in going to scale (Barrera et al., 2011). The belief is that programs developed through a CBRP model may be more likely to be adopted and sustained because they are responsive to the cultural and local conditions, organizational structure, and history that influence implementation and because the community has an established investment in the program from the outset (Wandersman, 2003).

PROCESS MODELS OF CULTURAL ADAPTATION: SYSTEMATIC APPLICATION OF BEST PRACTICES

Perhaps the most significant advance in the cultural adaptation literature over the past two decades is the proliferation of conceptual frameworks that describe the processes that can be used in designing, implementing, and evaluating a culturally adapted EBI. To date, more than 13 different models of cultural adaptation spanning both prevention and treatment have been published, almost all within the past 10 years (for reviews, see Castro et al., 2010; Domenech Rodríguez & Bernal, 2012; Ferrer-Wreder et al., 2012). Frameworks relevant to

prevention are listed in Table 17.1, which also identifies similarities and differences in their content, comprehensiveness, and scope. Although developed independently, these frameworks exhibit considerable consensus in their recommendations. For example, most models delineate specific stages or phases in the adaptation process, ranging from three to nine steps across models, but generally covering the four phases recommended by Barrera and Castro's (2006) Heuristic Model (HM): gather information, make preliminary adaptations to the intervention, test the preliminary adaptations, and refine adaptations.

Like most models, the first step outlined by Barrera and Castro (2006) involves a formative stage of information gathering to be used in planning along the lines of Lau's selective and adaptive recommendations. Across models, this phase relies on multiple sources of both quantitative and qualitative information, such as reviews of the literature to understand common and unique risk factors and focus groups to assess perceived positives and negatives of the original EBI. Domenech Rodríguez and Bernal (2012) highlighted the importance of blending a positivist paradigm in which randomized controlled trials (RCTs) are the gold standard for testing the utility of interventions with a pragmatist view that also uses qualitative sources of knowledge to guide decisions. Collaboration with relevant community stakeholders, such as program developers, agency staff, and community members, is another common feature at this stage and throughout the cultural adaptation process. The second phase in Barrera and Castro's model involves program design in which changes are made along the many dimensions described by Bernal et al. (1995) and Resnicow et al. (2000), including to the intervention protocol, interventionists, training, recruitment, and monitoring systems. This stage often involves multiple iterations of cultural adaptation and feedback from community stakeholders, including intervention participants themselves, in an attempt to maximize cultural fit. In the third step, case studies or pilot studies are used to refine recruitment, intervention, and assessment processes, again using both quantitative and qualitative data to evaluate impact of the intervention on engagement, consumer satisfaction, and intervention processes. This stage also may involve multiple iterations of pilot testing and refinement to prepare for the fourth stage, in which the final intervention package is prepared for a more robust test of the culturally adapted intervention.

Although most of the models listed in Table 17.1 cover similar phases and recommendations, there are important differences between them. Two of the models, the Adaptation for International Transport of Strengthening Families Program and the International Implementation of Multisystemic Therapy, were developed in relation to the adaptation of specific programs, whereas others offer generic or general guidelines for the field. The models also vary in terms of their intended application in different countries versus a primary focus on domestic ethnocultural groups. Finally, whereas some models are focused on the endpoint of preparing for evaluation of program efficacy, others are oriented toward effectiveness and dissemination. For example, the model for international implementation of MST was developed to support cross-national adaptation and dissemination of multisystemic therapy (Schoenwald, 2008). MST, a systems-oriented family therapy designed to benefit troubled adolescents who have exhibited conduct and/or substance abuse problems, has been implemented in 34 states in the United States and 15 countries to date (Henggeler & Schaeffer, 2010). In contrast to cultural adaptation models focused primarily on program content and design, the international implementation of MST model attends to implementation issues, such as the selection of appropriate clinical staff, training materials and procedures, and the clinical delivery system. Kumpfer and colleagues (2008) delineated a model based on their experience disseminating the SFP around the globe. Their 9-step model (see Table 17.1) begins with a needs assessment and selection of an appropriate EBI and ends with a model that is ready for cross-national dissemination.

The Planned Intervention Adaptation (PIA) protocol is unique because it is a generic model for cross-national adaptation of interventions and is geared toward the design of effectiveness and dissemination trials of imported EBIs (Sundell & Ferrer-Wreder, & Fraser, 2014). In PIA, cultural groups are conceptualized as nested, recognizing that distinct subgroups (e.g., Swedes with a Latino family background) are nested within a larger cultural context (e.g., a Swedish community), thus attempting to address the challenge of attaining cultural sensitivity to the unique conditions produced by these intersecting aspects of culture. PIA begins with formative research (phase I), followed by an effectiveness trial (phase II), which provides evidence that may indicate a need for another round of adaptation or a dissemination study. At the conclusion of PIA's phase II, the feasibility of a dissemination trial is evaluated by program developers and new stakeholders. PIA also specifies a time period for the initial adaptation stages and a sampling strategy for formative studies. Phase I of PIA is recommended as a roughly 1.5- to 2-year period when intervention developers and stakeholders (agency staff, potential consumers) agree to collaborate on five preliminary steps that are summarized in a table and detailed

TABLE 17.1 Models of Cultural Adaptation by Date of First Publication

		Content of Adaptation	Steps/Phases of Adaptation	Stage of Research	Cultural Groups Targeted[1]	Generic vs. Specific Application
Ecological Validity Model (EVM)	Bernal et al. (1995)	Language, persons, metaphors, content, concepts, goals, methods, context	None specified	General use in research and practice contexts	Broadly applicable (domestic, international)	Generic
Cultural Sensitivity Model	Resnicow, Baranowski, Ahluwalia, & Braithwaite (1999); Resnicow et al. (2000)	Distinguished 2 adaptation types: Surface structure Deep structure	None specified Recommended use of both qualitative and quantitative data sources	Broadly focused on preparing for implementation	Broadly applicable (domestic)	Substance use and public health programs
Cultural Adaptation Process Model	Domenech Rodríguez & Wieling (2004)	Emphasized EVM dimensions (Bernal et al., 1995)	Set the stage Initial adaptation Adaptation iterations	General use in research and practice contexts	Broadly applicable (domestic)	Generic
Selective and Directed Treatment Adaptation Framework	Lau (2006)	Identified 2 goals: Enhance engagement Enhance program effects	None specified Decisions about whether to adapt and what to adapt should be guided by evidence	Not specified	Broadly applicable (domestic)	Generic
Heuristic Framework for the Cultural Adaptation of Interventions	Barrera & Castro (2006); Castro et al. (2010)	Adaptations address: Ineffective engagement Unique risk or resilience factors Unique symptoms Lack of efficacy	Gather information Preliminary adaptations Pilot test adaptations Refine adaptations	Adaptation of EBI for efficacy trial with distinct group	Broadly applicable (domestic)	Generic
Culturally Specific Prevention Model	Whitbeck (2006)	Culture-specific risk and protective factors must be considered. Target group knowledge equally important as scientific evidence.	Review existing evidence Target group reviews existing evidence Cultural translation of risk and protective factors Identify unique risk and protective factors Conduct efficacy trial	Model starts with local community defining the problem and extends to efficacy trial	American Indian communities	Generic
Adaptation for International Transport of Strengthening Families Program	Kumpfer et al. (2008)	Fidelity requires cultural adaptation but not modification of program components, timings, or overall structure	Needs assessment Select EBI to adapt Implement original EBI with minor modifications Select and train staff Implement with fidelity Adapt continuously through pilot tests Revise to enhance engagement Conduct evaluation Disseminate results	Dissemination	International	Strengthening Families Program
International Implementation of Multisystemic Therapy	Schoenwald et al. (2008)	Adaptations relevant to: implementation processes, clinical staff, training materials and procedures, clinical service delivery	Pre-implementation (assess needs and stakeholders; understand legal and social standards; determine staffing and consultants) Implementation (translate and "tweak" intervention; adapt training protocols) Service delivery (consider service duration; time and caseload standards; on-call systems; cultural advisors)	Dissemination	International	Multisystemic therapy

TABLE 17.1 (*Continued*)

		Content of Adaptation	Steps/Phases of Adaptation	Stage of Research	Cultural Groups Targeted[1]	Generic vs. Specific Application
ADAPT-ITT	Wingood & DiClemente (2008); Latham et al. (2010)	Adapt program to maintain fidelity to core components	Assess needs of target group and agency capacity to implement. Decide on EBI. Target group input. Adapt program. Topical experts review first draft. Integrate feedback in second draft. Train implementation staff. Pilot test, revise, evaluate.	Dissemination	Broadly applicable (domestic, international)	HIV interventions
Planned Intervention Adaptation Protocol	Ferrer-Wreder et al. (2012)	Use formative research to evaluate relevance of risk and protective processes and the need for surface and deep adaptations	Formative research. Effectiveness trial. Dissemination.	Effectiveness and dissemination	International	Generic

[1] Indicates cultural groups targeted and whether the model has been applied domestically, internationally, or both.

in text (e.g., language translations, tests of translated materials, focus group checks on cultural appropriateness of intervention materials and activities). These preliminary steps help shape the adapted intervention. In phase II of PIA, the authors recommend a three-arm effectiveness study in which a minimally adapted intervention (just surface structure changes, such as language translation), a fully adapted intervention (both surface and deep structure changes), and a control condition are tested. They also recommended the inclusion of appropriate measures and data analytic procedures to identify possible mediators and moderators of intervention effects. Unfortunately, based on Sundell et al.'s (2014) article, it is not certain that the PIA framework actually has been used in international adaptations of interventions.

Common to all models is the expectation that cultural adaptations will be evaluated, either in randomized efficacy or in effectiveness studies. Several questions are critical to address, including effects on engagement and program outcomes and test of mediators and moderators. In efficacy trials, effects on program mediators are useful to identify core components of the intervention to guide future dissemination and effectiveness studies in other contexts or with other populations (e.g., Gonzales et al., 2012; Lau et al., 2011; Murry et al., 2013). Studies of culturally adapted interventions also offer important opportunities to test whether cultural elements included in the adaptation contribute to intervention efficacy (Castro et al., 2010; B. D. M. Wilson & Miller, 2003). Evaluation of cultural adaptation in the context of effectiveness studies can test whether cultural adaptations impact program uptake and fidelity, the best methods to train interventionists and monitor delivery, and program effects on distinct ethnocultural groups receiving services in natural delivery settings, and whether interventionists are more or less likely to adhere to the intervention protocol when delivering culturally adapted interventions (Spoth et al., 2013). Test of moderators can identify subgroups that may show differential response in terms of engagement or outcomes based on dimensions such as acculturation or adversity (Gonzales et al., 2011; Lau et al., 2011), thus advancing understanding of the need for population segmentation while also identifying subgroups most likely to benefit and those that may need further adaptations. Perhaps the most important question rarely addressed when evaluating culturally adapted interventions is whether the adapted EBI is more effective or offers other added benefits (e.g., increased likelihood of adoption in the community, higher enrollment rates) when compared with the original EBI (Castro et al., 2010; Resnicow et al., 2000).

Although it remains a largely unaddressed empirical question, it is possible that the extent of optimal changes to an EBI also will depend on the nature of the EBI to be adapted. For example, adaptations may be more important

for interventions that target family processes than for those delivered in schools, or when they target specific mediators or outcomes. In the next sections, we present a qualitative summary of culturally adapted interventions to prevent a range of child and adolescent emotional, behavioral, and health problems that have been evaluated in RCTs. Our presentation features exemplars and is not intended as an exhaustive review. Because the nature and impact of cultural adaptation may vary depending on the nature of the intervention, we focused our review on four distinct domains. Two broad domains—adaptations of PT interventions and adaptations of sexual risk and drug preventive interventions—were chosen because they represent the most active areas for past research on cultural adaptation. We also include a summary of adapted prevention interventions targeting child and adolescent internalizing outcomes that are less common due to a relative lack of focus in prevention on problems such as anxiety and depression. Our final domain includes health-focused preventive interventions, a newly emerging and important area of emphasis for reducing minority health disparities. Our purposes in presenting this collection of exemplars is to examine: (a) the extent to which child and adolescent interventions have been adapted for distinct ethnocultural groups, including for which groups and for what types of preventive interventions; (b) the processes used and the nature of adaptations that have resulted; (c) and the evidence base for addressing key question about efficacy or effectiveness, including tests of underlying cultural dimensions that account for program effects, subgroup differences in intervention responsiveness, and the most salient question: Do cultural adaptations make a noticeable impact on outcomes? In each section, we first describe the prevention domain, the types of EBIs in each domain that have been culturally adapted and the evidence base to support them, and the empirical or epidemiological basis to suggest that cultural adaptations of these EBIs may be relevant to the public health needs of targeted groups.

PARENT TRAINING INTERVENTIONS

Maladaptive parent-child interactions have been found to precede the onset of or to maintain multiple forms of child psychopathology across both externalizing and internalizing spectrums. Even in conditions not primarily driven by environmental socialization factors, research has documented the ameliorative effects of instantiating specific types of parent-child interactions in improving outcomes of various forms of psychopathology (e.g., joint attention and symbolic play for autism spectrum disorders). As such, family-based interventions often form the foundation of prevention and intervention programs across a range of psychopathology targets. In particular, EBIs for conduct disorder and related externalizing behavior problems in youth almost uniformly include PT as the sole or first line intervention, or as a major component of a multisystemic intervention. The purpose of PT is to prevent and decrease disruptive behavior and increase prosocial behaviors in children. The efficacy of PT is well established with robust evidence of clinically significant improvements in child conduct problems (Eyberg, Nelson, & Boggs, 2008; Sheldrick, Kendall, & Heimberg, 2001). Treatment aims to improve on parents' skills and increase the consistent use of those skills. PT is rooted in social learning theory (Bandura, 1977) with specific strategies designed to interrupt cyclical coercive interactions during which aversive behaviors emitted by parents and children are negatively reinforced (Patterson, Chamberlain, & Reid, 1982). Common elements across PT interventions serve to reinforce appropriate child behavior (e.g., positive attention, praise, tangible rewards) while removing reinforcement or punishing negative child behavior (e.g., differential attention, time-out, response cost) (Garland, Hawley, Brookman-Frazee, & Hurlburt, 2008). Parents are also instructed to structure expectations for appropriate behavior through limit setting, routines and rules, and effective commands. Consistent with the Hanf (1969) two-stage model, PT interventions typically begin with instruction, modeling, and rehearsal of positive reinforcement skills to increase prosocial behavior before introducing elements intended to address child misconduct. The rationale is that a more positive parent-child relationship sets the stage for more child compliance and better uptake of positive discipline strategies. Yet some experimental evidence refutes this assumption (Eisenstadt, Eyeberg, McNeil, Newcomb, & Funderburk, 1993).

The application of interventions prescribing fundamental changes in child-rearing practices at the population level has been questioned. Parenting sensibilities and routines are embedded within a system of meanings, shaped by cultural context and values regarding the socialization of the moral child and the expected roles of adult caregivers and children within family structures (Harkness & Super, 1996; Weisner, 2002). Discourse on the application of PT with ethnic minority families has enumerated potential cultural barriers to engagement among parents whose own socialization experiences fall outside middle-class European American heritage (e.g., Barker, Cook, & Borrego, 2010; Forehand & Kotchick, 1996; Lau, 2006). Given

that parent-child relations and discipline practices are the proximal targets of change, many have cautioned that cultural barriers may threaten the generalizability of PT effects. Wide cultural variation in parenting practices and values across ethnic groups may influence receptivity to PT elements, perhaps accounting for increased attrition (e.g., Kazdin & Whitley, 2003), low enrollment (e.g., August, Lee, Bloomquist, Realmuto, & Hektner, 2003; Cunningham et al., 2000) and reduced participation (e.g., Orrell-Valente, Pinderhughes, Valente, & Laird, 1999) among ethnic minorities and immigrants.

Central questions concerning the application of PT with culturally diverse families emerge from sociopolitical and moral perspectives as well as from epistemological and developmental science perspectives. First, widespread dissemination of PT might be viewed as a form of cultural hegemony or colonialism to the extent that it promotes assimilation to European American child rearing as superior (Dionne, Davis, Sheeber, & Madrigal, 2009). Second, the dissemination of PT interventions that were largely developed with middle-class European American families to culturally diverse communities reflects the assumption that treatment effects will generalize across distinct social and cultural family contexts (Bernal & Scharró-del-Rio, 2001). Yet some research suggests diversity in relations among parenting behaviors, family processes, and child developmental outcomes (e.g., Deater-Deckard & Dodge, 1997; Halgunseth, Ispa, & Rudy, 2006; C. Ho, Bluestein, & Jenkins, 2008; Lansford et al., 2005).

For these reasons, PT has come under scrutiny as a class of interventions with effects that may be subject to boundary conditions Accordingly, PT has been well represented among efforts in the cultural adaptation of behavioral interventions. Two distinct themes have emerged in endeavors to enhance the outcomes of PT with ethnic minority and international populations (Lau, 2006). Beyond surface adaptations and basic translation, the range of adaptations that fundamentally alter intervention content or process can be organized into those that work toward enhancing engagement versus those that focus on tailoring intervention content to augment skills training.

Cultural Adaptations to Enhance Engagement in PT

Limited engagement in PT represents a major threat to effective dissemination and implementation in disadvantaged and ethnic minority families. Clinical observations from single-case design experiments and controlled trials of PT with ethnic minority families previously suggested notable cultural distance between skills typically taught in PT and values governing parent-child relations in ethnic minority families (Borrego, Ibanez, Spendlove, & Pemberton, 2007; J. Ho, Yeh, McCabe, & Lau, 2012; T. Ho et al., 1999; Lau, Fung, L. Ho, Liu, & Gudiño, 2011; Lau, Fung, & Yung, 2010). For example, because of a cultural priority to avoid losing face and the need for constant correction of improper behavior, Chinese parents objected to ignoring misbehavior based on principles of differential attention (Lieh-Mak, Lee, & Luk, 1984). Likewise, Mexican American parents have rated differential attention as less acceptable than other PT practices (Borrego et al., 2007), with some parents objecting because ignoring may harm the parent-child relationship (Pemberton & Borrego, 2007). While praise is often rated as among the most acceptable PT techniques (J. Ho et al., 2012) some interventionists have noted that praise is problematic for Chinese parents owing to beliefs that it results in a lack of humility and complacency over persistence (Crisante & Ng, 2003; T. Ho et al., 1999).

Given that many of the concerns about PT for culturally diverse populations have focused on issues of acceptability, and most disparities in PT controlled trial research relate to differential enrollment and premature attrition, PT interventions targeting ethnic minority families have been culturally adapted by attending to barriers to engagement (e.g., Dillman Carpentier et al., 2007; Matos, Bauermeister, & Bernal, 2009; McCabe & Yeh, 2009). Engagement-focused adaptations encompass surface structure modifications (Resnicow et al., 2000) intended to sufficiently engage the target community so that the intervention can be delivered with fidelity to the so-called deep structure. Fidelity to deep structure maintains the key elements of the intervention's theory of change, or logic model specifying the theoretical relations between the treatment procedures (e.g., teaching parents to praise children for appropriate behavior), mechanisms of change (e.g., alteration of reinforcement schedules), and ultimate outcomes (e.g., increased child compliance) (McKleroy et al., 2006). Most such adaptations focus on adopting a collaborative stance by soliciting and defusing concerns about specific skill elements in PT, reframing techniques to optimize fit with parents' values, and using motivational strategies to stoke parental investment in agreed-on treatment goals.

There is, of course, within-group heterogeneity in attitudes toward PT interventions, with these attitudes covarying with cultural values in distinct ways for different groups. Among Chinese American parents, low levels of acculturation and endorsement of traditional values concerning strict discipline and shaming are associated

with lower perceived acceptability of PT (J. Ho et al., 2012). Yet endorsement of traditional Latino values that emphasize strong orientation and commitment to family, *familismo,* among Mexican Americans has been associated with positive attitudes toward PT (Pemberton & Borrego, 2007). Notably, at least one culturally adapted intervention has adopted an adaptive assessment-driven strategy to tailor the delivery of PT to promote optimal participation and acceptance among parents with a range of baseline attitudes (McCabe, Yeh, Garland, et al., 2005).

Augmenting Intervention Content to Improve Outcomes for Ethnic Minority Families

A second major class of adaptations to PT involves the introduction of novel intervention content to target risk factors for youth psychopathology or family adjustment difficulties that fall outside the original foci of PT. In this way, interventionists targeting culturally diverse families have supplemented PT content to address ecological risk and protective factors associated with child behavior problems and parenting competence pertinent to specific cultural communities (e.g., Coard et al., 2004; Lau et al., 2011; C. R. Martinez & Eddy, 2005). As with other efforts to augment PT, these adaptations address ancillary family stressors that can heighten child vulnerability and interfere with parent skill acquisition (G. E. Miller & Prinz, 1990). These culturally adapted PT protocols have addressed risk processes such as parental acculturative stress, family-level acculturation dissonance, and experiences of discrimination (Lau, 2006). In this way, these adaptations revise the intervention's deep structure or theory of change within a causal model informed by studies of risk and protective factors that highlight potential mediators of change that can improve target outcomes in the population of interest.

Cultural Adaptations of Evidence-Based Parent Training Interventions

Parent-Child Interaction Therapy

Parent-Child Interaction Therapy (PCIT) is designed to treat 2- to 7-year-olds with conduct problems (Herschell, Calzada, Eyberg, & McNeil, 2002). Parents are taught skills to establish a nurturing and secure relationship while reinforcing prosocial behavior and decreasing negative behavior. It is conducted in the context of parent-child play interactions during which the therapist actively coaches the parent in the use of skills, often unobtrusively from behind an observation window. PCIT is assessment driven and terminates when parents demonstrate mastery of the skills and their child's behavior is within the normal range on a validated scale of child conduct problems (Eyberg Child Behavior Inventory; Eyberg & Pincus, 1999). Treatment begins with the child-directed interaction (CDI) phase designed to create a mutually rewarding parent-child relationship. Toward this end, parents are taught to praise, imitate, and describe the child's appropriate play behavior, reflect appropriate child speech, ignore inappropriate behavior, and allow their child to lead the activity. Parents are also taught to refrain from criticism, commands, and questions. The goal of the second, parent-directed interaction (PDI), phase is for parents to decrease problematic behavior by directing child activity using clear, positively stated, direct commands and consistent consequences (e.g., praise for compliance, time-out for noncompliance).

PCIT has been used with diverse ethnic minority families in the United States with positive results. For example, the effects of PCIT in reducing recidivism in child maltreatment appeared to generalize across racial/ethnic groups including non-Hispanic Whites, Latinos, and African Americans, with no apparent intervention by ethnicity interactions (Chaffin et al., 2004). However, some data reveal disparities in rates of engagement and outcomes in PCIT. Fernandez, Butler, and Eyberg (2011) reported a 60% rate of attrition from PCIT in a sample of low-income African American families of preschoolers with disruptive behavior disorders. Further, only half of the treatment completers showed clinically significant change in child conduct problems, and there was no significant effect of treatment on parenting stress, as has been shown for non-Hispanic White families in PCIT. Previous trials have revealed associations between low SES and dropout from PCIT (Fernandez & Eyberg, 2009); motivational enhancement appears to prevent such attrition among ethnically diverse and disadvantaged families (Chaffin et al., 2009).

Multiple investigators have culturally adapted PCIT using varying approaches to increase responsiveness to the needs of Latino families. Borrego et al. (2006) first demonstrated the feasibility of delivering PCIT in Spanish. Matos, Torres, Santiago, Jurado, and Rodríguez (2006) went further to adapt PCIT for Puerto Rican families of young children with hyperactivity. This also represented primarily a language-based adaptation that included translation of written materials and modification of examples to reflect the daily experiences and idiomatic expressions of Puerto Rican families. Unstructured additional time was allotted to the beginning of each PCIT session to establish and maintain therapeutic rapport through personal interactions and to discuss any issues that could be affecting

treatment progress. Matos et al. (2009) reported large effect sizes (Cohen's $d = 1.37$ to 2.04) in their waitlist controlled trial, with 65% to 75% of treated families evincing clinically significant decreases in conduct problems.

McCabe and colleagues (2005) described a more comprehensive adaptation of PCIT for Mexican American families that adopted a tailoring approach to address barriers to engagement. The adaptation design involved the integration of studies of treatment barriers among Latino families and original qualitative research. The authors noted that cultural barriers for Mexican American parents included feared negative consequences of treatment (e.g., breached confidentiality), disapproval from family members, and doubts of effectiveness or alternately unrealistic expectations of rapid improvement. Specific adaptations of PCIT were informed by focus groups and interviews with Mexican American parents of youth with disruptive disorders. PCIT was described, and participants were invited to comment on its features and suggest improvements. The considerable variability in attitudes (e.g., some Latino parents viewed time-out as not punitive enough, while others felt it was too severe) suggested that adaptations must flexibly accommodate variation in values and acculturation. Yet several clear themes emerged. Given concerns about blame and stigma, mothers preferred the program to be framed as educational rather than therapeutic. Mothers highlighted the need for clear explanations for how activities, such as play, can reduce behavior problems. They also requested additional intervention materials, such as father testimonials, and augmented content, such as discussion of the negative consequences of paternal absence, to promote involvement of fathers and extended family

Based on these data and consultation with an expert panel and the PCIT developer, McCabe et al. (2005) developed Guiando A Ninos Activos (GANA) to include an intensive engagement protocol beginning with the initial phone contact to problem solve barriers to attendance, increase investment in treatment, and create a plan to enlist fathers and other caregivers. GANA is framed as an educational program, offered by a teacher (*maestro*). CDI teaches communication skills (Ejercicios de Communicacion) while PDI teaches consistent discipline (Disciplina Consistente). The use of assessment-based tailoring is unique. Given the heterogeneity in attitudes, McCabe et al. designed an initial assessment to direct the implementation of treatment elements. GANA teachers receive a computer-generated report that contains guidance for addressing potential issues (e.g., unrealistic expectations for treatment) and highlights elements that may require reframing to increase acceptability. For example, among parents favoring strict discipline, time-out is framed as a punishment (*silla de castigo*) whereas for parents who disavow punitive methods, time-out is framed as a time for calming and reflection (*silla de pensativa*).

In a controlled trial that was noteworthy as one of few that compared the culturally adapted intervention with the original EBI, McCabe and Yeh (2009) randomized 58 Mexican American parents with a child with a disruptive disorder to receive standard PCIT, GANA, or treatment as usual (TAU). McCabe and Yeh found that both PCIT and GANA outperformed TAU at posttreatment, and although the differences between PCIT and GANA were not statistically different, the mean effect sizes associated with the GANA-PCIT planned contrast were encouraging (Cohen's $\delta = .28$ for conduct symptoms, $\delta = .42$ for parenting). At follow-up, McCabe, Yeh, Lau, and Argote (2012) reported that GANA outcomes were superior to TAU on most parent-report measures, while PCIT did not maintain an advantage over TAU. Thus, the efficacy and maintenance of gains in GANA have been supported, and there is some limited evidence to suggest that GANA may yield greater longer-term benefit than standard PCIT. However, although GANA adaptations were explicitly designed to enhance engagement, there was no effect of condition on premature termination.

The Incredible Years

The Incredible Years (IY) group intervention is effective in reducing child behavior problems, improving parents' child management skills, and decreasing parenting stress (Reid, Webster-Stratton, & Baydar, 2004). Videotape modeling is an important feature of IY, to both demonstrate techniques and stimulate discussion. As with other PT programs, skill rehearsal is emphasized through role play and homework. IY incorporates many features that may promote parental engagement by introducing skills in a collaborative rather than a didactic manner. As each skill is introduced, parents discuss the benefits and barriers to using the skill, opening up issues of perceived acceptability and fit with parents' values. The group leader encourages investment by highlighting how the benefits of the skill fit with the parents' own goals. The group leader uses Socratic questioning to allow parents to identify the principles underlying effective parenting skills. Treatment manuals orient group leaders to common concerns about each PT skill (e.g., concerns that praise will "spoil" children, worries that time-out is not severe enough). Group process leverages peer-to-peer teaching and experiential learning, such as praising and rewarding parents in session as they are instructed to do with their children. Thus, IY builds in multiple, effective

strategies for enhancing engagement for culturally diverse families. Data from prevention trials fielded in Head Start preschools have shown that IY achieves parity in parenting and child behavior outcomes and parent satisfaction across non-Hispanic White, Latino, African American, and Asian American families, with the number of ethnic differences in attrition and outcomes not exceeding that expected by chance (Reid, Webster-Stratton, & Beauchaine, 2001).

However, some independent investigations of IY suggest that treatment gains among African American and Latino families may not be lasting. For example, Gross et al. (2003) showed improvements in parenting behaviors from IY among low-income, largely African American (57%) and Latino (29%) parents of toddlers in Chicago. However, there were no lasting reductions in child behavior problems based on parent reports or observer ratings at the 1-year follow-up. Similarly, Brotman et al. (2003) found significant initial improvements in parent responsiveness and parent-reported behavior problems following IY in a sample of 20 African American and 10 Latino preschoolers, but these effects were not maintained over 6 months.

IY has been augmented in order to address risk factors that appear relevant to the development of disrupted family relations and child behavior problems in ethnic minority populations. Lau et al. (2011) adapted IY to address risk factors for maladaptive discipline in high-risk immigrant Chinese families in southern California. Lau (2010) found that children's school problems are strongly associated with harsh physical discipline among Chinese immigrant families and that parent-child acculturation conflicts were related to physical discipline when parents held traditional values about firm parental authority. In a waitlist controlled trial including 54 families, PT was augmented with three skill components to reduce contextual stress to allow parents to follow through with effective PT strategies. First, cognitive restructuring was added to help parents to control upsetting thoughts about children's bids for autonomy and school problems that lead to ineffective parenting. Second, psychoeducation and communication skills training helped parents reframe and resolve acculturation-related conflicts. Parents were taught active listening skills and problem-solving steps to elicit the child's perspective and communicate their own concerns effectively. Third, to prevent punitive responses to school problems, parents were taught to increase positive involvement in children's schooling by showing interest in their child's learning, structuring a homework routine, and limiting (television and computer) screen time.

Results of the trial revealed good retention with 83% of families completing the 14-week intervention. Relative to parents in the delayed-treatment condition, parents who received the intervention responded with lower levels of negative discipline and child internalizing and externalizing problems. Posttreatment effect sizes were in the medium to large range for child behavior problems, with good durability of results at 6-month follow-up. Mediation analyses revealed that decreases in negative discipline accounted for improvements in child externalizing problems. Treatment effects were moderated by baseline parenting stress, such that more distressed parents benefited less from treatment. In contrast, an analysis of outcomes of IY among 514 families across six randomized trials did not find baseline parenting stress to moderate outcomes (Beauchaine, Webster-Stratton, & Reid, 2005). Moreover, despite the inclusion of augmented PT content to address stress in immigrant parent-child relations, intervention effects on parenting stress were not observed at posttreatment. This finding suggests that the cognitive restructuring and communication training components were not sufficient to produce effects among the most distressed immigrant parents in the sample.

ParentCorps is a culturally adapted PT protocol, strongly informed by IY, to prevent child behavior problems and promote school readiness in low-income African American and Latino families of preschoolers in New York (Brotman et al., 2008). Intervention content and process aim to be universally relevant and engaging to all families yet sufficiently intensive and tailored for families residing in disadvantaged, urban communities with risk factors such as community violence, overcrowded schools, and diverse immigrant populations. Guided by the assumption that culture informs all aspects of caregiver psychology (i.e., expected family roles, appraisals of child behavior, future aspirations, and appropriate parenting), ParentCorps focuses explicitly on cultural values, beliefs, and norms and encourages parents toward treatment goals that are culturally relevant. For example, session plans outline discussions concerning values related to obedience and respect for elders and the influence of parents' own childhood experiences on their beliefs about parenting. As in IY, videotape modeling introduces each skill in the context of the daily lives and interactions of three ethnic minority families. Group leaders individualize the use of the skill for each family's unique context and use group activities and role-plays and troubleshoot homework. Parents also receive a ParentCorps item each session to spur uptake of the assigned skill (e.g., a timer for time-outs).

A randomized trial of ParentCorps including 171 families of 4-year-olds in a university preschool program in a large New York public school district revealed effect sizes

in the .50 range for parenting practices and child behavior problems (Brotman et al., 2011). Recruitment results in this trial were good for a universal prevention design: 71% of parents in the intervention schools attended at least one session. However, in terms of retention only 54% attended at least five of 13 sessions.

Indian Family Wellness Program

In their cultural approach to implementing IY, Dionne et al. (2009) designed an initial motivation phase to engage American Indian parents in PT by acknowledging the historical role of colonization in the disruption of traditional parenting and resultant social illnesses. This phase is a three-session motivational interview designed to help parents recognize: (a) how intergenerational transmission of parenting knowledge has been disrupted by colonization, (b) the impact of historical trauma and ongoing injustices on parenting, (c) strengths across generations despite this history, and (d) their responsibility for summoning strengths and adapting their parenting to protect their children from social illnesses. In the intervention phase, IY was delivered with fidelity, but at the beginning of each session, the interventionists drew connections between the PT skill and Central American Indian traditions, beliefs, and values. For example, when teaching alternatives to corporal punishment, parents were reminded that this tactic was introduced by European colonists and in boarding schools and was not consistent with Indian teachings that children were gifts who were never to be hurt. In a controlled trial, 49 American Indian families received the motivational interview and were then randomized to receive the culturally adapted IY or no treatment. Results at posttreatment revealed significant reductions in ineffective parenting and child externalizing and internalizing problems in the treatment group relative to controls.

The Chicago Parenting Program

The Chicago Parenting Program (CPP) is another intervention building on IY that capitalizes on the strengths of videotaped modeling followed by group discussion to elicit principles of effective behavior management and a collaborative approach to engage parents. The CPP was designed in partnership with a parent advisory council of African American and Latino parents from different Chicago neighborhoods. The council advised the program developers on challenges they faced as parents, situations that should be portrayed in videotape modeling, and how best to depict PT skills to be congruent with their cultural values and lifestyle (Gross, Garvey, Julion, & Fogg, 2007). Videos were shot in homes and in public places and depicted African American, Latino, and White families in situations that are familiar, relevant, and stressful. In a departure from IY, the CPP intervention did not proscribe spanking, given the views in some communities. The 11 sessions covered child-centered time; family routines and traditions; praise and encouragement; rewards for reducing challenging behavior; setting clear limits and following through; consequences for misbehavior; strategies of ignore, distract, and time-out; stress management; and problem-solving skills. A booster session is offered 2 months later to help parents maintain gains.

The efficacy of CPP was demonstrated in a controlled trial of families from Chicago area preschools serving low-income families. Families were randomized to receive CPP or assessment only. The study had a recruitment rate of 34%, with average attendance of 4.3 (39%) of 11 sessions. Results indicated that CPP reduced corporal punishment, commands, and observed child behavior problems up to 1-year postintervention. Dosage effects were clear; mean effect sizes for observed child behavior problems, parent behaviors, and parenting self-efficacy increased by 50% when dose was included in the model. Parents of children with more behavior problems at baseline attended more sessions, suggesting that CPP was differentially reaching families who need it most.

Parent Management Training—Oregon Model

Parent Management Training–Oregon Model (PMTO) was derived from social interaction learning theory and grounded in direct observation of family interactions with a critical focus on reducing coercive family processes (Forgatch & Patterson, 2010). Child behavior problems are thought to begin with small negative behaviors that escalate over time (e.g., noncompliance, to shouting, to tantrums) through repeated escape conditioning sequences. Common parental responses to child aversive behaviors inadvertently increase their frequency. For example, a mother finds her son watching television instead of doing homework. The mother scolds, the boy complains and claims he has no homework, the mother relents and changes the topic, and the boy stops arguing. The interaction has increased the likelihood of the boy protesting; he has learned how to turn off the mother's aversive behavior. In ensuing interactions, he may escalate his protest behavior. This is conceptualized as a coercive cycle. Blame is not directed toward individuals in the family but to the interaction between them. Five core parenting practices are identified as mechanisms for change: (1) skill encouragement (promoting prosocial behavior through

teaching and contingent positive reinforcement), (2) limit setting (decreasing deviant behavior through appropriate and contingent use of mild sanctions), (3) positive involvement (ways to invest time and plan activities with children), (4) problem solving (negotiating disagreement, establishing rules and consequences for rule violations), and (5) monitoring (protecting children from involvement in risk behaviors and affiliation with deviant peers).

Cultural adaptations of the PMTO model have been described in the literature. Domenech Rodríguez, Baumann, and Schwartz (2011) described the process by which they developed, Criando con Amor: Promoviendo Armonía y Superacín (CAPAS) for Latino parents, using their Cultural Adaptation Process Model mentioned on Table 17.1. CAPAS is a product of systematic adaptations to PMTO guided by Bernal's (1995) ecological validity model and a three-stage process employing community engagement and deployment focused iterative adaptation. CAPAS incorporated adaptations to content and process to promote active parental engagement in PMTO. Adaptations focused on six areas:

1. Careful language translation, with simplified terminology and greater reliance on visual aids;
2. Inclusion of Latino-specific *dichos*, proverbs and sayings in Spanish, to provide familiar metaphors for concepts;
3. Incorporating Latino values (e.g., *respeto*, *buena educacion, valerse por si mismo*) to frame treatment goals, discussion of parent versus child values reflecting emphasis on Latino versus American orientations;
4. Framing PT as promoting family harmony and success;
5. Inviting extended family members; and
6. Attending to contextual challenges in parenting (e.g., fear of children calling child protective services, deportation).

These adaptations preserve the core PMTO elements and the putative mechanisms of change—increasing skill encouragement, positive involvement, problem solving, limit setting, and monitoring.

Consistent with the CAPAS example, C. R. Martinez and Eddy (2005) attended to many of the same cultural and contextual considerations in their adaptation of PMTO called Nuestras Familias: Andando Entre Culturas (Our Families: Moving Between Cultures) for Latino families. Nuestras Familias was developed over a 2-year period through a collaborative effort between the Oregon Social Learning Center project team, Centro Latino/Americano, other community partners, and senior Latino family intervention researchers around the country. During the intervention development phase, five Latino family interventionists from the community were provided training in basic Oregon Social Learning Center PMT. After training (which included applying PMT principles to real and fictional cases), project staff, together with community experts and trained interventionists, began the process of adapting the existing PMT intervention model. In addition to keeping the core PMTO components and framing the intervention with consonant cultural values, Martinez and Eddy augmented intervention content with two modules that focused explicitly on bridging two cultures. This augmentation focused on differential acculturation between Latino parents and youth as a specific risk factor for youth maladjustment and behavior problems. Differential acculturation is related to increases in family stress and decreases in effective parenting practices, and these processes mediated the association between discrepant acculturation and adolescent substance risk (C. R. Martinez, 2006). Nuestras Familias targets "acculturation gaps" that can increase stress and disrupt effective parenting. C. R. Martinez and Eddy (2005) reasoned that for PT to be maximally effective in this context, it must address how parents manage family relations in the context of differential acculturation. In addition to the core PMTO content, the program includes four components to provide psychoeducation about differential family acculturation and empower parents to bridge acculturation gaps through the use of effective parenting practices associated with standard PMTO. In a randomized trial of Nuestras Familias, parents in the intervention condition reported an increase in overall parenting effectiveness and a decrease in child behavior problems compared to the no-intervention control. Furthermore, some evidence indicated that the intervention resulted in stronger effects for families with U. S.-born youth, for whom family adjustment difficulties associated with differential acculturation may be more prominent (Martinez & Eddy, 2005).

PMTO was implemented nationwide in Norway in 1999 with an effectiveness trial indicating positive intervention effects. Yet the sample enrolled in the trial was predominantly native Norwegian families, with few ethnic minorities represented (Ogden & Hagen, 2008). Developmental research was conducted in 2005 to 2007 to investigate strategies for recruiting immigrant Somali and Pakistani families and to determine what types of cultural adaptations may be necessary. The investigators studied the cost-effectiveness of three strategies for recruiting ethnic minority mothers to participate: (a) referrals from human service professionals from public agencies, (b) open

information meetings in community settings, and (c) social network referrals from research staff link workers. All three recruitment strategies yielded families eligible with regard to risk for child conduct problems. However, the information meetings were the most cost-effective strategy, and the highest proportion of the sample was recruited this way. The intervention groups were not mixed gender owing to Islamic religious norms requiring gender segregation. Groups were ethnically homogeneous and led by a Norwegian therapist assisted by trained bilingual assistants (i.e., link workers) who provided direct translation in Somali/Urdu. Link workers also served as "culture-builders" to strengthen relationships between therapists and mothers. In terms of intervention content, there was an expanded focus on certain topics relevant in the context of the immigrant communities targeted, including large sibling groups, and emphasis on cultivating control over emotions.

Findings from intent-to-treat analysis of a randomized waitlist controlled trial of 96 Somali and Pakistani mothers revealed that PMTO was effective in increasing positive parenting and decreasing harsh discipline and child conduct problems, according to maternal report (Bjørknes & Manger, 2013). The largest effect sizes were found among mothers who attended more than 50% of sessions. However, teacher reports showed no significant intervention effects on conduct problems and social competence. This study provides support for contextual and cultural adaptation in order to secure recruitment to and participant attendance in available interventions.

The Triple P Positive Parenting Program

Triple P spans the prevention-intervention continuum and aims to prevent behavioral, emotional, and developmental problems in children by enhancing the knowledge, skills, and confidence of parents (Sanders, 1999). Within a public health model, Triple P incorporates five levels of intervention on a tiered continuum of increasing intensity and narrowing reach. Level 1 includes media-based psychoeducation campaigns targeting whole communities. Level 2 is Selective Triple P delivered in 1 to 2 brief consultations during well child pediatric care. Level 3 Triple P is a four-session consultation model for use in primary care. Level 4 Standard Triple P is an eight- to ten-session parenting skills program that can be delivered in a group, individual, or self-help format. Level 5 is Enhanced Triple P, which provides adjunctive interventions for families in which parenting concerns are situated in the context of other problems, such as marital conflict and parental depression. Most trials with diverse populations have examined Level 4 Standard Triple P. Meta-analyses have concluded that Triple P has a positive effect on children's behavior and adjustment, with evidence being strongest in the toddler, preschool, and elementary-school age groups (de Graaf, Speetjens, Smit, de Wolff, & Tavecchio, 2008). Effect sizes range widely from small to large positive effects, which is not be surprising that Triple P contains multiple levels of intensity across prevention and treatment trials.

Data from controlled trials, focus groups, and survey methods support the acceptability and effectiveness of parenting strategies used in Triple P with samples of parents from Australia, the United States, New Zealand, Japan, Singapore, Hong Kong, Iran, Scotland, England, Ireland, Sweden, Belgium, the Netherlands, Germany, Turkey, Switzerland, South Africa, and Panama (Sanders, 2012). The International Triple P Research Network coordinates a network of scientists and facilitates communication about research activity around the world involving Triple P. The network has created a data repository for outcome studies and coordinates an international conference for researchers, practitioners, and policymakers in a different country annually. Training in Triple P encourages practitioners to work collaboratively with parents and to be responsive to parent values, preferences, and context while preserving core elements. These needs for tailoring can be met by adapting examples used to illustrate teaching points and by customizing homework assignments.

Perhaps given the foregoing discussion of workforce training in flexible and tailored delivery, there have been few cultural adaptations of Triple P. A notable exception is Turner, Richard, and Sanders's (2007) Group Triple P tailored for Australian Indigenous families. The authors conceded that mainstream parenting programs find it difficult to recruit and engage Indigenous parents. In collaboration with Indigenous workers over 5 years, Triple P was tailored to reduce barriers for Indigenous families and to develop resources. The team assumed that the core principles of positive parenting would transcend cultures but the goals and target behaviors, practical implementation of skills, and ways of sharing information would require adaptation. Modifications were made to the language, images, and examples used to illustrate skills in the production of tailored videos, workbooks, and presentation aids. In addition, more time was devoted in sessions to sharing personal stories, developing trust, discussing the social and political context for parenting, and slowing the pace of presentation.

In a waitlist controlled trial of the adapted Triple P program with 51 Indigenous families, treatment parents

reported decreased child behavior problems and less frequent dysfunctional parenting compared to waitlist families. Effects were primarily maintained at 6-month follow-up. Qualitative data revealed high satisfaction with the intervention. Yet engagement was lower than in previous trials of Group Triple P, with only 60.9% families commencing groups. Moreover, only 28% of families randomized to waitlist subsequently attended treatment, suggesting the importance of engaging families upon first contact, reducing barriers to care, and providing care whenever family circumstances permit.

The Effective Black Parenting Program

The Effective Black Parenting Program was an early example of a culturally adapted PT intervention developed by Myers and colleagues (1992) and adapted from the Confident Parenting Program (Eimers & Aitchison, 1977). Specific skills training is provided in describing and monitoring child behavior, specific labeled praise is used for appropriate behavior, special incentives are used for respectful child behavior, and mild social disapproval, active ignoring, and time-outs are used for misbehavior. Parents are instructed in two general approaches to parenting within which these skills can be utilized. First, parents are taught a Family Rule Guideline Strategy, in which they examine the rules they have for their children and the reasoning behind their rules. This orients parents toward developing rules that have an articulated rationale. Next, the Thinking Parents Approach encourages parents to think before they act and to entertain multiple possible attributions for their child's behavior, including stage of development. The intervention is introduced in a discussion that asks parents to contrast the goals of traditional Black discipline (i.e., discipline is achieved through punishment and spanking to instill obedience) versus modern Black self-discipline (i.e., internalizing standards of effective behavior). Discussion aims to situate coercive parenting practices as once protective in African American families but perhaps no longer as adaptive in empowering African American children to strive for achievement and social change. Additional discussion is devoted to instilling pride in Blackness, avoiding racial self-disparagement, and promoting strategies for coping with racism. The program is delivered by African American professionals and organized within a framework called the Pyramid of Success for Black Children.

In a quasi-experimental design, seven schools with high African American enrollment were assigned to the intervention condition (five schools) or to the control condition (two schools). All African American families with children in the first or second grade were invited to participate in fifteen 3-hour sessions of the Effective Black Parenting Program. Across two cohorts, 109 parents were enrolled in treatment and compared over time to 64 parents in control schools. Results suggested that the intervention produced improvements in some target outcomes, including parental rejection, family relationship quality, and child behavior outcomes. One-year follow-up data from the first cohort suggested maintained effects in parental rejection and selected child behavior problems, although some return to coercive parenting practices was noted. Ultimately, the authors noted that the intensive short-term Effective Black Parenting Program was promising but that results were modest and circumscribed, even when the program was delivered in a culturally sensitive manner.

The Black Parenting Strengths and Strategies

The Black Parenting Strengths and Strategies (BPSS) program (Coard, Wallace, Stevenson & Brotman, 2004; Coard, Foy-Watson, Zimmer & Wallace, 2007) is a cultural adaptation of the Parenting the Strong-Willed Child program (Forehand & Long, 2002). BPSS teaches behavioral management skills (i.e., attending, rewarding and ignoring, giving effective directions, and how to use time-out appropriately) while also mobilizing racial socialization practices found to be protective among African American families. Coard's work is guided by the premise that for African American youth, developmental competence requires the ability to make sense of and cope with prejudice and discrimination. Coard and colleagues (2004, 2007) reviewed research linking parent racial socialization practices to child outcomes including a positive racial identity, academic functioning, self-esteem, positive parent-child interactions, and decreased depression and anger. Coard et al. (2004) conducted qualitative interviews to analyze socialization messages related to racial achievement, preparation for bias, racial equality, and racial pride emphasized by mothers of young African American children living in low-income neighborhoods. The narratives provided the basis for program components for BPSS, a PT intervention augmented to mobilize culturally specific protective factors. Content adaptations included lessons in six areas of how to:

1. Deal with common in-group events (e.g., overt and subtle incidences of racism, prejudice, and discrimination);
2. Problem-solve negative peer interactions (e.g., social exclusion because of skin color);
3. Promote achievement despite barriers (e.g., advocating for a child when low expectations are evident);

4. Reflect on one's own experiences as an African American woman or man;
5. Discuss race-related content in a developmentally appropriate manner; and
6. Access culturally affirming resources for children.

The five delivery-related adaptations included:

1. Using African American language expression and the African American–perspective use of "we";
2. Emphasis on African American values about collective responsibility, cooperation, and interdependence;
3. Use of African proverbs, sayings and affirmations, poems, quotes, symbols, and pledges;
4. Use of prayer, role-playing, storytelling, extended family participation, and humor; and
5. Use of a setting and motifs representative of the population.

Throughout the adaptation process, consultation with the original developers helped to ensure that key elements of the standard PT program were maintained and not diluted when content was augmented.

In a waitlist controlled trial of BPSS, 32 parents from urban, low-income neighborhoods were randomized to immediate or delayed 12-week treatment. Attendance and retention were strong with 88% of parents being retained in the study, with participants attending 85% of sessions on average and all participants attending at least six sessions. Results indicated significant effects of treatment on six of eight parent-reported outcomes assessed posttreatment. Relative to controls, intervention parents used significantly more racial socialization strategies, positive parenting practices, and less harsh discipline. Parent-reported externalizing problems increased in the control group but decreased in the immediate treatment group. Effect sizes were large for positive parenting, harsh discipline, racial socialization, and conduct problems.

Culturally Grounded Parent Training Interventions

The African Migrant Parenting Program

The African Migrant Parenting Program is a PT intervention for immigrant and refugee families from Africa who resettle in high-income countries, such as Australia (Renhazo & Vignjevic, 2011). The program aims to enhance effective parenting and relationship skills in order to help parents to raise their children confidently and understand their children's needs across developmental stages in the new cultural, social, and educational environment. Resettlement challenges encountered by refugee and migrant families include: adaptation to new work demands; needs for housing and schooling; changing family structure, roles, and responsibilities; establishing social networks; and learning English (Renhazo, 2002). Previously accepted practices, such as reliance on sibling care and corporal punishment, may no longer be viable. Differential family acculturation and acculturative family distancing are pertinent for these families who are transitioning from collectivistic cultures into high-income countries with social environments promoting individualism. In this context, strain on family relations and parenting are pressing (Renhazo, Swinburn, & McCabe, 2008).

The African Migrant Parenting Program consists of eight 2-hour sessions cofacilitated by African parenting educators and experienced family counselors; three 45-minute home visits by African parenting educators were used to monitor barriers to learning and skill enactment. The sessions were modeled on the Parent Skills module of the Parenting in a New Culture Guide developed for Australian Samoan parents. Session activities incorporate computer slide presentations, discussions, mini case studies, and videotape modeling. Sessions were devoted to a variety of issues including improved family relations, family stress reduction, and even family finances and legal issues.

In an open trial, 44 families receiving counseling for parenting issues at a social service agency were invited to participate. All agreed to participate, and 88.6% of families completed treatment despite a very low level of literacy and multiple barriers to treatment (e.g., housing, transportation, legal problems). Pre-post analyses suggested change on key dimensions: appropriate expectations of children, increased empathy toward children's needs, and attitudes toward corporal punishment. Treatment dose was associated with degree of change on developmental expectations and views on corporal punishment. However, key outcomes of parenting behavior and child adjustment were not examined.

The Exploring Together Program

The Exploring Together Program is a preventive intervention adapted to reduce disparities in the developmental profiles of Australian Aboriginal children relative to the general Australian population. Disparities include the higher prevalence of emotional and behavioral disorders and lower performance of Aboriginal children on national tests for literacy and numeracy. The program combines

elements of PT and children's social skills training for parents of children ages 4 to 6 years old (Littlefield et al., 2005). Children attend with one parent for 10 weekly 2-hour sessions. The first hour consists of an interactive group with all parents and children facilitated by four group leaders and focuses on parent-child interaction. Components of group activity involve turn taking, talk and play based on themes that complement content of the other groups. Then the dyads split into separate groups for parents and children for an hour. Facilitated by two group leaders, parent groups discuss observations of children's behavior, triggers for problem behaviors in the context of family interactions, and factors affecting parenting. Children play together in a separate group, with a focus on social skills and the learning of rules and consequences.

Collaboration with Aboriginal team members resulted in adaptations that drew on songs and storytelling in Aboriginal languages. Drawing activities were used to promote discussion of families, networks, and relationships and to tap into cultural symbols and idioms. These practices aimed to encourage parents to talk about the place of parent and child in the family and values of shared responsibility for children among caregivers in extended family networks. The focus was on identifying strengths and sources of difficulty in each family.

The delivery of interventions for this population faces formidable challenges in geographical dispersal and the linguistic and cultural diversity of Aboriginal communities. An open trial evaluation study was mounted for both Aboriginal and non-Aboriginal children in urban Darwin and for Aboriginal children in three communities of the Tiwi Islands, near Darwin (G. Robinson, Tyler, Jones, Silburn, & Zubrick, 2012). A wide variety of implementation strategies was used to promote reach of the intervention. Children were referred from schools; parents were invited by teachers and then visited at home when they expressed interest. Community leaders explained the program at public meetings, spoke to parents privately, and sought referrals from schools. Group leaders were mature community members with backgrounds in health, child care, or education.

Following the intensive and multipronged approach to recruitment, over 250 children were referred over 3 years, yielding an evaluation sample of 225. However, only 110 (48.9%) commenced the intervention, and only 86 (38.2%) attended at least half of the sessions. The lowest commencement and completion rates were observed among urban Aboriginal families (14% commenced and 11.5% attended at least half of the sessions). Despite the high attrition, outcomes suggested significant reduction in problem behavior and parental distress at posttreatment. However, improvement was significantly greater for non-Aboriginal families, with the least change observed among urban Aboriginal families. Despite highly flexible strategies of engagement and cultural adaptation of the intervention, results suggested the adapted program still had limited reach and impact on urban Indigenous families.

Discussion

In summary, the research base on cultural adaptation in the area of parenting interventions is relatively mature. The four most frequently cited PT interventions—Triple P, IY, PCIT, and Parent Management Training–Oregon model—have all been subject to cultural adaptations. In addition, other extensive adaptations and culturally grounded PT interventions have been developed and evaluated. We now have ample data suggesting that culturally adapted PT can be efficacious, yielding positive effects in the improvement of parenting behaviors and the prevention and treatment of externalizing as well as internalizing child behavior problems. Thus, the effects of PT interventions appear robust to cultural adaptations.

Enhancing Engagement: Remaining Questions

Most PT adaptations tested to date target changes to promote engagement of underserved or culturally diverse groups. However, as yet there is no conclusive evidence that these engagement-focused adaptations improve the attendance and retention of ethnocultural groups for whom disparities in engagement in standard PT have been observed. Benchmarking studies may be called for since it typically would be neither pragmatic nor ethical to randomize to conditions in which PT is not optimized to engage targeted ethnocultural groups (Cardemil, 2010). Only a single small controlled trial has addressed this question, with negative results on engagement outcomes. McCabe and her colleagues (2008, 2012) found culturally adapted PCIT (GANA) did not outperform standard PCIT in terms of promoting attendance or retention even though adaptations focused on engagement through enhanced treatment orientation, framing PCIT skills based on a pretreatment values assessment, or situating PT as educational rather than therapeutic.

Moreover, although positive engagement results were found in many studies, our review noted examples of trials of PT adapted for engagement that yielded disappointing recruitment, commencement, and completion rates. For example, the CPP adaption of IY yielded a

recruitment of 37% of African American and Latino parents in low-income preschools, and the average family attended only 39% of sessions (Gross et al., 2009). Once recruited into the trial, there was high attrition from the Indigenous adaptation of Triple P for Australian Aboriginal families with nearly 40% of families failing to attend a single session in the immediate treatment group (Turner et al., 2007). Even lower commencement and attendance rates were found in the Exploring Together PT program also targeting Aboriginal families in urban and rural Australia (G. Robinson et al., 2012). These and other findings demonstrate that even complex and concerted efforts to connect with families and communities are at times insufficient for reducing barriers to PT.

Indeed, engagement may remain an impediment to the public health impact of PT. It can also be argued that modifications to intervention content and process do little to address problems with low recruitment and intervention commencement rates. Parents' perceptions of acceptability of PT when they do arrive at treatment may help to explain low retention, which may be a smaller part of the implementation problem. Triple P developer, Sanders (2012), argues that the single major threat to the reach of PT stems from the fact that they are commonly restricted to small numbers of vulnerable parents with problems. As such, the interventions are seen as for "failed" parents, such as those involved in child protection or mental health systems, and participation is stigmatized. Thus, he argues that a public health approach offering PT to all can result in greater engagement at the population level and that cultural adaptations to intervention content need not be emphasized.

Reliance on self-referred parents and mass media outreach may result in self-selected samples who are motivated and able to attend and whose parenting may more closely resemble PT skill targets (G. Robinson et al., 2012). These recruitment strategies may screen out disadvantaged groups with high need. When Triple P moved beyond universal outreach to target a disadvantaged underserved group with an Indigenous adaptation of the program, substantially lower commencement rates were observed than in general community trials (Turner et al., 2007). Again, the challenge may be getting parents into the room rather than engaging them once they arrive.

Augmented Intervention Content: Paucity of Data

Relatively few PT interventions have been augmented to address the etiological context of parenting dysfunction or child behavior problems in diverse families. Frameworks guiding cultural adaptation often mention the need to address unique etiological factors but provide little guidance on the development of this content. The few examples of augmented PT interventions have addressed: (a) the protective factor of racial socialization in African American families (Coard et al., 2004; Myers et al., 1992); (b) the school achievement context of ineffective discipline in Asian American immigrant families (Lau et al., 2011); and (c) the risks associated with differential acculturation between immigrant parents and their children (Lau et al., 2011; C. R. Martinez & Eddy, 2005; Renhazo & Vignjevic, 2011). Although the absolute efficacy of these augmented PT interventions has been established, dismantling and process studies are needed to understand whether the additional content remediates the risk processes targeted and whether those changes facilitate ultimate outcomes on child psychopathology.

Additional Directions for PT Adaptation

Although some models of cultural adaptation stress that changes to the pacing, sequence, and length of standard PT should not be made (Kumpfer et al., 2008), these proscriptions appear to guard against unwanted omission of core content. However, some observations from controlled trials suggest that pacing and dosing of PT might be an explicit focus of cultural adaptation to help bridge the cultural distance between cultural traditions of diverse families and prescribed changes to parent-child interactions in PT. In general, controlled trials have revealed dose-response effects associated with standard and culturally adapted PT (e.g., Baydar, Reid, & Webster-Stratton, 2003; Gross et al., 2007; Renhazo et al., 2008). In trials of PCIT, which uses mastery-based criteria to determine length of treatment, trials have shown that the number of sessions required for ethnic minority families to reach performance criteria on CDI and PDI skills exceeded that found in trials of predominantly European American families (Fernandez et al., 2011). For example, in Matos et al.'s (2009) trial, the investigators adapted their mastery criteria using different criterion goals that they felt could be more easily attained by the Puerto Rican families in their sample, and hoped to limit CDI to eight sessions and PDI to nine sessions (doses that are still above published averages), but many families required additional sessions above this limit. McCabe and colleagues (2008) likewise found that Mexican American parents required four to five– more sessions than is typical to complete PCIT. Differences in treatment duration may reflect the need for more behavioral rehearsal of practices that are

unfamiliar and culturally foreign. These problems may be pronounced for immigrant and ethnic minority parents who, given their diverse upbringing, are unacquainted with skills like child-directed play, labeled praise, differential attention, and time-out. Qualitative data from group leaders in Lau et al.'s (2011) trial of IY adapted for Chinese Americans suggested that slowing the pace of skill lessons and increasing the dosage of behavioral rehearsal may be a promising adaptation to achieve meaningful and enduring changes in parenting in immigrant families. This is, of course, not a culturally specific proscription for enhancing PT and can be said of parents from across cultural groups. The issue of dosing may be vital in implementation of PT with diverse parents domestically and internationally, and yet this consideration has generally not entered discussions of cultural adaptation.

YOUTH RISK PREVENTION PROGRAMS

National data from the 2011 Youth Risk Behavior Survey revealed that youths in grades 9 to 12 participated into multiple risky behaviors. During the 30 days before the survey, 38.7% had drunk alcohol, 23.1% had used marijuana, 47.4% of the students had ever had sexual intercourse, 33.7% had had sexual intercourse during the 3 months before the survey, and 15.3% had had sexual intercourse with four or more people during their life. Further, 18.1% of high school students had smoked cigarettes and 7.7% had used smokeless tobacco (Eaton et al., 2012). Studies also consistently find that youth's risky behaviors co-occur; specifically, drinking, smoking, and risky sexual behaviors might have occurred in the same situation because youth lost control of themselves. The co-occurrence of substance use and risky sexual practices has been associated with increased prevalence of HIV/AIDS among youth. In 2009, youth ages 13 to 29 accounted for 39% of the new cases of human immunodeficiency virus (HIV) infection, but they represented only 21% of the American population. African American youths disproportionately represented 65% of the new youth HIV infection cases (Centers for Disease Control, 2011).

Further, the report published by the Centers for Disease Control and Prevention in 2011 showed that, among all new cases of HIV infection in the United States, more than 45% are African American adolescents and adults and more than 20% are Hispanic/Latino adolescents and adults. African American females are particularly at higher risk, representing 63% of all new female cases of HIV infection. More than 50% of the new cases were caused by male-to-male sexual contact (38.2% are African American, 23.5% are Hispanic/Latino), with other new cases due to heterosexual contact (65.3% are African American, 18.1% are Hispanic/Latino) and injection drug use (47% are African American, 25% are Hispanic/Latino).

One unambiguous implication of these statistics is that African Americans and Hispanics are confronted with high risk of HIV infection. Consequently, they are in more urgent need of access to HIV/AIDS knowledge, skills to negotiate and refuse, and support from family and peer leaders. A second clear implication is that unprotected sexual intercourse and drug use are the primary causes of HIV/AIDS infection among minority youth. Whenever these behaviors co-occur, the risk grows tremendously. Multiple sexual partners worsen the situation as it increases the risk of exposure for youth who do not have a direct relationship with an HIV/AIDS-infected partner (Santelli, Lindberg, Abma, McNeely, & Resnick, 2000). It has been suggested that the consequences of poverty and racism are the most salient predictors of risk-taking behaviors. Education, urbanization, social norms, values, and life goals influence academic aspirations and future orientation. Lack of opportunities for success may cause these youth to seek nontraditional methods of achieving adult status, such as early sexual initiation and the initiation and escalation of substance and drug use (Bakken & Winter, 2002; Stanton et al., 1994). African American and Hispanic youth have traditionally reported high rates of these risk behaviors (Eaton et al., 2008). For example, among adolescents surveyed in 2007, only 67.3% of African Americans and 61.5% of Hispanics reported using condoms during the last time they had sexual intercourse. Additionally, greater percentages of African American (27.6%) and Hispanic (17.3%) youth have had four or more sex partners than non-Hispanic Whites (11.5%). Studies also show that Hispanic and African American youth report higher rates of lifetime drug use than do non-Hispanic White youth (Johnston, Bachman, O'Malley, & Schulenberg, 2008). For example, 25.0% of Hispanic, 19.4% of Black, and 17.9% of non-Hispanic White eighth graders report using drugs in their lifetime (Johnston, O'Malley, Bachman, & Schulenberg, 2009).

Racial-ethnic substance and drug use comparison data that include American Indians and Alaska Natives, however, also show that these youth initiate tobacco, alcohol, and other drugs earlier, at higher rates and with more severe health, social, and economic consequences than adolescents of other ethnic-racial groups in the United States. The prevalence rate of smokeless tobacco use is

especially high among American Indian and Alaska Native children, adolescents, and young women (Schinke et al., 1986). Further, rates of cigarette smoking and heavy use of cigarettes—consumption of at least a pack of cigarettes a day for the last 30 days—are dramatically higher among American Indian and Alaska Natives, exceeding rates for every other ethnic-racial group (Schinke, Moncher, Holden, Botvin, & Orlandi, 1989). Drunkenness and use of substances, including alcohol and nearly all other drugs, is higher among American Indian youth compared to youth in other racial-ethnic groups (Nelson & Nazbah, 2011; Young, 1988). Collectively, these findings underscore the importance of identifying effective ways to prevent engagement in high risk behaviors that compromise the health and well-being of all youth and especially that of racial-ethnic minorities.

A plethora of youth risk preventive intervention programs have been developed and have taken many forms, including school-based prevention programs, mass media campaigns, youth clubs and activities designed as alternatives to substance use, family interventions, and comprehensive, community-wide prevention strategies (Sloboda & Bukoski, 2003). Earlier school-based substance abuse prevention approaches included either resistance-skills training, alone or in combination with competence-enhancement or life-skills training (Botvin, Baker, Dusenbury, Tortu, & Botvin, 1990), that were based on social influence models of risk taking and Bandura's (1977) social learning theory. In this approach, drug use and abuse were conceptualized as socially learned and functional behavior resulting from an interplay between social (e.g., modeling, imitation, reinforcement, pro-drug norms) and individual (e.g. personality) factors. In contrast to drug-specific resistance strategies, competence-enhancement approaches aim to teach a repertoire of skills that adolescents can use to deal with many of the challenges confronting them in their everyday lives, not just drug and alcohol use, such as decision-making and problem-solving skills, cognitive skills for resisting interpersonal and media influences, skills for enhancing self-esteem (goal-setting and self-directed behavior-change techniques), adaptive coping strategies for dealing with stress and anxiety, general social skills (conversational skills and skills for forming new friendships), and assertiveness. These skills are typically taught using a combination of proven cognitive-behavioral methods, such as instruction and demonstration, group feedback and reinforcement, behavioral rehearsal, and extended practice through behavioral homework assignments.

Although resistance and life skills training remain central features, prevention programing expanded over the years to better address the co-occurrence of multiple risk-taking behaviors (e.g., alcohol and drug use, sexual risk taking, HIV) and a widening range of risk and protective processes identified as possible targets (Hawkins, Catalano, & Miller, 1992). Programming enhancements also were informed by developmental and social learning research and theories suggesting that adolescents face pressures to engage (or motivations to avoid) in risk taking from multiple sources and transactions outside of school (e.g., peers, parents, other adults in the community, mass media, community policies) and by evidence that single-channel programs (e.g., school-based drug prevention) may not be powerful enough to produce lasting prevention effects against these broader influences (Dryfoos, 1993). Alternative models, particularly family interventions to be used as the primary approach (Dishion, Kavanagh, Schneiger, Nelson, & Kaufman, 2002) or in combination with youth-focused programs (Spoth, Redomond, & Shin, 2001) were developed to strengthen family relationships, bonding, communication about difficult topics (e.g., sex, drugs) and parent management practices and to engage parents in supporting skills taught in youth programs (Anderson et al., 1999). Comprehensive prevention strategies that combine school-based interventions with those affecting the family, social institutions, and the larger community (e.g., Pentz et al., 1989) were recommended in the National Institute of Drug Abuse (1997) publication titled *Preventing Drug Abuse Among Children and Adolescents: A Research-Based Guide* that is recognized for marking the beginning of the evidence-based drug abuse prevention movement. This report identified the tailoring of interventions to address risks specific to ethnic minority populations as one of 14 principles guiding the field.

In this section we assemble the scattered collection of culturally adapted youth risk prevention programs that have been evaluated to date, all but one published since the 1997 NIDA report, and the effectiveness of such programs for preventing and reducing risky sexual behavior and alcohol and substance use among racial/ethnic minority adolescents. As in the prior section on PT, our review is organized to distinguish culturally adapted programs, including those that might be more aptly described as "culturally tailored" (Bernal & Domenech-Rodríguez, 2012), from culturally grounded programs in which community members were involved throughout the initial program inception, design and evaluation, although we acknowledge again that these are not precise distinctions.

Cultural Adaptations of Youth Risk Preventive Interventions

Aban Aya Youth Project

Aban Aya Youth Project is a 4-year-long culturally tailored intervention that is designed to prevent multiple risky behaviors among urban African American youth (Flay, Graumlich, Segawa, Burns, & Holliday, 2004). The program screened the public schools in metropolitan Chicago and built the initial sampling pool based on these standards: enrollment greater than 500; more than 80% of the students are African American and less than 10% are Latino or Hispanic; not on probation or slated for reorganization; not a special designed school; and moderate mobility. The 155 schools selected were then stratified into four quartiles of risk (based on school report card data, such as enrollment, attendance and truancy, mobility, family income, and achievement scores), and 12 of them were sampled (nine inner city schools and three near-suburban schools).

The participants were 153 fifth graders in the 1994–1995 school year. Using schools as units, the students were randomly assigned to one of the three conditions: The social development curriculum (SDC), the school/community intervention (SCI), and the control condition. Students in the SDC arm received 16 to 21 lessons each year, which taught them cognitive-behavioral skills to avoid drug use, risky sexual behaviors, and other risky behaviors. SDC is the Afrocentric arm intervention and was based on *Nguzo Saba* (a Swahili term that means the Seven Principles), which emphasizes the importance of promoting "unity, self-determination, and responsibility" (Flay et al., 2004, p. 377) in youth risk prevention approaches (Flay et al., 2004, p. 377). Instructional methods were based on oral traditions of African American heritage including storytelling and the use of proverbs, history, and literature. Finally, the project assigned homework that aimed at encouraging parental involvement and communicative skill building. The authors did not indicate whether community members and parents were involved in the curriculum development and design of SDC.

The SCI arm is a comprehensive intervention designed to enhance the SDC classroom intervention by providing community empowerment sections that include programs for parents, school staff, and youth. This component of the intervention also has an overarching community element to promote positive connections among parents, schools, local businesses, and agencies. Parent support sought to increase skills to boost children's learning in school and to enhance parent-child communication. Students in the control condition received similar amounts of classes as those assigned to the SDC with topics focused on promoting healthy behaviors, such as nutrition, physical activities, and general health care. The intervention classes were taught by university-based health educators. Data were collected at multiple points for each condition. The pretest was done in the fall of 1994, and the follow-up posttest was done in the fall of 1995. Further follow-up tests were done annually until 1998.

Results revealed intervention effects differed for boys and girls. For boys, both the intervention arms (SDC and SCI) led to a salient reduction on drug use and recent sexual intercourse and improved condom use compared to boys in the control condition. It was worth noting that boys exposed to the SCI intervention arm fared better than those assigned to the SDC arm. Neither intervention condition was shown to be effective for girls (Flay et al., 2004). Lack of program effectiveness for girls was attributed to low baseline risk compared to males, as boys demonstrated higher baseline levels than girls on each of the targeted outcomes (Flay et al., 2004).

Adult Identity Mentoring

Adult Identity Mentoring, or Project AIM, is a school-based intervention program designed to reduce risky sexual behaviors among African American youth. The primary goals of Project AIM include delaying initiation of first sexual intercourse, promoting abstinence, and increasing condom use (Clark et al., 2005). The conceptual framework was based on the theoretical tenets of the Possible Selves program (Oyserman & Markus, 1990), which posits that people's current lives are motivated by their mental images of their future selves. Such mental images can be enhanced by a balance between positive images (desired selves) and negative images (selves to be avoided). AIM was delivered in small groups in which role modeling was used as a teaching strategy to highlight negative connections between desired future life and risky behaviors. Project AIM targeted seventh-grade, primarily low-income African American families in a suburban town near a southeastern metropolitan area. African American students who were previously enrolled in a required 9-week health education class were enrolled in the program. A total of 248 students completed pre-intervention assessment, and 6 were dropped due to missing data; 211 completed posttest, 19 weeks after baseline, and 156 completed 1-year follow-up assessment.

In terms of implementation, AIM consisted of 10 sessions delivered over the course of 6 consecutive weeks during the school year and offered in 20 health education

classes. Of the 20 classes, 11 were randomly assigned to receive AIM intervention, and 9 were assigned to receive standard health education curriculum. AIM sessions were conducted by trained African American college students, while the health education classes were taught by the regular classroom instructor. Besides inclusion of African American educational facilitators, Project AIM also had a session that focused on the importance of "legacy, positive role models, and peers" for youth identity development. In this session, African American youths saw examples of African Americans who left legacies, and each participant was required to compose thank you letters to the visiting positive role models and peers. The inclusion of positive role models and peers was based on the premise that African American youth "lack strong role models and mentors to guide them through the explorations that naturally occur as a part of adolescent self-identity development" (Clark et al., 2005, p. 337). Youth also participated in discussions on topics such as how peers, family, and other environmental factors influence their lives and how their choices affect future goals. The authors gave limited information about ways in which the program was specifically tailored for African American youths. There were no details, for example, on how the role models were recruited to visit the classes. Findings revealed that adolescents in the intervention group reported higher rates of abstinence and less sexual intentions than those in the control group when assessed 19 weeks after the baseline survey. For the youth who did not have any sexual behaviors before the start of the study, those in the intervention groups were less likely to report the initiation of sexual activity than were controls. At 1-year follow-up, the abstinence effect was still significant among the male participants in the intervention group.

The Strengthening Families Program

The Strengthening Families Program (SFP) is a family skills training approach developed in the United States that uses 2-hour-long sessions with parallel Parent Skills Training and Children's Skills Training groups in the first hour, followed by multifamily family skills training groups in the second hour. This multicomponent approach combines youth enhancement with a focus on family strengthening and improve parenting to support and guide youth. Designed to increase resilience and reduce risk factors for a broad range of behavioral, emotional, academic, and social problems in children 3 to 16 years old, the program is widely recognized as an effective substance abuse prevention program. SFP has been evaluated many times by independent researchers in randomized control trials or health services research with very positive results in reducing substance abuse and delinquency risk factors by improving family relationships (e.g., Aktan, Kumpfer, & Turner, 1996; Gottfredson, et al., 2006; Kumpfer, Alvarado, Tait, & Turner, 2002; Spoth & Molgaard, 1999).

During the 1990s, cultural adaptations of SFP were made and evaluated among five ethnic minority groups (African, Hispanic, Asian, Pacific Islander, and Native American). Findings generally supported the efficacy of these adapted versions; however, important insights were gained. Although the culturally specific adaptations did not yield better effects compared to the core version, improvements were shown on recruitment and retention. Kumpfer et al. (2002) also reported that an adaptation of SFP for Hawaiian families (Kameoka, 1996) resulted in weakened prevention effects when behavioral skills training was curtailed to allow for extended focus on Hawaiian cultural values. This was an early exemplar of the principle of maintaining fidelity of deep structure or core intervention components while including adaptations to promote engagement. In 2003 the Cochrane Collaboration Reviews published a meta-analysis identifying SFP having demonstrably larger effects than other alcohol prevention programs (Foxcroft, Ireland, Lister-Sharp, Lowe, & Breen, 2003). This prompted international dissemination efforts in a number of nations. Several international adaptations that have used the Kumpfer model of cultural adaptation (see Table 17.1) have been subject to controlled trials, and all have demonstrated positive results among families with substance using parents (Kumpfer et al., 2008).

The Multiethnic Drug Abuse Prevention Program

The Multiethnic Drug Abuse Prevention Program was developed by Botvin, Griffin, Diaz, and Ifill-Williams (2001) using a cognitive-behavioral approach to enhance risk resistance skills among youth. Specific components of the curriculum include building self-esteem, resisting advertising pressure, managing anxiety, communicating effectively, developing personal relationships, and self-advocacy. The project was first tested on White youths in the state of New York in the 1990s and adapted for multicultural implementation with African American and Hispanic youth in 2001. Although the curriculum content and core elements of both programs were similar, several adaptations were made in preparation for delivering the program to youth of color. Focus groups were used to obtain feedback on ways to modify the intervention manual and adopt culturally appropriate and relevant teaching strategies. Adaptations included multiple strategies, such as creating graphics that contained the image

of minority youth, translating and adjusting the reading levels of program materials and questionnaires, and adding culturally relevant stories and role-play scenarios to the curriculum.

To test the culturally adapted program, participants were recruited from 29 public schools in New York City. Of the 5,222 seventh graders recruited, 3,621 completed the pre-intervention test, the posttest, and the 12-month follow-up survey. More than 60% of the participants were African American, and 22% were Hispanic. The schools were randomly assigned to an intervention condition or a control condition. Students in the intervention arm were taught by trained classroom teachers in 15 sessions in the seventh grade and 10 booster sessions in the eighth grade, while youths in the control group did not receive any project interventions (Botvin et al., 2001). The findings in the 3-month and 12-month postintervention tests revealed that the youth assigned to the drug prevention program reported greater reduction in smoking, drinking, and use of inhalant and polydrugs compared to youth in the control group. Programmatic effects observed in the culturally tailored program were similar to what Botvin et al. found among White, middle-class youth (Botvin et al., 1990; Botvin, Baker, Dusenbury, & Botvin, 1995). This program is one of few to advocate for programs that are multicultural rather than monocultural. Further, Botvin et al.(1995) found positive programmatic effects for both inner city minority and White, middle-class youth by making surface changes to the generic curriculum. These surface structure changes included inserting language and words to ensure that the reading level was appropriate for the targeted audiences and using photos of each racial/ethnic group to increase a sense of program relevance for each targeted audience.

Life Skills Training for Native American Youth

Schinke, Tepavac, and Cole, (2000) adapted the core curriculum from the Life Skills Training Program (Botvin et al., 1990, 1995, 2001) to prevent drug abuse among Native American adolescents. The program aimed to teach cognitive and behavioral skills to resist smoking of cigarettes or smokeless tobacco, drinking alcohol, and marijuana use. The participants (n = 1,396) were recruited from 27 tribal and public schools in 10 reservations in five states: North Dakota, South Dakota, Idaho, Montana, and Oklahoma. Participating schools were randomly assigned to one of three arms: two intervention arms (a skills-only intervention group and skills plus community involvement intervention group) and a control arm. Youth assigned to the two interventions attended fifteen 50-minute weekly sessions. The intervention sessions were designed to contain the important common cultural elements of Native American tribes, including values, legends, and stories that reflected issues in the Indian society. Specific consideration was given to including cultural content that celebrated Native American traditions, which were further tailored to be reflective of various reservations, tribes, and Indian groups. Similar to other culturally tailored programs, Schinke et al. (2000) included role-playing, storytelling, programmatic activities, and small-group discussions to foster cognitive-behavioral skill development. In addition, homework was assigned to encourage youth to use lessons learned in sessions in their everyday lives. Native American leaders facilitated the group sessions and also served as coaches and to facilitate resistance skills usage and efficacy. Family and community members who had frequent contact with youth also were involved in the intervention to elevate their awareness of substance use prevention and ways to support and encourage youth to avoid drugs and substances. Youth in the intervention arms received boosters semiannually, delivered in two 50-minute sessions. Youth in the control did not receive any intervention. The authors did not provide detailed descriptions of how the curriculum itself was culturally tailored or pilot-tested prior to implementing the program.

All youth completed a pretest, immediate and 6 months posttests, and follow-up assessments every 12 months over the course of 3 years. Outcome analyses showed lower levels of alcohol, smokeless tobacco, and marijuana use among youth exposed to the skills-only intervention compared to those assigned to the skills plus community involvement arm and those in the control group. The absence of intervention effects for the skills plus community involvement condition was thought to have been associated with potential dilution of the program effectiveness. The skills-only program allowed youth to focus more on internalizing core elements of the program, thereby enhancing resistance skills to prepare youth to avoid risky situations. Given the prior lack of culturally sensitive interventions for Native American youth, these findings were important for demonstrating that benefits of culturally tailored risk prevention programs for tribal communities. There remains a great need for conceptual models to guide the development and testing of new prevention approaches and to refine existing interventions for Native American youth.

Keepin' It R.E.A.L.!

Keepin' It R.E.A.L. is a program designed to reduce sexual risk among African American adolescents, with specific

emphasis on relationship development between mothers and sons (DiIorio et al., 2006). Mother-son dyads are randomly assigned to one of two conditions: a program based on social cognitive theory (SCT) or the life skills program (LSK) based on problem behavior theory. Participants in both conditions meet for seven sessions over 14 weeks for 2 hours each session. In the SCT condition, mothers and adolescents attended joint sessions together for four of the seven sessions and separately in concurrent sessions for the remaining three. Sessions included information about reducing HIV transmission, general communication skills, as well as specific communication about sex, values, decision making, and peer influence. In the LSK condition, participants attended separate concurrent sessions, except for a portion of the first and last sessions, where they attended joint sessions. In addition, mothers participated in a stress reduction activity and discussion about ways to apply session topics to personal life. Youth also received a stress reduction activity at the beginning of session accompanied by discussion about a specific risk behavior. The LSK condition also included community service activities, such as an overnight trip to a historically Black college or university. Both the SCT and LSK conditions were highly interactive, and home practice exercises were assigned at each meeting.

Keepin' It R.E.A.L.! was evaluated in a RCT with the two described intervention conditions (SCT: n= 194; LSK: n = 187) and a control condition (n = 201) that received 1 hour of training on HIV prevention. Assessments were given at baseline, followed by 4-, 12-, and 24-month postintervention assessments. Results revealed greater change in HIV knowledge and more recent conversations about sex with their sons among mothers assigned to the SCT condition compared to those in the LSK and control conditions. Mothers in the SCT and LSK conditions, however, scored higher on intent and comfort about discussing sex with their sons than mothers in the control group. Regardless of conditions, sons demonstrated significant increases in sexual behavior over time and increased sense of self-efficacy for abstinence. Further, SCT youth reported greater increase in HIV knowledge, twice the rate reported by those in the LSK condition. Further, compared to youth in the control condition, youth in both SCT and LSK conditions who were sexually active were more likely to use condoms and reported having intentions to end their sexual activity until they were older.

Keepin' It R.E.A.L.! was subsequently adapted as a father and son program, based on the SCT approach, which was similar in format and content to the mothers' program (DiIorio, McCarty, Resnicow, Lehr, & Denzmore, 2007). The father-son program was evaluated with a randomized cluster design comparing effects of the SCT condition (n = 141) with a control condition focusing on nutrition and exercise (n = 132). Fathers in the SCT condition reported more communication and greater intent to communicate. Sons in the SCT condition reported less sexual behavior and more condom use among those who were sexually active. Increased condom use was a more robust finding than abstinence, despite being addressed in only one of the program sessions. The authors suggest that for African American male adolescents, condom use may be a more acceptable HIV prevention strategy than abstinence. The implications of cultural tailoring for study findings were not addressed.

Culturally Grounded Interventions

Strong African American Families

Strong African American Families (SAAF) is a family-based preventive intervention program, specifically designed for rural African American families to delay sexual debut and prevent the onset and escalation of alcohol and substance use during early adolescence. SAAF's theoretical and empirical underpinnings were based on data that Murry, Brody, and colleagues (Brody et al., 1994; Brody, Flor, & Neubaum, 1998; Brody, Murry, Kim, & Brown, 2002; Brody Murry, Gerrard, et al., 2004; Gibbons, Gerrard, Cleveland, Wills, & Brody, 2004; Wills, Gibbons, Gerrard, & Brody, 2000; Wills, Gibbons, Gerrard, Murry, & Brody, 2003) gathered for more than a decade from the target population. Community members were involved in numerous aspects of SAAF's design, development, and implementation. Community members, who are residents of the counties in which SAAF families live, act as contacts between Murry's research group and the prevention-targeted communities. These individuals are selected on the basis of their positive reputations and extensive social contacts in their communities. Their feedback is sought on the cultural relevance and sensitivity of measures, protocols, and procedures for rural African American parents and youth. They also provide feedback about families' and communities' cultural identities, meanings, customs, religious practices, languages, expectations, worldviews, and cultural values, all of which impact the successful design and implementation of the SAAF program. Community members reviewed and provided feedback on each session, and the program was pilot tested with rural African American families and refined prior to implementation. Further, to enhance rapport, minimize cultural bias, and enhance cultural understanding, African

American community members serve as home visitors to collect data, and African American community members were trained to implement the program.

The SAAF program consists of 2-hour sessions that take place for 7 consecutive weeks. After a meal catered by local African American providers, caregivers and children attend concurrent breakout sessions and then join together for the last hour of large group discussion. Parent sessions focus on both general (e.g., monitoring and communication with children about sex) and racially specific (e.g., racial socialization) parenting practices via videotaped vignettes and group discussions designed to foster social support. Adolescent sessions focus on topics such as dealing with difficult situations (e.g., racism), images of risk behaviors, and peer pressure resistance strategies via games and activities. Family sessions reinforce the messages from parent and adolescent sessions and build mutual understanding and communication. Each session includes videotapes of African American family interactions that were specifically produced for the SAAF program to illustrate key points. Further, each participating family receives program worksheets, homework assignments, and publications designed to reinforce program content. Every session includes a review of homework, didactic presentation of information, group discussion, and skills training activities designed to reinforce learning.

The SAAF program was evaluated by randomizing counties in the rural South to either the SAAF condition or a minimum-control condition in which parents were mailed information about early adolescent development, stress management, and techniques to promote exercise. Pretest assessment occurred prior to SAAF exposure, followed by 3-month posttest, with follow-up assessments at 9, 27, 54, and 65 months postintervention. The trial included 677 families with an 11-year-old child and has yielded favorable behavioral outcomes and supported SAAF's efficacy in delaying sexual debut and substance and drug use avoidance 54 months postintervention (Murry, Berkel, Brody, Miller, & Chen, 2009), with sustaining effects 65 months postintervention (Murry, Berkel, Pantin, & Guillermo, 2011) among SAAF youth. The researchers tested the mediating mechanisms of the program and found that participating in SAAF evoked increases in regulated-communicative parenting and intrapersonal protective processes in youth (racial identity, self-esteem, self-regulation, and positive self-image). SAAF-induced effects on parenting behavior deterred not only precursors to risk behavior, such as risk-related attitudes, future orientation, self-regulatory capacity, and resistance efficacy, but also immediate HIV-related risk behavior, including early onset of substance use and sexual intercourse and alcohol use trajectories (Berkel et al., 2009; Brody, Murry, Gerrard, et al., 2004; Brody, Murry, McNair, et al., 2005; Murryet al., 2011; Murry et al., 2012;).

Mexican/Mexican American Keepin' It R.E.A.L.

Mexican/Mexican American REAL is a school-based program to reduce drug/substance use, alcohol use and other risky behaviors that included a multicultural version and a specific adaptation of Keepin' It R.E.A.L.! for Hispanic youth. The developers describe the program as a culturally grounded intervention (Hecht et al., 2003) because the core elements of the curriculum were selected and designed to specifically reflect narratives and stories of indigenous youth (Hecht, Graham, & Elek, 2006). The curriculum focuses on five core components: communication competence, narrative knowledge, motivating norms, social learning, and resistance skills. In addition, cognitive skills, appropriate behaviors, and communication for effective use of four "REAL" resistance strategies (*r*efuse, *e*xplain, *a*void, and *l*eave are emphasized (Kulis et al., 2005).

Multiple strategies were used to adapt the curriculum to fit the ecological culture of the targeted audience. Each session was translated into Spanish for the Mexican American version, while English was the language included in programs targeting White and African American youth. Local youth were involved in the production of curriculum videos, as part of the development team, and also served as actors for the videos. Examples from local mass media also were included as supplemental materials. For the boosters, activities were added that were developmentally appropriate for eighth graders, such as group poster projects, mural paintings, neighborhood nights out, and an essay contest (Kulis et al., 2005). The adapted curricula were subsequently tested on the three ethnic groups.

Three versions of Keepin' It R.E.A.L. were taught by trained classroom teachers of seventh graders in an efficacy trial to address the question as to which version was most effective for Mexican American youth: a Mexican American–focused version, a White and African American version, and a multicultural version. The program was delivered in ten 40- to 45-minute sessions to a sample of 3,402 seventh graders from 35 middle school in Phoenix, Arizona (Hecht et al., 2006; Kulis et al., 2005). Participants in the multicultural version received half of the lessons from the Mexican American–focused version and the other half from the White and African American version. After the intervention sessions were conducted, the youth in the intervention group received monthly boosters for the following year. Youth in the control group were not

exposed to programmatic materials or information. Data were collected at four time points, with a pre-intervention survey and three follow-up surveys. Results revealed significant reduction in substance and drug use, intentions for future drug/substance use, and positive images of peers who use drug/substance among participants across each of the program versions. Further, Hecht et al. (2006) noted that Mexican youth exposed to the program, regardless of version, delayed onset of drug/substance use and reported lower rates of increase in drug/substance use, over time, compared to youth in the control groups. On the contrary, the White and African American version had no significant effect. The authors highlighted the importance of cultural inclusion rather than exclusion in program content, targeting risk reduction among Mexican American youth. The positive behavioral outcomes manifested in a multicultural risk prevention curriculum suggests that programs narrowly tailored to each specific subgroup, in this instance Mexican Americans, may not be necessary.

Familias Unidas

Familias Unidas is a preventive intervention for Hispanic youth based on ecodevelopmental theory (Pantin, Schwartz, Sullivan, Prado, & Szapocznik, 2004) that promotes four major family processes that are protective against substance use and unsafe sexual behavior: positive parenting, parent-adolescent communication, parental involvement, and family support (Pantin et al., 2003; Prado et al., 2007). Consistent with Hispanic cultural expectations, Familias Unidas places parents in positions of leadership and expertise in helping to prevent problematic outcomes in their adolescents.

Familias Unidas has been evaluated in two separate RCTs, and a third and a fourth are ongoing. In the first RCT, Pantin, Coatsworth et al. (2003) found that Familias Unidas was efficacious (in a sample of 167 Hispanic youth), relative to a no-intervention control group, in (a) increasing parental involvement, parent-adolescent communication, and parental support for the adolescent; and in (b) reducing adolescent behavior problems, a risk factor for drug use and HIV risk behaviors. Results also indicated that increases in parental investment were related to decreases in behavior problems. In the second RCT, Prado et al. (2007) evaluated the efficacy of Familias Unidas relative to a family-centered HIV preventive intervention and a family-centered adolescent cardiovascular health intervention over a 3-year period. The results of the study found that, over time, Familias Unidas was efficacious in reducing illicit drug use relative to the cardiovascular preventive intervention. Familias Unidas was also found to be efficacious in reducing cigarette use over time when compared to both the HIV preventive intervention and the cardiovascular preventive intervention. Finally, Familias Unidas was efficacious in reducing unprotected sexual behavior and preventing the incidence of sexually transmitted diseases. The effects of Familias Unidas on smoking and illicit drug were partially mediated by improvements in family functioning. Specifically, improvements in positive parenting (reward contingencies offered by parents) and in parent-adolescent communication explained some of the effects of intervention condition on cigarette and illicit drug use.

CHAMP Family Program

CHAMP was designed in close collaboration with community members, who played major roles in the program's design, implementation, and evaluation to reduce HIV risk among urban African American adolescents (McKay et al., 2004). CHAMP utilized a community participatory approach and framework to design, develop, and implement the program. The framework focuses on several core principles: (a) linking collaborators from outside and within a setting to design a program; (b) creating a stakeholder advisory group to oversee program activities; (c) designing programs that integrate scholarly and indigenous knowledge and perspectives relevant to a setting to shape prevention messages and activities; and (d) using credible messengers, such as those already connected to a setting, to implement interventions in their own neighborhoods (Baptiste et al., 2006).

All CHAMP participants (n = 227 families) were chosen randomly from a roster of 550 youth attending four inner city public elementary schools. Families were recruited via research staff making presentations to fourth- and sixth-grade classes, personal contact with parents at schools, telephone calls, or home visits to parents. As with other family-based interventions, CHAMP was designed as a multiple-family group format. This delivery format was thought to be especially useful in increasing social support and mutual aid, creating strategies to deal with common problems, and reducing the stigma associated with talking about sensitive issues (McBride et al., 2007). The format is somewhat unique in that pretest data collection occurs in session 2, after the participants have had the opportunity to meet facilitators and other families and find out more about the goals of the program. Posttest data collection occurs in session 11, before the celebration in the final session. In the non–data collection sessions, families meet for 20 minutes to discuss the topic of that night's meeting and then break out for 45-minute concurrent parent and

child sessions. In youth sessions, participants learn and role-play peer-pressure scenarios and communication with parents. The parent sessions focus on monitoring, social support, problem solving, and communication with young people about sensitive topics. At the conclusion of each meeting, parents and children reconvene to make an action plan for their home practice activities.

CHAMP was initially evaluated with a pretest-posttest design that included a no-treatment comparison group from the CHAMP longitudinal study (McKay et al., 2004). Results from parents demonstrated a positive increase in family decision making relative to the comparison group, as did comfort in communicating about sensitive topics with their children. Among adolescents, those in the intervention group were less often exposed to mixed-gender settings without parental supervision (McBride et al., 2007). Youth in the intervention condition reported higher family conflict, perhaps because the intervention encouraged them to communicate more with their parents about sensitive topics. In addition, CHAMP has demonstrated effects on externalizing behaviors. Moreover, the CHAMP Family Program has been adapted for and piloted in several other contexts, including HIV-positive youth (McKay et al., 2007), in multiple international settings, such as South Africa (Bell et al., 2008) and Trinidad and Tobago (Baptiste, Voisin, Smithgall, Martinez, & Henderson, 2007). The program developers attribute positive results to the use of core community participatory principles to inform and guide efforts to refine a disease prevention and health promotion model and to refine research methods that embed culture as well as context in the design, development, and implementation of the CHAMP program.

The initial CHAMP outcome study did not include a control arm, but subsequent adaptations of the program have added experimental control comparisons, showing continued strong programmatic effects on increased HIV transmission knowledge, less stigmatizing attitudes toward people with HIV, increased sexual conversation between parents and youth, and increased community protective influences, via more social control and the promotion of social action to foster health-enabling communities for youth (McBride, Baptiste, Traube et al., 2007).

Puentes a la Secundária/Bridges to High School

Puentes a la Secundária/Bridges to High School (Puentes/Bridges) is a family-based program originally intended to prevent mental health disorders and prevent school dropout among Mexican American adolescents attending schools in low-income, urban communities (Gonzales, Dumka, Millsap, et al., 2012); however, it also produced reductions in adolescents' overall substance use, sexual risk taking, and alcohol use disorder (Germán, Gonzales, West & Dumka, in review; Gonzales et al., 2012; Gonzales, Jensen, Wong et al., in review; Gonzales Wong, Toomey, Millsap, Dumka, & Mauricio, 2014; Jensen, Wong, Gonzales, et al., 2014). Content and structural elements of Puentes/Bridges were based on: (a) qualitative interviews and focus groups with Mexican-origin families including Spanish-speaking and English-speaking parents who were born in the United States or Mexico; (b) key informant interviews with school personnel and service providers; (c) more than a decade of programmatic, longitudinal research on risk and protective processes within the targeted communities (Dumka, Gonzales, Woods, & Formoso, 1998; Gonzales, Dumka, Mauricio, & Germán, 2007); and (d) extensive pilot testing and refinement with schools and families in these communities (Dumka et al., 1998; Gonzales, Dumka, Deardorff, Jacobs-Carter, & McCray, 2004). The program's nine weekly sessions and two home visits targeted parenting practices, child coping, family cohesion, and school engagement. Puentes/Bridges was guided by an ecodevelopmental framework (Szapocznik & Coatsworth, 1999) that recognizes unique cultural factors and experiences that impact youth development at multiple levels and the challenges they encounter in their families, neighborhoods, and schools and with peers. In particular, school engagement can be a challenge for Mexican American youth in the United States. For example, since 1980, Mexican Americans have had the lowest rates of high school completion compared to Whites, Blacks, Asian, and Pacific-Islander groups and also compared to youth from other Latino groups (U.S. Census Bureau, 2010). Mexican American youth in low-income communities find it difficult to envision positive future possibilities (possible selves) in a context of low-wage jobs, unemployment, experiences of discrimination, and reduced expectations directed at them (Oyserman & Markus, 1990). These constraints combine with other features of low-income communities, such as the availability of drugs, deviant peers, and parents' diminished capacity for effective parenting, to reduce investment in education and increase risk for mental health problems (Barrera et al., 2002). Immigrant youth also encounter cultural conflicts in their schools and families, and their parents often have a poor understanding of U. S. schools and are therefore ill prepared to monitor and intervene when they have academic difficulties (Suarez-Orozco & Suarez-Orozco, 1995). Puentes/Bridges aimed to promote family and youth competencies shown in the general literature to protect against youth risk behaviors while also

empowering families to address these unique challenges and support their adolescents' school engagement across the middle school and high school years. In addition to program content specifically designed to increase knowledge and engagement of families in promoting their adoelscents' educational success, the program integrated the values of *familismo* (e.g., strong orientation and commitment to family) through both content (cohesiveness, coparenting, adolescent family support seeking) and structure (recruiting multiple caregivers, joint sessions with parents and children). Furthermore, traditional values were used as a motivational tool to encourage parents and adolescents to internalize and incorporate elements of the program into regular practice (Gonzales et al., 2007).

Puentes/Bridges was evaluated via an RCT with 516 families from four middle schools in Phoenix, Arizona (Gonzales et al., 2012). An efficacy trial showed desired effects on adolescent externalizing, internalizing, substance use, school disciplinary actions, and grades and also provided evidence that these effects were mediated by targeted changes in parenting, adolescent coping efficacy, family cohesion, and school engagement. However, tests of moderation also showed that effects on program mediators varied on the basis of family acculturation level. Greater changes in parental monitoring and family cohesion were found for more acculturated English-dominant families, whereas the less acculturated Spanish-dominant families showed greater intervention effects to reduce harsh parenting and to increase adolescent coping efficacy and school engagement. Patterns of engagement also varied, with less acculturated families enrolling and attending at higher rates. However, despite acculturation-related differences at immediate posttest, long-term follow-up showed similar improvements across groups on the quality of parent-child relationships (Jensen et al., 2014) and school engagement (Gonzales et al., 2014) following transition to high school (ninth grade), and these changes mediated subsequent effects to reduce internalizing and externalizing symptoms substance use, diagnosed alcohol use disorder, and school dropout at 5 years posttest when most adolescents were in the twelfth grade (Gonzales, Jensen, Wong et al, in review).

Be Proud! Be Responsible!

Be Proud! Be Responsible!, developed by Jemmott, Jemmott, and Fong (Jemmott, 1992; Jemmott, Jemmott, Fong, & McCaffree, 1999; Jemmott, Jemmott, Fong, 2010), was designed to increase minority youth knowledge on sexually transmitted diseases (STDs), HIV, and acquired immune deficiency syndrome (AIDS); to affect their attitudes and beliefs about safer sex (condom use and other prevention strategies); to inspire their understanding on individuals' vulnerability to STDs, HIV, and AIDS; and to build their skills on negotiation and resistance to risky sexual behaviors. This culturally grounded intervention was subsequently adapted and evaluated with different ethnic groups and subpopulations. Be Proud! Be Responsible! The African American Male version (Jemmott, 1992) sampled 157 Black male adolescents (mean age 14.4 years) from three sites in Philadelphia, Pennsylvania: a medical clinic, a local high school, and a local YMCA. Following a pretest evaluation, a total of 27 small groups were formulated of which 14 were assigned to the intervention condition and 13 to the control condition. Both conditions consisted of small group interventions lasting 5 hours in which the curriculum was delivered via videotapes, small-group discussions, exercises, and games. Prior to program implementation, curriculum materials were pilot tested and revised to fit the interests of African American boys in urban regions. Although limited information was provided about specific adaptations for African American males, it appears that the cultural tailoring primarily involved the use of African American images in the videos and a gaming format to deliver program content. For example, they revised the AIDS knowledge content to be delivered as "AIDS Basketball," with the game organized around how to avoid risky sexual behaviors. The program developers also characterized the selection of program implementers as evidence of cultural tailoring; all were African American adults with at least a 4-year college degree and were employed as educators, social workers, or health professionals. Posttests were administered immediately after the intervention, and a follow-up assessment was conducted 3 months later. Findings revealed that intervention targeted youths reported greater change in AIDS knowledge, less favorable attitudes toward risky sexual behaviors, and fewer intentions to participate in such behaviors. Intervention effects remained significant at 3 months follow-up.

Be Proud! Be Responsible! The New Jersey version (Jemmott et al., 1999) targeted 496 African American youth (male and female) residing in Trenton, an economically distressed urban community with high prevalence rates of unintended pregnancies and sexually transmitted infections (STIs). The participants were recruited from local public schools in seventh and eighth- grades (mean age 13.8 years). Similar to the original version, the students were randomly assigned to the intervention groups (HIV reduction intervention) and the control groups (general health promotion intervention). Each small group

contained six to eight adolescents, with youth attending a 5-hour session in one day. The intervention targeted "hedonistic beliefs about the positive consequences of condom use on sexual enjoyment and self-efficacy to implement condom use" (Jemmott et al., 1999, p. 168). Prior to implementation, this curriculum was pilot tested to ensure that the program content and activities were sensitive to urban African American adolescents' interests. For instance, the videos selected for the program included multiethnic actors talking about AIDS, such as Ruben Blades, a Latino actor, demonstrating how to put on a condom using a banana as a prop (Jemmott et al., 1999, p. 168). Participants in the general health promotion intervention groups were taught about nutrition, exercises, and diseases. Local African Americans were hired to deliver the program. Posttest data collection occurred immediately after the intervention, and follow-up tests were conducted 3 and 6 months postintervention. Results from the immediate postintervention test revealed more positive beliefs about condom uses, stronger condom use intentions, and higher self-efficacy among the participants in the intervention groups compared to those assigned to the control condition. However, no group differences on targeted behaviors were observed at 3-month follow-up. Finally, the 6-month follow-up tests found decreased HIV-related unprotected sexual behaviors and fewer sexual partners compared with youth in the general health promotion intervention groups.

The Children's Health and Responsible Mothering—Project CHARM

The Children's Health and Responsible Mothering—Project CHARM is another adaptation of Be Proud! Be Responsible! specifically designed to reduce repeated pregnancy among Hispanic and African American adolescent mothers. CHARM is based on the core elements of Be Proud! Be Responsible! Project, which aims to reduce the number of episodes of unprotected sexual intercourse and number of sexual partners as well as to facilitate increased willingness and intentions to use condoms in order to prevent repeated pregnancies (Koniak-Griffin et al., 2003). A total of 572 adolescents, age 16.7 on average, who were mothers or pregnant were recruited, with a total of 497 retained for all the data collection cycles. The evaluation sample was primarily Hispanic (78%), with a smaller representation of African American females (18%). Youth were grades 7 through 12 from four school districts in Los Angeles County, California. Schools were randomly assigned to treatment (HIV program) or control conditions (general health program). Each program consisted of four 2-hour sessions.

Compared to the original curriculum, Project CHARM focused more on the impact of STDs and HIV on the lives of pregnant girls and their babies, including STI prevention during pregnancy and the importance of avoiding risky sexual practices postpartum. Similar to the original program, supplemental materials included culturally and developmentally relevant videos, skill-building activities, and role-playing. In addition, an HIV-infected adolescent mother was invited to speak in the second intervention session to motivate participants to make healthy sexual decisions and to encourage them to be sexually responsible and accountable as well as politically aware of the effects of HIV/AIDS on inner-city communities and their children (Koniak-Griffin et al., 2003). Assessment occurred immediately after the intervention sessions ended, followed by 3-month, 6-month, and 1-year postintervention assessments. Findings revealed that at 6-month follow-up, compared to females in the control group, those assigned to the HIV program demonstrated greater change in AIDS knowledge, scored higher in behavioral intentions to use condoms, and reported greater reduction in number of sexual partners.

Following several demonstrations of positive program effects with varying subpopulations in the context of efficacy trials, Jemmott, Jemmott, Fong & Morales (2010) launched an implementation effectiveness trial of Be Proud! Be Responsible! wherein members of community-based organizations (CBOs) were randomly assigned to different training conditions to test the role of different program implementation training strategies on intervention effectiveness. The Be Proud! Be Responsible! effectiveness trial was a implemented through CBOs with 1,707 youth age 13 to 18 residing in Philadelphia, Pennsylvania, and Trenton, New Jersey. There were three training conditions: (1) CBOs received the two project manuals (HIV prevention and health and wellness curricula) and no face-to-face training; (2) CBOs received the project manual and attended a 2-day face-to-face training session; and (c) CBOs received the project manual, 2 days of training on the manual, followed by a practice intervention-implementation session and 2 days of additional training in which program implementers were videotaped and received feedback on their intervention implementation practice sessions. Similar to their other program designs, Jemmott et al. randomly assigned youth to one of two conditions: Youth in intervention group received the HIV/AIDS prevention program, and those in the control group received general health promotion intervention sessions. Subsequently, trained CBOs at each site were randomly assigned to each youth group.

Preintervention data were collected and follow-up tests were administered at 3, 6, and 12 months postintervention exposure. However, results revealed no statistically significant program impacts on frequency of sexual intercourse in the past 3 months or condom use at last intercourse, and there were no effects of training condition on intervention effectiveness. The researchers concluded that there was no evidence that the amount of time training community members improved facilitators' efficacy in program delivery. Further, they offered several explanations for lack of significant program effects. First, they surmised that there may have been a selection bias among CBOs, as many who declined to participate held strong values about teaching abstinence that conflicted with the program's philosophy. Further, they speculated that the community-based delivery site may have affected study findings as prior school-based evaluations consistently showed expected benefits on risk behaviors for youth that received the intervention compared to those in the control group.

Respeto/Proteger

The Project Respecting and Protecting Our Relationships (Respeto/Proteger) is an adapted version of Be Proud! Be Responsible! designed to prevent HIV/AIDS among Latino adolescent couples who are new parents. The program focuses specifically on enhancing parental protectiveness as a mechanism to foster resiliency and motivate youth to reduce risky sexual practices (Lesser, Koniak-Griffin, Huang, Takayanagi, & Cumberland, 2009). Respeto/Proteger was informed by results from Project CHARM, which revealed that young Latino mothers felt less empowered to negotiate condom use, compared to their male partners. Lesser, Koniak-Griffin, Huang, Takayanagi, and Cumberland (2009) concluded from these findings that there is a need to include young fathers in pregnancy and sexual risk reduction program to increase sexual protection among young mothers.

Adolescent mothers and their partners were recruited from 28 Women, Infants, and Children (WIC, a federal assistance program of the Food and Nutrition Service of the United States Department of Agriculture (USDA) for healthcare and nutrition of low-income women, infants, and children) sites, eight alternative schools, two community-based organizations, and one community-based clinic in Los Angeles (Lesser et al., 2009, p. 92). Through randomization, 84 couples were assigned to the treatment condition and 86 couples were assigned to the control condition. The mean age was 20 years for males and 18 years for females; 78% of the male parents and 86% of the female parents were Latino. Young parents in the intervention group received a 12-hour curriculum (six 2-hour sessions) while their counterparts in the control group received a 1.5-hour didactic HIV prevention education program. A total of 41 program series were held in local settings, such as CBOs and health clinics. Evaluative surveys were conducted at pre-intervention, immediately after the intervention, and during follow-up periods.

Respeto/Proteger program design and development were informed by qualitative data received from Latino mothers attending health promotion projects for young mothers, and intervention approaches and strategies adopted from Project CHARM, Project EL Joven Noble, and Project Con los Padres. The Project EL Joven Noble and Project Con los Padres were programs designed to influence Latino youth understanding of romantic relationships, the "macho" man stereotype, and strategies to deal with daily challenges. Prior to implementing Respeto/Proteger, the program was pilot tested with groups similar to the targeted audience. Programmatic changes were made based on pilot test results. Findings revealed that the couples, both adolescent mothers and their partners in the intervention arm of the study, reported less unprotected sexual behaviors 6 months after the intervention sessions. Further analysis indicated that, compared to the adolescent mothers in the control group, those in the intervention group whose male partner scored higher on protectiveness at the baseline reported even less unprotected sexual behaviors. Interestingly, female protectiveness did not show significant influences on males' unprotected sexual behaviors.

¡Cuídate!

¡Cuídate! (English translation means: take care of yourself) is a program to increase parent-child communication about sex in Mexican-heritage families (Villarruel, Cherry, Cabriales, Ronis, & Zhou, 2008). The theory of planned behavior was combined with a focus on Mexican cultural values, including familism and religiosity, in the design of the program. Familism was utilized as a motivational impetus to frame the importance of talking with children about sex. Religiosity was considered for its influence on decision making about sexual behavior, for example, whether to address condom use or abstinence. The 6-hour program was conducted with separate sessions for parents and adolescents on two consecutive Saturdays. The intervention group (n = 404) was provided with information about the prevention of HIV and pregnancy as well as support for general and sexual communication with children. The control group (n = 317) received a 6-hour general health intervention, which also emphasized the principal

role of parents in determining adolescents' health but did not discuss parent-child communication. Both groups were assigned homework to complete with their adolescents. Participants in the intervention group reported more communication, communication about sex, and comfort in communication than parents in the control group. Moreover, this effect was mediated by the perceived utility of communication about sex; attitudes of the adolescent, family, and church related to communication about sex; and parents' comfort in discussing sex with adolescents. Effects were not moderated by familism, religiosity, or the gender of parents or children.

Discussion

Several observations emerged from our review of youth risk prevention programs. The majority of programs were delivered and tested in school based settings, with a significant proportion using community- and family-based approaches, and the majority of programs included multiple intervention components. Our review also revealed that the majority of programs targeting African Americans and Hispanics were designed to prevent risky sexual behavior and its consequences (e.g., STIs and HIV/AIDS). The program targeting Native American youth focused solely on substance and drug use prevention. Findings are generally positive in showing that these programs fostered significant reductions in risky sexual practices, increased sexual and HIV/AIDS knowledge, and reduced youth intentions to participate in risk behaviors, including reduced intent to use drugs/substances. Evidence of condom use and positive attitudes about condoms as a means for protecting against unintended pregnancies, STIs, and HIV was also noted. We also can conclude these programs foster sustained effects, extending from 12 months to 6 years after the intervention, on outcomes such as sexual debut, substance and drug use, number of sexual partners, and diagnosed substance use disorder. Thus, our review offers support for the usefulness of culturally tailored programs to prevent the consequences of early sexual activity onset and substance and drug use among youth of color. Finally, while each of the programs included in our review focused on the prevention of sexual initiation, there was a lack of consideration given to the inclusion of culturally tailored alcohol and substance use programs for youth of color.

Content of Adaptations: Beyond Surface Structure

In contrast to adaptations of PT interventions that have augmented well-established EBIs previously validated with White samples, the majority of programs reviewed here were originally designed and developed for targeted youth of color. Only two programs, Life Skills Training (Botvin et al., 1990, 1995, 2001) and the SFP (Spoth, Redmond, & Shin, 2001), were first evaluated with White youth prior to being adapted for other ethnocultural groups (African American and Hispanic). In addition, our review determined that 10 of the 16 programs emerged from culturally grounded strategies involving extensive, in-depth community involvement and input on program design, measures, and various aspects of the program's deep structure. The integration of cultural values, beliefs, norms, and information about legacy and ancestry were apparent in most of the adapted and culturally grounded program. In addition, role-playing, role models, the use of storytelling, and the inclusion of culturally relevant materials, videos with images familiar to targeted audiences, and games were incorporated in the cultural adaptations. A noteworthy observation, however, is that none of the studies in this review, with the exception of SAAF program developers (Berkel et al., 2009; Murry, McNair, Myers et al., 2014), included measures to assess cultural dimensions in summative assessments of program effects.

Subgroup Differences

Our review also revealed evidence of subgroup differences in program responsiveness. For example, the Aban Aya Youth program demonstrated greater improvements in sexual risk and drug reduction among males than females. Projects that involved both teen mothers and fathers indicated that the intervention is more effective on the young fathers for condom use. In the one study that examined within-group variability based on culture, Puentes/Bridges showed differences in levels of engagement and program effects between low-acculturated (primarily immigrant Spanish-speaking) and high-acculturated (English-speaking) families. However, it was noteworthy that similar long-term effects on targeted mental health, substance use outcomes, and school dropout were found across levels of acculturation, suggesting that diverse families may benefit in different ways, depending on their unique needs when participating in comprehensive, multicomponent interventions. This finding underscores the need for greater attention to within-group variability in tests of efficacy and effectiveness in order to determine whether and how EBIs can address subgroup differences for racial/ethnic groups that are neither monolithic nor static on cultural dimensions.

Remaining Gaps and Questions

To further advance this area of research, there is a need to address several gaps and unresolved questions. Several groups are not visible in preventive intervention research—namely Alaska Native, Asian Americans, and Asian Pacific Island adolescents. No programs targeting these youth emerged in our comprehensive literature search, and very few have been evaluated with American Indian youth. American Indians and Alaska Natives are disproportionately affected by all major youth risk behaviors, including alcohol, tobacco, drug use, risky sex, and suicidal behaviors. Further, available studies have shown that while Asian Pacific Island youth are less likely to engage in risky sexual practices than any other group of adolescents (Grunbaum, Lowry, Kann, & Pateman, 2000), when this population has been included, findings reveal greater endorsement of having used alcohol or drugs at last intercourse compared to other racial/ethnic groups. Sexual risk protection was comparable to other ethnocultural groups in reports of using a condom at last intercourse. That there is a major void in targeting these subgroups in preventive interventions is of great concern. That the majority of risk prevention programs have been developed and tested on urban youth suggests the need to determine how to translate these programs in rural contexts. This information can further our understanding of the utility of developing programs to specifically address the needs of rural youth. The paucity of studies in our review that targeted rural youth is of concern, given that rural youth are at increased risk for using a variety of substances, including tobacco (Zollinger, Saywell, Overgaard, Przybylski, & Dutta-Bergman, 2006), alcohol (Hutchison & Blakely, 2003), and methamphetamines (Johnston et al., 2009). Several researchers have noted that rural Whites, especially those living in the Appalachian region, appear to be at greater risk for early onset of substance use than their more frequently studied urban counterparts (Johnston et al., 2009; Pruitt, 2009; Spoth et al., 2001; Zollinger, Saywell, Overgaard, Przybylski, & Dutta-Bergman, 2006). Not only are these youth infrequently included in epidemiological studies, but, to our knowledge, few programs specifically target White youth residing in southern rural communities.

Finally, only one study included in the current review directly compared whether a culturally adapted program is more effective than a generic or multicultural program (Keepin' It R.E.A.L.), and the findings did not support the cultural adaptation with Hispanic youth. Notwithstanding these limitations, our review offers support that it is possible to provide effective programming for youth from a variety of cultural backgrounds with proven, culturally generic, evidence based programs. However, it remains unknown when, how, for whom, and under what circumstances culturally tailored youth risk prevention program will foster targeted programmatic effects.

PREVENTION OF ANXIETY AND MOOD DISORDERS

Anxiety and mood disorders are prevalent among children and adolescents, causing significant impairment at home, with peers, and at school (e.g., Kessler, Avenevoli, & Merikangas, 2001; Pina, Zerr, Gonzales, & Ortiz, 2009). Data from the National Comorbidity Survey Adolescent Supplement showed that among youth 13 to 17 years old, anxiety disorders were the most prevalent class of disorders (24.9%) with mood being the third most prevalent class of disorders (10%) (Kessler et al., 2012). In addition, Kessler, Avenevoli, and Ries Merikangas's (2001) seminal review of epidemiological and large-scale prospective longitudinal studies (e.g., Costello, Angold, & Keeler, 1999; Kovacs, Gastonis, Paulauskas, & Richards, 1989) revealed that anxiety disorders were not only the conditions most commonly comorbid with depression but that about three-fourths of depressed youth had a history of at least one anxiety disorder. There also are data suggesting some variations in the prevalence and co-occurrence of anxiety and mood problems (e.g., age, sex), albeit epidemiological or large scale studies focusing on ethnicity-race are scant.

In the adult literature, for example, Karnoet al. (1989) found that the lifetime prevalence for any anxiety disorder was higher among U. S.-born Mexican Americans compared to Mexican Americans born in Mexico (22.6 versus 13.7), based on the Los Angeles Site of the National Institute of Mental Health Epidemiologic Catchment Area study. In another study using data from the National Epidemiologic Survey on Alcohol and Related Conditions, Grant et al. (2004) found that the lifetime prevalence of any anxiety disorder was higher for U. S.-born Mexican Americans (16.3%) than for foreign-born Mexican Americans (9.1%). In addition, for any mood disorder, the lifetime prevalence was higher for U. S.-born Mexican Americans (19.3%) than for foreign-born Mexican Americans (10.2%). Turning to the National Health and Nutrition Examination Survey-III, Riolo, Nguyen, Greden, and King (2005) found that Mexican Americans and Caucasians had a significantly earlier onset of major depressive disorder compared to African Americans. In addition, education (less than 8 years of school) was associated with

major depressive disorder for Mexican Americans only. Also, dysthymic disorder was greater among Mexican Americans and African Americans, even after controlling for the effects of poverty and education. (No age by ethnicity data were presented, albeit the youngest responders were 15 to 19 years old.) No comparable research focusing on Native Americans and Asian Americans has examined variations in the prevalence and co-occurrence of anxiety and mood problems.

When it comes to ethnic minority children and adolescents, there also is a scarcity of anxiety and depression disparities research from large-scale and methodologically robust studies; the little work that has been conducted has focused on African American and Hispanic/Latino youth. Bird (1996), for example, reported prevalence rates of psychiatric disorders in children and adolescents (age 4–16 years) in Puerto Rico. Findings showed that depression was the second most common diagnosis (5.9%) with only separation anxiety disorder and specific phobias emerging from the anxiety disorder modules at 4.7% and 2.6%, respectively. More recently, Alegría et al (2012) reported data from the National Comorbidity Survey Adolescent Supplement. Findings showed that for non-Latino Black youth, the lifetime prevalence of separation anxiety disorder was significantly higher (10.8%) compared to non-Latino Whites (6.8%) or Latinos (7.9%). No additional differences relevant to ethnicity and anxiety-depression were found.

The high prevalence of anxiety and depressive disorders in children and adolescents (Costello, Egger, & Angold, 2005), coupled with the fact that these conditions also are typically chronic and lead to significant impairment (including early initiation of the use of alcohol, tobacco, and other illicit drugs; Conger & Rueter, 1996; Glantz & Leshner, 2000), has prompted much interest in developing EBIs (Beidel & Turner, 2007; Silverman, Pina, & Viswesvaran, 2008). In addition, data showing some ethnic variations in the prevalence of these disorders prompted some research focused on culturally adapted interventions focused on reducing and preventing disparities in these psychiatric conditions among youth (Cardemil, Reivich, & Seligman, 2002; Cooley-Strickland, Griffin, Darney, Otte, & Ko, 2011).

In the clinical child and adolescent area, several randomized, controlled prevention trials have been published at the universal, selective, and indicated levels focusing on anxiety and/or depression. In the anxiety area, most anxiety prevention studies have been conducted at the universal level, and only a handful of studies have tested selective or indicated protocols. Indicated programs have been directed at children due to a family history of anxiety (Ginsburg, 2009), a known predisposition (e.g., behavioral inhibition; Rapee, Kennedy, Ingram, Edwards, & Sweeney, 2005), or some anxiety symptoms (Pina, Zerr, Villalta, & Gonzales, 2012). Selective or indicated depression prevention programs have been directed to youth at risk for depression due to a family history or diagnosis of depression (Beardslee, Gladstone, Wright, & Cooper, 2003) or exposure to stressors that place them at high risk, such as urban poverty (Cardemilet al., 2002) or the loss of a parent (Sandler et al., 2003). Anxiety prevention strategies show content overlap with prevention protocols, typically focusing on negative cognitions, social skills training, and problem-solving skills (Barrett & Turner, 2001; Dadds, Spence, Holland, Barrett, & Laurens, 1997; Essau, Conradt, Sasagawa, & Ollendick, 2012; Lock & Barrett, 2003; Lowry-Webster, Barrett, & Dadds, 2001; Pina et al., 2012; Simon, Bogels, & Voncken, 2011; Warner, Weissman, Fendrich, Wickramaratne, & Moreau, 1992).

In a nutshell, research shows that pathological levels of childhood and adolescent anxiety and depression may be preventable. Using meta-analyses, Fisak, Richard, and Mann (2011) found a significant overall mean weighted effect size of about .18 as well as a slightly greater effect for targeted (i.e., selective or indicated) anxiety prevention over universal protocols. In another meta-analysis, Teubert and Pinquart (2011) found significant effect sizes on anxiety at posttest (about .22 for symptoms and .23 for diagnoses) and follow-up (about .19 for symptoms and .32 for diagnoses) as well as significant variations of program effects, giving targeted programs an advantage over universal programs. When it comes to the prevention of depression, targeted (selective/indicated) programs also appear to be more effective than universal programs. In Horowitz and Garber's (2006) meta-analyses, the pretest-to-posttest effect size for targeted programs ranged from about .23 to .30 compared to only .12 for universal programs. At follow-up, the effect size for targeted programs ranged from about .31 to .34 compared to .02 for universal programs. Similarly, Stice, Shaw, Bohon, Marti, and Rohde's (2009) meta-analyses found an average effect size ranging from .14 to .23 for targeted programs compared to .06 to .04 for universal programs. It is important to note, however, that there was some overlap in the trials included in the anxiety and depression meta-analyses, making these effect size evaluations nonindependent. For example, the FRIENDS for Life program was included in both anxiety and depression meta-analyses (e.g., Barrett, Farrell, Ollendick, & Dadds, 2006). Nonetheless, based on these findings, preventing anxiety and depressive disorders appears to be both an

effective and an efficient way to reduce the incidence of these psychiatric conditions, especially when the protocols are targeted.

Cultural Adaptation and the Prevention of Anxiety and Depression

Despite the promising overall effects of childhood anxiety and depression prevention programs, evidence seems to suggest that prevention efforts need to be strengthened, particularly for ethnic minority or culturally diverse child populations (e.g., Barrett, Sonderegger, & Xenos, 2003; Cardemilet al., 2002; Cooley-Strickland et al., 2011; I. D. Miller et al., 2011). Studies testing cultural adaptations of anxiety and depression prevention programs are far less common than for substance use, externalizing problems, or other youth risk behaviors. In this section we highlight the few prominent exemplars that have been evaluated to date.

The Penn Resiliency Program

The Penn Resiliency Program is a school-based depression prevention program that teaches cognitive and social problem-solving skills to groups of middle school students who might be at risk for developing depressive symptoms by virtue of their low-income status. The program is an adaptation of an EBI established with predominately middle-income Caucasian children (Gillman, Reivich, Jaycox, & Seligman, 1995) that Cardemil et al. (2002) applied to low-income African American and Latino children. In their study, the original structure of the program was maintained, but cultural modifications were made. In particular, the characters and examples used in the program were made culturally and contextually relevant by illustrating the skills in the context of challenges associated with growing up in a single-parent home and managing peer conflict in urban settings. For Latino youth, fewer depression symptoms, negative automatic thoughts, and hopeless thoughts were found from pretest to posttest and at 6-month follow-up. In addition, at the follow-up only, Latino youth also evidenced higher self-esteem over time compared to no-treatment controls. For African American youth, however, findings were not encouraging. There were no differences between the intervention and the control conditions on any of the measures or at any measurement point. At the 2-year follow-up (Cardemil, Reivich, Beevers, Seligman, & James, 2007) Latino youth continued to show program-related gains but African American youth did not. The finding with African American children was interpreted as possibly being related to six potential factors, two of which seem especially plausible: cross-ethnic differential reporting of depressive symptoms and/or differential expression of depression symptoms. However, with no data about the measurement equivalence of the assessment tools used in the study, it is difficult ascertain the viability of these possibilities (Pina, Gonzales, Holly, Zerr, & Wynne, 2012).

FRIENDS for Life (African American Youth)

In another study focusing on African American youth, Cooley, Boyd, and Grados (2004) and Cooley-Strickland et al. (2011) described their adaptation of the FRIENDS for Life childhood anxiety prevention program developed in Australia to prevent anxiety and depression (Barrett et al., 2006). The original EBI is a school-based intervention shown to reduce risk of anxiety disorders by teaching cognitive and emotional skills to cope with feelings of fear, worry, and depression. In the cultural adaptation work of Cooley and colleagues, modifications focused on replacing references specific to Australian culture and including examples relevant to the contexts of inner city African American youth. In terms of language, for example, the word *vegemite* was replaced with *peanut butter*, *sugar glider possum* was replaced with *bat*, and *tucker* was explained as *food*. Also, relaxation exercises were modified, and references to animals indigenous to Australia (e.g., koalas, cattle dogs, crocodiles) were replaced with those found in urban America (e.g., pigeons, mice, dogs, kittens). As far as incorporating the contexts of inner-city African American youth into the intervention, children drew pictures of real-life violence that had occurred in their communities, and examples of incidents relevant to living in violent and chaotic environments (e.g., fights, gangs, drugs, low resources) were integrated into the sessions. In their trial, Cooley-Strickland et al. found no statistically significant program differences compared to waitlist on any of the primary outcome variables including anxiety symptom levels (not even for those children with higher levels of pretest community violence exposure or as a function of the child's sex).

FRIENDS for Life (Aboriginal Children in Canada)

Focusing on Aboriginal children in the West Coast Nations of Canada, I. D. Miller et al. (2011) implemented and tested a culturally adapted FRIENDS for Life protocol. This adaptation focused primarily on cultural enrichments, such as adding a new character (Rusty the Raven) and narrative to facilitate the use of storytelling as part of the protocol. The adaptation also entailed: introducing the craft and use of a medicine pouch decorated with Aboriginal symbols; replacing a support team activity with a circle

of support activity that focused on family, community, culture, and natural and spiritual world resources: and adding a "FRIENDS Wheel" modeled after the medicine wheel. In this study, the FRIENDS program was delivered to elementary school students in Canada (including many Aboriginal children). Findings showed that, for both Aboriginal and non-Aboriginal children, no statistically significant reductions in anxiety levels could be attributed to the intervention.

Acercamiento

Pina et al. (2012) reported on an indicated prevention and early intervention for childhood anxiety trial (about 48% of Latinos who were Spanish speaking and requiring services in Spanish) that included a significant proportion of Mexican-origin families. As such, services were made available in Spanish, and interventionists were trained in a culturally prescriptive protocol (Pina et al., 2009) that calls for personalizing or tailoring program implementation strategies to the unique cultural characteristics of the client. This is achieved by including in the protocol references to norms and values (e.g., *familismo*) that can help the client engage in the use of core program components, such as gradual exposures via motivational procedures. In terms of culture, a focus was on developing cultural enrichments and implementing them prescriptively with high fidelity in the application of standard cognitive and behavioral procedures. The cultural adaptation was conceptualized in terms of program materials and program implementation strategies. In terms of program materials, for example, child and parent handouts were available in Spanish, and cultural enrichments focused on incorporating *dichos* (sayings), proverbs, and refrains that could assist content delivery. In terms of strategies, interventionists were trained both to be attuned to various terminology used by children and families and to use such terminology during the sessions, and to identify "windows of opportunities" to use key cultural values (e.g., *familismo*) potentially relevant to promoting program engagement and practice of program skills, as necessary. Two conditions were compared, "child-only" or "child plus parent," in Pina et al. (2012), based on knowledge gained from parent focus groups and in-depth interviews showing that Mexican-origin caregivers prefer parental involvement in child-focused interventions (similar findings have been reported by others; Dumka et al., 1998), perhaps because Hispanic/Latinos place great emphasis on caregiving and family. Significant program effects were found in terms of child anxiety symptoms based on a diagnostic interview schedule, parent and child rating scales, and clinically significant change, although the child-plus-parent condition showed slightly greater gains in terms of child self-reported anxiety and depression levels as well as parent-reported anxiety symptoms about the child. No program moderation effects were found for ethnicity or language (Spanish versus English).

Discussion: Limited Evidence

Despite efforts made to develop culturally robust anxiety and depression prevention programs, overall findings have been somewhat unsuccessful. This appears to be true when regarding African American children in particular (Cardemil et al., 2002; Cooley-Strickland et al., 2011). In contrast, the evidence for Latino youth seems to be more encouraging (Cardemil et al., 2002; Pina et al., 2012). It is important to highlight, however, that the literature is limited to two studies focusing on African American youth and two studies focusing on Latino youth, both exploratory in nature and lacking statistical power for the analyses conducted. For African American youth, deep-level adaptations might be necessary as current findings are not very encouraging. For example, given the importance African Americans place on the family and the caregiving roles grandparents often play, it might be important to enhance anxiety and depression prevention efforts by providing caregivers with substantial PT sessions that focus on evidence-based mediators of child outcomes (e.g., parenting, family functioning variables). Turning to other groups, there was little to no representation in the literature of programs focusing on Asian and/or Pacific Islander children (Barrett et al., 2003; Yu & Seligman, 2002). Barrett et al. (2003), for instance, implemented the FRIENDS program (original nonmodified version) to former Yugoslavian, Chinese, and multi-ethnic children residing in Australia. At posttest, former Yugoslavian youth in FRIENDS showed greater gains than their Chinese counterparts on self-reported anxiety and self-esteem compared to waitlist (along secondary outcomes measures, FRIENDS showed similar cross-ethnic gains including at the 6-month follow-up). Also, there are no anxiety or depression prevention studies focusing on Native American youth, although there is some encouraging research focusing on the prevention of posttraumatic stress reactions in this population (Goodkind, LaNoue, & Milford, 2010).

As we move forward to advance prevention methods focusing on anxiety and depression among ethnic minority children, it would be important to identify program adaptation parameters beyond language and contextually relevant examples. For example, when it comes to Latino children, it would be important to test the extent to which

cultural values such as *familismo* are likely to enhance program effects. Emerging tailoring work by Beardslee and colleagues (D'Angelo et al., 2009) in the area of depression suggests there might be a need to focus on immigration history, adaptation to the host culture, and consideration of key cultural values (trust, respect) during the intervention. However, substantial data about the impact of these types of modifications have not been published to date (D'Angelo et al., 2009; Feinberg et al., 2012). For Asian American children, focusing on cultural values also might hold promise. For instance, Huey and Pan (2006) reported on a small randomized demonstration trial with clinically anxious/phobic Asian American adults. Findings revealed that Asian Americans benefited slightly more from a culturally adapted protocol that considered traditional Asian values compared to a standard protocol. This was true in terms of catastrophic thinking and behavioral approach, two core features of pathological anxiety. Building on these data, it appears that "culture" might definitely need to be considered when targeting anxiety and depression in ethnically and/or culturally diverse children and adolescents. We caution, however, that it might be possible to saturate a program and distract away from critical change processes by infusing too much culture into an intervention (Pina et al., 2009).

HEALTH-FOCUSED INTERVENTIONS

Health disparities for subcultural group children and adolescents are well documented (Flores, 2010; Flores & Tomany-Korman, 2008). In the most extensive analysis of childhood health disparities, Flores (2010) reviewed 111 articles published between 1950 and March 2007. Consistent with the definition provided by the U. S. Department of Health and Health Services, disparities covered by that review included subcultural group differences in disease prevalence, health outcomes, and access to health care. African American, Asian/Pacific Islander, Latino, and Native American children showed disparities relative to non-Hispanic White children in one or more categories of mortality, injuries and illnesses, obesity, physical activity, proper nutrition, and medical care. Culturally adapted interventions often are initiated with the primary intention of reducing disparities by promoting cultural elements that are healthful or modifying those that are associated with health risks. Culture influences health through a variety of mechanisms, such as food preferences, traditional methods of food preparation, celebrations involving food and beverage consumption, perceived desirability of certain body shapes, consumption of alcohol, and norms for physical activity (MacLachlan, 2006). Understanding how culture influences the health of children informs the development of interventions that incorporate cultural beliefs and practices. By focusing on children's health, cultural adaptations of childhood interventions can not only affect proximal child health outcomes but also can change the trajectory of health outcomes into adulthood. There is a developmental component to some health behaviors and illnesses (such as Type 2 diabetes and cardiovascular disease) that justifies early intervention efforts (Berenson, 2002; Guo & Chumlea, 1999; Magarey, Daniels, Boulton, & Cockington, 2003; Must, Jacques, Dallal, Bajema, & Dietz, 1992; Serdula et al., 1992). Thus, it is worthwhile to develop culturally informed health interventions for children and adolescents that reduce health disparities, incorporate an understanding of culture's influence on health, and disrupt risky health behaviors that threaten to extend from childhood into adulthood.

The Cases of Obesity and Physical Activity

Research on the interrelated topics of obesity and physical activity illustrates the need for culturally adapted interventions and their thorough evaluation. Obesity is a prominent preventable risk factor in the major illness categories of heart disease, cancer, and Type 2 diabetes (Eyre, Kahn, & Robertson, 2004). Unfortunately, across various national studies, there are consistent ethnic group disparities on the prevalence of obesity. For adults, the combined prevalence of overweight and obesity was 64.2%, 76.1%, and 75.8% for non-Hispanic Whites, Blacks, and Mexican Americans, respectively (Wang & Beydoun, 2007). For children, African American, Latino, Native American, and some Pacific Islander subgroups (e.g., Filipinos) show elevated rates of obesity when compared with non-Hispanic Whites (Flores, 2010; Wang & Beydoun, 2007). Wang and Beydoun (2007) reported that the combined prevalence rates for overweight and obesity were 28.2%, 35.4%, and 39.9% for non-Hispanic White, African American, and Mexican American children and adolescents. Disparities were particularly apparent for girls. For instance, in their justification for a targeted preventive intervention, T. N. Robinson et al. (2010) noted that since the 1960s, obesity among African American girls has tripled; they differ from non-Hispanic White girls on body mass index (BMI) as young as age 6, and obesity disparities increase as girls mature into adolescence and young adulthood.

There is a suggestion in the literature that disparities on obesity for African American girls cannot be explained

readily by SES differences (Gordon-Larsen, Adair, & Popkin, 2003). Utilizing data from a nationally representative sample of U. S. adolescents, one report focused on a subsample of over 13,000 that included non-Hispanic White, Hispanic, African American, and Asian American males and females who were 12 to 20 years of age. Ethnic-racial disparities were evident in the prevalence of overweight girls: Asian American: 10.37%; non-Hispanic White: 22.24%; Hispanic: 29.59%: and African American: 37.94%. It was particularly interesting that there was a negative relation between overweight status and SES for non-Hispanic White and Hispanic girls but not for African American girls, whose prevalence of being overweight was relatively elevated at higher levels of SES. For African American girls, it appears that factors such as income and education might increase risk rather than lessen risk as they do for other subcultural groups. Subcultural group differences in risk and protective factors are intriguing because they suggest possible differences in modifiable variables that could be included in culturally adapted interventions for childhood obesity (Barrera et al., 2013).

One chronic illness associated with obesity, Type 2 diabetes, disproportionately affects African Americans, Latinos, and Native Americans (Cowie et al., 2006; Fagot-Campagna et al., 2000; Gahagan & Silverstein, 2003) and is a leading cause of death, blindness, heart disease and amputations (Wong et al., 2005). Particularly disturbing are the estimates of the prevalence of diabetes for the next generation, an anticipated development largely attributable to the rise in obesity. Forecasts suggest that for those born in the year 2000, 45.4% of Latino men, 52.5% of Latino women, 40.2% of Black men, and 49% of Black women will be diagnosed with diabetes within their lifetimes (Narayan, Boyle, Thompson, Sorensen, & Williamson, 2003). Those projections are substantially higher than projections for White men (26.7%) and women (31.2%), which are, nevertheless, still disturbing in their magnitude.

Physical Activity

Comparative research on the physical activity of ethnic minority children is less developed than research on obesity (Flores, 2010). When compared with non-Hispanic White youth, African American and Hispanic youth had lower aerobic fitness, less vigorous physical activity among girls, and more television viewing during weekdays (Flores, 2010). Those conclusions were based primarily on findings from the well-known Monitoring the Future annual surveys (Delva, O'Malley, & Johnston, 2006). The report by Delva, O'Malley, and Johnston (2006) used surveys from 1993–19–94 to 2001–2003 for eighth and tenth graders and surveys from 1986–1988 to 2001–2003 for twelfth graders. Results indicated that for boys, only one of 14 grade-by-survey year comparisons on frequency of vigorous physical activity showed ethnic/racial differences. For girls, the results were drastically different. African American and Hispanic girls reported less vigorous physical activity than non-Hispanic White girls on all annual surveys and for all grade levels. For hours of TV viewing, African American and Hispanic boys and girls reported more TV viewing than non-Hispanic White boys and girls on all annual surveys and for all grade levels. These findings indicate the clear need for interventions that are designed to increase physical activity and decrease sedentary behavior among African American and Hispanic children and adolescents.

Exemplary Research Programs Integrating Culture and Children's Health

Several model health interventions illustrated extensive and systematic cultural adaptation efforts. In this section we highlight three that are exemplary in the procedures they implemented to become informed about relevant cultural considerations, integrate those considerations into intervention designs, and then evaluate adapted interventions' engagement and efficacy. Other important controlled studies on interventions designed to improve the diet and physical activity of ethnocultural group children have been conducted, but published reports lack detailed descriptions of cultural adaptation procedures (Crespo et al., 2012; J. N. Davis et al., 2012; de Heer, Koehly, Pederson, & Morera 2011; Klesges et al., 2010; Nadar et al., 1999; Resnicow,Taylor, Baskin, & McCarty, 2005; Treviño et al., 2004; D. K. Wilson et al., 2011).

Stanford GEMS

The Stanford GEMS (Girls health Enrichment Multi-site Studies) was a culturally adapted after-school dance program and an in-home sedentary behavior (television and other screen viewing) reduction intervention for African American girls (T. N. Robinson et al., 2010). Stanford GEMS emphasized physical activity as a means for body weight reduction. The research team described their programmatic research in key articles that contained literature reviews, theoretical considerations, pilot research, and a randomized controlled trial efficacy study (Kumanyika et al., 2003; T. N. Robinson et al., 2003, 2008, 2010). Many features of exemplary cultural adaptation procedures (Barrera et al., 2013) were illustrated in the development of Stanford GEMS.

An initial report described a literature review that identified special considerations for obesity interventions directed at African American youth (T. N. Robinson et al., 2003). The authors noted that because African American girls, family members, and men might be less concerned about thinness than White counterparts, African American girls and women might be less motivated to achieve distal goals of weight loss and fitness. They surmised that intervention activities might need to be intrinsically and immediately appealing to sustain engagement of African American girls. The authors explained the considerations they made in identifying dance as a gratifying, culturally appropriate after-school physical activity. They conducted other extensive formative research that they summarized in this way: "The treatment and control interventions were developed through extensive formative research, including focus groups with girls; focus groups with parents/guardians; written questionnaires; interviews of community youth workers and community leaders; and testing the feasibility of the dance classes and TV reduction lessons with small groups of girls and individual families" (T. N. Robinson et al., 2003, S1–67 to S1–77.).

Cultural adaptations included surface structure elements, such as culturally matched participants and staff and participant-selected music and dance as the featured physical activity. The intervention developers indicated that deep structure elements associated with African American culture (e.g., collectivism, importance of family, present orientation, religiosity, sense of historical racism and prejudice, and use of social support) were infused into the intervention. The early cultural adaptation phases of Stanford GEMS contained a 12-week pilot study (T. N. Robinson et al., 2003), another feature of high-quality adaptation efforts (Barrera et al., 2013). Goals of the pilot were to evaluate the recruitment strategy and participants' satisfaction with intervention activities' and the intervention's effects on BMI, physical activity, screen (TV, video) viewing, and other outcomes. Sixty-one African American girls age 8 through 10 were recruited through community centers and after-school programs in low-income neighborhoods of Oakland and East Palo Alto California. To be eligible, girls had to have a BMI that was greater or equal to the fiftieth percentile for their age group and/or one overweight parent or guardian with a BMI of greater or equal to 25. Girls who were randomly assigned to the active intervention could attend dance classes that were offered 5 days per week at neighborhood community centers. They could attend dance classes as often as they liked for the 12 weeks of intervention. In addition, intervention participants received 5 in-home lessons that were designed to reduce TV and video viewing. Participants assigned to the control condition received a health education program that emphasized healthful eating and physical activity. They also received newsletters containing information about health risks that might lead to obesity, heart disease, and diabetes.

The pilot showed that the researchers were successful in enrolling more than their targeted number of participants, and participants met eligibility criteria. They also retained all but one of the participants over the 12 weeks of the pilot. Satisfaction with the intervention and participation in it were very good with one exception. The lack of affordable transportation in one community resulted in less than half the dance class participation that was achieved in the other community. Due to a lack of power, the intention was to estimate effect sizes rather than to show statistically significant intervention effects. Encouraging effect sizes were found for BMI, waist circumference, physical activity, and TV viewing that favored the intervention condition. Overall, the pilot study demonstrated the feasibility, appeal, and potential efficacy of the combined dance and TV-viewing-reduction intervention.

Ultimately, the Stanford GEMS team conducted a 2-year randomized controlled trial with 261 African American girls and their parents or guardians (T. N. Robinson et al., 2010). As in the pilot, participating girls were between the ages of 8 and 10 and were either overweight or had at least one parent/guardian who was overweight. Participants randomly assigned to the active intervention had access to after-school dance classes 5 days each week for 2 years and received up to 24 in-home sessions for reducing screen viewing. Over the 2-year period, the control condition included health education, monthly newsletters, and quarterly lectures at community centers. Despite the exemplary methods for creating a culturally adapted intervention, extending the intervention period to 2 years, and attracting an adequate number of participants, there was not a statistically significant treatment effect on the primary outcome measure, BMI. However, there were statistically significant intervention effects on total cholesterol, low-density lipoprotein cholesterol, and depression. In tests of moderation when BMI was the outcome variable, the intervention was more effective when parents or guardians were unmarried and when baseline television viewing was high. The research team suspected that treatment effects were not stronger because of barriers participants encountered in attending dance classes due to transportation difficulties and episodes of violent crime near the sites where dance classes were held.

Hip-Hop to Health Jr.

A second exemplary program of research, Hip-Hop to Health Jr., was a community-based obesity prevention program that was culturally adapted for African American and Latino Head Start preschool children (Fitzgibbon et al., 2002). It was an adaptation of Hip-Hop to Health, an intervention for African American 6- to 10-year-old children (Fitzgibbon et al., 1998). In an article that described the rationale and design of Hip-Hop to Health Jr., the research team reviewed the literature on diet and exercise of African America and Latino children to identify specific characteristics (e.g., fat and fiber consumption) that might account for disparities in childhood and adult obesity. They also explained that the theoretical framework guiding intervention development was an integration of social learning theory (Bandura, 1986), self-determination theory (Deci, 1992; Deci, Driver, Hotchkiss, Robbins, & Wilson, 1993), and the transtheoretical model (Prochaska & DiClemente, 1992). Consistent with the guidelines for cultural adaptation phases (Barrera et al., 2013), this first phase of information gathering included a literature review.

Also consistent with adaptation guidelines, the Hip-Hop to Health Jr. research team conducted a 3-week pilot study to test the feasibility and appeal of both the parent and child intervention components. The child portion of the pilot intervention contained three 40-minute sessions per week. The first half of each session was devoted to nutrition, and the second half was devoted to physical activity. In the nutrition lessons, "go and grow" foods (healthful) were contrasted with "slow" foods (unhealthful). In the parent component, parents attended one 30-minute nutrition class and two 30-minute aerobics classes each week.

Several changes were made to the intervention following the pilot study. The distinction between "go and grow foods" and "slow foods" was difficult for preschool children to understand. For the revised intervention, researchers created puppets to represent the food groups (Ms. Grain, Ms. Fruit, Mr. Vegetable, Mr. Fat, Ms. Sugar) in nutrition lessons. They also recognized the need for greater emphasis on the importance of physical activity. In the pilot parent component, nutrition lessons were attended poorly. Based on focus group recommendations that followed the pilot study, weekly newsletters and homework assignments replaced the in-person nutrition lessons in the revised parent intervention component.

A revised intervention was evaluated in two RCTs, one conducted with primarily African American families (Fitzgibbon et al., 2005) and one conducted with primarily Latino families (Fitzgibbon et al., 2006). The intervention was provided for 14 weeks. Children received 20 minutes of nutrition instruction (utilizing puppets) and 20 minutes of physical activity three times each week. Parents received weekly newsletters that were coordinated with the content of their children's instruction. In addition, parents could participate in 30-minute aerobic classes twice each week at their children's Head Start facilities.

The authors summarized the five special considerations they made in developing the intervention for African American and Latino preschoolers and their parents:

1. Offer the sessions in locations that are safe and that can be reached easily.
2. Establish personal relationships between participants and intervention staff.
3. Reduce barriers (e.g., negative attitudes, competing responsibilities) that interfere with improvements in nutrition and exercise.
4. Provide behavioral demonstrations of strategies for lifestyle change.
5. Make intervention accessible for participants at all levels of literacy.

The RCTs found significant intervention effects in predominantly African American Head Start centers (Fitzgibbon et al., 2005) but not in predominantly Latino centers (Fitzgibbon et al., 2006). In African American centers, children in the intervention condition showed smaller BMI increases than children in the control condition 1 year and 2 years after the end of the intervention, and less saturated fat consumption at 1-year follow-up. In contrast, there were no significant intervention effects for children and parents who attended primarily Latino Head Start centers. The researchers noted that children in the Latino centers had higher BMI levels at baseline than children in the African American centers. They speculated that relatively high initial levels of overweight and obesity might have made it difficult for children in the Latino centers to modify their eating and weight. Overall, they recognized that additional changes were needed to assist unacculturated Latino parents in making changes to diet and physical activity. On a positive note, retention of participants was quite high and did not differ between intervention and control groups. The retention rates were 97%, 86%, and 85%, at posttest, Year 1, and Year 2 follow-ups, respectively.

Pathways

Pathways was a multifaceted, multisite obesity prevention program for American Indian schoolchildren, which

started in grade 3 and continued through grade 5. It was developed and evaluated in two 3-year phases. The first 3-year phase was used to systematically develop culturally appropriate intervention and assessment methods. An entire supplemental issue of the *American Journal of Clinical Nutrition* (1999) was devoted to detailed descriptions of the formative research (e.g., S. M. Davis et al., 1999; Gittelsohn et al., 1999; Teufel et al., 1999). An additional 3 years was required to conduct a randomized controlled trial to assess intervention effects on body fat, dietary fat intake, physical activity, knowledge of the diet and physical activity curriculum, and self-efficacy for physical activity and healthful food choices (Caballero et al., 2003). Articles in a special supplemental issue of *Preventive Medicine* (2003) reported detailed results of the massive project.

The intervention consisted of four components: a classroom curriculum, school food services, physical activity during and after school, and family support and involvement. Formative research groups were created to develop each of the components. Unusually thorough input from many constituencies was obtained throughout intervention development. Each section of the intervention was reviewed by "tribal representatives, American Indian members of the Pathways study, intervention committee members, and the Pathways steering committee, composed of the principal investigators from all five participating institutions, the National Heart, Lung, and Blood Institute project scientist, and two American Indian representatives" (S. M. Davis et al., 1999, p. S798).

They instituted an information gathering phase when information relevant for understanding the communities, risk factors, and potential intervention strategies were obtained from school staff members, students, and their caregivers in detailed interviews, focus groups, and direct observation. That information informed a culturally adapted intervention that incorporated American Indian concepts and traditions pertinent to nutrition and physical activity. For example, the classroom component integrated "stories, games, music, artwork, foods, family activities, videos, and events contributed by members of the seven tribes" (S. M. Davis et al., 2003, p. S26). An initial version of the intervention was pilot tested in six American Indian communities. Observers made notes of the intervention's implementation, and researchers interviewed intervention staff members (e.g., teachers, food service workers) to ascertain strengths, weaknesses, and recommendations for changes. A revised intervention was evaluated in a randomized controlled trial of 1704 children in 41 schools in seven American Indian communities in Arizona, New Mexico, and South Dakota (Caballero et al., 2003). The intervention began in third grade and extended to fifth grade. Retention from baseline to follow-up assessment was 83% in both the intervention and control conditions.

Despite rigorous cultural adaptation methods, the comprehensive intervention was not more successful than the control condition in reducing body fat, the primary outcome measure. Motion sensor measurement of physical activity also did not show significant intervention effects. Significant intervention effects were found for self-reported and observed dietary fat intake and for self-reported physical activity. In discussing their results, the researchers noted that several other comprehensive interventions used diet and physical activity outcomes but did not treat children's body weight and adiposity as endpoints (e.g., Luepker et al., 1996; Simons-Morton, Parcel, Baranowski, Forthofer, & O'Hara, 1991).

Stanford GEMS, Hip-Hop to Health Jr., and Pathways were exemplary in their illustration of cultural adaptation procedures. As noted previously, several other studies on the nutrition and/or physical activity of ethnocultural group children did not provide substantive descriptions of cultural adaptation considerations and procedures. For instance, Bienestar was a large-scale study that involved 13 intervention elementary schools and 14 control schools in which 713 fourth-grade students participated in the intervention and 706 students participated in the control condition (Treviño et al., 1998, 2004; Treviño, Hernandez, Yin, Garcia, & Hernandez, 2005). Eighty percent of the participants were of Mexican heritage. Much like Pathways' comprehensive intervention, the Bienestar comprehensive intervention involved four social systems: parents, school classrooms, school cafeterias, and after-school programs. However, unlike Pathways, it is not certain if formative research was funded to conduct systematically a cultural adaptation of the intervention. The other studies of nutrition and/or physical activity interventions that were directed at subcultural group children (Crespo et al., 2012; J. N. Davis et al., 2012; de Heer et al., 2011; Klesges et al., 2010; Nadar et al., 1999; Resnicow et al., 2005; D. K. Wilson et al., 2011) might have included cultural adaptation phases, but detailed descriptions of adaptation methods did not appear in the literature we were able to locate and review. Many of these studies showed significant intervention effects on physical activity and healthful nutrition measures (Crespo et al., 2012; de Heer et al., 2011; Nadar et al., 1999; Treviño et al., 2004).

Discussion

The three exemplary studies we highlighted—Stanford GEMS, Hip Hop to Health Jr., and Pathways—were

pioneers in using intervention development procedures that we now recognize as high-quality features of cultural adaptation stages: information gathering with literature searches to document health disparities and to identify subcultural risk and protective factors that should be considered in intervention development; formative studies that include focus groups as well as quantitative surveys; pilot studies to test the feasibility and effects of a draft intervention; satisfaction surveys to gauge the appeal of recruitment and intervention procedures; and formal RCTs of adapted interventions. The exemplary projects benefited from funded, multiyear developmental stages that permitted thorough cultural adaptation efforts.

Despite those systematic efforts, culturally adapted interventions were not always successful in changing primary endpoints of BMI or adiposity (see Fitzgibbon et al., 2005, for an exception). Those outcomes are notoriously resistant to change, particularly in primary prevention interventions with nonclinical populations (Caballero et al., 2003). In a meta-analysis of school-based obesity interventions in the United States and United Kingdom, Kanekar and Sharma (2009) found that the interventions were not successful in reducing BMI. Similarly, a review of 20 after-school obesity prevention interventions concluded that the results were generally unfavorable when obesity-related variables were the outcomes (Branscum & Sharma, 2012). Nevertheless, culturally adapted interventions were often successful in improving secondary (yet important) outcomes, such as dietary fat consumption, fiber consumption, and physical activity. Childhood obesity and its subcultural group disparities will persist for some time. They have such critical importance for the nation's health that research must continue to seek solutions that will reach children in all segments of communities.

One of the lessons from the Stanford GEMS project (T. N. Robinson et al., 2010) is that well-conceived interventions must include effective methods for overcoming barriers to participation in intervention components. The GEMS' goal for attendance at after-school dance classes in community centers was three of five school days, but by the end of the intervention, participants averaged only one of five school days. Of 24 in-home TV reduction visits, participating families received an average of 12.4 lessons over a 2-year period. In-school interventions avoid the participation slippage that occurs when children are required to travel to intervention venues or when family participation is required. However, true lifestyle change occurs during school hours and after school hours when the family has a key role in influencing food consumption and physical activity. Cultural adaptation efforts should continue to address both engagement methods and intervention content (Barrera & Castro, 2006).

CONCLUSIONS AND FUTURE RESEARCH DIRECTIONS

The cultural adaptation of interventions for youth is a maturing and still-vibrant topic in developmental psychopathology. There is a persistent need for interventions to reach and engage ethnic and racial minority youth just as there are persistent disparities in youth problem behavior and health risk. This chapter has highlighted the most influential work on cultural adaptations that has been done to date, leading to several conclusions about what we have learned, limitations to our knowledge, and ways we might advance our understanding in the near future. Basic conclusions and future research directions are integrated in the next sections.

Adaptation Effectiveness

In this chapter, as well as in other reviews (Benish, Quintana, & Wampold, 2011; Griner & Smith, 2006; Huey & Polo, 2008; Ortiz & Del Vecchio, 2013), the emphasis was on evaluating intervention efficacy. Are cultural adaptations effective? That question should be qualified by another question that has been raised repeatedly: Compared to what? There is interest in the question not only of the efficacy of cultural adaptations relative to benign control conditions but also relative to unadapted, recognized interventions, such as the original versions of interventions. For some, demonstrating the value added by modifications to original EBIs is of critical importance (Ortiz & Del Vecchio, 2013). Yet calls for research that compares the effectiveness of culturally adapted EBIs to their original versions are qualified by skepticism: It is hard to imagine providing unaltered original EBIs to ethnocultural groups without making basic adaptations, such as language translations or delivery by bilingual staff; and it would be costly to launch an adequately powered study comparing an original EBI, a culturally adapted intervention, and a control condition, particularly if differences between the original and adaptation are expected to be modest (Barrera et al., 2013). Lau, Chang, Okazaki, and Bernal (in press) questioned the value of original EBI-adaptation comparisons, also citing the substantial statistical power required for such comparisons, the need for at least some cultural adaptations to effectively engage

ethnocultural participants into comparative research, and potential ethical concerns about withholding culturally sensitive care from participants who receive unadapted EBIs. Given the onerousness, methodological challenges, and ethical quandaries of conducting adequately powered relative efficacy trials of adapted EBIs (Cardemil, 2010), Domenech Rodriguez and Bernal (2012) noted that researchers are subject to a catch-22 when expected to demonstrate relative efficacy prior to pursuing questions about mediators and moderators of change within the clinical trials tradition. From our qualitative review of culturally adapted interventions for internalizing disorders, externalizing and high-risk youth behaviors, health, and PT, there was good evidence of absolute intervention effects when compared to control conditions. However, substantial heterogeneity was observed in the efficacy of culturally adapted EBIs across the diverse outcomes that have been studied. Although some outcomes (e.g., obesity) have been notoriously intractable to remediation or prevention even for majority group youth, it was still disappointing when well-conceived, systematic, and community-informed adaptation efforts were unsuccessful in achieving goals.

Our analysis of the literature was qualitative and not intended to be exhaustive or capable of supplying quantitative answers to questions of relative efficacy. Fortunately, four meta-analyses of culturally adapted interventions (Benish et al., 2011; Griner & Smith, 2006; Huey & Polo, 2008; Smith, Domenech-Rodriguez, & Bernal, 2011) and a formal review of PT interventions (Ortiz & Del Vecchio, 2013) have been published. There was some overlap in the studies that were analyzed in these reviews, but the reviews differed in their inclusion and exclusion criteria. Using relatively broad inclusion criteria, Griner and Smith (2006) evaluated 76 published and unpublished studies that made at least some reference to adaptation because of culture, ethnicity. or race. Only studies of EBIs with children were reviewed by Huey and Polo (2008). Psychotherapy studies conducted with children or adults (excluding preventive interventions) were the foci of the meta-analysis by Benish et al. (2011). That review also contrasted effect sizes that were obtained when culturally adapted interventions were compared to some other treatments or benign control conditions and when cultural adaptations were compared to just other bona fide psychotherapies. Bona fide psychotherapies were defined by "a relationship with a therapist tailored to the client and is evidenced by the inclusion of two or more of the following conditions: use of an established psychotherapy approach, incorporation of the use of psychological processes, use of a manual or training as a guide for therapists, and/or identification of the active ingredients of the therapy" (Benish et al., 2011, p. 280). Smith et al. (2011) conducted a meta-analysis of studies concerned with mental health outcomes. That review excluded research on health, substance abuse, and educational outcomes. Ortiz and Del Viccho's (2013) review dealt exclusively with PT interventions. Because of differences in scope and reference groups used in comparisons, it is understandable that there were differences in conclusions regarding adaptation efficacy.

The five most basic findings from these reviews are summarized next.

1. Overall, culturally adapted interventions were moderately effective (average effect size was $d = .45$) but were less effective for children than they were for adults (Griner & Smith, 2006).
2. For interventions conducted with ethnic minority children, culturally adapted treatments and unadapted treatments showed comparable effect sizes (Huey & Polo, 2008).
3. On mental health outcomes, culturally adapted therapies showed a moderate effect size (average effect size $d = .46$) (Smith et al., 2011). Similar to the age effect found by Griner and Smith (2006), participants older than 35 appeared to benefit more from adapted therapies compared with benefits for children, adolescents, and young adults. The number of cultural adaptations made in interventions was positively correlated (.28) with intervention efficacy.
4. Analyses comparing culturally adapted psychotherapies to other bona fide (unadapted) psychotherapies showed an average effect size of .32. In contrast to other reviews (Griner & Smith, 2006; Smith et al., 2011), the average effect size was comparable for adults and children (Benish et al., 2011).
5. In studies of parent training, the reviewers concluded that "treatment outcomes from adapted PT interventions are not superior to those unadapted interventions typically achieve" (Ortiz & Del Vecchio, 2013, p. 452).

In general, cultural adaptations show moderate effect sizes when compared with control conditions, but there was some evidence that effects might be attenuated for research conducted with children and adolescents. Age might moderate effects if cultural adaptations are most beneficial for the least acculturated participants who are often older adults rather than children (Griner & Smith, 2006). It was notable, however, that no age effects were observed in

what was arguably the most rigorous comparison, that is, when adapted interventions were found to be moderately more effective than unadapted bona fide therapies (Benish et al., 2011).

Two additional observations provide important context for interpreting these findings. First, there was considerable heterogeneity in treatment effects, which calls for caution in making broad generalizations about efficacy. Second, some analyses were based on a small number of studies. We agree with Smith et al.'s (2011) conclusion that because the full assessment of efficacy "depends on the consistent replication of supportive findings, the single greatest need of the research on culturally adapted interventions is for more evidence to accumulate" (p. 171). They noted that a consistent rate of about two studies each year was produced since 1981 that met the inclusion criteria for their meta-analytic review. Even Ortiz and Del Veccio (2013), who questioned the evidence supporting the value of cultural adaptations, acknowledged that ethnic minority children and families (particularly Hispanics) were underrepresented in controlled, peer-reviewed studies of parent training.

Cultural Adaptation Process

Researchers and program developers turn to the literature to inform decisions about pursuing cultural adaptations and to learn strategies for conducting them. That literature shows large variability in the thoroughness of adaptation descriptions—descriptions ranging from cryptic accounts of seemingly modest tailoring efforts to extensive efforts that required several years to craft interventions that subsequently were evaluated in controlled trials. Multiyear projects to culturally adapt children's health interventions (e.g., T. N. Robinson et al., 2003) were innovative during their time, implementing sequential steps that are now reflected in the stage models listed in Table 17.1 for developing culturally adapted versions of EBIs. We have learned that when EBIs are identified for modifications, there are generally accepted procedures for conducting them. An alternative approach to tailoring EBIs was exemplified with approaches that began with basic developmental psychopathology research to identify the risk factors that appear to contribute to psychopathology or youth problem behaviors (e.g., Gonzales et al., 2007; Murry et al., 2007). In the future, greater structure in the procedures used to culturally adapt interventions might decrease the heterogeneity in effects that were found in our review and recent meta-analyses. Many of the studies included in reviews were conducted prior to published conceptual models of adaptation procedures.

Reach and Engagement

Lau (2006) made the distinction between the ability of interventions to change outcomes, such as disability and distress, and their ability to draw participants into interventions, engage them in intervention activities, and retain them throughout treatment and maintenance phases. As shown in this review, the effects of cultural adaptations on reach and engagement have not been studied and reported as systematically as intervention efficacy, yet there are examples of how tailoring can improve engagement. Kumpfer and Alvarado (1995) found that original versions of Strengthening Families had slightly better outcomes than adapted versions. However, recruitment and retention of participants receiving culturally adapted versions were 41% better, instantiating the potential of cultural adaptations to substantially improve involvement in interventions for ethnic minority families. Unfortunately, there are countervailing examples of well-conceived efforts to boost the intervention engagement of ethnic minority youth and parents that were not successful (e.g., McCabe et al., 2012; T. N. Robinson et al., 2010). The exigencies of living in stressful, low-resource environments will continue to present barriers to ethnic minority participants in intervention research. Developing and evaluating methods for improving reach, engagement, and sustained participation in interventions are among the most important topics for future research.

Understanding Cultural Components Added to Culturally Adapted Interventions

Several reviewers were critical of cultural adaptations that lacked theoretical frameworks for specifying why cultural concepts could be added to interventions to improve reach, engagement, or efficacy (Castro et al., 2010; Ortiz & Del Vecchio, 2013; B. D. M. Wilson & Miller, 2003). Little progress has been made on this front. When cultural adaptations are explicitly designed to influence a cultural construct that could operate as a mediator of change (e.g., enhancing cultural identity), studies could inform culturally relevant theory by evaluating whether the intervention succeeded in changing that construct and whether that change affected the outcome (e.g., Murry et al., 2007). Toward this important aim, the designers of culturally relevant interventions should be explicit about the hypothesized roles of specific cultural variables and should design evaluation research that tests theoretical assertions. This approach was illustrated in the study by Lau et al. (2011) that included special therapy procedures to reduce negative parenting strategies of immigrant Chinese parents.

Problematic parenting practices identified in preliminary research (Lau, 2010) were improved in a culturally adapted version of an EBI, and those improvements mediated the intervention's beneficial effects on children's externalizing problems (Lau et al., 2011). Murry et al. (2007) provided a mediation analysis of the Strong African American Families Program that could serve as another model for future research on the cultural mechanisms that mediate the effects of cultural adaptations.

Accommodating Within-Group Diversity

A major impetus for conducting cultural adaptations is to address special needs and characteristics of ethnocultural groups that were not addressed adequately by the original versions of the interventions. However, ethnocultural groups are not homogeneous. Within-group diversity is derived from differences in acculturation, nativity, language use, immigration experiences, skin color, religion, and a host of other factors that might be related to adversity exposure and responsiveness to interventions. For example, Gonzales and colleagues (2012) reported differential program effects on the basis of family linguistic acculturation, yet program benefits were nonetheless shown over time for both low- and high-acculturated families (Jensen et al., in 2014). A complexity in designing culturally adapted interventions is to accommodate within-group diversity. It is not feasible to create fixed interventions that are relevant and effective for narrow segments of an ethnocultural group. Instead, there is promise in creating assessment and intervention procedures that guide individualized tailoring within the context of a standardized intervention. Standardized decision rules for varying the content and dosage of treatment, depending on the characteristics of participants is the essence of adaptive intervention designs (Collins et al., 2004). In the same spirit of adaptive interventions, Pina et al. (2009) described a culturally prescriptive intervention framework that guides the tailoring of childhood anxiety interventions depending on the cultural features of the individual child or family. Rather than applying a fixed set of adaptation activities, their treatment manual describes a uniform set of guidelines to assist interventionists in determining how to attend to language and other cultural considerations (e.g., familism) in tailoring the intervention. McCabe et al.'s (2005) use of an initial assessment of participants' attitudes and preferences to guide the individualized application of treatment elements was innovative and merits additional research and development as a strategy for addressing within-group diversity.

International Application and Dissemination

It could be said that the strongest test of the need for cultural adaptation may come from international dissemination of interventions to non-Western and developing nations. The need for linguistic adaptations and other cultural considerations is likely to be magnified in international applications with non-Western developing countries in Africa, Asia, and the Middle East. Earlier in the chapter we noted the emerging trend for international dissemination of EBI, including several PT interventions that have been adapted for international dissemination. The same has been true of programs to prevent HIV/AIDS (Wingood & DiClemente, 2008). Undoubtedly, the best examples of international adaptations were concerned with the SFP, a family skills intervention for the prevention of substance abuse (Kumpfer et al., 2008). SFP was initially developed and tested in the United States and subsequently evaluated in non-RCT studies in about 17 countries and RCTs in nine countries (United States, Canada, Australia, United Kingdom, Sweden, the Netherlands, Spain, Italy, and Thailand). Kumpfer and her colleagues (2008, 2012) detailed 10 steps shown in Table 17.1 that should be followed in creating international adaptations of SFP and perhaps other evidence-based programs. In Kumpfer et al. (2008), the steps were illustrated with examples from their extensive experience in many countries. That informative paper is filled with general guidance and best practices for those who are planning international adaptations of EBIs.

International adaptation of interventions is a prime topic for future research and practice. However, in their recent review of PT interventions that have been implemented and evaluated internationally, Knerr et al. (2013) noted that the four PT interventions with the strongest evidence base have been replicated in RCTs in many developed Western countries, but these major programs have not been implemented in low-income or developing countries. On the contrary, many PT interventions transported to these contexts lacked strong efficacy data in the countries in which they originated. Thus, it is unclear whether international efforts to deploy PT or other types of interventions will be informed by domestic efforts in cultural adaptation.

It is important to note that although some EBIs are gaining traction in usual care settings, and the recent federal emphasis on prevention services as outlined in the Affordable Care Act (U.S. Department of Health and Human Services, 2010) has potential to accelerate this pattern, there is little evidence that their culturally adapted counterparts have been adopted outside the original efficacy trials and the occasional dissemination trials.

Zayas et al. (2012) argued that one of the shortcomings in the cultural adaptation literature is the inattention to the multiple service contexts that influence the implementation of interventions and the critical features that enhance the uptake of interventions and services. Larger contextual factors, in addition to sociocultural factors, must be considered in the adaptation process, such as the different service sectors (e.g., child welfare, education, juvenile justice, medical) and the organizational contexts (e.g., agencies, hospitals, clinics, health care) in which interventions are implemented, and the types of modifications required at different levels of the service delivery and implementation chain. It is possible that, in each context, cultural adaptations must be conceptualized and operationalized differently (Schoenwald 2008). An integrated approach to cultural adaptation, which includes the careful consideration of both the service contexts as well as the cultural diversity represented among the families and children within these contexts, may be necessary (Wolchik et al., 2009; Zayas et al., 2012). As the field of child, youth, and family prevention services pushes forward to solve the problem that EBIs have not been adopted broadly and are not accessible, scalable, replicable, and sustainable, intervention adaptation will be a major thrust in the next generation of efforts to design and diffuse EBIs (Rotheram-Borus, Swendeman, & Chorpita, 2012). The role that culture and the cultural adaptation processes described in this review will play in this agenda has yet to be determined.

PRÉCIS

Centuries ago many women died in childbirth or at a young age, often leaving the care of their infants or young children in doubt. War, disease, poverty, and, in some cases, government policies have replaced, in many instances, maternal mortality as a major contributor to abandoned children. Historically, a common societal response to these children, at least since the eighteenth century, was to place them in institutions. From the nineteenth century, literature has many portrayals of the grim plight of orphans—Oliver Twist and David Copperfield—cared for in structured but bleak facilities. However, institutional care for orphaned and abandoned children still exists, especially in Central and South America, Africa, the Middle East, Asia, and Eastern and Western Europe. Worldwide estimates are that as many as 8 million children are being raised in institutions (Save the Children, 2009).

Despite the millions of children cared for in this way over the centuries, until the past decade or so, studies of institutional rearing were quite limited. In the middle of the twentieth century, small descriptive studies comparing children in foster care to children in institutions began to appear in the literature. These studies uniformly found that children in foster care had better physical, behavioral, and psychological outcomes than did children in institutions. The British child psychiatrist and psychoanalyst John Bowlby was among the first to note the effects of maternal separation and abandonment during infancy and early childhood. In his 1944 paper describing 44 juvenile thieves, he called attention to early experiences of maternal separation and asserted its relation to subsequent deviant behavior. After World War II he authored a report for the World Health Organization in 1952 describing the plight of children being

The writing of this chapter was made possible by funds provided by the John D. and Catherine T. MacArthur Foundation, the Binder Family Foundation, and the National Institute of Mental Health (MH091363). raised in institutions and advocated for their removal into family or foster homes.

More recently, children adopted out of institutions have been studied and, consistent with past work, have been found to suffer from a variety of developmental sequelae, although the severity of the effects covary with the duration of institutionalization (Chisholm, 1998; Rutter et al., 2010). Specifically, these studies find significant gains for children who are adopted out of institutions in infancy with more adverse consequences for those adopted later in childhood. Although these studies uniformly suggest that being raised in families is better for children's development than being raised in an institution, these results must be tempered by the fact that children were not randomly selected for adoption. This bias makes it challenging to determine how much recovery is possible for the modal institutionalized child.

We developed the Bucharest Early Intervention Project (BEIP)—the primary focus of this chapter—in part to address the limitations of previous studies about children reared in institutions and to address important questions about the mechanisms by which institutional rearing affects children's development. In addition, we also sought to shed light on a number of key developmental processes, including the role of experience in brain-behavioral development and, in particular, the role of sensitive periods. This project, now entering its second decade, has yielded a wealth of information not only about children reared in institutions versus families but, more broadly, about the effects of early experience on brain and behavioral development. As Cicchetti and Gunnar (2008) have noted, there is great value in including measures of biological processes in preventive intervention trials. We adhere to two basic principles in neuroscience: that many elements of postnatal brain development are dependent on experience for their full elaboration; and that, in many domains, such experiences need to occur during sensitive periods of development, when experience exerts its greatest effects. Experiences that occur after a sensitive period have a more limited chance of influencing development.

We begin this chapter with a brief review of the history of institutionalization in Romania. Then we discuss what we have learned from the past 50 years of research about the sequelae that follow a history of institutional care. Because there are recent reviews of this literature (see Nelson, Fox, & Zeanah, 2014), we summarize the major findings. We next turn to what lies behind the creation and implementation of this project. We describe the experimental design that was adopted, followed by a discussion of the many ethical issues that we confronted at the outset of the project and continue to confront. We conclude this section by describing our foster care intervention.

Finally, we turn our attention to the findings to date in the BEIP. Here we organize the chapter topically, beginning with cognitive development, then brain development, then social-emotional development, and finally, psychopathology. With this review behind us, we turn our attention to several knotty theoretical issues, including the mechanisms that underpinned our intervention, including the role of sensitive periods. A second challenging issue is the implications this work has had for understanding key developmental processes, notably the development and importance of attachment relationships during early childhood. We conclude our chapter with a general discussion of the implications this work has for domestic and international policy regarding the care of orphaned, abandoned, or maltreated children.

HISTORY OF INSTITUTIONAL CARE IN ROMANIA

Institutionalization during the twentieth century in Romania has its own unique history. In 1965, Nicolai Ceaușescu assumed leadership of Romania. At that time, the country had a low birth rate, abortion was legal, and women had access to contraception. Ceaușescu decided to change these policies, reasoning that the best way to increase human capital (and perhaps his own authority) was to increase the birth rate across the country and organize the social structure so that families could have many children but not have to worry about their care. Ceaușescu implemented a set of policies designed to increase the population, ban abortion, make contraception inaccessible, and reward families for having many children. To enforce these policies, Ceaușescu assigned doctors and nurses involved in gynecology to "demographic control units." These units (which became known as the menstrual police), conducted interrogations and gynecological exams in women's workplaces or schools to ensure that if they were pregnant, they would carry the baby to term. In addition, infertility treatment was recommended to infertile couples, and miscarriages were to be investigated (Bachman, 1991).

At the same time, because of deteriorating economic conditions, Romania set up a network of institutions that were designed to care for the overflow of children produced as a result of these new policies. The institutional system had a number of tiers that were organized both by the age of the child and a judgment as to whether the child would have a future as a worker in Ceaușescu's state. Infants and young children were placed in institutions called *leagens*

(this means "crib" in Romanian). Infants and children were raised there until around the age of 3, at which time, via a pediatrician, nurse or administrator, their status was reviewed. Those judged to be capable of growing up to be participating workers were allowed to stay on while those judged to be defective (either handicapped, with some genetic syndrome, or often of Roma ethnicity) were sent to one of two types of institutions. If there was a chance the child could be rehabilitated they would be sent to a *Camin Spitale* (essentially an institution for handicapped children or children who were considered to be handicapped based on a superficial pediatric exam) if there was no hope of recovery, they were sent to an Institute Neurologie (essentially an institution where children received next to no care or services and, in some cases, were left to die).

All of these institutions were run by the state. The administrators were generally physicians, and the staff was untrained in child development or special education. Children judged fit who remained in the *leagans* were sent to local schools; older children were sent to vocational schools to learn a trade. Children assigned to the rehabilitation institutes or to institutions for the irrecoverable lived in unspeakably horrible conditions with lack of sanitation, medical care, and even food (see, e.g., http://www.youtube.com/watch?v=ZgZJ-IV8Et0).

Once Ceauşescu was overthrown in 1989, evidence of neglect and mistreatment of children began to surface in the West. Media reports described the housing of thousands of young children with no apparent disabilities in institutions around the country. In December 1989, estimates of the total number of children living in institutions varied from 50,000 (by the Romanian Department of Child Protection) to 150,000 by the U.S. media and nongovernmental organizations (NGOs). (Many current authorities in Romania and in UNICEF place the real figure at closer to 170,000.) Reports about specific institutions in the early 1990s consistently described a variety of substandard living conditions in various orphanages. Infants in *leagans* were forced to spend most of their time in cribs; as they got older, they spent their time in huge rooms of 10 to 50 children (Zamfir, 1998). An example can be seen in Figure 18.1.

In sum, as the plight of children gradually became known to countries in the West, thousands of previously institutionalized children were adopted into families who more often than not were unaware of what these children had undergone. As a result, these families (most of whom resided in the United Kingdom, Canada, and the United States) were unprepared for the range of developmental problems that afflicted these children. It is this topic—the developmental sequelae of institutional rearing—to which we next turn our attention.

Developmental Sequelae of Institutional Care

There is a large literature on the developmental sequelae of institutional care. For purposes of this chapter, we review only that literature that is directly relevant to the findings we report on the BEIP (for reviews, see Nelson, Furtado, Fox, & Zeanah, 2009; Nelson, Fox, & Zeanah, 2013, 2014; Nelson, Westerlund, McDermott, Zeanah, & Fox, 2013).

Cognitive Development

The effects of institutionalization on cognitive functioning have been well documented. As early as 1957, Dennis and Najarian described significant impairments in IQ scores for Lebanese children living in an orphanage as compared to a community sample. Similar findings had previously been

reported by Goldfarb (1945) and Spitz (1945) and later by Provence and Lipton (1962).

In an important longitudinal study conducted by Tizard and colleagues (e.g., Tizard, 1977; Tizard & Hodges, 1978; Tizard & Rees, 1974; Hodges & Tizard, 1989), IQ was examined for children living in British institutions in which there was an adequate environment that included toys, books, and stimulation but did not involve the establishment of warm interpersonal relationships between caregiver and child. Tizard assessed the children at 8 years of age and found that children adopted before 4.5 years of age had normal IQ scores while those adopted later were delayed (Tizard & Hodges, 1978).

In a meta-analytic review, van IJzendoorn, Luijk, and Juffer (2008) found across 75 studies that children reared in orphanages had consistently lower IQ scores when compared to their peers reared in foster families. The authors attempted to identify what factors could be pinpointed to affect IQ scores. They found that children from orphanages assessed before 4 years of age performed less well compared with children assessed after their fourth birthday. Age at entry into the children's home was also a relevant moderator. Children placed into the orphanage before 12 months of age did less well than their peers reared in families, and this delay was significantly larger than with children who entered the orphanage after 12 months. The authors also examined whether a longer stay in the orphanage would lead to larger intellectual delays. Contrary to their initial hypothesis, they did not find an overall significant effect such as between children staying less than 12 months in the children's home versus children who remained longer. A cutoff at 24 months did not make a difference either. Finally, differences in caregiver-child ratio between the orphanages were not significantly related to differences in effect sizes. Even the contrast between the most favorable caregiver-child ratio (maximum of 3 children per caregiver) versus other orphanages did not lead to a significant difference. Thus, while there was a definite effect of institutional care on IQ, the reasons for this effect were not evident from the meta-analysis of the studies reviewed. In part, this is a function of the great variability in caregiving contexts across the 75 studies as well as differences in the reasons children were placed into institutions.

In post-1989 Romania, many families in the United States, United Kingdom, and Canada began to adopt Romanian children then living in institutions. A number of studies have followed up on these adopted children; perhaps the largest and most comprehensive was one in the United Kingdom, initially directed by Michael Rutter, called the English Romanian Adoptees Study (ERAS). The ERAS compared infants and young children with a history of institutionalization in Romania who were adopted into U. K. homes to infants and young children born in the United Kingdom and adopted into U. K. homes (Rutter & the English and Romanian Adoptees Study Team, 1998, Rutter et al., 2010). These studies report that infants adopted before 6 months of age were indistinguishable in their IQ scores from U. K.-born adoptees or a typical control sample. However, infants and children adopted at later ages displayed impairments in IQ with remediation a function of age of adoption (later adoption, less remediation of IQ scores at follow-up). These findings persisted on through 11 years of age (Beckett et al., 2006).

In sum, in conditions of severe psychosocial deprivation, such as the institutions in Romania, there are significant effects on the IQ of young children. The ERAS data suggest that while very early exposure to such conditions does not have long-term effects, living in institutions past 6 months of age leads to long-term decrements in intelligence.

EFFECTS OF INSTITUTIONALIZATION ON NEUROPSYCHOLOGICAL FUNCTIONING

Although IQ is a general measure of intelligence, psychologists have long realized the importance of assessing basic cognitive processes in order to understand a child's cognitive development. These processes include attention and what is known as executive functions (EFs). Most researchers agree that EFs (e.g., working memory, inhibitory control, planfulness, attention shifting) play a critical role in the emergence of adaptive cognitive and social behavior. These processes appear to be linked to particular areas of the prefrontal cortex (PFC) and begin to emerge in early childhood, with a large increase in capability during the preschool and early school period. A number of studies have evaluated these processes in postinstitutionalized, adopted children. Pollak and colleagues (2010), for example, assessed memory, attention, and EF using two well-validated test batteries, the Cambridge Neuropsychological Test Automated Battery (CANTAB), a computerized series of neuropsychological tests, and the NEPSY, a developmental neuropsychological assessment. Internationally adopted children between the ages of 8 and 10 years with a history of prolonged institutionalization performed worse on tests of memory, visual attention, and learning than early-adopted or nonadopted control children. More time spent in an institution was associated with poorer performance on tests of inhibitory control, visual attention, and visual memory.

Colvert et al. (2008) in the ERAS examined theory of mind (ToM) and EF in their sample of adopted postinstitutionalized children. The Romanian adoptees displayed deficits on both measures, with the effects strongest among those who had experienced more than 6 months of institutional deprivation. Deficits in both domains (ToM and EF) were associated with quasi-autism, disinhibited attachment, and inattention/overactivity. Both ToM and EF mediated quasi-autism, although mediating effects of EF for inattention/overactivity were less marked. However, neither ToM nor EF accounts fully for the overall pattern of deprivation-related difficulties.

Finally, Loman et al. (2013) extended these earlier findings to the domain of attention, inhibitory control, and error monitoring. These authors reported that postinstitutionalized children showed both behavioral and electrophysiological impairments in all domains, and they drew an analogy between these findings and those of nonadopted children with attention-deficit/hyperactivity disorder (ADHD).

Neuroanatomical Correlates of Institutionalization

One approach to understanding the mechanisms by which institutionalization affects behavior is through an examination of the neural correlates of cognitive and social functioning among children who experienced institutionalization. A number of investigators have examined these issues. Chugani and colleagues (2001) used positron emission tomography (PET) to study ten 8-year-old children who had been adopted from a Romanian institution. Nearly all children had been placed in the institution before age 18 months and had lived in the institution an average of 38 months before being adopted. These children were compared to a group of healthy adults and a group of 10-year-old children with medically refractory epilepsy. The authors reported that the adoptees showed significantly reduced brain metabolism in select regions of the PFC (e.g., orbitofrontal cortex) and the temporal lobe (e.g., amygdala).

In a follow-up, white matter connectivity was examined using magnetic resonance imaging (MRI) (Eluvanthingal et al., 2006). Eluvanthingal et al. (2006) reported that white matter connectivity was diminished in the uncinate fasciculus in the early-deprivation group compared with controls. The uncinate fasciculus is a major pathway of communication between brain areas involved in higher cognitive and emotional function (e.g., amygdala and frontal lobe).

In a third study by this group (Govindan et al., 2010), tract-based spatial statistics (TBSS) was employed to evaluate white matter changes in children with a history of early deprivation. Seventeen children with a history of institutional care since birth and subsequent adoption were compared to 15 typically developing nonadopted children. The postinstitutionalized adopted children were found to have reduced organization of portions of the bilateral uncinate and superior longitudinal fasiculi, with the magnitude of white matter disorganization significantly associated with duration of time spent in institutional care.

Also using MRI, Bauer, Hanson, Pierson, Davidson, and Pollak (2009) completed a structural imaging study of 31 postinstitutionalized children, most from institutions in Eastern Europe (Romania, Russia), China, and other European countries. Their average age at adoption was 31 months. Children were also administered a set of neuropsychological tasks from the CANTAB. The researchers found that the postinstitutionalized children had smaller volumes of the superior-posterior cerebellar lobes and had poorer performance on memory and EF tasks compared to typically developing children who served as controls. These structural differences in cerebellum mediated the relation between institution history and cognitive performance.

Tottenham and Sheridan (2009) and Tottenham and colleagues (2011) published two imaging studies with postinstitutionalized children. In the first study, the authors split the group of postinstitutionalized children into those adopted early versus those adopted late. The median age of adoption was 15 months, resulting in one group of 17 early-adopted children (16 from Asia and 1 from Eastern Europe) and a second group of 17 late-adopted children (11 from Asia and 6 from Eastern Europe). The authors found no differences in cortical volume or gray matter between the two groups of children. But the late-adopted children had larger amygdala volume compared to the early-adopted children and compared to the typically developing controls. There also was a modest but significant correlation between age adopted out of the institution and amygdala volume that could not be explained by variations among the sample in IQ.

In their second study, Tottenham and colleagues (2011) utilized functional MRI to examine amygdala activity in response to faces in a modified Go No Go task. In such a task, subjects have to press a button to a frequently presented stimulus (in this case a face posing a neutral expression) and inhibit pressing the button when a less frequent face expression (the emotion of fear) appears. The study reported finding greater amygdala activity in the postinstitutionalized (PI) group to the fear stimuli with amygdala activity mediating the relation between early institutional care and eye gaze pattern (PI children

showed less direct eye fixation on faces). These two studies emphasized the importance of this subcortical structure and its apparent sensitivity to deprivation experiences in children. Importantly, in both studies, the imaging took place years after the children had left the institutions and were now adopted into stable families in the United States, thus emphasizing the effects of early experience on amygdala volume and activity.

Finally, Gee et al. (2013) examined functional connectivity between the medial prefrontal cortex and the amygdala, a key connection that has important implications for emotion regulation. Average age of the sample was 11 years, but both preadolescent and adolescent children were included. Compared to never-institutionalized control children, the post-institutionalized children had a more mature pattern of connectivity, more closely resembling the typically developing controls. The authors argued that this more mature pattern was mediated by cortisol, a finding consistent with their hypothesis that early institutionalization is a form of adversity that leads to dysregulation of the hypothalamic-pituitary-adrenocortical axis.

The third group completing neuroimaging on a post-institutionalized sample was led by Michael Rutter. A paper from the ERAS by Mehta and colleagues (2009) used structural MRI to explore the influence of early institutional care on the hippocampus, amygdala, and corpus callosum, three key brain structures that previous research identified as sensitive to early adverse experiences. Study participants were adolescents and included 14 Romanian adoptees, all with a history of severe early institutional deprivation, and 11 noninstitutionalized, healthy controls. The authors found that the adoptees had significantly reduced total gray and white matter volumes compared to the control group. After correcting for brain volume, the adoptees had enlarged relative amygdala volumes compared to the control group, particularly in the right hemisphere. However, further analyses found that the left-amygdala volume correlated significantly with the duration of institutional care, with longer stays in an institution correlated with a smaller left-amygdala volume.

Attachment and Institutional Care

The formation of an attachment relationship between an infant and caregiver(s) is one of the essential tasks of the first years of life. An attachment relationship between a young child and caregivers requires sufficient ongoing interaction between the two so that the child learns to seek comfort, support, and nurturance selectively from those caregivers. Institutional care, which limits the child's opportunities to form selective attachments, therefore, might be expected to be associated with disturbances of attachment.

The effects of institutional care on attachment were first examined by Tizard and her colleagues (Tizard and Hodeges, 1978; Tizard and Rees, 1974) in a study of 65 young children placed in residential nurseries in London. Compared to institutions in many parts of the world, these facilities were smaller, with more favorable caregiver-to-child ratios, and more adequate toys and stimulation. Tizard does make the point that caregivers were told not to establish emotional bonds with any of the children but rather to remain aloof and distant (Tizard & Rees, 1974). Among the 26 continually institutionalized children, most had seriously disturbed attachments (Tizard & Rees, 1974). Ten of these children were "overly friendly"; that is, they approached unfamiliar adults as often as familiar adults. Evidence of reticence around unfamiliar adults was absent, and these children sometimes exhibited separation protest from strangers. They displayed attention-seeking behavior and were indiscriminate in seeking comfort. The children's attachment to others seemed superficial since adults seemed to be interchangeable. Eight children from the continuously institutionalized group had even more seriously disturbed relatedness. They were emotionally withdrawn, odd, and unresponsive. They tended not to seek comfort when distressed and did not respond to comfort when it was offered. They demonstrated disturbances of emotion regulation as evidenced by diminished positive affect and outbursts of fearfulness, irritability, or sadness for which precipitants were unclear.

These patterns of disturbed attachment had been observed in institutionalized children in older descriptive studies (e.g., Provence & Lipton, 1962), and they have been observed in more rigorous contemporary studies (Smyke, Dumitrescu, & Zeanah, 2002). In fact, these patterns of emotionally withdrawn, unresponsive behavior and indiscriminate behavior became the basis for the clinical phenomenology of disorders of attachment. In a sample of infants in a Greek institution, Vorria et al. (2003) reported that a majority of these infants (65%) had "disorganized" attachments to their caregivers. This is a classification of attachment derived from aberrant behavior that the child displays in the paradigm developed to assess attachment in young children, the Strange Situation Procedure, and is associated with substantially increased risk for subsequent maladaptive behaviors.

Three studies have examined patterns of attachment in preschool children adopted out of Romanian institutions. These studies all have found a high proportion of

unusual classifications. Marcovitch et al. (1997) found that only 30% of young children adopted from Romania were securely attached (compared to 42% in a Canadian-born, never-institutionalized comparison group), and 42% were insecure/controlling (compared to 10% in the comparison group). Chisholm (1998) reported more insecure attachments in Romanian adoptees (63%) than in Canadian-born comparison children (42%). Additionally, more than 21% of the Romanian adoptees displayed atypical insecure patterns while none of the Canadian children did so. Finally, O'Connor et al. (2003) found that at age 6, following adoption into the United Kingdom out of Romanian institutions, 51% of children were classified as insecure/controlling or insecure/other compared to only 17% of children adopted within the United Kingdom (but never institutionalized). In addition, 36% of children adopted out of Romanian institutions, compared to only 13% of intra-U.K. adopted children, exhibited nonnormative behavior in separations and reunions, such as extreme forms of emotional overexuberance, nervous excitement, silliness, coyness, and excessive playfulness more typical of a much younger child.

Emotion Recognition

The ability to identify basic emotional expressions and the ability to match emotional expressions with appropriate social contexts are important skills necessary for adaptive social behavior. Although relatively little research has been conducted specifically with institutionalized children, Pollak, Cicchetti, Hornung, and Reed (2000) reported that in a sample of children who experienced neglect, this history was associated with an overall impairment in the ability to recognize and discriminate between different facial expressions of emotion. A study by Wismer Fries and Pollak (2004) was among the first to examine these skills in children who experienced institutionalization. Postinstitutionalized children from Russia and Romania were given two tasks, one in which they had to identify photographs of facial expressions of emotion and the second in which they had to match photographs of facial expressions of emotion with certain emotional situations. The postinstitutionalized children had difficulty identifying facial expressions of emotion. More interestingly, they had trouble matching the facial expressions of emotion of happy, fear, and sadness to specific situations that were described to them. They performed as well as controls only in matching photographs of angry facial expressions of emotion to descriptions of situations involving anger. These results speak to two parts of the difficulty postinstitutionalized children may have in social situations. First, they may have difficulty interpreting facial cues in the social environment, and second, they may focus more intently on situations eliciting anger rather than those eliciting other emotions.

Psychopathology

Much like the research on development of attachment relationships to caregivers, the findings on children's social and emotional functioning have identified common cross-study themes and some inconsistencies. The consistent finding across studies is with regard to inattention/hyperactivity (e.g., Doolittle, 1995; Goldfarb, 1944; Roy, Rutter, & Pickles, 2004; Wiik et al., 2011). Inconsistencies, though, emerge regarding other aspects of social or emotional behavior, such as peer relationships and emotion identification. Goldfarb (1943) suggested that children who first experienced institutional care and were then transferred, at around age 36 months, into foster care were more likely to experience externalizing behaviors. These included aggression, hyperactivity, and destructiveness, and have difficulty appreciating the feelings and needs of others and difficulty in forming attachments. Children who had been institutionalized for the first 3 years of life demonstrated consistently greater levels of problem behaviors, ranging from feeding and sleeping difficulties, to problems with aggressive behavior and hyperactivity, to marked overdependence on adults characterized by attention-seeking behavior (Goldfarb, 1943).

The findings of hyperactivity and difficulty with attention among previously institutionalized children have been linked with difficulty in establishing and maintaining selective attachments (Roy et al., 2004). At age 6, children who were raised in institutions for the first 3 years of their lives displayed more hyperactivity, anxiety, and difficulty with attention than did their counterparts raised exclusively in foster care, as reported by social workers familiar with them (Goldfarb, 1944). Lowrey (1940) noted a pattern of hyperactivity, particularly as formerly institutionalized children were transferred into "boarding" or foster homes (Lowrey, 1940). In the Tizard study, adopted children were less distractible and restless than children either remaining in the institution or reunified with their families (Tizard & Rees, 1974).

The ERAS group has argued for an institution syndrome that includes inattention and hyperactivity. Descriptions of the children from this study affirm early reports of restlessness, hyperactivity, and difficulty with attention (Doolittle, 1995; Kreppner, O'Connor, & Rutter,

2001; Roy et al.2004; Rutter et al., 2001), difficulties that have been proposed as a possible link to problems in establishing and maintaining selective attachments (Roy et al., 2004).

Autistic Spectrum Disorders

Based on clinical observations of hundreds of institutionalized children in Russia and Romania, Federici (1998) reported that some of the children appeared to display an unusual constellation of behaviors, including cognitive impairment, stereotypies, and socially withdrawn and unresponsive behaviors. He described this constellation as "institutional autism." Rutter and colleagues (1999) used state-of-the-art diagnostic procedures to evaluate 4-year-old children in their sample of Romanian orphans adopted into the United Kingdom. They found that 6% met diagnostic criteria for autism and that another 6% had mild, often isolated, features of the disorder. Given that most children were placed in institutions at or shortly after birth, and given the proportion of children affected, it did not seem that the likelihood of meeting criteria for an autism spectrum disorder reflected a placement bias but rather that the experience of institutionalization produced a phenotype that was indistinguishable from autism. Interestingly, when reevaluated at age 6, most of the children in this sample were much improved and no longer met criteria for autism, although some continued to exhibit unusual behaviors. Because the children had responded so dramatically to more favorable caregiving environments, the investigators described the syndrome as "quasi-autistic." What vulnerabilities in individual children might lead to such a clinical picture among institutionalized children and the processes through which the caregiving environment ameliorates such symptomatology remain to be elucidated.

The Bucharest Early Intervention Project

The BEIP was the product of a MacArthur Foundation research network that the three authors belonged to from 1997 to 2005. The mission of this network was to examine the effects of early experience on brain development. In keeping with a long tradition in neuroscience, some of the work of the network was focused on what happens to the developing brain when it is deprived of experience. The BEIP followed on the heels of a monkey project being overseen by network member Judy Cameron, who was raising monkeys that had been separated from their mothers at different points in development. That work was instrumental in shaping the experimental design of the BEIP, which is discussed next.

EXPERIMENTAL DESIGN AND METHODOLOGY

Participants

Institutionalized Group

At the time we launched the BEIP, there were approximately 100,000 children living in institutions in Romania. We decided to recruit our sample from the institutionalized infants and young children living in Bucharest. The city has six sectors and each sector had an institution. For the institutionalized group (IG), inclusion criteria were all children living in institutions in Bucharest who were younger than 31 months of age and who had spent at least half of their lives living in an institution. Children were administered a pediatric/neurological exam by a pediatrician and a pediatric nurse practioneer, and growth (height, weight and head circumference) was ascertained as was an assessment of any physical abnormalities. We excluded children with known genetic syndromes (e.g., Down syndrome), frank signs of fetal alcohol syndrome, and microcephaly (see Zeanah et al., 2003, for details).

We originally screened a total of 187 institutionalized children but excluded 51 based on our exclusionary criteria. The remaining 136 children were judged to be in reasonably fair health (at least at the time this assessment was performed) and met our inclusion and exclusion criteria.

Of the final sample of 136 children, 57% were of Romanian ethnicity, 27% were Roma (Gypsy), one child was Turkish, one was of subcontinent Indian extraction, and the remaining 15% were mixed or could not be classified. All children at the time of the baseline assessment had spent between 51% and 100% of their lives in the institution, with 52% having spent their entire lives institutionalized.

Birth records indicated that children were born between 30 and 42 weeks, and birthweight ranged from 900 g to 4150 g (M = 2767 g, standard deviation [SD] = 609 g), which differed somewhat from the community control children (M = 3338 g, SD = 467 g). Finally, the average age at baseline assessment for the institutionalized children was 22 months.

Never-Institutionalized Group

Our initial research question involved examination of the 136 children while they still lived in the institution. We wished to assess them on multiple standardized measures, and it was important for us to recruit a typically

developing Romanian comparison sample. Most of the measures we used had never before been used in Romania, and we needed to know if typically developing children in Romania performed similarly or differently than typically developing children in the United States, on whom most of these measures were normed.

With this in mind, we recruited 72 children who had never been institutionalized (never-institutionalized group—NIG) and who had been born at the same maternity hospitals where the foster care group (FCG) and care-as-usual group (CAUG), meaning continued institutional care, had been born. We matched to the other groups by child age and gender, and they underwent a similar screening as the children who had been institutionalized. All community children fell within 2 SD of the mean for physical growth (weight, length, occipitofrontal circumference). Ninety-two percent of the sample was Romanian, 6% were Roma, one child was Spanish, and one child was Turkish.

Fortunately, on nearly all measures we employed, the Romanian community children's were very similar to U.S. norms. As a result, we then had an in-country comparison sample of typically developing Romanian children against whom to compare both children in foster care and those receiving care as usual.

Randomization

Following a comprehensive baseline assessments, children in the institutionalized group were randomly assigned either to the FCG or the CAUG. Random assignment was determined by drawing pieces of paper from a hat (each piece had the name of one of the children, but four pieces had two siblings each). We compared children in the two groups, and no differences were observed in gender distribution, age, birth weight, or percentage of life spent in an institution.

Assessing children prior to randomization ensured that the intervention and control groups were comparable and increased our confidence that any differences in outcome would reflect true intervention effects. Importantly, randomization prior to intervention increased the likelihood that prenatal and other risk factors (e.g., iron deficiency, lead exposure, drug exposure), which could not be ascertained with certainty, would be evenly distributed across the two groups.

As a result of our experimental design, children ranged in age from 6 to 31 months at baseline. Half were then assigned to different foster care homes. They thus varied in their age of placement, which allowed us to examine the outcome data for the presence of sensitive periods (age after which placement into foster care no longer affected outcome). Age at placement was related to length of time in institutionalization. With age of assessment (42, 54, and 96 months), we could calculate length of time the child was exposed to intervention.

Children were initially evaluated at 42 and 54 months, at which point we ended the intervention phase of the trial (i.e., we concluded financial support of our foster care network); however, we followed up the sample at 8 and 12 years, and we have received support to conduct an additional assessment at age 16 years. In later sections of this chapter, we report our findings through age 8, as our 12-year follow-up is not complete as of this writing.

Measures

Because we viewed this project as a once-in-a-lifetime opportunity, we tried to study as many domains of function as possible, ranging from simple height, weight, and head circumference to telomere length. The tables later in the chapter illustrate the many measures and constructs we included.

Summary of Design

The BEIP is the first-ever randomized controlled trial (RCT) of foster care as an intervention for early institutionalization. Its five strengths as a study include: (1) baseline assessments while the children resided in an institution; (2) randomization; (3) a focus on both neural and biological methods; (4) the use of an assortment of state-of-the-art and multimodal psychological methods and measures; and (5) an in-country comparison group. In addition, certain limitations must be noted. First, because of the child protection system at the time the study began, abandoned children were not transferred from maternity hospitals to institutions until they were about 6 months of age. As a result, the children in our study already had experienced many months of institutional rearing. Thus, any claims we make about sensitive periods must be qualified by the fact that no children were less than 6 months old at the onset of the study (and conversely, none was older than approximately 31 months). Second, although we were able to randomly assign children to foster care, we were (obviously) unable to randomly assign children to institutional rearing. We must consider the possibility that children who are abandoned at birth and placed in institutions are likely different from children born into comparably poor families who were not abandoned. Third, for ethical reasons (see the next section), over the course

of the study, children moved from one setting to another (e.g., an institutionalized child was reunited with his/her biological family). Although we have dealt with this issue by continuing to adopt an intent-to-treat approach to our data analyses, this likely underestimates effects of the settings on children's development. In attempting to juxtapose the effects of early experience against those of subsequent life experience, the small sample we have will prove limiting in this regard.

Ethical Issues

We considered a number of ethical issues from the outset of the study, and we have been mindful of others throughout the study. First and foremost is the issue of the vulnerability of the study participants. There are two components to this issue: whether vulnerable participants were being studied for others' benefit, and whether the methods used posed only minimal risk. In regard to whether vulnerable participants were being studied for the benefit of others, rather than themselves, the beneficiaries of the RCT would be children placed in institutions—in other words, populations similar to the study sample. In regard to whether measures and methods of more than minimal risk were being used in a vulnerable population, the answer is that none of the measures used in this study presented more than minimal risk. All were standard measures used in child development research in many parts of the world, and they had been used previously by the three principal investigators in hundreds of children with parents. There is also a legitimate question as to whether we could ethically randomize children to "care as usual," because then only half of the children would receive the putative benefits of foster care. Our answer is that because there was essentially no foster care in Bucharest when we started the study, no children would benefit if we did not conduct the study. An additional concern is whether the course of children's placements were altered by the study—specifically, whether children were to be maintained in institutional settings so that they could be studied. The answer is that once children were randomized to the CAUG or FCG, we adopted a policy of noninterference. This meant that if the authorities elected to change the placement status of a child, we did not interfere. (The same applied to families who sought to take their child out of the institution.) Not surprisingly, over time, many of the children in the CAUG left the institution and were reunited with their biological family, placed in government foster care, or adopted (see Figure 18.2). The one exception to noninterference is that we worked with various NGOs and government authorities to ensure that any child we placed in foster care would not be returned to an institution.

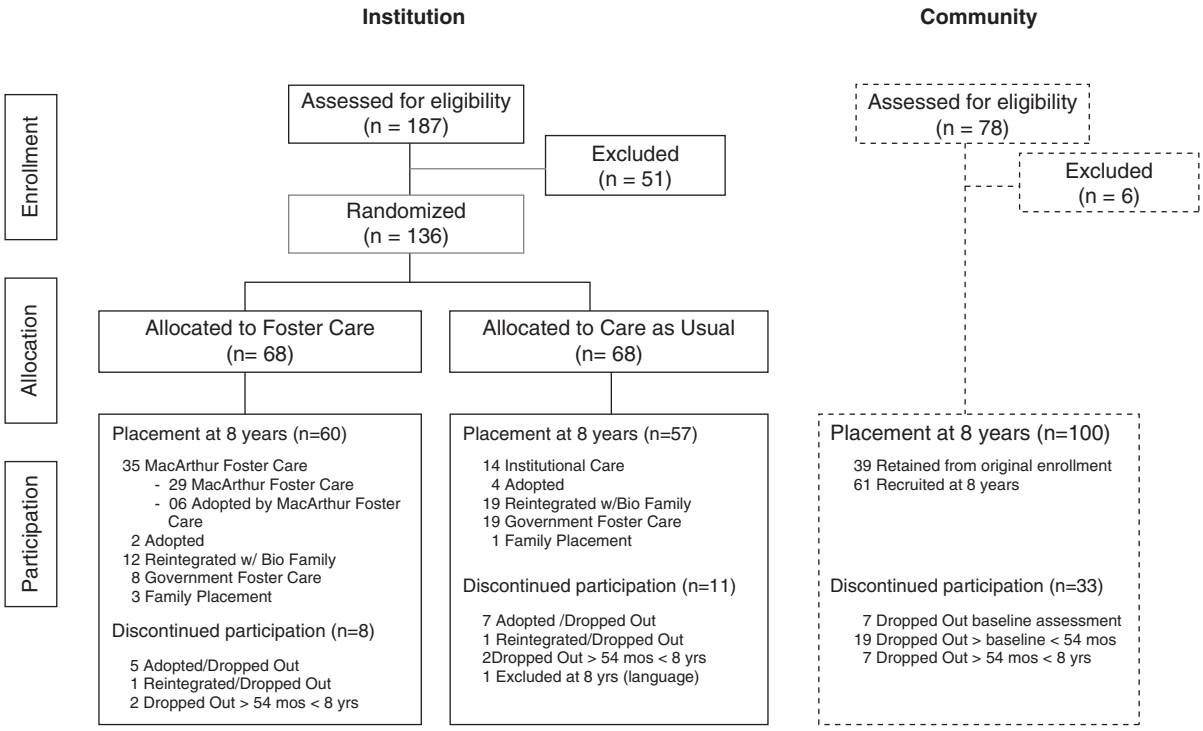

Figure 18.2 Illustration of the initial recruitment of children into the study and over time, their placement status at age 8 years.

For oversight, we sought and received permission to conduct the study from the U.S. universities of the three principal investigators as well as the local authorities in Bucharest and children's legal guardians. After the study began, the Romanian government appointed an ethics commission to review the study, and they deemed it ethically sound. In the past several years, we have also been overseen by an ethics committee at Bucharest University.

A final issue we confronted was that once we realized that children in the FCG were doing better than children in the CAUG on a variety of developmental measures, we faced the conundrum all clinical investigators face: Do we continue the study knowing that one group (FCG) is benefiting more than another (CAUG)? In drug or device RCTs, for example, if the intervention is proving efficacious, one typically stops the trial and offers the treatment to all participants. We could not do this, as we lacked the resources to support or even identify additional foster families. As a result, if we stopped the study, all the children we placed in foster care would likely be returned to the institution.

Instead, we elected to call a press conference, to which relevant government authorities were invited, along with the media. At this event, hosted by the then U.S. Ambassador to Romania, we announced preliminary findings, which we hoped would lead to policy changes regarding abandoned children (a topic we take up later in this chapter). We also established a Data Safety Monitoring Board, which would enable all study participants and their families to express concerns about the study to an impartial third party. Finally, our team of social workers and psychologists worked closely with the families to improve the care our study participants received and to offer referrals, when possible, to children who required medical or psychological care.

We and others have written extensively about BEIP ethics. The interested reader is referred to Miller and Brody (2003); Millum and Emanuel (2007); Nelson et al. (2007, 2009, 2014); Nelson, Fox, and Zeanah (2013); Rid (2012); Wassenaar (2006); Zeanah, Fox, and Nelson (2012); and Zeanah et al. (2006a,b)

Foster Care Intervention

As mentioned earlier, there were virtually no foster homes in Bucharest in 2000 when we started our project. However, legislation passed in 1997 had encouraged the development of foster care, and it existed in some parts of Romania. The government had adopted a French model of foster care in which "maternal assistants" or foster parents were full-time employees of the government, receiving salaries rather than subsidies to care for children. As established in Romanian legislation, all foster care parents were licensed and had received didactic training.

We hired three BEIP social workers who recruited and screened foster parents. With considerable effort, we identified 53 foster parents to care for the 68 children. Ten foster parents agreed to care for two children each. For four parents, this involved two siblings, whereas each of the remaining six parents agreed to care for two unrelated children.

These foster mothers ranged in age from 29 to 65, and most (29/53) were married and living with their spouses. Another 11 were widowed, 9 were divorced, and 4 had never married. A few of the mothers had fostered children previously (12/53), mostly because they had been hired by NGOs dealing with international adoption. These previous foster children typically had stayed in care only for a few months.

Of course, we understood that there were risks of implementing a model of foster care in Romania that was simply imported from other countries and applied in Romania. In order to ensure cultural appropriateness, we were able to use a foster care training manual that had been developed by a large NGO, World Vision. This manual had been written by and for Romanians, derived from and modeled after similar manuals in the United States. Our administrative partner, SERA Romania, had had several years of experience implementing foster care in other parts of Romania. We vetted our training and consultation model with SERA Romania, as well as with our own social work staff, to ensure the cultural appropriateness of the approaches we were implementing.

The training provided to foster parents was conducted over 6 weeks. It included 22 hours of information about children's rights, recent reforms in Romanian child protection, and the rights and obligations of foster parents. Another 20 hours covered child development, including information from educational and child psychology. Finally, 18 hours were devoted to managing children's challenging behaviors and disabilities as well as social challenges. Additional time was spent with foster parents on common characteristics of children living in institutions, and they visited institutions to observe the children and, when possible, they visited with the children they would foster before the placement (see Nelson, Fox, et al., 2014; Smyke, Zeanah, Fox, Nelson, & Guthrie, 2010, for more details).

Our approach during the training and throughout the intervention was to make the parent-child relationship the central component of the intervention, in keeping with contemporary research and practice (Dozier et al., 2006; Zeanah et al., 2011). Therefore, we advocated that BEIP foster parents care about and for the children as if they were their own. Drawing from contemporary literature on parenting maltreated children, we incorporated several

points of emphasis for our foster care intervention. First, BEIP social workers encouraged foster parents to make a full psychological commitment to the children in their care (Dozier & Lindheim, 2006; Lindheim & Dozier, 2007). Second, we wanted parents to provide sensitive care to the young children assigned to them (Bick & Dozier, 2013). This meant getting to know the child as an individual and emotionally investing in him or her, in the context of a long-term commitment. Third, because of limited infant mental health resources in Bucharest in 2001, the BEIP team had to provide interventions for typical behavioral and regulatory issues that present in young, maltreated children—oppositional and aggressive behavior; social withdrawal; toileting difficulties; bedtime struggles and waking at night; refusal to eat, stuffing, or hoarding; hyperactivity; and indiscriminate behavior, all of which are common (Smyke, Zeanah, Fox, & Nelson, 2009).

One of the striking differences in foster care in Romania and foster care in the United States was the commitment for a particular duration: In the United States, foster care is a temporary condition, intended to keep children safe while parents remediate the problems that led to the children's removal. In Romania, however, foster care was not viewed as a temporary placement.

Another important issue was that social work had been banned as a profession in Romania in the communist era. In 2000 when the BEIP began, the School of Social Work at the Bucharest University had been open only for a few years, and the faculty included almost no senior social workers. Therefore, BEIP social workers had not received much in the way of mentoring and had no experience with foster care prior to their project participation. In order to provide them with experienced mentoring, they received weekly consultation by video from clinicians experienced in working with maltreated families in the United States. The social workers learned about parent and child characteristics that might impede, limit, or diminish a close and engaged parent-child relationship as well as interventions to enhance the relationship.

We provided extensive support to the families, including all material and medical support; moreover, we provided staff support so that staff members could better help the families. We linked foster care placement to permanency planning, and, indeed, nearly a third of our foster care families ultimately adopted their children. Each family was monitored—specifically, our social workers visited the families roughly every 10 days initially and at longer intervals as the intervention continued on, and were available for consultation in between visits. (For details about our foster care program, see Smyke et al., 2009.)

The Findings

The BEIP represented a unique research opportunity, and as such we elected to study multiple domains of development. In part this was because we believed that the risks associated with early deprivation were likely to affect many domains but not necessarily affect all of them in the same way. We were interested in delineating outcomes and in identifying mechanisms underlying the process of exposure to psychosocial deprivation and these outcomes. Tables 18.1 through 18.9 provide a complete listing of all measures used to date.

In this chapter, we focus on a number of key domains. Even within those domains, we provide only broad overviews of our findings; again, the interested reader

is referred to our published work. (For key summaries, see Fox, Almas, Degnan, Nelson, & Zeanah, 2011; Leiden Conference on the Development and Care of Children without Permanent Parents, 2012; Nelson, Fox, et al., 2013; and Zeanah, Gunnar, McCall, Kreppner, & Fox., 2011.)

Cognitive Development

In the BEIP, we were interested in evaluating children's cognitive abilities using a combination of standardized measures of intellectual function (e.g., developmental tests, IQ tests) and experimental measures that permit us to draw inferences about specific cognitive functions (e.g., inhibitory control and working memory) and their relation to underlying brain circuitry.

IQ

We administered the Bayley Scales of Mental Development to the children living in the institutions prior to randomization to the two arms of our study. In follow-up visits at 30 and 42 months, we continued to use the Bayley Scales because of the children's level of performance. We switched to the Wechsler preschool version of the IQ test at the 54-month session (Weschler preschool and Primary Scale of Intelligence; WIPPSI) and to the Wechsler Intelligence Scale for Children (WISC) when children were tested at age 8.

Baseline scores revealed that the institutionalized children had a Mental Development index (MDI) of 62 while community children had an MDI of 102. Immediately after the baseline assessments, the children were randomized

into the two arms of the study. The MDI is a standardized score with a mean of 100 and an SD of 15. Thus, infants and young children (ages 6–31 months) living in institutions were severely delayed as assessed on this measure of infant IQ. Our next three assessment points occurred when the children were 30, 42, and 54 months of age. Since children entered the intervention at ages ranging from 6 to 31 months, children would vary in the length of time they were exposed to the intervention at each of these immediate follow-up points. A child who went into the intervention at the age of 28 months might have had only 2 months of the intervention at the 30-month assessment while others who were 8 months at placement would have had 22 months of exposure to the intervention.

We asked two questions of the IQ data collected at these three age points: at each age, first, was there an effect of intervention? That is, did the children randomized to the foster care group outperform the children randomized to the institution? Second, in the foster care group, was there an effect of age of placement or duration of intervention on IQ?

The children placed into foster care outperformed their age-mates who had remained in more prolonged institutional rearing. Although this finding confirmed our hypothesis about the efficacy of our intervention, it is important to point out that at each age, the children placed into foster care still lagged behind typically developing community children from Bucharest.

We next examined the relations between age of placement and IQ at each age as well as length of time in intervention and IQ at each age for the children placed into foster care. We found that only age of placement (more than duration of time in foster care) was positively related to IQ scores at each age. That is, it was more important how old the children were when they left the institution and were placed into foster care than how long they spent in the foster care home. Of course, both these factors—age at placement and length of time in care—confounded (i.e., highly correlated with one another). But we could examine which factor was a more powerful a predictor of IQ; age of placement was. Indeed, within the confines of the distribution of ages in our sample (ages of children at placement), we could identify a cut point for age of placement before which children placed into foster care outperformed their institutionalized age-mates and after which there was little difference between a foster care child and a child randomized to remain in the institution.

If children were younger than 24 months at placement, then at each of the three ages—30, 42, and 54 months—they were more likely to outperform children older than 24 months at placement. This finding strongly argued for a sensitive period in cognitive recovery—at least with regard to IQ in early childhood—such that children placed after the age of 24 months more closely resembled institutionalized children and those placed before the age of 24 months begin to approximate never-institutionalized children.

The next assessment point for the children in the study was when they were 8 years of age. At that time, we administered the WISC, which provided us scores for each child in full-scale IQ as well as four subscales (processing speed, verbal comprehension, perceptual reasoning, and working memory). Our first analysis approach was the intent-to-treat analysis in which children who were originally assigned to either the foster care or institution groups were analyzed as if they had remained in their original caregiving settings. We found when using this approach that there were no differences in any of the subscales or in full-scale IQ between the two groups. The full-scale IQ of the foster care group was 81.5; for the CAUG, it was 76.2. It appeared that while the IQ scores of the foster care children remained stable over time, the scores of the children randomized to the institution began to catch up. As before, the scores of both groups were significantly below the mean scores of the community controls. As well, the timing effects we had identified at 30, 42, and 54 months were no longer evident.

There are several plausible explanations to account for the failure to replicate the timing effects observed at earlier ages. First, if we examine the changes in context for the children in our study at age 8, we find that only 14 of the original 68 children randomized to remain in the institution still lived in this setting. The remainder had been reunited with their biological parents, placed into government foster care, or adopted by Romanian families. Similarly, of the 68 children randomized to our foster care intervention, 31 were still in these homes; the other children had either been adopted or reunited with their biological families. So, there was a great deal of movement in the lives of the children in our study between 4.5 and 8 years of age. Also, most all the children started school at age 6 so that by the time we tested them, they had 2 years of schooling.

We decided to investigate further the pattern of IQ data in our sample by examining scores of children based on their current placement status. For example, we wondered whether children who were originally assigned to BEIP foster homes and who remained there would do better than children who remained in the institution or who were placed into government foster care. These analyses showed that children who remained in our foster homes had higher scores than the children in the two other groups

on three of the four subscales (working memory, verbal comprehension, and processing speed) and significantly higher full-scale IQs. As a further check, we found that among our foster care group, those who had remained in the homes did better than those who left. These two sets of results clearly show the benefit of a stable positive family environment on IQ scores. Although the initial uptick in IQ scores was due to our intervention, sustaining those intervention effects was a result of the child remaining in a stable placement over time.

We then decided to make use of the longitudinal nature of our data, examining the pattern of IQ scores in both the FCG and CAUG groups. In each group, there were two obvious trajectories over time. One involved children who had stable but low scores across age while the other involved higher stable scores over time. We examined predictors of these different trajectories and found for the FCG group, attachment security and positive responsive caregiving at 42 months predicted a high and stable pattern of IQ. In addition, strong language skills at 42 months contributed to these stable high patterns. We could not, however, find predictors of patterns within the CAUG group, except for poor language abilities at 42 months related to low and stable trajectories in IQ.

SUMMARY

When we survey our results from baseline to age 8, two key findings emerge. First, leaving children in institutional care, or even spending the first 2 years of life in institutional care, leads to a dramatic reduction in cognitive performance. Second, placing children in families *before* the age of 2 years dramatically improves cognitive performance, at least through age 4.5 years. By age 8, our foster care effects are maintained, but group differences (between CAUG and FCG) diminish, likely due to an upward shift in IQ among the CAUG. Nevertheless, the general conclusion that children raised in families versus institutions have higher IQs is beyond dispute, and consistent with decades of earlier research.

Neuropsychological Functioning at 8 Years

We felt it essential to include measures of cognitive function that would permit reasonable inferences to be drawn about underlying brain architecture, because the BEIP was conceptualized as a project designed to examine experiential effects on brain development. We were particularly interested in tasks that tapped the functioning of the PFC, as the PFC is the primary seat of higher cognitive functions, so-called EFs, and it is highly sensitive to early experience and stress. Executive functions (EFs) represent a collection of skills and abilities, including working memory, planning, cognitive flexibility, inhibitory control, and attention, to name just a few (Blair, Zelazo, & Greenberg, 2005; Nelson & Luciana, 2008; Zelazo et al., 2003).

Based on previous research by other investigators, as well as our own previous findings at earlier ages (including IQ), we anticipated that we would find impairments in planning behavior, inhibitory control, and learning and memory among children with a history of early institutional care compared to children without such a history. Similarly, given what is known about the protracted development of the PFC, we expected that our FCG would show improvements in EFs compared to the CAUG (although the FCG performance might not be equivalent to that of the NIG); however, we were less sure about timing effects. As for memory, given the well-known plasticity of the hippocampus and surrounding cortex (which makes learning and memory possible for much of the life span), we expected that the CAUG would show much worse performance than our other two groups, but that the FCG would show an improvement in memory, although again, we were unable to make predictions about timing.

To test these hypotheses, at 54 months we performed the Bear-Dragon test, which evaluates a form of inhibitory control, and at 8 years, we performed an event-related potential (ERP) test of inhibitory control (Go No Go) and also drew from an automated battery of neuropsychological tasks that one of us (CAN) has made extensive use of in the past (e.g., Luciana & Nelson, 1998; McDermott, Westerlund, Zeanah, Nelson, & Fox, 2012). We discuss each of these in turn.

Inhibitory Control at 54 Months: Bear-Dragon

The child's ability to inhibit a prepotent motor response (i.e., one built up over time) develops over the preschool period. It is seen as an essential skill for adaptive social behavior as well as behavior necessary for learning. We used the Bear-Dragon paradigm, in which a child is told that whatever the Bear puppet says to do ("touch your nose"), the child should do, and whatever the Dragon puppet says to do, the child should ignore. The child and experimenter then play Bear-Dragon. The child has 20 trials with two-thirds being Bear trials and one-third being Dragon trials. We count the number of correct responses across both types of trials. When we examined the children's performance, we found that the care as usual children were able to follow directions, but unable to inhibit responses. Foster care children were significantly better at inhibiting responses although not nearly as accurate as typically developing children from the community. Thus,

children assigned to the CAUG show the worst inhibitory control, the NIG the best, and the FCG were in between.

Inhibitory Control at 8 Years (Go No Go)

Inhibitory control, which is critically involved in learning and is also involved in both the cognitive and social functioning elements of school success (e.g., the ability to sit at one's desk and do one's work without distraction; the ability to inhibit saying hurtful things to one's friend) was of particular interest, given the high rate of ADHD that has been observed among ever-institutionalized children.

Inhibitory control is conceptualized as the ability to inhibit a response in the face of potentially distracting stimuli. It is often assessed using tasks that require participants to respond to a particular type of stimulus, while inhibiting a prepotent response to another type. Inhibitory control increases throughout middle childhood (Cragg & Nation, 2008), and this improvement has been linked to the development of prefrontal neural circuitry (e.g., Casey et al., 1997; Durston, Thomas, Worden, Yang, & Casey, 2002; Hwang et al., 2011).

In our 8-year follow-up, we administered a well-known task of inhibitory control, the Go No Go task, while recording both button press accuracy and ERPs (see McDermott et al., 2012). This task begins by presenting the same stimulus repeatedly, asking the child to push a button on every trial (i.e., all "Go" trials). The purpose is to prime children to respond quickly and on every trial, so that they develop a tendency to push (i.e., they develop a so-called prepotent response). We then present an interleaved sequence of Go and No Go trials, in which children were instructed to press a button for when they see a certain stimulus and not to press a button when they see another stimulus. In our case, 70% of the trials were "Go" trials (all letters of the alphabet except the letter "X") and 30% of the trials were No Go trials (when they see an "X," they should *not* press the button).

Overall, children who remained in care as usual were less accurate and exhibited longer ERP latencies (i.e., slower neural responses) compared to children in the FCG or NIG. However, children in both the CAUG and FCG exhibited diminished processing of No Go cues as inferred from one particular ERP component—the P300—which serves as an index of staying on task. Foster care children also showed an enhanced ERP component that reflects error monitoring (the so-called error-related negativity, or ERN) compared to children in the CAUG, which suggests they were better at monitoring their performance and more sensitive to errors. Collectively, these results supported the hypothesis that institutional care led to performance deficits in inhibitory control and in error monitoring and that being placed in foster care appeared to bring inhibitory control into alignment with that of the never-institutionalized children, although there remained some deficits in brain activity.

Having demonstrated that institutional rearing has a negative impact on inhibitory control, we were also interested to see if other EF skills might be affected. Here we drew from the CANTAB, similar to the research by Pollak and Loman reviewed earlier in the chapter (Pollak et al, 2004 and Loman et al 2013). The CANTAB represents a collection of more than 12 neuropsychological tests, many drawn from the experimental neuropsychology literature of human patients. Unlike a clinical neuropsychological battery, many of the CANTAB tasks have reasonable neural specificity. What makes the CANTAB ideally suited to young children is that the tasks are all done on a touch-screen monitor, in the form of a game, and do not require very sophisticated motor or language ability.

We were unable to perform all of the CANTAB tasks due to limited time, but instead focused on a subset that included tests of simple motor learning (motor screening), memory (delayed match to sample, paired associate learning), planning (stockings of Cambridge, a variant on the well-known Tower of London planning task) and spatial working memory. Unfortunately, the results can be summarized very briefly. First, although the groups performed similarly on a simple test of motor function (motor screening), we found no difference on any other task between the CAUG and the FCG—basically, both groups (which we refer to as ever institutionalized) performed more poorly than the NIG on all other CANTAB tasks. This finding suggests, of course, that (a) institutionalization had a negative impact on both memory and some aspects of EF and that (b) the foster care intervention failed to have a positive effect on performance on any of these tasks.

Collectively, it appears that ever-institutionalized children experience a decline in performance in both memory and EFs compared to never-institutionalized children. Moreover, placing such a child in foster care appears not to improve their performance in these domains, with the exception of inhibitory control (see McDermott et al., 2012).

Brain and Biological Development

One of our major interests was in the effects severe psychosocial deprivation may have on the developing brain and whether removing a child from a deprived institutional environment, and placing that child in a foster family changed brain structure and functioning. We also hoped to explore whether the timing of the intervention would have an impact on outcome; specifically, is there a

period during which intervention would have its greatest impact? These questions had not been addressed previously in children who were living in institutions, or in those systematically removed and placed in foster care.

To explore these questions, we used brain imaging methods that were suitable for infants and young children—the electroencephalogram (EEG), and the ERP. By the time the children were 8 years old, we had gained access to a 1.5 Tesla scanner and could use MRI to perform structural imaging on the sample. Table 18.1 illustrates our brain-based battery.

Electroencephalogram

We recorded the EEG prior to the children being randomized, when they were still living in the institutions, and then again after randomization at 30 and 42 months and at 8 years. EEG was recorded while children viewed bingo balls rotating in a bingo cage (the goal of which was to engage the child's attention for a few minutes, standardizing attention to the wheel and minimizing movement).

At baseline, we observed large differences in EEG between the children living in institutions and community controls. The children living in institutions had greater slow-frequency activity (theta) and less high-frequency (alpha and beta) activity relative to the community controls (Marshall, Fox, & the BEIP Core Group, 2004). This less mature profile was maintained through the initial period of the intervention.

When we recorded EEG at the 8-year assessment, children in the FCG had been in their foster care families for between 5.5 to 7.5 years. At age 8 years, there was a strong intervention effect and a timing effect in the EEG data. Children placed into our foster care intervention before the age of 24 months displayed a pattern of brain activity that was indistinguishable from the NIG. The children who were taken out of the institution before age 24 months showed a pattern of higher mature alpha activity and lower less mature theta activity (Vanderwert, Marshall, Nelson, Zeanah, & Fox, 2010). Foster care children also had more significant high-frequency beta activity compared to children randomized to the institution. Indeed, like the alpha power finding, there was both an intervention and a timing effect for beta power at age 8.

These findings suggested two important conclusions. First, there appears to be a sensitive period for the development of neural structures underlying increased alpha and beta power in the EEG signal, with amelioration of the deprived environment prior to 2 years of age being critical for remediation. Second, although this developmental "catch-up" was made possible by placement into foster care before the age of 2, it required years of exposure to foster care to emerge.

Although we had recorded EEG at 30 and 42 months, we found little change over that period of time. Of course, since the mean age of the children placed into foster care was 22 months, the average duration of intervention at 30 months was only 8 months and at 42 months, 20 months, perhaps not long enough to affect brain activity as detected by our measures. By 8 years of age, children had experienced the intervention and other life events that may have facilitated brain changes, particularly among those who received the initial intervention. Thus, the intervention and timing effects could reflect subtle combination of age of placement *and* duration of intervention. But as time went on and children began to spend more time out of institutional care (e.g., the CAUG who is removed by the child protection authorities at age 3 and reunited with his/her family), the effects of current life experience began to weigh more than the effects of early life experience.

Event-Related Potentials

ERP Studies of Familiar versus Unfamiliar Faces. The characteristics of institutional care make it likely that institutionalized children have atypical experiences with faces compared to children reared in typical families. Examples include a high child-to-caregiver ratio, high caregiver turnover, and limited adult-child interactions within institutions (as reviewed in Zeanah et al., 2003). These factors may lead to more limited exposure to adult faces among institutionalized compared to family-reared children. It is also possible that institutionalized children have access to a more limited range of facial expressions of emotion or have disproportionate experience with particular facial expressions (e.g., negative or neutral expressions) compared to children reared in typical homes. It is undoubtedly the case that the quality of social interactions of institutionalized children and the quality of facial affect during those interactions differ from family-reared children. We therefore sought to examine two aspects of BEIP children's responses to faces: their ability to discriminate a familiar from an unfamiliar face and their ability to discriminate different facial expressions of emotions. Both elements of face processing were examined at baseline and at follow-up.

To address these questions, we conducted a simple test: Children were presented with alternating images of their primary caregiver's face and the face of a stranger, and ERPs were recorded during this time. We examined a series of ERP components across groups, both at baseline

(S. W. Parker, Nelson, & the BEIP Core Group, 2005a) and at later ages (see Moulson et al., 2009a,b). We discuss the baseline findings first, followed by the 30 and 42 month findings.

Baseline Three major observations were made at baseline. First, for all ERP components examined, the NIG showed much larger amplitude responses than the IG. Second, for the critical component of interest—the negative component (NC), which reflects allocation of attention—both groups showed the same response, with a larger NC to the stranger's face compared to the caregiver's face. Third, for the Positive Slow Wave (PSW) which reflects the updating of memory, the IG displayed a greater amplitude response to the familiar face (versus the novel face), whereas the NIG showed no ERP difference. Collectively, the amplitude differences we observed between the IG and NIG are consistent with what we observed in the EEG. In addition, the PSW difference suggests that the children in the IG were attending more to the caregiver's face, implying that this face was not well encoded into memory, whereas the NIG responded equally to both familiar and unfamiliar faces (suggesting both were equally well encoded).

Overall, the reduction in amplitudes among the IG is consistent with the EEG findings reviewed earlier, in which we observed a dramatic reduction in brain activity. In terms of facial discrimination, it appears that for one component (NC), the IG and NIG performed identically, but for another (PSW), the IG displayed a very different response than the NIG. This finding suggests that institutionalization leads to subtle differences in processing familiar and novel faces. The next question was whether such differences carried forward to the 42-month follow-up. In other words, if there were slight differences in processing faces early in life, would these be magnified over time so that later in life, there would be substantial differences?

Follow-up testing (to examine intervention effects) when children were 42 months of age was identical to baseline testing: Children were presented with alternating images of their caregiver's face and the face of a stranger while ERPs were recorded. Several findings were noteworthy. First, as we observed at baseline, the CAUG displayed markedly smaller ERP amplitudes. This finding suggests that the hypocortical arousal observed at baseline persisted at 42 months, suggesting that this brain pattern is a result of early experience, not subsequent life experience. Second, for most components, both the CAUG and the NIG displayed very similar profiles of ERP differentiation of caregiver versus stranger faces: specifically, larger amplitude and shorter latencies to stranger versus caregiver faces. Again, consistent with the baseline findings, this suggests that, much to our surprise, early institutionalization has relatively little impact on discriminating caregiver versus stranger faces. That is, children raised in institutions are as capable of distinguishing familiar and unfamiliar faces as are children who have never been institutionalized. This may be because the development of face processing may require relatively little input in order to proceed normally (Righi & Nelson, 2012). Perhaps just being around other children and a multitude of caregivers is sufficient exposure for the neural circuitry that underlies faces to develop in a typical fashion.

Finally, we observed that the amplitude of a key ERP component that has face-sensitivity—the P1—was enhanced among children in the FCG compared to the CAUG, although it was not quite as large as among children in the NIG. This finding suggests that the foster care intervention had, by 42 months, begun to normalize this aspect of visual processing (although we cannot say for certain that this was an improvement in face processing specifically), which is very encouraging. This result is consistent with our EEG data, in that placing children in families, following early institutionalization, leads to a reduction in the hypocortical arousal observed at baseline among the IG children. Interestingly, no timing effects were observed, suggesting that normalization occurs regardless of when a child is placed in foster care.

Summary First, as is the case with EEG, children assigned to remain in institutional care showed a marked reduction in all ERP components. This cortical hypoarousal is of some concern, as it suggests that the brains of institutionalized children (and children who spent the first part of their life in institutional care but eventually went into care of families) are developing differently from never-institutionalized children. (We return to this issue when we discuss our MRI findings.) Second, unlike virtually every other domain observed in the BEIP, institutional rearing appears to have had relatively little effect on the ability to distinguish familiar from unfamiliar faces. In other words, for only a single component, and only at baseline, did institutionalized children differ from community children—both groups discriminated a familiar face from an unfamiliar face. This finding, in turn, argues that there is sufficient facial information in the institutional environment to support the typical development of the neural circuitry that underlies face processing. Of course, it remains to be seen whether more complex forms of face processing are observed at later ages.

ERP Studies of Facial Emotion Processing. As alluded to earlier, it is well established that experience has a powerful effect on the development of face processing. The development of face processing most probably reflects an experience-expectant, activity-dependent process, in which cortical specialization for face processing is driven by experiences with faces over the first years of life (Nelson, 2001). Particularly relevant to the BEIP are studies that have examined facial emotion processing in children experiencing early institutionalization followed by adoption (e.g., Wismer Fries & Pollak, 2004).

At both baseline and follow-up, we utilized a very simple experimental design: Infants/children were presented with four facial expressions—happy, sad, angry, and fearful—posed by the same female model. These four expressions appeared equally often, during which we recorded ERPs.

Baseline Several findings are noteworthy (see S. W. Parker, Nelson, & the BEIP Core Group, 2005b). First, as we observed in our familiar-unfamiliar face task, the amplitude of all ERP components was dramatically reduced among the IG compared to the NIG. This is what we would anticipate since the EEG power amplitudes were similarly reduced. Second, the NIG displayed greater N170 amplitudes to the sad expression, whereas the IG exhibited greater N170 amplitudes to the fear expression. In addition, the NIG and IG exhibited greater P250 amplitudes in response to the sad and fearful expressions, respectively. Thus, for the early components, N170 and P250, the NIG and IG displayed different ERP patterns in response to the different emotion expressions, particularly fearful and sad. Finally, hemispheric differences were observed between the groups, with the NIG showing greater right than left activation among several ERP components and the IG showing virtually no hemispheric differences. The lack of such a laterality effect suggests that the IG children show less cortical specialization for emotion processing than the NIG.

Follow-up This same experimental paradigm was administered at 42 months following randomization to foster care (Moulson et al., 2009b). As was the case at baseline, at 42 months, institutionalized children showed markedly smaller amplitudes and longer latencies for the P1, N170, and P400 components compared to family-reared children (NIG). And, as was the case for our familiar-unfamiliar face task, by 42 months, ERP amplitudes and latencies of children placed in foster care were intermediate between the CAUG and NIG, suggesting that foster care may be partially effective in ameliorating adverse neural changes caused by institutionalization. The age at which children were placed into foster care was unrelated to their ERP outcomes at 42 months. Finally, for all three groups of children (CAUG, FCG, and NIG), fearful faces elicited larger amplitude and longer latency responses than happy faces for the P250 and NC components. This last finding (greater responses to fearful than to other expressions) is consistent with past research with typically developing children (e.g., de Haan & Nelson, 1997) and suggests that institutional rearing appears to have limited impact on discriminating facial expressions of emotion.

Collectively, through 42 months, we observed a number of differences in emotion processing between institutionalized and never-institutionalized children, although these differences by and large were quite subtle. As was the case in our familiar-unfamiliar face task, this finding suggests that the ability to perceptually discriminate different facial expressions is relatively unperturbed by institutional rearing, a finding we have also observed across the first 42 months of life using a behavioral task of emotion processing (Jeon, Nelson, & Moulson, 2010; Nelson, Parker, Guthrie, & the BEIP Core Group, 2006). However, as was also the case in our familiar-unfamiliar face task, in our emotion discrimination task, we also observed marked reduction in the amplitude of all ERP components recorded, which was partially remediated by our foster care intervention. This finding suggests reduced brain activity despite intact skills to detect facial expressions of emotion.

ERP Studies of Emotion Processing at Age 8 The two tasks discussed thus far place relatively few demands on higher social-cognitive processes, and we were therefore curious what might be observed when our children were a bit older, confronted with a more demanding test of face processing. In other words, perhaps more basic perceptual-discrimination abilities of face processing are relatively unaffected by institutional rearing, but how would our children perform on a task that required them to recognize facial emotions, not just discriminate one expression from another?

Children were presented with angry, fearful, and neutral faces modeled by eight different female actresses (for details, see Nelson, Fox, et al., 2013). Each expression was presented equally often. ERPs were recorded, and children were instructed to push a button whenever they saw an angry face.

Several findings of interest emerged. First, all three groups were equally accurate at recognizing anger, which suggests there were no group differences in being able to follow task instructions. Second, all three groups had a more difficult time recognizing fearful faces, which

is consistent with the observation that fear is the last expression to be recognized at adult levels (generally in adolescence; see Thomas, De Bellis, Graham, & LaBar, 2007). Third, the NIG and FCG were both better at inhibiting a button press to neutral and fearful faces than the CAUG, suggesting either that the CAUG was generally less accurate at recognizing these two emotions or that they had more difficulty with inhibiting a response generally. This finding also suggests that the foster care intervention was effective in improving previously institutionalized children's ability to recognize the emotions neutral and fear. Finally, there were no group differences in reaction time.

Regarding the ERP data, several intriguing findings emerged. First, the P1, a component that possesses some face sensitivity, was largest to angry faces for the NIG, smallest among the CAUG and intermediate for the FCG. In addition, as we observed more generally with ERP amplitudes at 42 months (Moulson et al., 2009b discussed earlier), this finding also supports the notion that foster care improved the ability to process facial emotion.

In contrast to the P1, the N170 and the P300 were biggest to fear in all groups. So, although all three groups were equally good at recognizing anger, the task-relevant stimulus, and showed comparable P300 amplitudes to anger, their ERP responses (for both the N170 and P300) were biggest to fear. This finding supports the assertion put forth by Leppänen and Nelson (2009, 2012) that fear is of high signal value (even as early as 7 months of life; see Nelson & de Haan, 1996), and responses to this emotion are unperturbed by institutional rearing.

Although the children in foster care showed improvements in their ability to recognize fear and neutral faces (to a comparable level of performance as never-institutionalized children) and their P1 to angry faces was midway between the NIG and CAUG, we observed no timing effects. On the whole, this finding is identical to what we observed at 42 months, both for face processing generally and for processing facial emotion.

These findings stand in contrast to the perceptual discrimination observed at earlier ages. Whereas at earlier ages we observed relative sparing in the ability to discriminate facial expressions (as well as differentiating familiar from unfamiliar faces), here we observed differences among the CAUG in processing facial emotion, both behaviorally and electrophysiologically. Moreover, we observed a number of subtle improvements in processing facial emotion among the foster care group, although their performance did not become comparable to the never institutionalized group. The fact that no timing effects were observed suggests that children placed in foster care improve, although they do so regardless of the age at which they were placed in foster care. Of course, the fact that the average age of placement was 22 months urges caution in this interpretation, for earlier placement might have revealed timing effects.

Conclusions Regarding Face and Emotion Processing. When we reflect on the studies focused on face processing, we conclude that basic perceptual abilities are affected only modestly by institutionalization, although higher-level recognition abilities do seem to be impacted by early institutionalization. Second, in line with our EEG findings, it appears that institutionalization leads to dramatic reductions in ERP amplitudes; by 8 years, these reductions appear to be remediated among children placed in foster care, regardless of age of placement. Thus, we have intervention effects in this domain but no demonstrable timing effect.

Magnetic Resonance Imaging

The EEG findings of pervasive reductions in power have intrigued us since our initial observations, when we first began the study. Over the years, we have entertained a number of possible interpretations of these data. In an examination of physical growth, we found that the children from the institution had smaller head circumferences than the NIG. This initial finding did not change with the intervention, at least for those children placed after 12 months. Thus, if smaller heads correlate with smaller brains, what exactly is it about the brain of the institutionalized child that is smaller? Is it the loss of neurons of neuronal elements, such as axons and dendrites, or of synapses? Might it be that the normal process of apoptosis—programmed cell death—has gone awry, such that there has been an overpruning of neurons? Finally, might there be less white matter—the portions of neurons that contain myelin and that lead to short- and long-distance connections among neurons—which might contribute to our EEG and ERP observations (i.e., the brain might be less well interconnected and, as a result, the brain's electrical activity might be reduced)?

When the sample was between 8 and 10 years of age, we performed structural MRIs. We evaluated 78 BEIP children, 20 from the NIG, 27 from the FCG, and 31 from CAUG. We observed a number of significant differences across groups, which are summarized below.

1. We observed a reduction in total cortical volume among ever-institutionalized children (CAUG and FCG), compared to never-institutionalized children.
2. In terms of gray matter, we also observed a reduction in the CAUG and FCG compared to NIG.

3. With regard to white matter, we found that the NIG had significantly more white matter than the FCG and CAUG, but the FCG had significantly more than the CAUG.
4. Although there was some regional variation within the corpus callosum, we observed a general reduction in volume of this structure in the CAUG compared to the other two groups (which do not differ from each other).

   These last two findings collectively suggest that the foster care intervention is having a beneficial effect on white matter volume but not on gray matter, which would be consistent with the experience-dependent nature of white matter (which permits the inference that children in the CAUG may have a less myelinated brains).
5. We did not observe any differences across the three groups in either the hippocampus or the amygdala, and only very subtle (and yet to be confirmed) changes in one or two regions of the basal ganglia.

The findings about brain structure helped explain our EEG and ERP findings. Indeed, when we performed a mediation analysis, we found that white matter differences mediated the relation between deprivation and EEG power.

Summary. This section of the chapter has been concerned with the neural sequelae of psychosocial deprivation in the BEIP sample. The findings suggest that across multiple biological domains, institutional rearing exerts a heavy toll on brain development. Children reared in institutions have smaller brains and show dramatic reductions in the brain's electrical activity compared to never-institutionalized children. Children reared early in institutions but then assigned to foster care, by contrast, show significant increases in brain electrical activity and in white matter volume relative to children in the CAUG. However, children in foster care do not show the same catch-up gray matter volume.

In those domains where intervention effects were noted, some, such as EEG, had sensitive periods attached to them, whereas others, such as ERP to faces, did not. This finding suggests either that (a) some domains are more experience-dependent than others or (b) the *relatively* late age of placement did not permit us to detect sensitive periods that might have been evident at earlier ages.

Social-Emotional Development

Abnormalities in social and emotional behavior in children raised in institutions have been described for more than 100 years (see Zeanah, Smyke, & Settles, 2006). They were the most striking atypical behaviors in the descriptive studies of Spitz (1945) and Goldfarb (1943, 1944, 1945 a,b) in the mid–twentieth century about children living in institutions.

These descriptive studies were important in drawing attention to the significant effects of psychosocial deprivation on socioemotional development, but they did not systematically assess social and emotional behavior in institutionalized children other than descriptively. The adoption of large numbers of children from Romania and other Soviet bloc countries that began 20 years ago led to renewed interest in the topic in the psychological and pediatric literature (e.g., Chisholm, 1998; Chisholm, Carter, Ames, & Morison, 1995; Marcovitch et al., 1997; O'Connor, Bredenkamp, Rutter, & the English and Romanian Adoptees Study Team, 2000; Wismer Fries & Pollak, 2004) among children who had been adopted out of institutions. Our study extends these findings by examining children while they were still living in institutions and following randomization to foster care versus more prolonged institutional care. Our goal was to determine experimentally the effects of placement in families on these children's expressions of social and emotional behavior.

Based on our observations and on previous research, we assumed that because young children raised in institutions have reduced exposure to appropriate social stimulation and contingent sensitive and responsive caregiving, their social development would be compromised. In particular, we were curious about three potential areas likely to be affected: attachment, social skills, and relations with peers.

We were curious about the effects of institutional rearing on children's attachment behaviors because the context of institutions does not lend itself to facilitating attachments (see Zeanah et al., 2003) and because serious disturbances in attachment have been reported in children raised in such environments (see Tizard & Rees, 1975). Discriminating a significant caregiver or caregivers from others and preferring these caregivers for security and social support is crucial for development and this can be severely compromised by conditions of extreme neglect. In addition, some of the most compelling descriptions in the psychological literature of children lacking attachments were of those being raised in institutions (see Provence & Lipton, 1962; Tizard & Rees, 1975). Thus, this was a major area of interest for our research. We also investigated social skills and peer relationships among institutionalized children, because as children enter middle childhood and adolescence, peer relationships are perhaps the most important indicator of their social functioning. Further, a previous study had noted significantly impaired

peer relations among formerly institutionalized children (Hodges & Tizard, 1989).

Attachment in Institutionalized Children

Attachment is defined in different ways, but we are referring to the organization of a young child's behaviors that involve seeking comfort, support, nurturance, and protection from selected caregiving adults. In ordinary rearing conditions, infants who reach 7 to 9 months of age begin to exhibit clear preferences for certain caregivers when they are frightened or distressed. Infants protest separation from selected caregivers, and they exhibit reticence that had not been present before with unfamiliar adults. The hallmark of infants' capacity to form attachments is their ability to seek comfort and security from specific caregivers. Once these behaviors appear, an infant is described as "attached" to those caregiving adults to whom the infant turns preferentially.

The BEIP afforded us an opportunity to study the attachment behaviors of young children living in institutions with standardized assessments and to examine the effects of a family-based intervention on these behaviors. We wanted to determine if validated measures of attachment would replicate observations about serious attachment disturbances among many children raised in institutions that had been made in older descriptive studies. Another goal was to examine young children's capacity for recovery, having been raised at least initially with what we presumed were limited opportunities to form selective attachments. Caregiving quality has long been asserted to be necessary for healthy development of attachment, so institutional rearing provided a stark test of that assertion. Finally, we wanted to determine if aberrant attachment is predictive of the emergence of psychopathology, as it has been shown to be in noninstitutionalized children.

The child-caregiver attachment relationship may be assessed by observing the young child's behaviors in a paradigm known as the Strange Situation Procedure (Ainsworth, Blehar, Waters, & Wall, 1978). An infant between the ages of 1 and 2 years is observed with a parent/caregiver in a series of brief separation and reunion episodes designed to assess the infant's exploratory and comfort-seeking behavior with an attachment figure and an unfamiliar adult. Infant behavior, particularly during reunion episodes with the attachment figure, is noted for degree of proximity seeking, contact comfort and calming of any distress that the infant might express in the prior separation episode. The organization of the child's responses during these separation and reunion episodes, based on these behaviors, allows trained coders to determine the quality of the child's attachment relationship to the caregiver. Infants in the Strange Situation Procedure (SSP) are classified as securely/insecurely attached to their caregivers or to have an organized or not organized attachment to their caregivers.

Patterns of Attachment in Institutionalized Children. The BEIP was the first study of patterns of attachment in Romanian infants and toddlers. It was also the second study of patterns of attachment in young children living in institutions. We were initially unsure whether using the SSP as a method was appropriate because it assumes an attachment exists and yields qualitative differences, whereas many of the institutionalized children might not even have attachments. We could not be sure at the outset whether institutionalized toddlers raised in large and impersonal institutions even had attachment figures. We selected the caregivers to assess by asking the staff if the child had a "favorite" caregiver. If so, we used that caregiver in the Strange Situation. If the child had no discernible favorite, we assessed the child with a caregiver who worked with the child regularly and knew the child. We also restricted the procedure to those children with a cognitive age of 11 months or higher to be sure that all children assessed had the capacity to form a selective attachment.

We determined that among the community children in Bucharest who had never been institutionalized, 74% had secure attachments, 4% had avoidant attachments, and 22% had disorganized attachments to their mothers. This is a slightly higher percentage of secure and disorganized patterns than we might expect within a typically developing sample in the United States. Among the institutionalized children, assessed with their favorite caregivers, only 18% had secure attachments, 3% had avoidant attachments, 65% had disorganized attachments, and 13% of the children had so little attachment behaviors that they were designated unclassified (Zeanah et al., 2005). This latter designation is exceedingly uncommon and has never been reported in children living in families.

These remarkable differences between institutionalized children and noninstitutionalized children were similar to what another group of investigators reported after the BEIP began from their study of Greek infants raised in institutions (Vorria et al., 2003). They also reported that 66% of the institutionalized children had disorganized attachment patterns, whereas only 25% had secure attachment patterns. A subsequent study of infants and toddlers raised in Ukrainian institutions revealed similar distributions of patterns of attachment. Institution-reared children positive for HIV were 28% secure, with 45% disorganized and 27% unclassified (Dobrova-Krol,

Bakermans-Kranenbury, Van Ijzendoorn, & Juffer, 2010). The similarities of findings in these other two studies regarding attachment contrast with IQ scores, which were much lower in the BEIP than in the Greek or Ukrainian children. This difference suggests that attachment may be a more sensitive indicator of a deprived environment than IQ. An important older study of residential nurseries in London in the 1970s also described modest effects on IQ but profound effects on young children's attachment (Tizard & Rees, 1974). The convergence of our results with other studies increased our confidence that the Strange Situation Procedure had yielded meaningful results.

We were also curious about whether we could predict which variables were important for developing an organized attachment to a caregiver in the extraordinary setting of an institution. Therefore, we contrasted organized attachment (secure and avoidant) with not organized (disorganized and unclassifiable) in this sample using the same predictors. Even when controlling for cognitive level, perceived competence, and quantitative ratings of caregiving behavior, we found that quality of caregiving predicted organized attachment. An increase of 1 unit in quality of caregiving was associated with an increase in the odds of an institutionalized child having an organized attachment by a factor of 1.29 (Zeanah et al., 2005). These results importantly suggest that individual differences in caregiving experienced by children in institutional settings (and other environments characterized by severe deprivation) matter a great deal.

Degree of Development of Attachments. Despite the remarkable differences in patterns of attachment between institutionalized and community Romanian children, other results more starkly illustrated the profundity of differences in attachment in children in institutions and children in families. Elizabeth Carlson, who coded the Strange Situation Procedure without knowing which children were institutionalized and which were not, developed ratings of the degree to which the child had developed an attachment to the caregiver in the procedure. She based this coding solely on attachment behaviors (or their lack) that the child exhibited during the procedure. A "5" indicated fully formed attachments, consistent with traditional classifications of attachment. Ratings of "4" indicated evidence of formed attachment behaviors but accompanied by extreme or pervasive behavioral anomalies (beyond the scope of traditional disorganization coding). Ratings of "3" were used when there were fragmented or incomplete sequences of attachment behavior that were directed toward the caregiver more than the stranger. At the next level, a "2," there was only a barely discernible difference in the child's behavior toward the familiar caregiver, with isolated attachment signals and responses. Finally, children who exhibited no discernible attachment behaviors were assigned the lowest rating of "1." Carlson's ratings converged with those of another attachment expert, Alan Sroufe.

With no knowledge about the children whose behavior they coded, the raters identified all 50 of the community children as Level 5—fully developed attachments. In contrast, they identified only 3 of 95 children in the institutionalized group as having fully formed attachments. In fact, 62 of the 95 children (65%) in the institutionalized group were Level 3 or below, meaning clearly incompletely formed attachment. And 10% of the institutionalized children had no discernible attachment behavior whatsoever (Zeanah et al., 2005).

These results illustrate the extraordinarily deprived caregiving setting that institutions represent and are among the first to describe young children in the second year of life who have not formed meaningful attachments to the adults in their lives. A subsequent study of institutionalized children in the Ukraine (Dobrova Krol et al., 2010) replicated our findings of most institutionalized children having incompletely formed attachments, although their children had a higher proportion of fully formed or Level 5 attachments than ours (24% versus 3%).

A number of points of interest emerged from comparing ratings of degree to which attachment had formed and patterns of attachment. First, all of the 9 children with ratings of "1" (no discernible attachments) were rated as unclassifiable. Second, 7 children (29%) whose attachment was rated as Level 2, 7 children (24%) whose attachment was rated Level 3, and 3 children (10%) whose attachment was rated Level 4 were securely attached. This means that when we forced the classification, they most resembled secure attachments—displaying a preference for the familiar caregiver rather than the stranger. But clearly, secure classifications in institutionalized children mean something other than what secure attachments in family-reared children mean.

To try to clarify what led children to have incompletely formed attachments, we examined several possible candidate variables. The only factor that we could identify was quality of caregiving. It appears that what was missing in these children's lives was a sensitive, responsive, loving caregiver who could provide them contingent positive social interaction. In the absence of such persons, these children did not form attachments to the human caregivers they had.

Disorders of Attachment

As we have seen, under typical rearing conditions, all infants form attachments to adult caregivers. In more extreme rearing conditions, such as institutions for young children, attachment may be seriously compromised or even absent. The work we have described up to now on patterns of attachment derives from the tradition of basic developmental research. Now we turn to another tradition of work in attachment, also having its roots in John Bowlby's work. This tradition is rooted more in clinical literature describing serious symptomatology in children raised in institutions, including a defined psychiatric disorder of aberrant attachment behaviors.

The term *reactive attachment disorder* (RAD) describes a constellation of deviant attachment behaviors believed to be the result of social neglect and deprivation. Two clinical patterns have been described: an emotionally withdrawn/inhibited pattern and an indiscriminately social/disinhibited pattern. In the emotionally withdrawn/inhibited pattern, the child demonstrates no discernible attachment to anyone, even when distressed. In addition, the child fails to seek comfort from caregivers for distress or to be comforted when distressed. These children have difficulties regulating their emotions and show emotion regulation difficulties, such as unexplained outbursts of irritability, fear, or withdrawal. In the indiscriminately social/disinhibited pattern, designated in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2013) as disinhibited social engagement disorder, the child exhibits lack of expected social reticence with unfamiliar adults, fails to check back with the caregiver in unfamiliar settings, and demonstrates a willingness to accompany strangers with little or no hesitation.

The BEIP was an opportunity to examine a number of questions about these disorders that had been previously studied, primarily in small, descriptive studies. We were able to evaluate attachment disorders systematically among currently institutionalized children, using state-of-the-art contemporary measures. We were thereby able to evaluate the natural history of attachment disorders within this extremely high-risk sample. We were also able to examine interrelationships between the developmental patterns of attachment—secure, avoidant, resistant, and disorganized—and clinical disorders of attachment. Individual differences in genes—polymorphisms—had not been examined previously as vulnerability factors for the disorders. Most important, we were able to determine if foster care—putatively an enhanced form of caregiving—is an effective intervention for disordered attachment. No intentional intervention for attachment disorders had ever been conducted previously, much less an RCT. Finally, we were interested to examine effects of timing of placement in foster care and determine the degree to which that mattered.

We found that young children living in institutions were rated by their caregivers as having significantly more signs of both emotionally withdrawn/inhibited and indiscriminately social/disinhibited RAD compared to the community children (Zeanah et al., 2005). Within the children living in institutions, however, there was no apparent relationship between length of institutionalization and signs of either type of disorder.

For children living in institutions, continuous ratings of the degree to which an attachment had formed were moderately correlated with caregiver ratings of emotionally withdrawn/inhibited attachment disorder, but they were not related to ratings of indiscriminately social/disinhibited attachment disorder. These findings are compatible with other evidence that indicates that that emotionally withdrawn/inhibited RAD describes young children who lack attachment relationships with caregivers, whereas children may be attached or not and still show high levels of indiscriminate behavior (Smyke et al., 2012).

Interrelations among Attachment Measures. Among institutionalized children at baseline, Strange Situation classification patterns were unrelated to signs of RAD at baseline, suggesting that these two are different indices of attachment in young children. However, continuous ratings of the degree to which attachment had developed were moderately correlated with caregiver ratings of emotionally withdrawn/inhibited RAD (as expected) but unrelated to ratings of indiscriminately social/disinhibited RAD.

Taken together, these results suggest that clinical disturbances of attachment, as reflected in signs of RAD, indicate incomplete development or expression of attachment behaviors in children cognitively able to form selective attachments. These attachment disorders are distinct from patterns of attachment, which are more properly considered risk and protective factors. Evidence to date indicates that young children with attachment disorders are more likely to have disorganized or aberrant attachment patterns than organized patterns, but the two constructs of attachment disorders and patterns of attachment are distinctly different indices (Smyke et al., 2012).

Intervention Effects: Patterns of Attachment. At 42 months of age, we readministered the Strange Situation Procedure. We predicted a higher proportion of secure attachments and higher ratings of security for children assigned to the

FCG versus those in the CAUG. We also predicted fewer atypical patterns among the children in foster care.

In keeping with predictions, at 42 months, only 18% of the CAUG were securely attached, but 49% of the FCG and 65% of the community children were securely attached. When security was coded continuously, community children were significantly more secure than the other two groups, but children in the FCG also were significantly more secure than children in the CAUG. So, if these results hold, even following extreme deprivation, it is clear that children can form secure attachments, although not to the same degree as if they had not experienced such severe deprivation.

We also examined the effects of timing of foster care placement on children's forming secure attachments. In other words, was there an age of placement after which the chances of a child developing a secure attachment began to diminish? We found that children placed in foster care before 24 months of age were significantly more likely to develop secure attachments than children placed after 24 months. More than two-thirds of the children placed before 24 months developed secure attachments whereas less than one-third of those placed after 24 months developed secure attachments. Later placement did not preclude the child developing a secure attachment to the foster parent, but it did significantly reduce the likelihood of that happening.

Intervention Effects: Disorders of Attachments

Whereas Strange Situation Procedure classifications of attachment were assessed only at baseline and at 42 months of age, caregiver reports of emotionally withdrawn/inhibited and indiscriminately social/disinhibited attachment disorders were obtained at every age and supplemented by observation at 54 months. The effects of the intervention on these outcomes were different for the two types of attachment disorders.

For the emotionally withdrawn inhibited type of RAD, significant positive effects of placement in foster care were evident at the very first assessment age—30 months—and at every subsequent assessment. That is, the FCG showed significantly fewer signs of emotionally withdrawn/inhibited RAD compared to the CAUG, and the levels of this type of attachment disorder were indistinguishable from the levels in the community children. This means that all of the signs of disorder were effectively eliminated at the earliest possible age of assessment. By 30 months of age, the children in foster care had received somewhere between 1 (the oldest children at the time the study began) and 23 (the youngest children at the time the study began) months of intervention, with an average of 8 months. We also should point out that there were no timing effects—signs of emotionally withdrawn/inhibited RAD disappeared regardless of the age at which the child was placed in care. It appears that these behaviors are plastic and can be remediated with intervention (see Smyke et al., 2012).

For the indiscriminately social/disinhibited type of attachment disorder, the response to the intervention was more complicated but also quite interesting. Based on caregiver and parent reports of indiscriminate behavior, and examining all data points from baseline through 8 years, children placed in BEIP foster care had fewer signs of indiscriminate behavior than those in the CAUG but more signs than children who had never been institutionalized. In addition, there were different recovery curves for indiscriminately social/disinhibited RAD in the foster care group and the CAUG, with decline of these signs in the FCG evident between each pair of assessment times, with the lone exception of no change between 42 and 54 months. In the CAUG, differences were noted only between 54 months and 8 years (Smyke et al., 2012).

We were also interested in supplementing caregiver reports with an observational measure of indiscriminate behavior. In typically developing children, stranger wariness appears at 7 to 9 months of age. Once evident, some degree of reticence with strangers is apparent for the next few years. In addition to our own frequent observations of indiscriminate behavior among children living in institutions, it is also one of the most persistent and common abnormalities reported in children who have been adopted out of Romanian (and other) institutions (Chisholm,1998; Hodges & Tizard, 1989). Therefore, we developed a procedure intended to capture individual differences in indiscriminate behavior.

When the children in the BEIP reached 54 months of age, we scheduled three home visits. At the conclusion of the first home visit, the mother/caregiver was instructed about what would occur during the second visit. A research assistant, unknown to the child, would appear at the door at a designated time of the second visit. Mother/caregiver and child were instructed to be present when the mother/caregiver opened the door. Mother/caregiver was told that she could look at the child but not to give verbal or nonverbal directions about how to respond to the "stranger." The research assistant looked at the child and said, "Hello, my name is Florin, what is your name?" Then the research assistant, still looking at the child, said, "Come with me, I have something to show

you." The mother/caregiver was instructed not to give any directions to the child about what to do. We coded whether the child left with the stranger or declined to leave. If the child did leave with the research assistant, the two walked a short distance, and then the child was greeted by a familiar research assistant from the week before who said, "Hello, I have returned to play more games with you this week." This became known as the Stranger at the Door Procedure (see Gleason et al., 2014). We anticipated that 4-year-old children would not likely leave their homes to accompany a stranger, and the response of the community children suggested that we were correct; only 1/28 (4%) community children accompanied the stranger. However, 13/31 (42%) of the CAUG readily accompanied the stranger. The foster care group was in between the other groups, as 7/29 (24%) left with the stranger. Not all children participated in the procedure because we added the procedure to the protocol after the 54-month assessments were already under way. A small number of caregivers declined or gave instructions to the child about what to do, and these were not included in data analysis. Although these group differences appeared striking, there was actually no statistically significant difference between the proportion of the CAUG and the FCG who left with the stranger, in part because the groups were small. Both CAUG and FCG children were more likely to leave than the community children. Importantly, there was a substantial convergence between caregiver reports of the children's indiscriminate behavior and observational coding of indiscriminate behavior from this procedure ($k = 0.70$), indicating that they were assessing the same phenomenon.

We observed timing effects (i.e., age of placement) for indiscriminately social/disinhibited RAD. For children placed earlier (<24 months), scores were generally lower, with the exception of 42 months and 8 years. For this early-placed group, scores dropped quickly between baseline and 30 months and then appeared to remain stable. For the later-placed group, a modest decrease in scores was noted between 30 and 42 months whereupon scores became stable again until the 54 months–8-year comparison, when they decreased.

Findings from longitudinal assessments of signs of attachment disorders indicate that placement in families eliminated signs of emotionally withdrawn/inhibited RAD among young children raised in institutions but had a less powerful effect on indiscriminately social/disinhibited RAD. This finding indicates that additional interventions beyond family care may be necessary to reduce or eliminate signs of social/disinhibited RAD of young children with high levels of indiscriminate behavior.

Peers, Social Skills, and Social Competence

As children get older, their social worlds expand from the immediate family to the school, classroom, and peers. In the BEIP, opportunities for social interaction were available at school and within institutional settings. We were curious about the emerging social skills and social competence of children raised in institutions as they interacted with same-age peers. In order to study this, we asked parents/caregivers as well as teachers to report on the children's social skills, and we also observed each of the children in the BEIP with a same-age, same-sex peer in our laboratory. We structured the interaction and videotaped it. We then had these tapes coded for behaviors that were indicative of social skills and competence by coders who were unaware of group status.

It is important to understand the influences of institutionalization on children's social development throughout childhood for a number of reasons. Most important, early social behaviors set the stage for children's success at negotiating the increasing social demands and social changes that occur later in development. Social rejection or exclusion can lead to adolescents' involvement in delinquent or risk-taking behaviors (Ollendick, Weist, Borden, & Greene, 1992). Indeed, Erol, Simsek, and Münir (2010) found that those institutionalized adolescents who reported fewer friends and poorer relations with friends also reported higher problem behavior scores on the Youth Self-Report. Furthermore, difficulties with peer relationships in early childhood have been linked to difficult adjustment in adulthood (see J. Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006, for a review). In order to avoid such negative outcomes, it is important to determine whether foster care intervention can potentially remediate some of the negative social effects of previous institutional care.

In order to assess social skills, children's primary caregivers and teachers were asked to report on the children's social skills using the Social Skills Rating System (Gresham & Elliot, 1990).

We compared children's social skills as reported by caregivers and teachers in the three groups: children who were randomly assigned to care as usual, children who were randomly assigned to foster care, and children from the community. We showed positive effects of the intervention on children's social behavior at age 8 years, which was 3.5 years after the intervention ended. Specifically, children in foster care were rated as more socially skilled by their caregivers than were children assigned to institutional care. Interestingly, teachers rated children in both the FCG and the CAUG as having fewer social skills than did biological parents or foster caregivers (Almas et al., 2012).

Another important finding was a significant effect of age at placement into foster care on teacher ratings of social behavior. That is, children who were placed before 20 months of age were rated by teachers as more socially skilled than those who were placed later. These results highlight the value of early intervention on the social skills of institutionalized children. However, foster care children were not rated as socially skilled as the community children, indicating a continued effect of early deprivation on development at age 8 years (Almas et al., 2012).

Children's interactions with an unfamiliar peer were assessed in the laboratory using six interactive tasks designed to assess each child's self-presentation skills, cooperative play skills, and competitive interactions. The children's behavior was videotaped and subsequently coded independently by a team of Romanian research assistants who were blind to the identity of the children. Individual behaviors were coded (such as duration of speech, cooperation), and composites were formed. This process allowed us to examine the children's social competence, social reticence, and anxious behaviors.

We also found group differences in how the children behaved in these tasks with peers. Rated blindly, foster children were rated as more competent and less reticent than institutionalized children. Children in the CAUG also showed significantly higher levels of speech reticence, while children in the FCG showed significantly higher levels of speech competence. These results highlight the positive effects of intervention on the competence of children while interacting with unfamiliar peers in two socially demanding tasks.

Further, using the Actor-Partner Interdependence Model, we demonstrated that the behavior of children in the CAUG, but not in the FCG, had negative effects on the behavior of unfamiliar peers. Specifically, CAUG children's reticent behavior during the initial task was related to less social engagement in the community children during the competitive tasks and somewhat during the cooperative tasks. There were no effects of the behavior of FCG children on the subsequent behavior of community children. Finally, there were no timing of foster care placement effects on the behavior of FCG children with unfamiliar peers (Almas et al., 2012).

A number of aspects of these findings deserve highlighting. First, we continue to see intervention effects on social behavior and social competence 6 years after the study began and 4 years after the intervention was completed. As in our other analyses, we used an intent-to-treat approach, so the positive intervention effects that we found are actually a conservative estimate of the true effects. Second, there appears to be a timing effect for the intervention effects, with children taken out of the institution before 20 months of age displaying better social skills than those placed into our intervention after age 20 months. What is also clear is that there are lasting effects of exposure to social deprivation among the sample. As a group, FCG children at age 8 still display lower social skills compared to typical community children.

Psychopathology

Previous reports of psychiatric disorders in children with histories of institutional rearing typically focused only on a single disorder (Hoeksbergen et al., 2003; O'Connor et al., 2000; Roy et al., 2004) or relied on parent checklist reports of behavior problems without systematic diagnostic interviews (L. Fisher, Ames, Chisholm, & Savoie, 1997; Marcovich et al., 1997). Other than ADHD, disruptive behavior disorders had not received systematic study, nor had anxiety disorders beyond posttraumatic stress disorder. Precursors of psychopathology also had received little attention. Finally, mechanisms through which psychopathology emerge in children reared in institutions had not been addressed. We considered all of these gaps in our understanding of psychopathology associated with institutional rearing to which the BEIP could potentially contribute.

When children were 54 months of age, we were able to use a structured psychiatric interview, the Preschool Age Psychiatric Assessment, Version 1.3 (PAPA; Egger, Ascher, & Angold, 1999), rather than behavior problem checklists. PAPA had been used previously with 2- to 5-year-old children in a large study of children attending primary care visits in North Carolina, demonstrating test-retest reliability comparable to that of structured psychiatric interviews used to assess older children and adults (Egger et al., 2006).

We took several steps to ensure that the psychopathology and impairment data were collected properly. The lead interviewer was trained in administration of the PAPA by the group at Duke University who developed the measure, and he subsequently trained other Romanian interviewers. After the PAPA was translated into Romanian, it was back-translated into English and assessed for meaning at each step by bilingual research staff.

Caregivers and parents were interviewed in detail about signs of psychiatric disorder in each child and about the degree to which these signs impaired the child's school and social functioning. For children living with biological parents or foster parents, the mother reported on the child's behavior. For children living in institutions, an institutional

caregiver reported on the child's behavior. As with other measures, the caregiver chosen was the one considered the child's favorite, according to staff consensus; if the child had no favorite, a caregiver who worked with the child regularly and who was reported to know the child well was chosen. Interviewers asked detailed questions about the frequency, duration, and dates of onset of symptoms of a large number of psychiatric disorders. Algorithms were then applied to responses to determine whether each child met diagnostic criteria for specific disorders. Further, caregivers and parents were interviewed about the degree to which symptoms interfered with the child's functioning at home, at school, and in close relationships. For purposes of the study, we derived diagnoses to examine prevalence of psychiatric disorders; derived symptom counts for constructs such as internalizing, externalizing, inattention, and aggression; and summed impairment ratings about each different setting to determine degree of functional impairment.

Children with a History of Institutional Rearing

We found that institutional rearing is an extraordinarily powerful risk factor for psychopathology. The majority of 4.5-year-old children with a history of institutional rearing had diagnosable psychiatric disorders (53%), whereas never-institutionalized children from the community were significantly less likely to have a disorder (22%). In addition, more than half of the children with a history of institutional rearing had two or more psychiatric diagnoses, whereas only 20% of the community children had multiple diagnoses.

Intervention Effects

To examine the effects of placement in foster care, we looked at prevalence of disorders in children in FCG versus those in CAUG. Children in foster care were significantly less likely to have a disorder (46%) than those who received care as usual (62%). Although there were no significant differences in externalizing disorders between the groups, there were clear group differences in internalizing disorders (22% in FCG versus 44% in CAUG). So, although the intervention reduced psychopathology, the differences between the groups were explained entirely by the differences in internalizing disorders.

Unfortunately, there are few comparable intervention studies that might help us understand this selective effect of foster placement on reducing internalizing but not externalizing disorders in preschool children. We identified one study of preschool children in foster care, however, that found that those who had been exposed to drugs prenatally and those who had lost multiple primary caregivers seemed to demonstrate consistently greater levels of aggression and had greater difficulties in developing trusting connections with their caregivers, even when intensive behavioral treatment was provided to foster parents (P. A. Fisher, Ellis, & Chamberlain, 1999). Obviously, many children in the BEIP likely had prenatal drug exposures, and all had multiple caregivers.

Moderators of the Intervention

Virtually all interventions are effective only for some participants who receive it, so an important question is: Who responds and who does not? We were interested in identifying moderators of the intervention (i.e., putative characteristics of participants that might affect the direction and/or strength of the relation between group status and various outcomes). Next we describe three moderators, gender, age at which the child was placed in foster care, and specific genes that may moderate the effects of early experience, as variables that we thought might help define who did and did not respond to the intervention with fewer signs of psychopathology.

Gender. At 54 months, boys in the FCG and CAUG were more symptomatic than girls in these groups, regardless of their caregiving environment. Moreover, unlike girls, boys had no reduction in total signs of psychiatric disorders following foster placement. These results were surprising because we had had found few differences based on gender.

We considered a number of possible explanations for this finding. First, boys are known to be more vulnerable biologically than girls; for example, the prevalence of pre- and perinatal complications tends to be higher in boys than in girls, and boys suffer from more neurodevelopmental disorders (e.g., autism) than girls (Volkmar, Lord, Klin, Schultz, & Cook, 2007). Boys are also less mature in early childhood, and therefore the abilities needed for adaptive behavior regulation may be underdeveloped, increasing their vulnerability in deprived environments. Indeed, this immaturity continues through the adolescent years, when boys' brain development tends to lag behind that of girls by 1 to 2 years. It is therefore notable that among the community children, boys also had more symptoms, more disorders, and more impairment than girls (Zeanah et al., 2009). This finding suggests that the institutional rearing environment may exacerbate a difference that is already evident.

It is also possible that caregivers "preferred" girls to boys. Hence, caregivers might have responded differently to externalizing behaviors in boys and girls. We explored

interactive differences of foster parents with boys and girls, but we could detect no differences in behaviors during unstructured activities based on gender. Nevertheless, boys may require different experiences with caregivers than girls to develop better emotion-regulation strategies.

Timing of Placement in Foster Care. A central theme in the BEIP has been our interest in whether timing of the foster placement was related to intervention effects. For IQ, EEG, security of attachment, and language skills, earlier placement was associated with more favorable outcomes. In the case of psychiatric symptoms, disorders, and impairment, there were no timing effects. So, getting into foster care mattered greatly for reductions in psychopathology, but whether it was at 7 months, when our youngest child was placed, or at 33 months, when our oldest child was placed, did not matter. There are a number of possible reasons for the lack of finding here. First, as mentioned earlier, the youngest infants in our study at the start of intervention were 6 months of age. The sensitive period for behavioral outcomes of internalizing and externalizing may be prior to that. Hence, because of the characteristics of our sample, we may have missed identifying this period. Second, the effects we identified may be a function of prenatal exposure to alcohol, stress or genetics of the biological family and less susceptible to intervention than other domains. As we show in the next section, individual differences in the child's genetic makeup may play a role in differential intervention outcomes.

Genetics. We wanted to explore whether individual differences in susceptibility as reflected in genetic polymorphisms might relate to variability in outcomes. For some time, the diathesis–stress model dominated formulations of understanding vulnerability. More recently, Belsky and colleagues (Belsky et al., 2007; Belsky & Pluess, 2009) have proposed a differential susceptibility model. In this model, specific polymorphisms confer a differential responsiveness to the environment instead of conferring risk or resilience per se. Responsivity alleles are hypothesized to enhance positive outcomes in what would be considered by most to be positive environments but also to amplify adverse outcomes in what most would be considered to be negative environments. In contrast, those individuals with the less responsive allelic variant are predicted to demonstrate much more limited variability in outcomes (i.e., exhibit less sensitivity).

To test for differential susceptibility, we decided to examine indiscriminate behavior, one of the most common social abnormalities reported in young children raised in institutions (Zeanah, 2000). Indiscriminate behavior also was not especially responsive to early foster care. We examined whether the interaction between functional polymorphisms in brain-derived neurotrophic factor (BDNF) and the serotonin transporter gene (5-HTT) interacted with group placement to predict indiscriminate behavior.

When we examined indiscriminate behavior as an outcome, we found cumulative differential susceptibility in children defined by the presence of plasticity alleles—the s/s genotype of the 5HTT and the met carriers of the val66met polymorphism of the BDNF gene. Specifically, CAUG children with the more responsive allelles had the highest levels of indiscriminate behavior whereas FCG children with the same allelles had the lowest levels of indiscriminate behavior. Children with the l/* allelles of 5-HTT and val/val allelles of BDNF had intermediate levels of indiscriminate behavior regardless of whether they were in the CAUG or the FCG. These findings are the first report of genetic associations for indiscriminate behavior and provide additional evidence for the differential susceptibility model for early development (see Bakersman-Kranenberg & van IJzendoorn, 2007; Belsky et al., 2007).

Mediator of the Intervention. An important issue in intervention studies in developmental psychopathology is identifying mediators, the methods through which outcomes are obtained. The question was whether we could identify a pathway through which foster placement in the first 30 months of life reduced internalizing symptomatology and disorders at 54 months.

We decided to examine security of attachment as a potential mediator of the intervention on internalizing and to test our attachment-informed foster care intervention to determine if it was involved in symptom reduction as we hoped.

We had already demonstrated that security of attachment was significantly more likely in the FCG versus the CAUG (Smyke et al., 2010). We next determined that security of attachment at 42 months predicted lower levels of internalizing symptoms and disorders at 54 months of age. When we tested whether security of attachment at 42 months mediated the relationship between foster placement and reduction in internalizing symptoms and disorders in girls, we found that it did. With security of attachment at 42 months included in the model, the direct pathway between group placement and internalizing disorders was no longer significant, meaning that there was a full mediation of the intervention effects on internalizing disorders in girls.

This clarified that boys did not show reductions in internalizing disorders at 54 months because they were

significantly less likely than girls to form secure attachments to their foster parents, at least at 42 months of age.

IMPLICATIONS OF THE BEIP FOR DEVELOPMENTAL PSYCHOPATHOLOGY

Cicchetti and Toth (2009) defined developmental psychopathology as an interdisciplinary scientific discipline that aims to elucidate the complex ongoing interplay of biological, psychological, and social/contextual aspects of typical and atypical development during the life course. Focusing on experience in the early years, the BEIP illustrates many of the major features of the conceptual model proposed by Cicchetti and Toth, including developmental process, adaptive and maladaptive trajectories, multiple levels of analysis, and prevention strategies. We consider selected aspects of the BEIP relevant to these core considerations of the discipline.

Developmental Process

Equifinality offers an explanatory mechanism for the observation that there may be multiple pathways for any given outcome (Cicchetti & Rogosch, 1996). For example, there are multiple paths to a diagnosis of ADHD. One may be heritability (one or both biological parents having this diagnosis). A second may be prenatal exposure to substances. A third may be the atypical experiences that young children have in conditions of extreme psychosocial neglect, such as institutions. All three pathways have a similar diagnostic outcome. As an example of an alternate pathway toward ADHD symptoms, we were able to demonstrate widespread cortical thinning in children raised in institutions (McLaughlin et al., 2013) similar to the cortical thinning that has been described in children attending clinics who have a diagnosis of ADHD. Further, we showed that cortical thinning in a priori selected key brain regions of children in the BEIP mediated the effects of institutional rearing on impulsivity and inattention as rated by teachers without specifying the genes involved. This finding provides evidence of equifinality in ADHD symptom outcome found in BEIP data. That is, ADHD symptoms may be a result of multiple different pathways or etiologies, including the experience of deprivation found in the BEIP.

Adaptive and Maladaptive Trajectories

Inherent in considering psychopathology from a developmental psychopathology perspective is to consider how pathology represents a disturbance, distortion, or deviation from typical development (Cicchetti & Toth, 2009). Thus, one must consider both typical and atypical experiences and how these may affect different domains of development.

An important contribution of the BEIP is to add to the growing literature that demonstrates that genetic predispositions neither increase nor decrease risk uniformly. We demonstrated that the same biological disposition may be more or less susceptible to environmental input. For example, based on previous findings and knowledge of neural circuitry, we examined genetic risk for indiscriminate behavior (Drury, Gleason, et al., 2012). We examined functional polymorphisms in BDNF and 5-HTT on levels of indiscriminate behavior over time. We found that at 54 months, children with either the s/s 5httlpr genotype or met66 BDNF allele carriers demonstrated the lowest levels of indiscriminate behavior if they were in the FCG but the highest levels of indiscriminate behavior if they were in the CAUG at 54 months.

In addition, we showed that the serotonin-transporter-linked polymorphic region (5-HTTPLR) exerted its effect on indiscriminate behavior earlier in development than the BDNF genotype. The difference may reflect developmental differences in the impact of these genes or differences in the mechanisms through which they influence indiscriminate behavior. Also of note, genetic sensitivity to change in the caregiving environment did not occur immediately. Instead, the reduction in indiscriminate behavior occurred over time as children's experiences accumulated in different caregiving environments.

Conceptualizing gene by environment interactions in terms of "differential susceptibility" (Belsky et al., 2007)—that is, considering genetic influences as fixed effects—this approach considers dispositions as neither "good" nor "bad" but rather as more or less responsive to environmental changes. That these biological characteristics may function as risk or protective factors is in keeping with established complexities of biological systems and is illustrative of the emphasis of developmental psychopathology on trajectories.

Multiple Levels of Analysis

A major contribution of the BEIP is its comprehensive focus on the effects of experience, in general, and of *sensitive periods of development*, in particular, on multiple domains of development. By systematically altering experience through an RCT design, we examined effects of early experience on a range of processes—from the molecular level, such as examining telomere length (Drury,

Theall, et al., 2012), to the level of endophenotypes, such as set shifting (Bos et al., 2009) and response monitoring (McDermott et al., 2012), to large-order constructs, such as attachment (Smyke et al., 2010) and psychiatric disorders (Zeanah et al., 2009). In addition to assessing intervention effects at multiple levels of analysis, we also have intentionally been mindful about including measures of brain structure (Sheridan et al., 2012) and brain functioning (Vanderwert et al., 2010) to enhance our understanding of the neural substrate of developmentally relevant processes. What we showed was that timing of intervention was especially relevant for some developmental domains, such as IQ, security of attachment, and language, but less so for other domains, such as executive functioning and psychopathology (Nelson, Fox, et al., 2014).

Prevention Strategies

There was no opportunity to attempt primary prevention because the children who participated in the BEIP already had experienced both prenatal and postnatal adversity. Rather, the BEIP was aimed at assessing recovery from early adversity and addressing questions of whether developmental trajectories can be altered and how timing of intervention effects outcomes.

Outcomes of the BEIP have implications for understanding the science of development as well as for social policies that address early childhood adversity.

CONCLUSIONS

The BEIP is the first RCT of a foster care intervention for infants and young children who have an early life history of institutionalization. In setting up this project, we intended to ask three questions about the effects of early experience on brain and behavioral development.

1. Are the effects of early psychosocial deprivation long lasting, or are they amenable to remediation?
2. Are there sensitive periods during which intervention is more successful than at other times?
3. Are there domains that appear unaffected (i.e., that have been spared) and others for which intervention does not work?

In order to answer these questions, we designed a study with random assignment, and we assessed multiple domains of functioning. We also assessed brain function and structure in addition to standard and experimental behavioral measures.

Unsurprisingly, we found that exposure to early psychosocial deprivation had profound consequences for children's cognitive and social behavior as well as for brain function and structure. Yet we did find that some domains were unresponsive to intervention, such as head circumference, externalizing behavior problems, and EFs assessed by the CANTAB. At least one domain seemed relatively unaffected by exposure to deprivation: face and face-emotion processing.

Perhaps the most surprising and novel finding from the study was that social and emotional functioning exhibited the greatest plasticity and was most responsive to intervention. Indeed, our data provide novel and unique information about the importance of the formation of attachment relationships and the power that secure attachment had for mediating outcomes as children got older. We found that some infants and young children exposed to institutional care, with its lack of consistent caregiving, showed absence or incompletely formed attachment behaviors. There have been case reports of young children in foster care who lack attachment (Heller et al., 2006), but it is not yet known how prevalent this may be in other high-risk samples, such as maltreated children. Even more remarkable, we found that these young children were able to form attachments, even secure attachments, especially if they were placed before 24 months into our foster care intervention. This finding illustrates the remarkable plasticity of the attachment system in the first years of life.

In addition to this plasticity, across multiple domains of social competence and psychopathology, we have found that developing a secure attachment once placed into the intervention was a powerful predictor of resilience in the face of adverse early experience. Hence, forming a secure attachment relationship, even after initial adverse experiences, had a significant effect in mediating outcomes.

The other area in which we have made significant discoveries is in the domain of brain function. From our initial observations of decreased alpha power in the EEG of the institutionalized children, we wondered what the origins of this finding were. Two findings inform our answer. First, we found that by 8 years of age, those children placed into our intervention before the age of 24 months were indistinguishable in terms of their EEG power from community controls. Thus, our intervention appeared to remediate this effect. The second finding that illuminated these patterns was when we conducted structural (MRI) imaging of the sample. We found that the children who were randomized to the institution had significantly less white matter volume compared to community controls. White matter volume fully mediated the relation between

institutionalization and EEG power. This finding provides a plausible mechanism of how early deprivation leads to reduced brain connectivity, which results in reduced brain electrical activity.

In closing, with its RCT design and measures of psychological, behavioral, neurological, and biological development, the BEIP is a unique project from which to draw conclusions about the effects of early experience on brain and behavioral development. To date we have studied our cohort from infancy through the transition to adolescence. We hope soon to conduct at least one more investigation as our sample reaches midadolescence and, if possible, as they make the transition to adulthood.

INTRODUCTION

The high degree of illness progression in the recurrent affective disorders is generally underappreciated, particularly in bipolar disorder. We review evidence that recurrent depressive and bipolar illness tends to run a deteriorating course involving multiple mechanisms and facets of the illness. Thus, this view is high compatible with Cicchetti's (2010) developmental psychological perspective. This includes: increases in responsivity to stressors (stress sensitization); increases in vulnerability to relapse after successive episodes (episode sensitization); and increases in pathological behavioral responsivity to repeated bouts of substance abuse, particularly involving psychomotor stimulants (stimulant-induced behavioral sensitization) (Post, 1992, 2002a,b). Not only does each of these processes manifest an increase in behavioral pathology upon repetition, but the processes can show cross-sensitization to the others such that increased responsivity in one domain can convey increased responsivity in the other two domains as well (Post, Fleming, & Kapczinski, 2012; Post & Kalivas, 2013).

Some of the neurobiological mechanisms underlying behavioral sensitization are reviewed, including long-lasting alterations in gene expression based on epigenetic mechanisms. The illness also tends to run a kindling-like

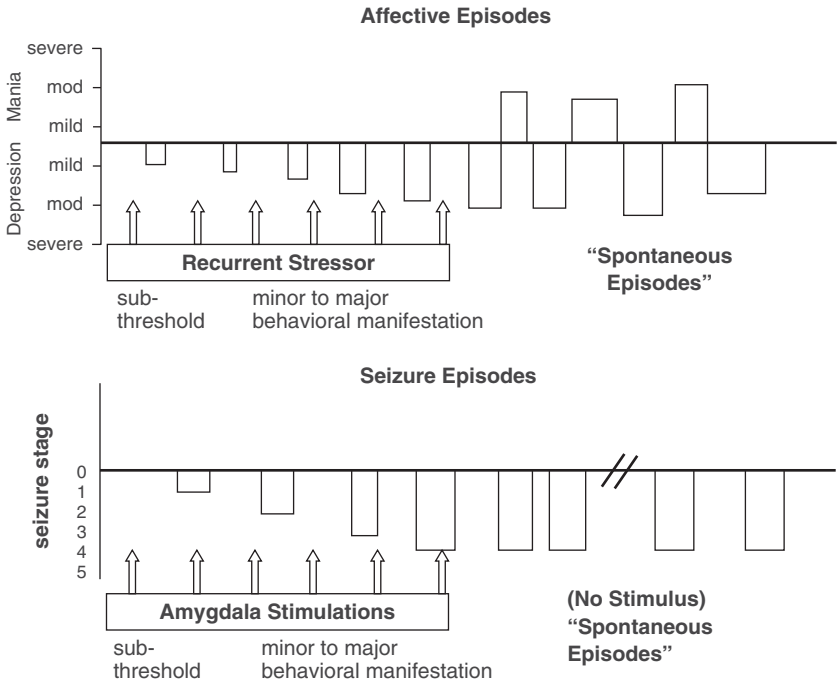

Figure 19.1 Parallelisms in Kindling of Seizures and Affective Episodes.

progression. In amygdala kindling, increasingly full-blown seizures are induced upon repetitive, once-daily stimulation of the amygdala. Following a sufficient number of triggered seizures, spontaneous seizures in the absence of exogenous amygdala stimulation begin to emerge (Goddard, McIntyre, & Leech, 1969; Racine, Steingart, & McIntyre, 1999). In a parallel fashion in the affective disorders, repeated stress-induced minor affective episodes can yield more major episodes upon stressor repetition (see Figure 19.1). Often there is a period of stressor-induced episode recurrence during which each episode tends to mirror that of the previous episode. However, with sufficient numbers of repetitions, episodes can also begin to emerge spontaneously in the absence of psychosocial precipitants (Post, 1992, 2002a,b).

These recurrences tend to be accompanied not only by increased autonomy from stressors but by an increase in the rapidity and unpredictability (chaos) of mood fluctuations and episode recurrence. This kind of temporal progression, from minor to major episodes, faster recurrences, and episodes that are initially precipitated by psychosocial stress to ones that also occur autonomously, bears considerable similarity to that occurring in the process of electrical kindling of the amygdala. However, the induced and then spontaneous behaviors of kindled seizures on one hand and of mood episodes on the other are obviously not behaviorally homologous, and the kindling model is useful only for conceptualizing the progressive temporal evolution of a syndrome upon repetition.

Yet some of the mechanisms underlying kindling evolution may have relevance for a similar spatiotemporal progression in the neural processes and substrates mediating the recurrent mood disorders. Given the potentially progressive and deteriorating course of inadequately treated unipolar and bipolar disorders, one would assume that there would be a variety of neurobiological alterations that correlate with either the number of prior episodes or duration of illness (Post, Fleming, & Kapczinski, 2012). We review the emerging evidence for these biological alterations in the hope that their consideration will further enhance the rationale for early intervention and long-term prophylaxis, to attempt to ameliorate both the clinical manifestations of recurrent illness and their neurobiological concomitants.

This view of the potentially deteriorating course of the recurrent affective disorders and some of the potential mechanisms should give a new impetus to clinical and public health measures aimed at prevention. (Cicchetti, 2010; Cicchetti & Toth, 2009). We discuss some of the sociopolitical issues involved in the reluctance and/or inability of medicine and psychiatry in the United States and elsewhere to adequately embrace these data and concepts and to change therapeutic strategies and paradigms accordingly.

One of the major difficulties has been in the recognition that bipolar disorder is an illness of childhood and adolescent onset, in the majority of instances (Perlis et al., 2004; Post, Leverich, et al., 2010), and all too often, inadequate treatment begins early in the illness (Geller, Tillman, Bolhofner, & Zimerman, 2010; Post & Kowatch, 2006) and, to some extent, continues throughout adulthood. This pattern has deleterious effects on the individual and society because multiple complications in the psychiatric and medical realm accumulate with the potential for enormous personal, social, and economic losses.

We also review evidence that many aspects of illness progression are more pernicious in the United States than in some European countries (Post et al., 2014a), and this view of the malignant progression of the illness in the United States compared with other locations further heightens the need to revise our typical treatment paradigms in the United States to attempt to intervene in a more judicious fashion.

TYPES OF SENSITIZATION MECHANISMS IN THE RECURRENT AFFECTIVE DISORDERS AND THEIR CROSS-REACTIVITY

Both clinical and basic studies reveal an increased responsivity to repetition of (a) stressors (Antelman, 1988); (b) stress-induced behavioral aberrations with depressive-like features (Miczek, 1999) and depressions themselves (Kessing, Mortensen, & Bolwig, 1998; Post, 1992); and (c) bouts of psychomotor stimulant administration (Post & Kalivas, 2013; Post, Weiss, & Pert, 1987). At the same time, there is considerable evidence for cross-sensitization among these three phenomena. Stressful life experiences can predispose to stimulant-induced behavioral sensitization, and the latter can be associated with increased stressor reactivity as well. In rodents, depressive-like behavior induced by repeated defeat stress can result in this depressed and anxious behavior generalizing to other environments as well leading to increases in drug self administration.

Clinical Evidence of Episode Sensitization

The general pattern of an acceleration of the rate of recurrence of episodes in bipolar disorder has been described since the initial observations of Kraeplin (1921) more than 100 years ago. Perhaps the most cogent evidence emanates from the work of Kessing and collaborators (1998) in the Danish case registry whereby they observed that the likelihood and the latency to relapse into another depression was directly proportional to the number of prior episodes/hospitalizations for either unipolar or bipolar depression. Kraeplin described this as a shortening of the well interval between successive episodes; others have labeled it as cycle acceleration or, in the absence of regular cyclicity, a pattern of faster recurrences. In some instances, this can progress from rapid cycling (four or more episodes per year) to ultra-rapid cycling (four or more episodes per month), and then to ultra-ultra-rapid (or ultradian) cycling in which dramatic mood shifts can occur within a 24-hour period with durations of manic and depressive phases lasting minutes to hours.

Although it is often cited that some 10% to 20% of individuals with bipolar illness have a rapid cycling pattern, more recently we have observed a very much higher proportion of 64.1% of 919 patients having rapid cycling (Kupka et al., 2005; Post, Altshuler, Kupka et al., 2014a) and approximately 20% even showing periods of ultradian cycling.

There are many potential explanations for this apparent general increase in rapidity of recurrence of the illness. One is that there appears to be evidence of a cohort (year of birth) effect, where each birth cohort since World War I has shown an increased incidence and earlier age of onset of both unipolar and bipolar disorder (Lange & McInnis, 2002). Early-onset disorder is associated with a more severe and rapidly cycling course of illness (Perlis et al., 2004, 2009; Post, Leverich, et al., 2010). In anticipation (a generational effect), if a parent had the onset of bipolar illness at age 25, and the child developed the illness, it would tend to occur at approximately age 15, or on average some 10 years earlier (Lange & McInnis, 2002). Faster patterns of illness recurrence and cycling, greater severity, and treatment resistance could likewise be associated with either the cohort or anticipation effects (Lange & McInnis, 2002).

It is important to note that the episode acceleration effect is the modal one and is not invariant in that with adequate treatment intervention, it can be halted or reversed. Moreover, some patients may from the outset begin their illness with a pattern of rapid or continuous cycling. Thus, the different patterns of course of illness are similar to that observed in multiple sclerosis, where some are benign, others recurrent and slowly progressive, and still others rapidly progressive. Although there is a subgroup of unipolar and bipolar patients with benign illnesses and rare recurrences, the majority of patients fit the category of recurrent progressive and show the pattern of episode sensitization.

Clinical Manifestations of Stress Sensitization

Kraepelin (1921) also noted that episodes early in the course of illness are often precipitated by psychosocial stressors, but episodes later in the course of illness could occur in both a precipitated fashion and also in the general absence of stressors or in the presence of minor, anticipated, or imagined stressors. Three studies in recurrent unipolar depression perhaps present the most specific and explicit data supporting this proposition. The studies found that following the first five to seven episodes of illness, in which stresses were often implicated in the onset of these depressions, subsequent episodes appeared to have less close links to psychosocial precipitants (Kendler, Thornton, & Gardner, 2000, 2001;Slavich, Monroe, & Gotlib, 2011). It is not that psychosocial stresses are no longer able to precipitate episodes; in fact, the opposite is the case: There is increased sensitivity to stressors to the point where minimal or conditioned stressors might be able to trigger these later episodes.

In the bipolar disorders, there appears to be not only stress sensitization but also stressor accumulation. We documented this in our series of patients in the Bipolar Collaborative Network, in that those with early psychosocial adversity in childhood subsequently had more negative stressors both prior to the onset of their first episode and prior to the last episode before Network entry, at average age 40 (Leverich, Perez, Luckenbaugh, & Post, 2002). Thus, early stresses predict a greater burden of later negative stressors in life. To the extent that there is also increased reactivity to these stressors (sensitization), one would expect more of both triggered and spontaneous episodes as the illness progresses.

Stimulant-Induced Behavioral Sensitization

In the preclinical model, animals given repeated similar doses of psychomotor stimulants show increased behavioral hyperactivity and stereotypy in response to readministration of the same dose of drug. There is also a context dependency or conditioned component to this sensitization, because animals show increased responsivity when the test dose of drug is administered in the same environmental context in which the animal previously received it, but not when the environmental context is changed (Post, Weiss, Pert, & Uhde, 1987; Post & Kalivas, 2013).

In this context-dependent behavioral sensitization, it appears that there are different biochemical and pharmacological mechanisms involved in the initial phases of the acquisition of the behavioral sensitization as opposed to when the already sensitized animal is later tested for the expression of sensitization. For example, antipsychotic drugs that block dopamine (DA) receptors are able to block the development of sensitization if they are delivered concomitantly with the initial doses of cocaine. Yet if the animals are sensitized to repeated cocaine administration and then given a DA blocker prior to the test injection, the expression of sensitization is not blocked (Weiss, Post, Pert, Woodward, & Murman, 1989).

Other drugs, including those that are alpha-2 agonists, such as clonidine, will, however, block the expression of sensitization. These observations are of some clinical importance in treating patients with comorbid substance abuse. Once an individual is sensitized to the effects of stimulants, different psychopharmacological agents (such as N-acetylcysteine [NAC] as discussed later) may be required to suppress the expression of this increased behavioral reactivity, as opposed to drugs (such as the antipsychotics) that can block only the acquisition of sensitization.

There appears to be cross-sensitization among stressors and stimulants, in that animals exposed to early stresses are more reactive to psychomotor stimulants (Post & Post, 2004) and more likely to adopt psychomotor stimulant self-administration. Conversely, once animals are sensitized to the effects of psychomotor stimulants, they appear to be more reactive to some stressors than animals not exposed to prior stimulant administration (see Figure 19.2).

With increasing numbers of repetitions of cocaine administration, animals appear to progress from predominantly hyperactivity to more frantic and disorganized stereotypic repetitive movements. This process may have clinical parallels. It is common experience for those who utilize stimulants to initially have euphoric and positive responses, with increased mood, energy, and social contacts, resembling euphoric hypomania. However, with longer-term administration, many of the positive elements of the cocaine experience become transmogrified.

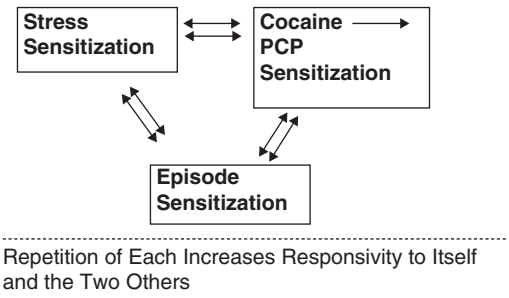

Figure 19.2 Cross-Sensitization among Stressors, Drugs of Abuse, and Episodes.

Instead of pure euphoria and pleasant physical sensations, there appear to be increasing amounts of dysphoria, anger, irritability, and anxiety, a syndrome closely resembling that of dysphoric hypomania. A history of drug abuse is a risk factor for developing dysphoric hypomania. Further in the evolution of stimulant use, there can be context-dependent paranoia and even the emergence of a paranoid psychosis, resembling many aspects of full-blown psychotic mania.

Thus, the progression of behavioral responsivity to cocaine appears to evolve over time and involve increasing amounts of dysphoria and disorganization. In the clinic, this sensitization effect cannot be separated readily from what is often a concomitant dose-escalation effect, but at least preclinically, it is clear that even administration of the same dose over time can lead to an altered pattern of behavioral reactivity. This progression to dysphoria and psychosis also appears to be the case with other psychomotor stimulants, such as amphetamine or methylphenidate, as well as with psychotomimetic drugs that block the glutamate receptor N-methyl-D-aspartate receptor (NMDA), such as phencyclidine (PCP), which can also produce dissociative symptoms and a schizophreniform psychosis.

Cocaine-Induced (Local Anesthetic) Kindling of Panic Attacks and Seizures

In electrophysiological kindling, the amygdala, for example, is stimulated electrically once daily for 1 second with a current that is initially subthreshold for afterdischarges or behavioral manifestations. However, with repeated stimulation, afterdischarges of increasing duration and complexity emerge and spread to other areas of brain, accompanied sequentially by altered behavioral responsivity starting with Stage 1, behavioral arrest and chewing movements, Stage 2, head nodding, Stage 3, unilateral minor motor seizures that then evolve into Stage 4, full-blown bilateral tonic-clonic seizures of the forepaws, and Stage 5 associated with a rat showing rearing and falling. As noted, following sufficient numbers of these induced seizures, spontaneous seizures can also begin to occur.

Cocaine is a potent local anesthetic in addition to its amphetamine-like properties as a psychomotor stimulant based on its ability to block the reuptake of DA. The local anesthetic effects of cocaine and lidocaine, dependent on blockade of sodium (Na+) channels, evoke increases in the reactivity of limbic areas of the brain, particularly the amygdala and anterior cingulate cortex, and doses of cocaine or lidocaine that were previously subconvulsive begin to produce increases in afterdischarges in the amygdala and, ultimately, full-blown behavioral convulsions resembling those of the electrical kindled variety.

Not only do animals become more seizure prone to the same dose of drug, but with repeated induction of lidocaine-induced seizures, spontaneous seizures also begin to emerge, similar to the progression seen with electrical kindling of the amygdala. In cocaine seizures, this transition to spontaneity is less likely to be observed, because both rodents and primates often succumb to the first or second cocaine-induced seizure and do not experience enough of the induced variety to ultimately show spontaneous seizures. We have dubbed these progressive effects of local anesthetics pharmacological kindling (Post, 2002b; Post et al., 1987).

What patients most readily do demonstrate with repeated use of cocaine is a kindling-like progression of panic attacks. Repeated bouts of cocaine use can be associated with progressive increases in anxiety, and eventually cocaine can begin to consistently precipitate full-blown panic attacks. Following a series of cocaine-induced panic attacks, the attacks can then begin to occur spontaneously, and this can be associated with considerable agoraphobia because they are occurring unpredictably (Post et al., 1987; Post & Leverich, 2008). In these individuals, spontaneous panic attacks can continue to occur even if cocaine use is stopped completely. Thus, it appears that the stimulant component of cocaine is associated with behavioral sensitization based on increases in motor reactivity to DA, while anxiety, panic attacks, and seizures appear to be progressively kindled by cocaine's local anesthetic properties with a major focus in the amygdala.

Adolescents with bipolar disorders are at approximately 7-fold increased risk, compared with adolescents in the general population, to develop substance abuse and addiction (Wilens et al., 2004). This occurs almost always after the onset of their bipolar illness. Therefore, engaging adolescents who have had an initial manic episode in educational and primary preventive approaches to attempt to avoid their beginning substance use would appear indicated. Considerable data suggest that those with substance abuse have a more difficult course of illness compared with bipolar patients without this comorbidity (Strakowski, DelBello, Fleck, & Arndt, 2000), which would certainly be in accord with the notion that substance use and mood episode can compound each other as well as generate more stressors which can then trigger further relapses of affective episodes and substance use (Post & Kalivas, 2013). Substance abuse sensitization, as we have indicated, thus appears to cross-sensitize to both stressors and episodes.

Patients with substance abuse are more likely to switch into mania on antidepressants (Goldberg & Whiteside, 2002), and episodes of affective illness can result in the relapse into substance use in those who had previously been abstinent (Kalivas & Volkow, 2005).

NEUROBIOLOGICAL COMMONALITIES IN STRESS, EPISODE, AND SUBSTANCE ABUSE SENSITIZATION

Stressors are able to decrease brain-derived neurotrophic factor (BDNF) in the hippocampus (Smith, Makino, Kvetnansky, & Post, 1995). Stressors occurring early in life are also capable of decreasing BDNF in the prefrontal cortex (PFC), and these BDNF reductions remain throughout an animal's lifetime (Roceri et al., 2004; Roth, Lubin, Funk, & Sweatt, 2009). Roth and collaborators (2009) have shown that poor maternal rearing behaviors during the first 10 days of a rat pup's life are associated with these persistent decrements in BDNF based on an epigenetic mechanism. The promoter for *Bdnf* is methylated following the early stressful life experiences, and this methylation results in lesser degrees of *Bdnf* transcription and lower amounts of BDNF protein in the brain. Roth and colleagues showed that if the methylation of the *Bdnf* promoter is prevented with a drug called zebularine, the decrements in cortical BDNF based on early life stresses do not occur. Preliminary data are analogous in humans. Adults with bipolar disorder who had early childhood experiences of abuse had lower levels of BDNF measured in blood compared with those without such early abuse histories (Kauer-Sant'Anna et al., 2007).

Episodes of both mania and depression are associated with decrements in BDNF in the blood in proportion to the severity of the episode (Post, 2007a). In this sense, BDNF appears to be a marker of episode severity, and it returns toward normal during well intervals. There is a useful animal model of depression in adult rodents subjected to repeated bouts of defeat stress. In these instances, rodents are repeatedly exposed to a home-cage mouse that is not only bigger than the intruder but aggressively defends its territory. If the intruder animal is left exposed to the resident, the intruder may be severely injured or even killed. Thus, after a short introduction to the resident animal, a glass partition is placed so that the intruder sees and smells the home-cage resident but is protected from attack.

The repeated experience of this anxiety-provoking situation for 10 days is associated with the emergence of depressive-like behaviors in the intruder that are manifested not only in this environment but in others as well (Miczek, 1999). This defeat stress is associated with decrements in BDNF in the hippocampus. If the BDNF decreases are prevented with treatment with antidepressants, the defeat stress depressive-like behaviors do not occur (Berton et al., 2006).

In addition to the hippocampal decrements in BDNF associated with repeated defeat stress, there are opposite changes or increases in BDNF in the ventral tegmental area and nucleus accumbens (NAc) (also called the ventral striatum), the dopaminergic reward area of brain. Here, too, if the BDNF increases are prevented, defeat stress behaviors do not emerge (Berton et al., 2006; Tsankova et al., 2006). Thus, the BDNF alterations—both the decrements in the hippocampus and the increases in the NAc—appear necessary and sufficient to produce the depressive behaviors.

These preclinical findings parallel those from autopsy specimens of depressed suicide victims who also show decrements in BDNF in the hippocampus and increases in BDNF in the nucleus accumbens compared with controls (Krishnan et al., 2007). In addition, there are similar dissociations in BDNF in animals given chronic cocaine. Cocaine sensitization is associated with increases in BDNF in the NAc; sensitization does not occur if the BDNF increases are prevented in that area of the brain. The stimulant-induced BDNF decreases in the hippocampus are dependent on the timing of withdrawal from cocaine.

Thus, it appears that stressors, cocaine, and defeat stress depressive-like behaviors are each associated with decrements in BDNF in the hippocampus and increases in BDNF in the NAc (Post and Kalivas, 2013). Given these common neurobiological mechanisms, one wonders whether these biochemical changes could in part contribute to the phenomenon of cross-sensitization among stressors, episodes, and substances of abuse. From a pathological perspective, such sensitization and cross-sensitization is likely to yield more problematic aspects of affective illness progression (see Figure 19.2).

THERAPEUTIC IMPLICATIONS

N-acetylcysteine: Efficacy in Multiple Syndromes

From a theoretical perspective, such common mechanisms such as BDNF alterations also raise the possibility that single treatments targeted at one type of sensitization may be of therapeutic utility in other domains as well. This theoretical possibility has not yet been demonstrated based on epigenetic mechanisms, but it has with another compound

that suppresses cue-induced increases in glutamate in the NAc. N-acetylcysteine (NAC) is a substance that has an interesting spectrum of therapeutic effects in mood, substance abuse disorders, and other habits (Berk, Malhi, Gray, & Dean, 2013; Post & Kalivas, 2013). Kalivas (2013), at the Medical College of University of South Carolina, found that animals that were taught to self-administer cocaine were highly prone to relapse into cocaine use (called cocaine reinstatement) upon exposure to stressors, minute doses of the drug, or environmental cues signaling the potential availability of cocaine. These types of triggers for relapse also occur clinically in patients who believe that their cocaine craving and proneness to re-addiction have been extinguished.

This cocaine reinstatement in rodents was associated with high levels of glutamate in the NAc upon presentation of the cocaine cue or stressor. Kalivas (2013) reasoned that if the conditioned glutamate spike could be lessened, animals would be less prone to cocaine reinstatement. This is, in fact, what he found, and these preclinical data were rapidly taken to the clinic by Kalivas and collaborators where it was demonstrated that human cocaine abusers had decreased cocaine craving when they were administered NAC. The animal data indicate that NAC downregulated a hyperreactive glutamate signal in the nucleus accumbens at first thought to be related to effects on a cystine-glutamate exchange mechanism but now thought to be attributable to the induction of glutamate transporters in glial cells, which increase the clearance of synaptic glutamate.

As indicated in Table 19.1, NAC exerts a remarkably broad therapeutic spectrum of effects in a variety of syndromes that might be characterized by overactivity or overreactivity in the habit memory system (see Table 19.2). The range of therapeutic effects of NAC include placebo-controlled positive data in bipolar and unipolar disorder: cocaine and gambling addiction; obsessive-compulsive disorder; trichotillomania; and the stereotypy and irritability of autism in 8- to 17-year-old children. In addition, preliminary evidence suggests that it may have therapeutic effects in alcohol and marijuana avoidance as well.

What is particularly notable is that Berk and collaborators (2008) showed that after a period of 3 months compared with placebo, NAC exerted dramatic antidepressant effects in bipolar depression, and these were sustained for another 3 months until the drug was discontinued at 6 months. Berk and collaborators were using NAC based on its antioxidant properties as a glutathione precursor. However, it remains to be ascertained whether NAC's effect on decreasing conditioned glutamate hypersecretion

TABLE 19.1 N-acetylcysteine (NAC) Dampens Conditioned (Cued) Glutamate Release in the Nucleus Accumbens: Is this a Common Mechanism for Suppressing Habit-Based Psychopathologies?

TABLE 19.2 Common Effects of Stress-, Episode-, and Cocaine-Induced Sensitization on BDNF in Brain Systems Mediating Habit and Representational Memory

Type of Memory:	Habit Memory	Representational Memory
Substrate	Striatum	Medial Temporal Lobe
Components	**1.** Dorsal striatum **2.** Ventral striatum (i.e., nucleus accumbens, NAc)	**1.** Hippocampus **2.** Amygdala
Process	Repetition and procedural learning	Declarative memory and single-trial learning
Awareness	Unconscious	Conscious
BDNF	Increased in: nucleus accumbens with defeat stress, human depression (suicide), and cocaine sensitization	Decreased in: hippocampus with defeat stress, human depression (suicide), and cocaine sensitization
Consequences	Repetition of stress, depression, and cocaine may result in overlearned habits	Hippocampal dysfunction may induce biased retrieval of long-term memories and disinhibit the ventral tegmental area pathway to nucleus accumbens, increasing burst firing of ventral tegmental area, increasing BDNF, depression, and cocaine sensitization

in the NAc is the basis for its effects, not only in a variety of habits and addictions but also in recurrent affective disorders.

We had previously postulated that because bipolar recurrences move from those that are generally precipitated by psychosocial stresses to those occurring more autonomously, the memory mechanisms involved likely moved from the conscious representational memory system mediated by the amygdala and hippocampus to the more unconscious habit memory system mediated by the striatum (Mishkin & Appenzeller, 1987; Post, 2002a). Thus, the more autonomous or automatic occurrence of manic and depressive episodes later in the course of the illness may be encoded at an unconscious level in the dorsal and ventral striatum (nucleus accumbens), most closely linked to the mood, motivation, activity, and reward system of this dopamine-rich area. Dias-Ferreira et al. (2009) show in animals that "chronic stress leads to a bias in behavioral strategies toward habit" based memory mechanism.

In trichotillomania and completion of other compulsive acts, there is temporary relief of anxiety following the execution of the habit. The cue for initiating these actions may be like the conditioned cue seen in the cocaine habit reinstatement paradigm and may be associated with a markedly increased release of glutamate in the NAc. Hence, following chronic administration of NAC, NAC downregulates the increased glutamate reactivity (Kalivas et al., 2003).

Such a dampening of overreactivity of glutamate in the NAc could theoretically also be involved in the inhibition of the automatic triggering of mood episodes seen in the late stages of the recurrent affective disorders. This mechanism would also be consistent with the preliminary data that the glutamate NMDA receptor blocker memantine (Namenda) is able to induce a high rate of response and remission in those with highly treatment refractory bipolar disorder (Koukopoulos, Serra, Koukopoulos, Reginaldi, & Serra, 2012).

Although this formulation remains to be directly tested, the therapeutic effectiveness of NAC in a variety of syndromes thought to be based on altered reactivity in the habit/reward system of the NAc provides preliminary evidence that a single therapeutic modality holds the promise of being able to exert therapeutic effects across a variety of paradigms associated with habits and sensitization to stressors, mood episodes, and abused substances and their potential for cross-sensitization (Post & Kalivas, 2013). That is, we are postulating that NAC can dampen sensitization to stress, episodes, and cocaine, although such an effect has been unequivocally demonstrated only in the paradigm of substance abuse addiction.

Consistent with this formulation, Kalivas and colleagues (2003) have also found that enhancing glutamate removal and reuptake via glial transporter mechanisms can also decrease cocaine reinstatement, using an antibiotic known to enhance the effectiveness of the glial glutamate transporter. Glial deficits have also been documented in the recurrent mood disorders (Rajkowska, Selemon, & Goldman-Rakic, 1998), and enhancement of glial activity and glutamate clearance could have therapeutic effects in the affective disorder spectrum as well.

NAC is a glutathione precursor with antioxidant properties on its own. The anterior cingulate gyrus, which is another key cortical structure for the modulation of emotional function, is particularly sensitive to oxidative stress during selected periods of development (Berk et al., 2013). Fast firing interneurons containing the inhibitory neurotransmitter GABA and parvalbumin are critical to neuronal modulation and are especially sensitive to oxidative stress. NAC treatment reverses the oxidative stress in these interneurons and preserves their normal function. A variety of childhood stressors are known to disrupt anterior cingulate function; thus, a protective effect of NAC on these sensitive interneurons could be an additional potential mechanism for its therapeutic effects in bipolar disorder and schizophrenia.

Epigenetic Manipulations: A Future Treatment Direction

Finally, based on the NAC data, it is possible to also envision manipulations at the level of epigenetics that might be capable of downregulating an overactive habit system and thus provide clinical improvement across a variety of syndromes linked to the sensitization phenomenon. In this regard, it is of interest that in the repeated exposure to the defeat stress model for the induction of depressive-like behaviors, epigenetic manipulations that prevent BDNF decreases in the hippocampus or increases in BDNF in the nucleus accumbens are sufficient to block the emergence of the depressive-like behaviors.

Antidepressants, which increase BDNF in the hippocampus, also prevent the emergence of depressive behavior, but they do not reverse or remove the defeat stress–induced epigenetic mark, in this case a repressive trimethylation of the DNA of the promotor of the *Bdnf* gene, which is the fundamental mechanism for the long-lasting BDNF decreases (Krishnan et al., 2007). Thus, while the antidepressants increase BDNF by other mechanisms, they are not sufficient to remove the long-term memory trace of the defeat stress behavior encoded at the level of epigenetic changes in DNA. This trimethylation

could be part of the long-term behavioral and biochemical trace that confers long-lasting vulnerability to depressive recurrences, as evidenced by a vulnerability to relapse when antidepressants are discontinued, either clinically in humans or in animal models of depression. Similarly, early life stressors, likely on an epigenetic basis (Roth et al., 2009), can lead to lifelong vulnerability to stressor-induced depressions in adulthood in genetically susceptible individuals (Caspi et al., 2003).

To the extent that this formulation is accurate, it suggests the optimistic possibility that epigenetic manipulations that would remove the environmentally-induced epigenetic marks on DNA and histones might exert more long-lasting therapeutic effects, even after the treatment is discontinued. One then looks forward to the next generation of therapeutic maneuvers that could prevent or reverse the long-lasting sensitization encoded epigenetically, as has already been demonstrated in animal models involving cocaine sensitization (Anier, Malinovskaja, Aonurm-Helm, Zharkovsky, & Kalda, 2010) and stress sensitization in the work of Roth and colleagues (2009).

Exploiting Memory Revision During the Reconsolidation Window in Order to More Permanently Extinguish Habit-Based Memories

In short-term memory, the memory trace in the hippocampus under goes consolidation as it is shifted to cortical locations for long-term storage. If protein synthesis is disrupted in this consolidation phase, what is learned is not placed in permanent memory storage. Recent data now suggest that there is a second phase—memory reconsolidation—during which an actively recalled long-term memory becomes transiently labile (for 5 minutes to 1 hour) and subject to revision or even erasure with protein synthesis inhibitors. Because such memory erasure achieved in animal models is not clinically feasible in humans, neuropsychological approaches have been explored to intervene in the reconsolidation window in order to enhance new learning and extinction effects. The feasibility of this approach has been demonstrated in patients with anxiety disorders, posttraumatic stress disorder, and even substance abuse involving cocaine or heroin (Xue et al., 2012).

When animals or humans addicted to cocaine (or heroin) are repeatedly exposed to addiction-related cues in the absence of drug reward, extinction takes place, and bar pressing for the drug in rodents or cued craving for the drug in humans ceases (Kalivas & Volkow, 2005). However, this extinction of craving in one environment or in the clinical laboratory is subject to spontaneous and stressor-induced relapse as well as cued relapse in other environments. This finding indicates that the extinction learning is not completely effective in removing the original habit-based memory trace.

In conditioned avoidance paradigms and in instances of substance self-administration, active recall of the long-term memory of the shock stress or drug reward (induced by exposure to the cued environment) followed by the extinction trials is associated with a more persistent and long-lasting memory erasure. It is thought that the cued environment renews and activates the memory trace which then opens a reconsolidation window that lasts from 5 minutes to 1 hour during which the long term memory becomes labile and subject to permanent revision. The extinction training occurring during this reconsolidation window is much more robust and long lasting than extinction trials occurring outside of the reconsolidation window.

This extinction of the memory of drug reward has now been demonstrated in animals addicted to cocaine and heroin self-administration addiction, whereby the reexposure and opening of the reconsolidation window results in a more effective and persistent extinction process (Xue et al., 2012). What is remarkable about this extinction process is that when animals are transferred to other environments or experience cues that would normally elicit cocaine reinstatement, such as stressors or a whiff of the drug itself, they do not reinstate cocaine self-administration. These preclinical data have been directly applied to cocaine- and heroin-addicted humans with similar and remarkably robust findings of long-lasting (up to 180 days) complete extinction of drug craving, blood pressure increases, and drug use when the extinction trials occurred 10 minutes after active memory recall of the positive drug experience, i.e., within the reconsolidation window, but not after the window had closed 6 hours after recall (Xue et al., 2012).

We raise this issue in some detail in a chapter on bipolar disorder because substance abuse comorbidity is a common occurrence in the disorder. It addition, it is possible that such extinction learning could exert positive, long-lasting therapeutic effects in the triggering of habit-based depressive-episode relapses in the affective disorders. Although the appropriate therapeutic paradigms have not been adequately spelled out or even preliminarily tested, the idea would be to have the patient recall with a written script typical stress-related cues that might ordinarily be triggers for affective episodes and thereby open the reconsolidation window. Within this 1-hour time

frame, the patient could then work in cognitive-behavioral therapy aimed at extinction of the emotional hyperreactivity to these individualized cues. Parenthetically, such paradigms are already being considered in the treatment of posttraumatic stress disorder, in which reactivity to conscious and unconscious cues may be sufficient to trigger memory replays, flashbacks, and nightmares. These reactions can be ameliorated by reworking the traumatic memory after opening the reconsolidation window.

The neural substrates of this type of reversal of conditioned fear have been demonstrated in humans using functional magnetic resonance imaging (Agren et al., 2012). On day 1, subjects are exposed to 16 trials of presentation of a visual cue followed by a shock. On day 2, subjects receive extinction training (5 visual cues with no shocks) either 10 minutes or 6 hours after the cue-reminded recall. Upon cue presentation on day 3, the functional magnetic resonance imaging shows striking activation of the amygdala and connectivity to activity to the anterior cingulate and bilateral insula and hippocampus (the fear circuit) only in the 6-hour extinction group, whose members on day 5 continue to show robust retention of conditioned fear, as evidenced by increases in skin conductance. In contrast, members of the 10-minute group (who received extinction within the reconsolidation window) show erasure of the fear memory trace as evidenced by the findings that the amygdala and its connectivity to the fear circuit is no longer activated in response to the fear cure, and on day 5, there is no conditioned fear or increase in skin conductance.

MODULATION OF SENSITIZATION MECHANISMS

Sensitization to stressors, mood episodes, and substances of abuse thus have the problematic clinical implications that they likely both mediate and exacerbate illness progression by multiple interacting mechanisms. At the same time, their cross-sensitization effects suggest the possibility that single types of pharmacological treatments (such as NAC) or neuropsychological maneuvers (such as memory revision in the reconsolidation window) may be capable of exerting therapeutic effects on several types of sensitization based on their common principles of induction. However, the primary therapeutic message of this view of the progressive nature of recurrent mood disorders is clearly to attempt to avoid or minimize each type of sensitization in the first place to the extent that it is clinically possible.

Preventing Episode Accumulation

Preventing episode accumulation becomes a readily achievable therapeutic target because episode prevention is clearly the long-term goal of both the patient and the clinician. In addition, the earlier institution of long-term prophylactic medications to prevent recurrent episodes, and the accompanying episode sensitization may yield a more treatment-responsive illness (Post & Leverich, 2008; Post, Leverich, et al., 2012). Later intervention after multiple episodes have already occurred yields a more treatment-refractory illness, typically requiring more complicated treatment regimens to achieve successful therapeutic results (Post, Fleming, & Kapczinski, 2012; Post, Leverich, et al., 2010).

Modulation of Stressors

Similarly, stresses cannot readily be avoided in life, but stress immunization and working on coping mechanisms can have a remarkable effect in ameliorating stressors. This finding has been demonstrated most readily in the area of conditioned or learned helplessness. If an animal is exposed to inescapable shock in an unpredictable fashion but is able to cope by pressing a lever that turns the shock off, it does not develop the helpless-related, depressive-like behavior or the associated biochemical perturbations. In contrast, the yoked control animal that receives the same electrical stimuli but does not have control over them because it does not have access to a bar to terminate the stimulation does develop the depressive-like behaviors of learned helplessness (Amat, Paul, Watkins, & Maier, 2008).

It appears important for the animal to know that it can cope and can press the bar to terminate the shock. These observations are based on the findings that if the medial PFC of the animal that does press a bar to turn off the shock is anesthetized, the animal apparently is not consciously aware that it is achieving this endpoint, and it too develops learned helplessness (Amat et al., 2008).

Thus, the ability to cope with stress and the knowledge that one can cope may be of special clinical importance in reducing the effects of stress-induced behavioral aberrations. The preclinical findings are also of particular interest in regard to the finding that many depressed patients have deficits in the activity of their PFC during depressive episodes and may be at a further loss to evoke or formulate adequate coping strategies or even to know that they are able to develop such coping strategies. Therapists may thus have to play an active role in providing depressed patients a more flexible and active substitute PFC until the depression is ameliorated.

Avoiding or Treating Substance Abuse Disorders

In the third domain of substance abuse sensitization, it is obvious that substance abuse avoidance should be another major goal of patients with mood disorders, one that is all too often not achieved. Yet as we have attempted to illustrate, even in individuals with a more malignant progression of their mood disorder based on multiple recurrences of episodes, clinical and psychopharmacological interventions are possible. Similarly, an array of effective interventions exists even for those who have already become substance users. However, the neuropsychological mechanisms and neurobiological substrates of the addictions, as well as their pharmacological interventions appear to differ as a function of phase of sensitization development, expression, persistence, and reconsolidation. Typically, effective intervention late in the course of addictive illness and its progression is more complex and difficult to achieve than intervention earlier in the course.

Even though there are currently no pharmacological treatments approved by the Food and Drug Administration (FDA) to intervene in alcohol, marijuana, or cocaine addiction that occurs in concert with bipolar disorder, a number of positive placebo-controlled studies have shown efficacy in patients with primary addiction. Possible interventions for cocaine addiction, for example, include the antinarcoleptic drug modafinil (Provigil), the anticonvulsant topiramate (Topamax), and, as noted, NAC. Each of these would appear more preferable in patients with mood disorders than the $GABA_B$ agonist baclofen, which also has positive placebo-controlled data in primary cocaine abuse disorders, but earlier work from our group has indicated that baclofen can exacerbate depressive phases of the illness (Post et al., 1998).

LESSONS FROM THE NEUROBIOLOGICAL MECHANISMS INVOLVED IN KINDLING PROGRESSION

Initially, repeated 1-second stimulation of the amygdala on a once-daily basis does not have much behavioral or electrophysiological effect. However, the threshold for afterdischarges decreases with repeated stimulation, and afterdischarges begin in the amygdala and spread to the hippocampus and cortex, first unilaterally and then bilaterally as seizures evolve from unilateral then bilateral. The kindling paradigm shows robustly that there is a spatiotemporal extension of the kindled memory trace as the seizures evolve and generalize.

Different Anatomical Substrates Involved

Initially, the proto-oncogene or immediate early gene c-Fos (a marker for cell activation and gene expression) and some of its downstream effects, including the induction of thyrotropin-releasing hormone, are involved in a unilateral fashion in the area around the amygdala and hippocampus on the side of the stimulation (Clark, Massenbury, Weiss, & Post, 1994). However, as the hippocampus is involved bilaterally, the seizures develop bilaterally, and then, increasingly, cortical areas are also activated. Intriguingly, when spontaneous seizures are observed, the usual afterdischarges seen during stimulated-induced amygdala-kindled seizures no longer occur in the amygdala, suggesting that the spontaneous seizure is generated elsewhere in the brain.

This spatiotemporal evolution in the neural substrates altered by the kindling process is paralleled by differences in pharmacological responsivity (see Table 19.3). The initial or development stage of kindling prior to a full-blown seizure is not blocked by many anticonvulsants, such as carbamazepine or lamotrigine, which do inhibit the midphase or expression of fully kindled seizures, while other drugs show the opposite pattern. In a double dissociation, diazepam blocks the early development and midphase seizures but not the spontaneous ones, while phenytoin

TABLE 19.3 Differential Pharmacology as a Function of the Stage of Amygdala-Kindled Seizure Evolution

Stage/Phase (Timing)	a. Development (Early)	b. Completed (Mid)	c. Spontaneous (Late)
Stimulation Duration	1 second	1 second	None—nontriggered
Afterdischarges & Anatomy	Local in amygdala and Hippocampus	Spread to cortex	Suppressed in amygdala
Behavioral Seizure	No response; then behavioral arrest; then unilateral and finally bilateral seizures	Bilateral, full-blown seizures with rearing and falling	Bilateral, full-blown seizures with rearing and falling
Pharmacological Efficacy:			
Valproate	+++	+++	
Levetiracetam	+++	+++	
Diazepam	+++	+++	0
Phenytoin	0	±	+++
Carbamazepine	0	+++	
Lamotrigine	0	+++	
MK801	+++	0	
Clonidine	+++	0	
Atropine	+++	0	

Legend: +++ = effective; ± = equivocal; 0 = not effective.

shows the opposite pattern. Phenytoin is not effective on the fully developed stimulation-induced seizures but does inhibit the late-stage spontaneous ones (Pinel, 1983). These data indicate that the pharmacology of kindled seizure prevention, as well as the biochemistry just noted, differ as functions of the early, middle, and late stages of development of kindled seizures.

Very different neural substrates are likely involved in the expression of seizures that last seconds to minutes in the rodent compared to mood episodes that last weeks to months in humans with affective disorders. Moreover, motor seizures are obviously not a routine concomitant of mood disorders. However, to the extent that there is a progression of behavioral phenomena from triggered mood episodes to those that emerge spontaneously similar to that seen in amygdala-kindled seizure episodes, there may be some parallelism in the increased spatiotemporal spread of the underlying neurobiological alterations. In both instances, there may be increasing spread throughout the limbic system, involvement of the habit memory system of the striatum, and then into widespread areas of the cerebral cortex. Similarly, as mood episodes begin to emerge spontaneously, there may be a further migration of the memory trace and neurobiological substrates from those involved in triggered mood episodes to elsewhere in the brain, as seen in the kindled seizure model.

TABLE 19.4 Does Drug Effectiveness Vary as a Function of Stage of Bipolar Illness Evolution?

Stage	I. Initial Development	II. Mid-Completed	III. Late Spontaneous
Bipolar Mood Episodes Triggers	Minor to Major Episodes of Depression (Bipolar Disorder Not Otherwise Specified) Triggered by Stressors	Recurrence of Full-Blown Depressive (or Manic) Episodes Triggered by Stressors	Ultra-Rapid and Ultradian Cycling of Mania and Depression Independent of Obvious Stressors
Pharmacological Responsiveness[1]			
Antidepressants	++	+/−	− −
Lithium	+/−	+++	+
Carbamazepine	?	+++	+
Valproate	?	+++	+
Lamotrigine	?	++	+
Antipsychotics	?	+++	+
Nimodipine	?	+	(++)
Benzodiazepines	+	+	−

[1]Preliminary and provisional categorization of the degree of drug effectiveness in each stage.

Different Pharmacology as a Function of Stage of Bipolar Illness Development?

If the neural substrates progressively evolve, one might expect that different pharmacological treatments would be effective in the initial (developmental), mid (intermediate), and late (spontaneous) phases of affective episode development and progression. A modicum of data support this proposition (Post, 2002b, 2008a), but the postulate requires further study (see Table 19.4). Nonetheless, the data offer a cautionary message that the different phases in the evolution and progression of mood episodes may require distinctly different therapeutic strategies.

For example, lithium is most effective in nonrapid cycling or midphases of illness evolution but is less effective in the late phases associated with ultra-rapid and ultradian cycling, and its ability to block the initial development of the illness is not known (Post & Leverich, 2008). Although much less well studied, nimodipine, in contrast, appears highly effective in the late, ultra-rapidly cycling phases of illness.

Interestingly, kindled seizure progression also appears to depend on BDNF alterations. If the BDNF receptor Trk B is inhibited or knocked out with molecular genetic manipulations, kindled seizure evolution does not occur (He et al., 2004). Thus, BDNF is involved in the kindled memory trace as well as in the defeat stress and cocaine sensitization memory trace in the nucleus accumbens. Not only are there decreases in BDNF with stresses in each episode of affective disorder (both depressions and manias in proportion to their severity), but there appear to be other, more active types of learning in the acquisition of repeated defeat stress–induced depressive-like behaviors. To the extent there are increasing widespread changes in gene transcription throughout the brain and increases in epigenetic alterations based on repeated environmental experiences, one can begin to view the recurrent affective disorders as progressive not only in their clinical manifestations but also in their underlying neurobiological substrates.

If sensitization to stressors, episodes, and abused substances involves epigenetic processes that convey the long-term memory traces involved, one would postulate that there would be an accumulation of epigenetic marks on the DNA and the histones around which DNA is wrapped in those with more complicated mood disorder progression. Preliminary investigations of this

possibility suggest this is in fact the case (Labonte et al., 2013; Rao, Keleshian, Klein, & Rapoport, 2012; Xin et al., 2012).

Early Treatment is More Effective than Later

The evolution and progression of the kindling paradigm also has other important implications for treatment timing. Early intervention in stopping the first few full-blown completed or midphase seizures is easier to achieve and sustain than waiting until many seizures have occurred. The number of prior mood episodes is also a risk factor for treatment nonresponse clinically (Post, 2007a; 2008).

Tolerance Can Develop to Repeated Treatment

Loss of drug effectiveness via a pharmacodynamic tolerance mechanism is readily demonstrated when some drugs are given repeated prior to kindled seizures. Tolerance develops more easily after many seizures have occurred (Post & Weiss, 2011; Weiss, Clark, Rosen, Smith, & Post, 1995). The kindled seizure model suggests many principles and manipulations that either slow or reverse tolerance to the anticonvulsant effects of drugs in kindling. These possibilities could be tested for their applicability and utility not only in epilepsy but also in the affective disorders. These manipulations could include treating earlier, with higher doses, and using combinations of drugs with different mechanisms of action that do not show cross-tolerance.

Cyclicity of Episode Recurrence May Be Driven at the Level of Gene Expression

Finally, the kindling model suggests new mechanisms for the development of cyclic emergence and suppression of seizure episodes based on changes in the ratio of pathological to adaptive alterations in episode-driven gene expression. In kindling, some neurobiological alterations are part of the primary pathological processes driving seizure progression (the bad guys), while other neurobiological alterations are seizure-induced compensatory adaptations, such as increases in endogenous anticonvulsant substances (the good guys), which include increased gene expression for inhibitory GABA and benzodiazepine receptors and anticonvulsant neuropeptides, such as thyrotropin-releasing hormone (Post, 2007a, 2008a; Post & Leverich, 2008; Weiss et al., 1995). When the ratio of pathological to adaptive alterations favors the primary pathological processes (i.e. the bad guys), seizures occur (see Figure 19.3). Conversely, when the endogenous compensatory adaptive mechanisms, (i.e., the good guys), are supplemented by the effects of exogenously administered anticonvulsant drugs, seizures are suppressed.

Such a changing and evolving ratio of pathological to adaptive alterations in gene expression may similarly be driving cyclicity in the recurrent affective disorders (Post, 2007a; 2008b). For example, increases in corticotropin-releasing hormone leading to cortisol hypersecretion may be part of the pathological processes (one of many

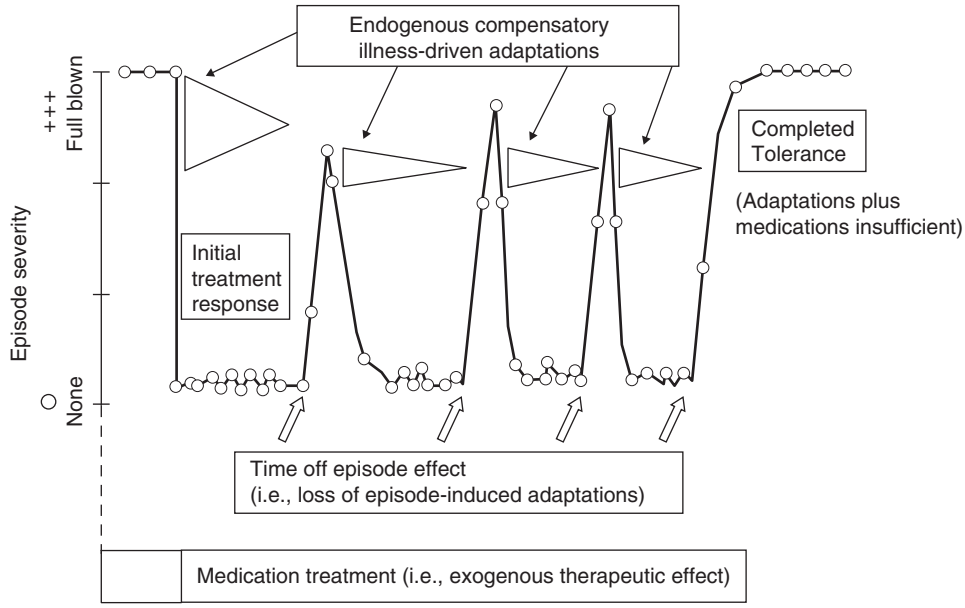

Figure 19.3 Postulate: The ratio of pathological versus adaptive changes accounts for cyclic emerge of episodes and tolerance development.

bad guys), while the increases in thyrotropin-releasing hormone during a depression may represent compensatory adaptations and attempts at increasing endogenous antidepressant mechanisms. Given this conceptual view, our job as clinicians is to prevent the sensitization of the pathological processes and treat them once an episode does emerge to add exogenous antidepressant and mood stabilizing mechanisms to the existing endogenous ones so that the ratio again favors the positive adaptations (i.e., the good guys predominate at least temporarily) and episodes are suppressed. As the multiple pathological processes sensitize and progress with the accumulation of stressors, episodes, and substance use, it may take increasingly vigorous therapeutic manipulations and multiple drug combinations to keep the ratio of pathological to adaptive factors persistently favoring the latter (good guys) to achieve effective long-term prophylaxis. The progressively diminishing ratio of adaptive to pathological changes in gene expression (based to a large extent on environmentally induced epigenetic changes) can be considered analogous to the progressive accumulation of somatic mutations mediating the loss of tumor suppressor factors and enhancing proliferative factors in the evolution of malignancies, such as colon cancer (Vogelstein et al., 2013). However, in the affective disorders, the accumulation would not be of somatic mutations in the tumor but of long-term yet potentially reversible epigenetic changes (epimutations) in the brain. Preliminary evidence supports this view of an increased number of epigenetic pockmarks in those with affective disorders complicated by stressors and early life adversity (D'Addario et al., 2012; Labonte et al., 2013; Mehta et al., 2013; Xin et al., 2012).

NEUROBIOLOGICAL CORRELATES OF ILLNESS PROGRESSION IN THE RECURRENT AFFECTIVE DISORDERS

If there are sensitization mechanisms that increase with illness progression, there should be direct or indirect evidence of them in the neurobiology of the illness. As illustrated in Table 19.5, a variety of neurobiological alterations appear to occur in proportion to surrogate markers of illness progression (i.e., the number of prior episodes or the duration of illness in unipolar and bipolar disorders) (Post, Fleming, & Kapczinski, 2012). These neurobiological abnormalities involve evidence of prefrontal cortical decrements in volume and/or function and increases in amygdala and nucleus accumbens activity. In addition, cerebellar alterations appear to occur as a function of number of prior episodes, as do a variety of neuroendocrine alterations. It remains to be determined which of these abnormalities reflect pathological processes (to be suppressed for positive clinical effects) and which may be compensatory and adaptive (to be further enhanced and supplemented for therapeutic benefit).

TABLE 19.5 Neurobiological Correlates of Number of Mood Episodes or Duration of Illness: Evidence of Illness Progression

Number of Mood Episodes	Neurobiological Abnormalities
INCREASED NUMBER OF MOOD EPISODES → via multiple epigenetic mechanisms, such as methylation of glucocorticoid receptors and the DNA promoter for pro-BDNF, and an overall 8 times greater methylation in depressed patients than in controls.	Decreased prefrontal cortex[1] structure, biochemistry, and function
	Increased amygdala reactivity and function[1]
	Endocrine dysregulation[1]
	Percentage of short telomeres
	Cortisol[1]
	Inflammation
	Decreased BDNF[1]
	Cognitive dysfunction[1]
	Early dementia

[1]Correlates of illness progression that could be further exacerbated by comorbid substance abuse.
See review in Post et al., 2013, for details; Labonte et al., 2013; Rao et al., 2012; Xin et al., 2012.

Remarkably, the percentage of short telomeres, which is a marker of aging, also decreases in bipolar II patients as a function of number of prior depressive episodes. This finding is of particular interest in relation to the estimated approximately 10 years of premature aging observed on the basis of the percentage of short telomeres in this study, which is convergent with the many years of lost life expectancy reported in patients with serious psychiatric illness, including both the unipolar and the bipolar mood disorders (J. C. Chang, Chen, Yen, Chen, & Lee, 2012; Colton & Manderscheid, 2006; Newcomer & Hennekens, 2007; Osby, Brandt, Correia, Ekbom, Sparen, 2001).

Although many of the correlational relationships illustrated in Table 19.5 may relate to number of episodes causing these abnormalities, we cannot definitively rule out that the causality is in the opposite direction and that some of these abnormalities are present in the first place and drive a more malignant course of illness. However, it would appear clinically wise to assume that the number of prior episodes and the concomitant increases in vulnerability to relapse are causally associated with some of these progressive neurobiological alterations so that greater efforts at pharmacoprophylaxis are fostered. In this fashion, one could hope to prevent the degree of cognitive dysfunction that emerges as a function of number of prior

episodes as well as the emergence of treatment resistance (Post, Fleming, & Kapczinski, 2012).

Moreover, if four prior unipolar or bipolar depressive episodes is the threshold for doubling the risk of acquiring a diagnosis of dementia in old age (Kessing & Andersen, 2004), it would appear prudent to attempt to prevent depressions after their second or third occurrence in the hope of never reaching this threshold for cognitive impairment. This conceptual viewpoint is in alignment with virtually all clinical treatment guidelines for unipolar depression, which recommend the initiation of long-term prophylaxis after two or three prior depressive episodes. As we have noted, most of the liabilities for illness progression by sensitization to episodes, stressors, and substance abuse are as great or greater in the bipolar disorders, are associated greater degrees of treatment resistance, and require even earlier efforts at long-term prevention.

In this regard, it is notable that all of the mood stabilizers (lithium, valproate, lamotrigine, and carbamazepine) and some atypical antipsychotics (such as lurasidone, olanzapine, and quetiapine) increase the neuroprotective factor BDNF. Moreover, lithium, via its ability to increase cell survival factors (BDNF and Bcl-2) and inhibit cell death factors (BAX and P 53), could have inherent neurotrophic and neuroprotective properties beyond its ability to prevent affective episode recurrence. Lithium increases hippocampal volume and volume in a number of cerebral cortical areas and may help delay the onset of dementia (Kessing, Sondergard, Forman, & Andersen, 2008; Post, Fleming, & Kapczinski, 2012). Lithium also increases telomere length, a critical correlate of good physical and psychiatric health (Martinsson et al., 2013).

A variety of other medical comorbidities appear to emerge as a function of number of prior episodes (Goldstein, Fagiolini, Houck, & Kupfer, 2009). Moreover, we have observed that the burden of medical comorbidities in patients with bipolar illness is correlated with indices of the severity of childhood adversity. The number of medical comorbidities patients have are associated with the degree of childhood adversity, as are 11 different individual medical conditions involving a wide range of somatic systems (see Table 19.6). These include allergy, asthma, migraine, chronic fatigue syndrome, menstrual-related irregularities, fibromyalgia, and arthritis. Thus, the long-term consequences of early stressful life events appear to convey a more adverse course of bipolar illness evolution and progression (Leverich et al., 2002: Post and Leverich, 2008); in addition, childhood stressors are involved in programming an increased risk for associated medical comorbidities (Post, Altshuler, et al., 2013; Shonkoff & Garner, 2012).

TABLE 19.6 Consequences of Childhood Adversity in Adulthood

I. Psychiatric	II. Medical[1]	III. Observed Changes
Retrospective findings:	Allergies	Altered central nervous system development, structure, function, and neurotrophic factors
A. Early onset	Arthritis	Inflammation
B. Anxiety disorder	Asthma	Oxidative stress
C. Substance abuse comorbidity	Chronic fatigue	Telomere shortening
D. Dysphoric mania	Chronic menstrual irregularities	Cortisol dysregulation
E. ≥ 20 episodes	Fibromyalgia	↓ BDNF in prefrontal cortex, Hippocampus
Prospective findings:	Head injury	↓ 5HT1A receptors
F. More time depressed	Hypertension	Reduced GABA transition from excitatory to inhibitory
G. More ultradian cycling	Hypotension	Corticotropin-releasing hormone transition from appetitive to Aversive
	Irritable bowel syndrome	Low oxytocin
	Migraine headache	
	Obesity	Obesity and metabolic syndrome

[1]See Post, Altshuler, et al., 2013.

Much of the loss of years of life expectancy is attributable to cardiovascular illness, and only a smaller component is due to loss of life expectancy based on suicide. Thus, the recurrent affective disorders are potentially lethal conditions, not only via suicide but also by the excess medical mortality associated with them.

MORE MALIGNANT AND PROGRESSIVE COURSE OF BIPOLAR DISORDER IN THE UNITED STATES COMPARED WITH SOME EUROPEAN COUNTRIES

Some clinicians and investigators have remarked about the possible over diagnosis of bipolar disorder in children in the United States compared with the Netherlands and Germany. However, recent epidemiological data indicate that some 2.2% of adolescents in the United States have a bipolar spectrum disorder (Merikangas et al., 2010, 2011, 2012). Moreover, the diagnosis of very early childhood onset bipolar illness may, in fact, be more common in the United States than in some other locales. In our

Bipolar Collaborative Network, we observed that 22% of the adults (average age just over 40) reported onset of illness before age 13, compared with only 2% in Europe (Post, Leverich, et al., 2010). Data from the full network cohort on childhood onset (<13) are now 31.0% from the United States compared to 5.4% from Europe (Post et al., 2014a). These data converge with the 28% of adult patients in the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) sponsored by the National Institute of Mental Health who reported this early onset of illness (Perlis et al., 2004). Between our Network and that of the STEP-BD, it appears that some two-thirds of bipolar illness in the United States begins in childhood and adolescence (prior to age 19). In contrast, only about one-third of adults with bipolar illness in the Netherlands and Germany had this early onset of their first episode in adolescence (Post, Altshuler, Frye, et al., 2014a).

This earlier age of onset of bipolar illness in the United States has now been replicated in another sample of several thousand patients both in the United States (acquired by the Pittsburgh case registry) and in multiple European countries. Bellivier and collaborators (2011) reported a much higher incidence of childhood-onset bipolar illness in the United States that was isolated to their early-onset patient distribution and not evident in the intermediate- and late-onset groups. They found, on average, mean age of onset of about 5 years earlier in the United States compared with Europe in general, while we found a 7-year earlier mean age of onset of bipolar disorder in the United States compared to Germany and the Netherlands.

These data have multiple and important clinical implications. In our Bipolar Collaborative Network, the STEP-BD Network, and many other series, those with early-onset bipolar illness fared more poorly than those with adult-onset illness (Post, Leverich, et al., 2010). In addition, in our Network, we found that the earlier age of onset of illness was inversely related to the duration of untreated illness. Independent of early onset, the longer the illness was untreated with antimanic or antidepressant agents was directly related to a poor outcome in adulthood in terms of more severity and time depressed, more episodes, and less time euthymic (Post, Leverich, et al., 2010). The duration of untreated interval was also associated with a more adverse course in the study of Suominen et al. (2007). Thus, early-onset illness may be a more pernicious form of bipolar illness, either in its own right or because of its delay in onset of adequate treatment.

These data converge with a variety of other studies in the United States that have reported substantial incidences of bipolar illness in hospitalized children and large numbers of children followed in naturalistic treatment of their bipolar disorder. In long-term follow-up series, these children with mania (usually about an average at of 11) appeared to be particularly difficult to treat, and while they improved in the majority of instances, relapse rates are extraordinarily high. Some half to two-thirds of the children in long term follow up remained symptomatic and were markedly adversely impacted by their illness (Birmaher et al., 2006; DelBello, Hanseman, Adler, Fleck, & Strakowski, 2007; Geller et al., 2010; Wozniak et al., 2011).

In an 8-year follow-up study, Geller and colleagues (2010) found that children with mania were symptomatic some two-thirds of the duration of follow-up. There was considerable continuity from the childhood-onset manias diagnosed at average age 11 to those occurring throughout adolescence. In addition, they found that a substantial 37% of youngsters during the 8-year follow-up who were managed with treatment as usual in the community were never treated with any of the treatments recommended in consensus guidelines (i.e., lithium, atypical antipsychotics, or mood stabilizers (Kowatch et al., 2005). However, the youngsters who were treated with lithium did show the best long-term course and the longest periods of remission (Geller et al., 2010). Thus, the long-term follow-up data of Geller and colleagues raise the specter that some of the very difficult course of bipolar illness in children may in part be attributable to the late, inadequate, or inappropriate treatment they often receive.

The earlier age of onset seen in these comparative and U.S. studies is also concordant with the results of high-risk studies in children by virtue of their having a parent or first-degree relative with bipolar disorder. In the series of high- risk studies from the United States (Birmaher et al., 2009, 2010; K. D. Chang, Steiner, & Ketter, 2000), more of the offspring develop bipolar disorder than in studies from the Netherlands (Wals et al., 2004), Switzerland (Vandeleur et al., 2012), or even Canada (Duffy et al., 2011), where earlier onset of anxiety disorders and depression is more common. Vandeleur et al. (2012) also found that in Switzerland, parents with bipolar disorder, compared to those with unipolar disorder or control patients, had more comorbidities and complicated illnesses. Parents with bipolar disorder from the United States also appear to have more complicated illness than those from non-U.S. countries, and this could be a factor in the higher incidence of bipolar disorder in the offspring (Birmaher et al., 2009, 2010; Post, Altshuler, Kupka, et al., 2014a). Such differences could yield a greater genetic and/environmental vulnerability to bipolar disorder, especially if many of the comorbidities convey addition risk genes for the onset of bipolar disorder.

Increased Incidence of Risk Factors for Bipolar Disorder in Patients from the United States Compared with Germany and the Netherlands

Early-onset bipolar illness has been most closely associated with two phenomena:— increases in genetic vulnerability and in the incidence of childhood adversity. Our data suggest that both of these vulnerability factors are more prevalent in the United States compared with Europe (see Figure 19.4). Bipolar patients from the United States had a significant three times higher incidence of parents with a diagnosis of bipolar disorder and, in addition, had a higher incidence of both parents having a mood disorder, either unipolar or bipolar illness (Post et al., 2014a,b). Bilineal vulnerability results in a higher incidence (some 60% or more) of the offspring having a lifetime history of a mood disorder (Gottesman, Laursen, Bertelsen, & Mortensen, 2010; Lapalme, Hodgins, & LaRoche, 1997).

In addition to this genetic/familial vulnerability, we found more psychosocial adversity in childhood as well as in the year prior to the onset of the first episode. The incidence of physical or sexual abuse was approximately double in the United States compared to that reported in Europe. Verbal abuse was also higher in the United States (58.8%) compared to Europe (30.8%). In the year prior to illness onset, there were also many more negative psychosocial stresses and lack of social support compared with those observed in Europe. In addition, when the same negative stresses were reassessed in the year prior to the last episode before Network entry, there was a further increase in the United States over the course of illness in contrast to the Europeans, where stressors remained relatively low and stable. Thus, in the United States, as the illness emerges and progresses, there appear to be not only more stresses prior to illness onset but increasing amounts of stresses and loss of social, economic, and health care support compared to lower and stable levels of these difficulties in Europe.

More Adverse Bipolar Illness Course in the United States than in Europe

Patients with bipolar disorder from the United States also had a higher incidence of anxiety and substance abuse comorbidity than the European patients. In addition, the United States had a higher prevalence of individuals with more than 20 prior episodes and more rapid cycling (four or more episodes/year) prior to Network entry. Thus, those from the United States would appear to have multiple poor prognosis factors in terms of genetic/familial and psychosocial vulnerability, the accumulation of negative stressors over the course of the illness, more episodes

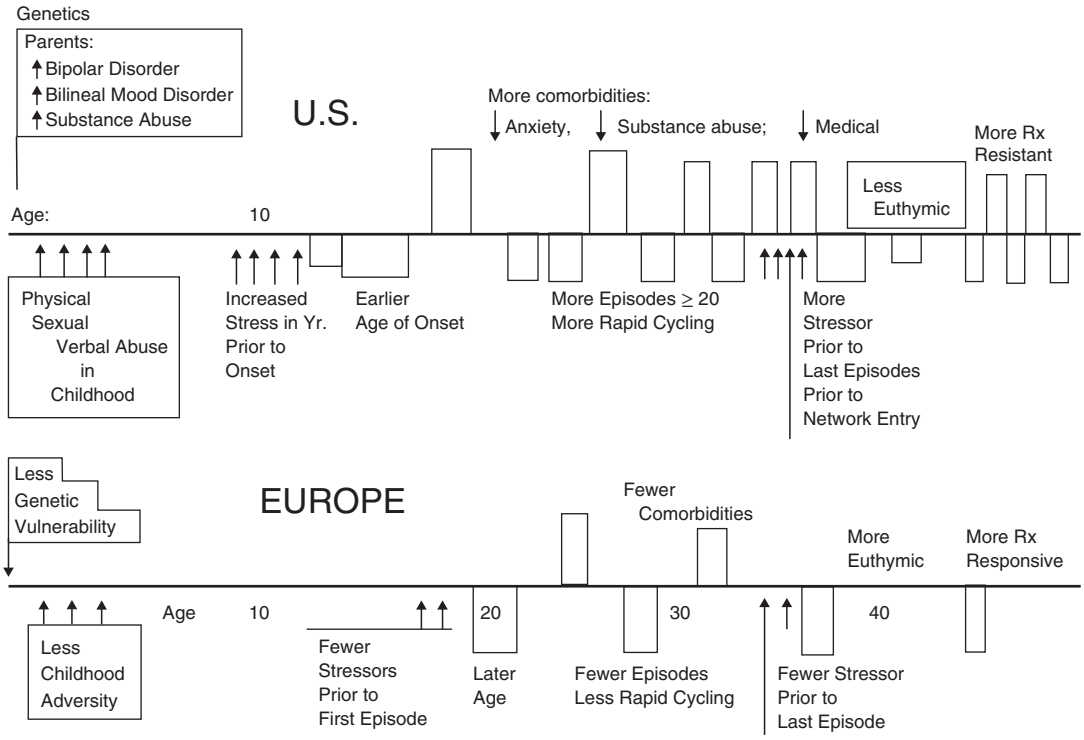

Figure 19.4 More Vulnerability Factors and Bipolar Illness Adversity in the United States Compared to Europe.

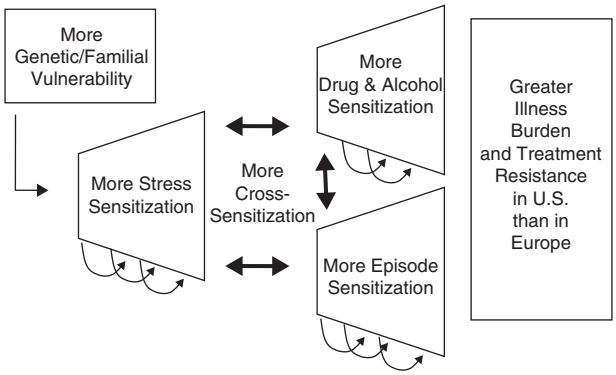

Figure 19.5 Bipolar Disorder in the United States Compared to the Netherlands and Germany.

and rapid cycling, and a higher incidence of anxiety and substance abuse comorbidity (Post et al., 2014a).

Thus, stress, mood episode, and substance abuse accumulation and sensitization would each appear to be feeding into a more difficult course of illness in the United States compared with Germany and the Netherlands. This was, in fact, documented because more patients from the United States (51.7%) failed to achieve a good long-term response to naturalistic treatment for a minimum of 6 months compared to only 31.1% of those from Germany and the Netherlands (Post, Altshuler, Frye, et al, 2010b).

These results are schematized in Figure 19.5, which illustrates the increase in psychosocial stressors, episodes, and substances of abuse in patients from the United States compared with Europe, and the likely increased degree of sensitization and cross-sensitization. Thus, while multiple factors interact in conveying the more adverse and treatment refractory course of illness in the United States compared with these two European countries, many are amenable to reduction or prevention.

PUBLIC HEALTH IMPLICATIONS

The public health implications of these findings are enormous. Since the accumulation of stressors, mood episodes, and bouts of drug abuse (and their likely sensitization effects) are each based on environmental processes, they are readily available targets for immediate attempts at treatment intervention, prevention, and remediation. However, there are a number of difficulties and impasses that make this desired set of approaches relatively unlikely to occur (Post, 2002a; Post & Kowatch, 2006; Post, Chang, & Frye, 2013) for a large portion of those with bipolar disorder—a group that makes up some 2 to 5% of the U.S. population and a much larger percent of those with recurrent unipolar depression (Merikangas et al., 2010, 2011).

What Are Some of These Complicating Factors?

First, some aspects of the diagnosis of childhood-onset bipolar illness remain controversial (although in reality there is more consensus among investigators than might be assumed). A few might argue that the illness is overdiagnosed in the community. There is certainly a subset of patients with severe mood dysregulation who do not meet full diagnostic criteria for bipolar disorder (Leibenluft, Blair, Charney, & Pine, 2003), and these are now called disruptive mood dysregulation disorder in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*. Some would argue that these individuals represent a particularly severe subgroup of those with attention-deficit/hyperactivity disorder and oppositional defiant disorder (Axelson et al., 2012; Biederman et al., 2010). However, there appears to be considerable agreement that these individuals, however they are labeled, do not have bipolar disorder, although the best treatment of these children remains uncharted.

Nonetheless, as noted, recent epidemiological data indicate that some 2% of the U.S. adolescent population does appear to have bona fide bipolar disorder (Merikangas et al., 2011). This results in an enormous number of people in the United States with a difficult-to-treat disorder that is associated with considerable disability and a marked increased risk of substance abuse. Thus, the field needs to move toward assessing the effectiveness of treatment interventions both for patients with bona fide bipolar illness and those with other nonbipolar variants.

Second, the conduct of systematic studies of the clinical effectiveness of different interventions for bipolar-like syndromes has lagged to an extraordinary degree in proportion to the need for these studies (Post, 2002b, 2009; Post & Kowatch, 2006). The lack of a large systematic treatment database is a crucial factor in youngsters not receiving timely or adequate treatment intervention. There are only several FDA-approved atypical antipsychotics for children with mania in the age range of 10 to 18, and lithium has been grandfathered into this approval for children 12 years and older. The mood stabilizers lithium, carbamazepine, valproate, and lamotrigine remain relatively unstudied in children with bipolar I disorder, and studies are virtually nonexistent in the youngest children with bipolar disorder who often have the very common form of bipolar not otherwise specified.

One way to break this impasse is to conduct relatively easier-to-complete and less expensive practical clinical trials using open, randomized designs to compare the efficacy and safety of different approaches to childhood-onset bipolar disorder (Post, 2009; Post & Kowatch, 2006; Post, Chang, Frye, 2013). Rather than these clinical

trials ending once the placebo or drug monotherapy phase is over as is the case in conventional, industry-sponsored randomized clinical trials, it would be particularly helpful to clinicians to have further crossovers and re-randomizations to other agents to ascertain what might be the next most appropriate drug and drug combinations for a given individual.

The recent clinical trial of Geller and colleagues (2012) is very much based on this paradigm and is extraordinarily clinically informative. They randomized patients to lithium, valproate, or the atypical antipsychotic risperidone and found that on almost all measures, risperidone was significantly superior to either lithium or valproate. However, it did convey a higher risk of side effects, including weight gain and prolactin increases. The study also had an add-on phase wherein the other agents could be explored in combination. When this was done, treatment regimens involving the atypical antipsychotic in combination with either lithium or valproate outperformed the combination of lithium and valproate when risperidone was not included.

The placebo-controlled clinical trials of different atypical antipsychotics in childhood-onset mania appear to produce a response rate in the 50% range compared with significantly lower rates with placebo (Geller et al., 2012). These data, along with the risperidone data just cited, suggest that the atypical antipsychotics as a class will all exert antimanic effects. This likelihood is further supported by the observations that all typical and atypical antipsychotics that have been approved for use in schizophrenia have been shown to be uniformly efficacious in adult-onset mania as well as in childhood-onset mania.

Therefore, it would appear important in the treatment of childhood-onset bipolar illness to select atypical antipsychotics on the basis of their safety profiles rather than on the basis of the number of times or the number of children in whom they have been studied. Weight gain appears to be a prominent side effect with some atypical antipsychotics, and the degree of weight gain and other indices of metabolic syndrome and extrapyramidal side effects are typically much more problematic in children and adolescents than in adults when studied on comparable drug regimens.

Given the epidemic of childhood obesity and the vulnerability of youngsters for dangerous degrees of weight gain when prescribed atypical antipsychotics, choosing the best drug within this class would appear to be paramount. This line of reasoning is reflected in recent guidelines (Kowatch et al., 2005) which recommend initiating treatment with agents that cause lesser degrees of weight gain compared with that of olanzapine or clozapine. In this regard, the weight gain associated with ziprasidone and lurasidone not only appears to be minimal in adults and children, but these agents are also associated with relatively benign metabolic side effect profiles in terms of their not increasing blood sugar, cholesterol, or triglycerides. Their comparative long-term effectiveness and tolerability versus other agents in pediatric patients deserve immediate study.

Third, all the data indicate that childhood bipolar disorder is difficult to treat and often requires combinations of medications.

The importance of combination treatment is further emphasized in the clinical trial of Findling et al. (2003) wherein they stabilized young children with mania on the combination of lithium and valproate and then randomized these individuals to monotherapy with either compound. A very high incidence of relapse was encountered during either monotherapy phase, and, importantly, there was an extremely high rate of re-responsiveness once the combination treatment was reinstituted. Many of these children were also maintained on psychomotor stimulants, indicating that a combination of three drugs often was required to optimally treat these individuals. Based on the available data with either an atypical antipsychotic or a mood stabilizer lead in (Geller et al., 2012), it would appear that combination treatment is most often required in childhood-onset bipolar disorder, and use of complex combination therapy in the community appears to be the clinical norm. Yet systematic approaches to combination and complex combination therapy in the literature are relatively sparse, with the few exceptions indicated in the text.

Delayed and inadequate treatment of bipolar illness in childhood and adolescence in the United States is creating an extraordinary personal burden of illness and disability as well as enormous social and economic costs. Adult-onset bipolar illness can be difficult to treat; shows a progressive course; and results in considerable dysfunction, disability, medical comorbidity, and premature mortality. Childhood-onset illness appears to run an even more difficult and adverse and complicated course, moving more rapidly through the different stages of illness progression (see Figure 19.6), as we have summarized. Thus, the treatment of childhood-onset bipolar illness needs to be enhanced in accord with its high prevalence in the United States and the seriousness of its clinical presentations and consequences.

There also needs to be increased clinical treatment and effectiveness research, allowing more adequate and rational choices among the drugs currently available. It is likely that this will happen only if there is a congressional mandate. I say this because virtually every investigator in

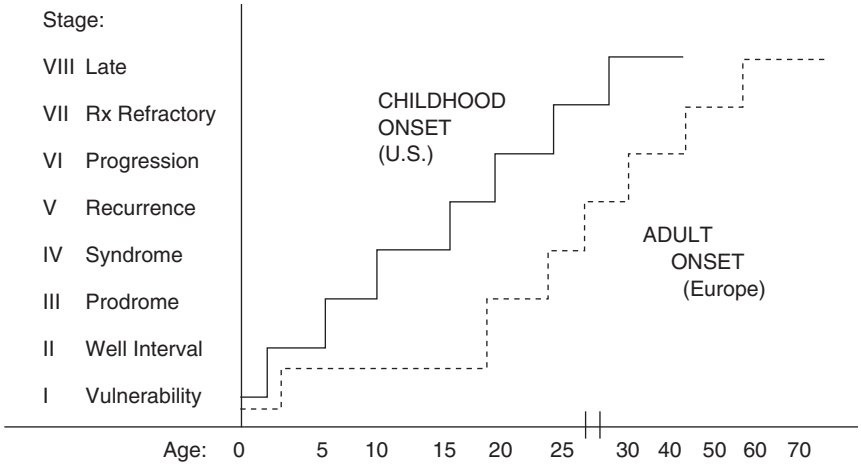

Figure 19.6 Bipolar Disorder Stage Progression in Childhood-Onset versus Adult-Onset Illness: Schematic Illustration.

childhood-onset bipolar illness of whom I am aware has urged that the field perform more treatment trials, yet these have not been forthcoming.

Fourth Funding of treatment research in bipolar disorder is inadequate. What are some alternative approaches and possibilities?

The National Institute of Mental Health is facing a budget crunch. Without monies specifically targeted for this kind of treatment research in bipolar disorder, the likelihood that rapid progress would be made under our current grant review system is virtually nil. Grants are typically reviewed on the basis of elegance of scientific question and scientific design. The treatment outcome studies required for elucidation of the best approaches to the treatment of childhood-onset bipolar illness rarely, if ever, fulfill these criteria. Nevertheless, they rank extraordinarily high on the criteria of need and public health import.

Although there has been a negative public outcry about the treatment of youngsters with multiple strong medications, exploration of milder and safer treatment options has not proceeded accordingly. Examples of this lack of appropriate study of relatively safer alternatives are plentiful. Mary Fristad presented a poster in 2010 reporting dramatic degrees of clinical improvement in open treatment of a small group of refractory manic children when they were given a complex vitamin and mineral preparation called EM Power, which is readily available on the Internet. Her request for funding of a controlled study was denied, and the field remains in the completely ambiguous posture of not knowing how safe or potentially effective this agent is. Similarly, there are multiple rationales for treatment trials with omega-3-fatty acids, since these agents have had some reported success in adults with unipolar and bipolar depression. Also, there has been 1 of 2 successful trials of primary prophylaxis of omega-3-fatty acids in those with prodromal schizophrenia.

There is considerable evidence for increases in inflammatory cytokines and other measures of inflammation such as C-reactive protein in childhood-onset bipolar disorder. Studying an agent such as omega-3-fatty acids, which has some anti-inflammatory properties, would appear highly indicated. In this regard, the antibiotic minocycline has received preliminary exploration in schizophrenia with positive results in adults with negative symptoms and improvement on some cognitive measures. This compound, with its anti-inflammatory and neuroprotective effects, deserves study in bipolar disorder. Similarly, NAC deserves extensive study in children in light of the literature discussed in this chapter about its efficacy in the treatment of unipolar and bipolar depression, anxiety disorders, and addictions in adults.

In schizophrenia, there have been multiple attempts in the past decade at achieving primary prophylaxis in those at very high risk. It is apparent that high-risk status can now also be estimated in bipolar disorder on the basis of: family loading for bipolar disorder; the occurrence of psychosocial adversity in childhood; the presence of prodromal symptoms, and other available clinical and neurobiological markers (Post, Chang, & Frye, 2013). In instances of high and ultra-high risk, the ability of agents with high degrees of safety to ward off illness onset (primary prophylaxis) or prevent its recurrence/progression (secondary prophylaxis) should be intensively explored. This is not supercreative science, which gets all the hype and the funds, but potentially mind- and person-saving practical clinical trials, which tend to get ignored or disparaged.

In addition to these ordinary but absolutely critical public health pharmacological approaches, there should be further implementation and adoption of psychosocial interventions that have proven effective in adult bipolar illness and have begun to be applied to childhood-onset illness as well. Not only has family-focused treatment been shown to help accelerate improvement in childhood-onset bipolar illness; in one high-risk study, it has been shown to prevent the development of full-blown symptomatology, suggesting potential utility of this approach in primary and secondary prevention. On the basis of his studies with David Miklowitz, Kiki Chang has indicated that he is already convinced that family-focused therapy with its psychoeducational component, family communication, and problem-solving techniques (or some other analogous type of focused intervention) should be given to all the families of children who are at the highest level of risk for the onset of bipolar disorder by virtue of a positive family history of the disorder and the presence of a depression or anxiety disorder or bipolar disorder not otherwise specified (Miklowitz et al., 2012, 2013). Cultivating resilience (Southwick & Charney, 2012) and increases in self-control (Moffitt et al., 2011) in those at high risk are also achievable possibilities.

As noted, when the high-risk studies of children of parents with bipolar illness are followed up longitudinally, they also show considerable differences between cohorts drawn from the United States and Europe. In Kiki Chang or Birmaher's cohorts, there appeared to be a moderately high incidence of bipolar disorder in young offspring of parents in the United States with bipolar disorder. In contrast, in similar high-risk offspring studies conducted outside the United States, there tends to a very low incidence of childhood-onset bipolar illness and a much higher incidence of initial presentations with anxiety disorders and then depression in children and adolescents (Duffy, et al., 2011, Post, Altshuler, Kupka, et al., 2014a).

Thus, it would appear appropriate to consider the possibility of differential interventions and timing of interventions in the exploration of potential modes of primary and secondary prophylaxis in those at high risk by virtue of a positive family history of bipolar disorder in the United States versus European cohorts. However, even in the European cohorts with more early anxiety and depression, the best treatments for these syndromes in high-risk children are not known and should be studied. These data, again, highlight the importance of early intervention studies in the United States where parental positivity for bipolar illness appears to convey a higher incidence of childhood-onset bipolar disorder.

These data on the early onset and pernicious course of illness in the United States have many other implications. Home visits (Eckenrode et al., 2001; Olds et al., 1999), group interventions (Lynch et al., 2005; Zlotnick, Miller, Pearlstein, Howard, & Sweeney, 2006), and early child care (Herba et al., 2013) have proven to have long-term positive effects on behavior in various high-risk populations (Eckenrode et al., 2001; Herba et al., 2013; Olds et al., 1999). These and related interventions should be considered in addition to family-focused treatment in children at risk for bipolar disorder (Post, Chang, & Frye, 2013).

CONCLUSIONS

The recurrent mood disorders - unipolar depression and especially bipolar disorder - are all-too-often misunderstood and assumed to be benign illnesses requiring only occasional intervention for more serious episodes. This view actually renders these illnesses much more malignant because of the failure to deal with them early and effectively with careful monitoring and long-term prophylaxis (Post, Altshuler, et al., 2010). Episodes beget more episodes with increasingly shorter well intervals. Eventually there is a failure to return to a euthymic baseline and the development of cognitive dysfunction and treatment resistance.

To a considerable extent, this typical adverse course is partially attributable to iatrogenic misadventures compounded by poor public health policy and medical access. The consequences can be disastrous for large numbers of individuals (Merikangas et al., 2011; Post & Kowatch, 2006). Inadequately controlled mood disorder is a huge risk factor for a patient both developing a substance abuse disorder and accumulating an increasing number of psychosocial stressors. Repetition of each—stressors, episodes, and bouts of substance abuse—can further exacerbate the condition and drive illness progression. Some of the increases in behavior reactivity to recurrent stressors, episodes, and substances are mediated at the level of epigenetics. Thus, epigenetic methyl, acetyl, and a host of other chemical marks accumulate on patients' DNA and histones, conveying further central nervous system dysregulation at the level of long-term changes in gene expression (D'Addario et al., 2012; Labonte et al., 2013; Mehta et al., 2013; Xin et al., 2012).

With such illness progression, not only do psychiatric symptoms worsen, but medical comorbidities accumulate, cognition deteriorates, and many years of life expectancy are lost compared to those in the general population.

Appropriate understanding of this wide range of untoward consequences of inadequately treated recurrent mood disorders should lead to the development of clinical and public health strategies that would help minimize these adversities and render the illness more tractable and benign. A call to prevent sensitization and kindling-like progression in the affective disorders does not adequately convey the importance of avoiding the accumulation of stressors, mood episodes, and substance abuse and their multiply interacting adversities. Perhaps the mantra "Prevent episodes; protect the brain" may better convey the urgency to change the paradigm toward earlier recognition, treatment, and consistent long-term prophylaxis. The benefits of early sustained expert treatment and patient psychoeducation are now amply documented in the study of Kessing, et al., (2013) where patients with a first hospitalization for mania randomized to 2 years of speciality clinic treatment resulted in many fewer relapses over the next 6 years compared to treatment as usual.

REFERENCES 1032

Crucial events occurring over the past few years indicate that the field of mental health, including developmental psychopathology, is in the throes of a professional and public relations upheaval—with profound implications for stigma and for the entire future of mental health care. First, as of this writing, the U.S. public has been exposed over the past several years to a number of extreme and well-publicized acts of gun violence, highly likely to have stemmed from untreated or inadequately recognized mental illness: Jared Loughner in Arizona; James Holmes in Colorado; Adam Lanza in Newtown, Connecticut; and Aaron Alexis in Washington, DC (see Barron, 2012; Frosch & Johnson, 2012; K. Johnson, Kovaleski, Frosch, & Lipton, 2011; Shear & Schmidt, 2013), plus more recent, tragic shootings in Fort Hood, Texas; Isla Vista, California; and Charleston, South Carolina. In the public's mind, mental disorder has become, once more, indelibly linked with images of horrific violence. This association persists even though few forms of mental illness are associated empirically with violent behavior. In fact, most forms of mental illness are linked with a major risk for becoming *victimized* by violence (e.g., Glied & Frank, 2014; Hiday, Swartz, Swanson, Borum, & Wagner, 1999).

A second critical event was the publication of the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, known as *DSM-5* (American Psychiatric Association [APA], 2013). *DSM-5*'s ever-expanding coverage of abnormal behavior has further blurred lines between normality and pathology. One salient example includes the removal of the bereavement exclusion for diagnosis of major depression (see discussion in Steka & Correll, 2013; Wakefield, Schmitz, First, & Horvitz, 2007). In brief, a person who has recently experienced a

major loss and shows relevant symptomatology can now be considered to have major depression, raising heated debate about the expanding bounds of mental disorder. Another example is the construct of autism spectrum disorders, which explicitly favors the dimensional/continuous as opposed to categorical nature of psychopathology. (McPartland, Reichow, & Volkmar, 2012, show that this conception has both expanded and contracted the domain of autism.) Regarding these examples, it is indisputable on one hand that most forms of mental disorder represent extremes of continua of impairing behavioral and emotional tendencies, belying the notion that one either has or does not have a certain mental disorder (e.g., Beauchaine & Hinshaw, 2013). On the other hand, this view has undoubtedly reinforced the view that the mental health community represents a profiteering effort—spearheaded by predatory pharmaceutical firms—intent on selling ever more medicines to an ever greater number of unduly pathologized individuals (e.g., Hinshaw & Scheffler, 2014; Hinshaw & Stier, 2008).

Moreover, recent data have documented (a) rapidly expanding diagnoses of such child-onset conditions as attention-deficit/hyperactivity disorder (ADHD; see Hinshaw & Scheffler, 2014; Visser et al., 2014) and autism spectrum disorders (Baio, 2012) and (b) a nearly 30% increase in suicide rates between 1999 and 2010 among U.S. adults (Sullivan, Annest, Luo, Simon, & Dahlberg, 2013). The first example concerns the fast-expanding rates of problem behavior, during childhood, that becomes branded as forms of mental illness. The second pattern raises the essential issue of structural/fiscal and psychological barriers to prevention and care for individuals at risk for suicidal thoughts and actions. Clearly, mental disorders—including their definitions, scientific status, treatments, and very legitimacy—are at the forefront of public health and public debate.

In many ways, progress in the mental health fields across the last half century has been stratospheric, as witnessed by the veritable explosion of research related to risk and etiologic factors and underlying mechanisms as well as evidence for validated treatments, both psychosocial and pharmacologic (see Nathan & Gorman, 2007). Distressingly, however, public attitudes have been surprisingly refractory to fundamental change with respect to mental illness. That is, despite the clear evidence for greater *knowledge* of mental health and mental illness today compared to the mid-twentieth century—revealed by a general increase in mental health literacy—public *attitudes* have not shown commensurate gains (for important data, see Pescosolido et al., 2010).

Thus, we must now confront the construct of stigma. Whereas the untreated symptoms of mental health conditions often produce considerable suffering and undermine the attainment of core developmental competencies, the contempt (both hidden and outright) toward persons with mental illness exponentially compounds these problems. It is essential to note that shunning, discrimination, and stigmatization constitute a fundamental social injustice (see Corrigan, 2005). Moreover, stigma thwarts treatment seeking and limits essential life opportunities. Indeed, current estimates are that the vast majority of children and adolescents with mental disorders in the United States never receive evaluation or treatment, and that all too few adults receive evidence-based intervention (e.g., Kazdin & Rabbitt, 2013).

This state of affairs reflects multiple factors, including (a) *ignorance* on the part of the general public that many behavioral and emotional problems reflect mental disorders; (b) *shame* on the part of individuals and families with respect to admitting that they or their children have a mental illness; and (c) *underfunding* for treatment, even if it is sought (Hinshaw, 2007). Furthermore, stigma erodes the potential for optimal educational and vocational functioning, meaningful interpersonal relationships, and social and economic autonomy (Thornicroft, 2006). Finally, stigma is an obstacle to the needed levels of research funding for fostering knowledge of the basic biological and social processes underlying mental dysfunction. It also undermines efforts to evaluate (and disseminate) treatments that can make recovery from mental illness possible (for an influential statement along these lines, see Sartorius, 1998).

As highlighted by Link and Phelan (2001, 2006; see also Bos, Pryor, Reeder, & Stutterheim, 2013 and Hatzenbuehler, Phelan, & Link, 2013), stigma occurs at the level of the general population (public stigma), within individuals and families (via stereotypes, beliefs, prejudicial attitudes, and discrimination), and at institutional levels in society (structural stigma, expressed through laws, cultural norms, and policies). Additional, salient constructs are (a) *self-stigmatization*, the process by which persons in denigrated groups internalize the negative messages they receive (Corrigan, 2004; Major & O'Brien, 2005) and (b) *courtesy stigma* (sometimes termed associated stigma), the castigation that often extends to individuals close to those in a stigmatized group, such as family members, friends, and even relevant professionals (see Goffman, 1963, for the original conception of courtesy stigma). Because mental illnesses are among the most debilitating diseases that exist worldwide in terms of creating disability and impairment (Collins et al., 2011), understanding the reasons for the

shunning, exclusion, and punishment of persons with mental illness is a research and clinical imperative. Indeed, without consideration of stigmatization, the entire effort to understand psychopathology and promote evidence-based prevention and treatment efforts will be greatly limited (Institute of Medicine, 2009).

Developmental factors are crucial to this discussion. First, many child and adolescent forms of mental illness incur impairments that persist well into adulthood, and most so-called adult forms of mental illness involve risk factors and precursors originating well before their adult years (see Hinshaw, 2013, for an overview). Thus, a life span perspective on mental illness—and its castigation—is of critical importance. Second, mental illness and maladaptive behavior are dynamic rather than static processes. Not only do symptoms and impairments fluctuate as a function of both context and development, but stigmatization encountered at a given age or phase of development is highly likely to have profound implications for future functioning (Hinshaw, 2005). Third, when parents suffer from mental illnesses, a host of processes (e.g., genetic, psychosocial, stigma-related) serve to adversely affect their children's development (Heflinger & Hinshaw, 2010; Hinshaw, 2005, 2007). Finally, the field still lacks crucial knowledge as to the developmental origins of stigma-related processes in young children and the mechanisms through which stigmatization matures (see subsequent sections). In brief, the stigma related to mental disorder is ripe for rich developmental theorizing and developmentally-oriented research efforts, both basic and applied.

In the following pages, we define stigma in greater detail and discuss key models and mechanisms, including psychological, social, and evolutionary perspectives. We then briefly consider historical themes related to stigma, particularly regarding children with mental disorders, to properly frame the salient issues of our current era. Next, we review both empirical data and broader information from general cultural practices with respect to the reach and impact of stigma. After considering developmental issues, we describe a theoretical model of stigmatization as it pertains to mental disorder. Finally, we raise key research questions that remain to be systematically elucidated by future investigators. Although overcoming stigma is a topic of clear importance, space limitations allow only brief coverage of prevention and intervention strategies related to stigma (see Corrigan, Morris, Michaels, Rafacz, & Rüsch, 2012, and Hinshaw, 2007, for reviews). To provide enduring benefits, we highlight that such strategies must be multilevel and continuous.

At the outset, we express our conclusion: Stigma is arguably *the* most fundamental issue in the entire mental health field (see Sartorius, 1998, 1999). It affects every participant in this enterprise, including basic scientists, clinicians, social theorists, and those contending with mental disorder, as well as their families and associates. Interrelated multilevel issues include research prioritization and funding, the dearth of appropriate clinical services that currently exist in most communities, and the dehumanizing attitudes that emerge from the long-standing, and pernicious, denigration of persons with mental disorder.

DEFINING STIGMA AND STIGMATIZATION

Stigma is a term originating from ancient Greece. Literally, it signifies an actual mark or brand burned or tattooed into the skin of members of castigated groups—such as slaves or traitors—thereby graphically signaling the devalued status of the carrier (Goffman, 1963). In present usage, the mark is typically symbolic and refers to the (a) social judgment placed on members of groups deemed deviant or immoral; (b) received discrimination; and (c) shame and degradation, as well as potential annihilation, likely to be experienced by those who are stigmatized.

Several key points are central to current notions of stigma. First, stigmatization exists as part of a series of interchanges within social settings, whereby a group carrying social power denigrates (and discriminates against) a group lower in power (Link & Phelan, 2001, 2006). Thus, stigmatization is inseparable from social hierarchies. Because what is considered proper and good is malleable—and subject to sociocultural input—there is reason to hope that mental illness stigma may diminish in the future. Indeed, some attributes or conditions formerly receiving high levels of stigma (e.g., left-handedness, cancer, gay/lesbian status) are now less likely to receive castigation, with some attributes/conditions revealing dramatic improvements and others to a lesser extent. Relevant processes include greater knowledge, changed cultural standards, contact with members of the formerly stigmatized groups, and the openness versus closed-off nature of particular societies with respect to acceptance of behavioral differences, disease states, or what are perceived as lifestyle choices.

Second, stigma carries particularly stressful consequences if the stigmatized condition is potentially concealable—as is the case for many if not most persons with histories of mental illness. A key reason relates to the ramifications of incessant decisions for the concealing

individual about whether to come out (Goffman, 1963; Jones et al., 1984; Karnieli-Miller et al., 2013; see also Pachankis, 2007). Unlike the overt nature of racial/ethnic characteristics, for example, the covert experience of mental disorder presents a host of choices: whether to maintain concealment or to disclose, and for the latter, to whom, when, and how. This iterative process may result in substantial anxiety for both individuals and family members, potentially straining social interactions. Thus, concealable stigmas are anything but benign.

Third, stigmatization can be viewed as a set of social processes (comparison, castigation, marking, long-term expectations) that lead to continuing denigration. One such process involves the nearly automatic social cognitions that are evoked when members of a society confront a member of an out-group (Myers, 2013). Another is the tendency for global attribution of negative traits to the individual's mark. Still another includes the potential for self-fulfilling prophecies, whereby the mere expectation of deeply dysfunctional behavior and interaction (on the part of both sides of a social encounter) may shape subsequent encounters with the individual. That is, when imperfections are automatically attributed to the flawed character of the affected person, the degraded individual's behavior may begin to conform to the initial stereotype (Jussim, Palumbo, Chatman, Madon, & Smith, 2000).

Fourth, at the level of social cognition and related behaviors, stigma shares elements with *stereotyping* (a fairly typical cognitive process of viewing groups in global terms), prejudice (an affective, negative prejudgment of members of a castigated group), and *discrimination* (the behavioral curtailing of rights of such a group; for distinctions, see Phelan, Link, & Dovidio, 2008). In terms of stereotypes, all humans use these to some extent to simplify the massive amount of social information related to daily interpersonal contact. In this sense, stigma-related processes can be considered part of normative social cognitive mechanisms. It is when stereotypes take on a negative valence (prejudice) and lead to indefensible and unjustified infringement of the rights of others (discrimination) that the major consequences of stigmatization ensue (Hinshaw, 2007).

Yet stigma transcends these three elements, as it also encompasses the strong tendency for perceivers to view *all* aspects of stigmatized individuals in terms of the fundamental flaw or deviance involved. Furthermore, as noted, there is a concurrent (although not inevitable) tendency for the stigmatized individual to internalize the aspersions that are made, a process called internalized or self-stigma (Major & O'Brien, 2005). For international perspectives on self-stigma related to mental illness, see Krajewski, Burazeri, and Brand (2013); linkages between public and self-stigma are analyzed in Evans-Lacko, Brohan, Mojtabai, and Thornicroft (2012). In sum, stigma processes are at once fascinating and complex. They are simultaneously related to principles of normative social interchange, linked to social power, and potentially iterative and pernicious.

A key underpinning of stigmatization was perceptively noted by Goffman (1963): The globalized, castigating nature of stigma often means that perceivers often come to believe that the marked person is less than human. When such an ascription is made, harsh punishment, exploitation, and even annihilation may follow (Sternberg, 2004). Later in the chapter we address the crucial issue, in terms of mental illness, as to the kinds of causal theories that may lead to perceptions of the fundamental humanity versus subhumanity of individuals with extremes of behavioral deviance (see Epley, Schroeder, & Waytz, 2013, Haslam, 2006, and Haslam & Loughnan, 2014, for essential considerations related to ascribed humanity and dehumanization).

A crucial question is whether stigma invariably portends negative self-image for members of stigmatized groups. In other words, is internalized stigma/self-stigma inevitable? Despite this classic view (see Allport, 1954), many stigmatized individuals, particularly those in racial/ethnic minorities, have relatively high self-esteem, even higher than individuals in the majority group (e.g., Crocker & Major, 1989; Major & O'Brien, 2005). Hence, lowered self-image is not an inevitable consequence. Yet in the case of mental illness—for which until relatively recently group support and solidarity have been abysmally low—internalized stigma may be a particularly likely occurrence. Crucially, internalized stigma among individuals with mental illness has been linked to nonengagement in treatment or early termination from intervention (see Sirey et al., 2001). Overall, self-stigmatization appears to be a crucial, although not inevitable, phenomenon in the developmental unfolding of stigma-related processes, with important implications for a lack of engagement in needed interventions.

Finally, is stigma universal or culturally specific? Increasing attention is being paid to the universal aspects of stigmatization, which may betray an evolutionary basis for at least some aspects of social exclusion (Kurzban & Leary, 2001). Indeed, mental illness has received consistent stigmatization across history, and across nearly all cultures, leading to intensive speculation as to the ingrained roots of fundamental social tendencies to exclude persons with

extreme behavioral deviance. If stigmatizing tendencies themselves are part and parcel of our shared humanity, the clear implications are that (a) evolutionary psychological views may be quite heuristic and (b) overcoming stigma will be a steep, uphill climb.

Yet human cultures vary dramatically in terms of acceptable behavioral and emotional styles. Moreover, traits or conditions that are stigmatized in one historical era may come to be valued in others. Take, for example, the fluctuating ideals of women's body size, in different nations and historical epochs, or the cultural variety regarding which parts of the human body are eroticized (see Farley, 2006). Moreover, racial/ethnic prejudice and stigma, which may also share automatic levels of bias, can be reduced over time via education, contact, and effort (Marsh, Mendoza-Denton, & Smith, 2010). Tolerance is demonstrably feasible and, in a just society, should be a fundamental goal. It may well be that, over time and through strong efforts linked to empathy promotion, and the fostering of equitable contact, stigmatization of mental illness can and will be reduced. Yet the belief that that such change will come about simply, swiftly, or easily is mistaken. As with nearly all other social problems related to perceptions of differences between groups (e.g., those with a different skin color, religion, disease process, or behavioral repertoire), altering entrenched attitudes and patterns of discrimination will be a long-term process.

THEORETICAL PERSPECTIVES ON STIGMA

Stigma is a vibrant topic in current research and scholarship in social-personality psychology, psychiatry, intergroup relations, evolutionary psychology, disability studies, and more. Although most research on stigma has focused on gender and racial/ethnic minority groups (Quinn & Chaudoir, 2009), evidence reveals (as noted) that mental illness is still highly stigmatized (Hinshaw, 2007; for a ranking of stigmatized attributes from 45 years ago, see Tringo, 1970). It is important to note, however, that whereas the overall construct of mental illness can and does receive strong stigma (e.g., Martinez, Piff, Mendoza-Denton, & Hinshaw, 2011), specific forms of mental disorder have unique stigma profiles. Whereas schizophrenia and substance abuse each attract substantial stigma, stigmatizing attitudes about depression are sometimes (but not always) more muted (Pescosolido et al., 2010). Thus, one should always consider specific forms of mental illness, in addition to the generic or global construct, when appraising findings and implications of stigma-related research. Indeed, given what appears by all counts to be more open attitudes toward difference among younger generations in today's world, it is particularly tempting to posit that stigmatizing attitudes and discriminatory practices have a strong chance of undergoing fundamental change in the coming years. Yet for the reasons noted already and discussed later in this chapter, the road ahead will not be smooth.

Our purpose in this section is to discuss some of the core themes from social psychological and evolutionary psychological perspectives on stigma and comment on their applicability to mental disorder. Research on stigma in recent years has been voluminous; see other sources for more comprehensive accounts (e.g., Crocker, Major, & Steele, 1998; Dovidio, Hewstone, Glick, & Esses, 2010; Gaertner & Dovidio, 2000; Heatherton, Kleck, Hebl, & Hull, 2000; Hewstone, Rubin, & Willis, 2002; Hinshaw, 2007; Link & Phelan, 2013; Thornicroft, 2006).

Social Psychological Approaches to Stigma

Half a century ago, most accounts from a psychological perspective were based on the view that prejudice and stigma stem from deep-seated, individual-difference proclivities, such as the authoritarian personality type (e.g., Adorno, Frankel-Brunswik, Levinson, & Sanford, 1950). However, evidence from taxometric studies suggests that prejudice is not categorical (Denson, Iyer, & Lickel, 2010). That is, the social world cannot be bifurcated into racists versus nonracists, given that prejudice and stigma exist on a set of continua. Current social psychological perspectives integrate notions of the ubiquity of stigmatization, the embeddedness of stigma in ordinary adaptive psychological processes, and the universality of social comparisons (e.g., see Fiske, 2011, and Pearson, Dovidio, & Gaertner, 2009). Social comparisons—that are sufficiently negative and harsh to earn the term *stigmatization*—emanate from common and pervasive social and developmental mechanisms. It is mistaken to view all aspects of stigma as pathological/morally flawed—or high stigmatizers as qualitatively distinct from other social perceivers. Thus, there is an intriguing parallel with conceptions of mental illness per se, for which dimensional views are now in ascendancy (e.g., Insel et al., 2010).

Social psychology begins with the axiom that the formation and maintenance of social groups is essential for survival (see Lewin, 1948). Accordingly, there is a fundamental tendency to identify with in-groups—those social groupings of which one is a member by birth or community—and to distinguish these fellow in-group

members from those in out-groups, those foreign social groupings, tribes, or communities posing a threat to survival (especially when resources are scarce). The deep-seated nature of in-group identification is revealed by minimal group research (Brewer, 1979; Tajfel, 1982). That is, even the apparently trivial act of flipping coin, or assigning different shirt colors, can elicit strong tendencies to align with like in-group members and castigate those in the out-group.

When an out-group member poses an actual or symbolic threat to the social perceiver, the likelihood of prejudice and stigmatization increases considerably (Stangor & Crandall, 2000). In the case of untreated, psychotic-proportion mental illness, the threat value of out-of-control, irrational symptoms may be palpable, even at the level of physical harm. Yet even in the case of forms of mental disorder that are not as overtly threatening, the very term *mental illness* connotes despair, weakness, and loss of reason, thereby posing symbolic threat. In pioneering research, Solomon, Greenberg, and Pyszcynski (1991) showed that harsh judgments against out-group members are intensified when thoughts of death or mortality are primed in perceivers (see Hayes, Schimel, Arndt, & Faucher, 2010, for a contemporary overview). This tendency may be especially strong when the out-group suffers from physical deformities or behavioral extremes, which may remind perceivers directly of the fragile and transitory nature of health and of life. The idea behind this provocative and replicated phenomenon of mortality salience incorporates existential, meaning-based perspectives into the types of situations that are likely to elicit harsh reactions against marked individuals—particularly those with the kinds of behavioral features consistent with mental illness.

Dimensions of Stigmatization

Several features of castigated traits and conditions have major implications for their propensity to be stigmatized (see the seminal and perennially relevant exposition of Jones et al., 1984). As noted, the *concealability* of a stigmatized attribute raises anxiety regarding decision-making with respect to openness versus disclosure (Goffman, 1963), clouding judgment and creating conflictual social interactions. Furthermore, the *threat* or *peril* induced by the mark has strong implications for stigmatization. Indeed, when strong and pervasive cultural stereotypes emphasize the dangerousness and violence potential of persons with mental disorders, the perception of threat—and of the likelihood for *disruptiveness* in social interchange—is magnified. Another core dimension is termed *aesthetics*: Conditions that lead to bodily disfigurements have often received great stigmatization (see section titled "Evolutionary Origins of Stigma").

The final dimensions from the taxonomy of Jones et al. (1984) are of clear relevance for mental disorder. First, the *course*, or longitudinal stability, of the mark in question is typically related to the propensity for stigmatization. Conditions viewed as long-lasting or chronic are far more likely to receive stigma than transitory states. In the case of mental disorder, a predominant view is that most forms are immutable, lifelong conditions, a perception that fuels high levels of stigmatization (see Martinez & Mendoza-Denton, 2011). The actual evidence for immutability and chronicity, however, is quite nuanced. For example, mood disorders are highly likely to be recurrent, meaning that great numbers of individuals with such conditions have protracted periods that are relatively symptom free (e.g., APA, 2013; Goodwin & Jamison, 2007). As for disorders of childhood onset, ADHD usually persists into adolescence, but adult outcomes show high variability (e.g., Hinshaw et al., 2012). The view that all types of mental illness yield immutable, chronic maladaptation is false; symptoms fluctuate, waning and waxing as a function of time, insight, and treatment engagement. Greater public knowledge of the malleability and treatability of mental disorders is an important goal, with high potential for stigma reduction. We note that the most important forms of such education are not likely to be strictly factual but instead should involve pointed personal examples that defy the pervasive stereotypes of mental disorder as permanent or incurable.

Second, a particularly crucial dimension is related to the *origin* or cause of stigmatized conditions as well as the closely linked feature of their perceived *controllability*. Attribution theory is clear in this regard: Negative behavioral traits or features that are believed to arise for reasons outside the individual's personal control should elicit sympathy and concern, whereas those that are directly controllable will engender anger and punishment (Weiner, 1985, 2006). In other words, if the deviant and threatening behavior is an individual's fault, society is highly likely to blame him or her (and in the case of children and adolescents, the parents). Weiner, Perry, and Magnusson (1988) presented clear experimental evidence in this regard: Disabling conditions viewed as out of the individual's control (i.e., physical deformities) were likely to be met with compassion, whereas those linked to personal blame (i.e., behavioral or mental problems) generated rejection and hostility (see Corrigan et al., 2000, for further extrapolation to mental disorder).

Along with the considerable advances in neuroscience and genetics of recent years, this attributional perspective presents a compelling reason for the promotion of efforts, across the past several decades, to portray mental illness in medical-model terms: as a set of conditions analogous to physical illnesses or, explicitly, as brain diseases (Insel et al., 2010; D. L. Johnson, 1989). Indeed, such views are strongly supported by many advocacy groups and even leaders in the mental health fields (for critical discussion, see Miller, 2010, who emphasized the theoretical, philosophical, and clinical implications of overfocused ascription of behaviors to brain-related mechanisms). In a nutshell, this perspective reasons that if mental illness is attributed to uncontrollable causes linked to genes and biological vulnerability, public attitudes should shift markedly toward reduced stigmatization.

We hasten to point out, however, that an unthinking rush to recast all mental disorder in reductionistic, biogenetic terms is no panacea for reducing stigma (Kvaale, Haslam, & Gottdiener, 2013; Rüsch, Todd, Bodenhausen, & Corrigan, 2010). For one thing, certain traits—most saliently, racial/ethnic characteristics—that are clearly beyond personal control have been among the most disparaged attributes throughout human history. Moreover, it may be a hard sell to convince the general public that constellations of behavior and affect result from genes and temperament, given the default cultural assumption that personal effort and volition are the sources of most behavioral displays. Yet even if a large segment of the public is convinced that strongly heritable, biologically based proclivities underlie mental disturbance, this altered attributional stance does not assure that benign attitudes will follow.

First, at its extremes, such a causal model is reductionistic, failing to account for the transactional nature of the development of nearly all forms of psychopathology (Hinshaw, 2013). Second, for reasons that should become clearer upon reading the section on evolutionary perspectives on stigma ("Evolutionary Origins of Stigma"), ascriptions to exclusively genetic etiologies and exclusively neural loci for mental illness may actually fuel a backlash, such that interpersonal responses will be harshly punitive (e.g., Mehta & Farina, 1997). Indeed, an exclusively biological/genetic perspective appears to promote the views that (a) mental disorder is immutable, unremitting, and hopeless (Martinez & Mendoza-Denton, 2011; Phelan, 2002; Phelan, Cruz-Rojas, & Reiff, 2002) and (b) mental illnesses are linked with genetic defects, rendering the individual less than fully human and categorically different from others (Haslam, 2011). The groundbreaking meta-analysis of Kvaale et al. (2013) revealed that whereas biogenetic attributions for mental illness tend to reduce perceptions of blame, they simultaneously evoke pessimism (with respect to the individual's eventual outcome) and may increase, rather than reduce, social distance. The well-intentioned push to emphasize the origins of mental illness as biological in nature may have unintended consequences, fueling rather than reducing stigmatization, especially when done in reductionistic fashion. Far more research needs to be done on the complex—and counterintuitive—relationship between control attributions and stigma related to mental illness.

Despite the undoubted psychobiological roots of mental disorder, we challenge the policy-related perspective that ascribing mental disorder to brain disease will automatically eradicate stigma. A realistic descriptive and explanatory account of mental health and illness is most accurately reflected in contextual, reciprocal, and transactional models—frameworks consistent with the developmental psychopathology perspective (Hinshaw, 2013). However, communicating this understanding to the general public may be difficult, in part because of its complexity, which renders it resistant to readily digestible sound bites.

Core Features of Stigma

There are several core features of stigma, extending from the psychological to the institutional. In the next section, we examine stigma's most central attributes.

Pervasiveness and Implicit Stigma

The most marked and castigated conditions or subgroups in a given society are likely to yield to widespread consensus from members of the culture as to their devalued status (Crocker et al., 1998). In other words, stereotypes about devalued groups are extremely pervasive. Especially given the access to print, visual, and electronic media in modern societies—but also through storytelling, literature, and folklore in many additional cultures—widespread consensus usually exists around the racial/ethnic, religious, subcultural, and behavioral subtypes that are shunned. As a result, nearly all members of a society are confronted with images of the stereotyped group: Children hear and see these portrayals at young ages, and the views of such negative characteristics are prone to become overlearned.

An upshot of such pervasiveness is that stereotypes and negative attitudes come to be automatically triggered when an out-group member is identified or recognized (Crocker et al., 1998). Furthermore, conscious efforts to

suppress the automatic stereotypes in question may backfire when the perceiver has limited or overtaxed cognitive resources, thereby fueling a paradoxical overaccessibility of the negative stereotype (see Wegner, 1997). Indeed, what are now termed *implicit* stereotypes and prejudices are those that are unconscious, automatic, and overlearned, as opposed to consciously and overtly expressed (Greenwald & Banaji, 1995; Greenwald, Poehlman, Uhlmann, & Banaji, 2009). A wealth of current research in social psychology relates to implicit stereotyping and prejudice, particularly with respect to racial/ethnic attitudes. Relevant investigations utilize reaction-time methods that capture automatic associations, made without conscious introspection or control.

In contrast to implicit processes involved in racial/ethnic stigma, the role of implicit processes in mental illness stigma is relatively understudied. What has been shown empirically thus far, however, is alarming. Among university student samples, evidence exists of strong implicit associations linking mental illness labels to negativity, helplessness/incompetence, and blameworthiness (Teachman, Wilson, & Komarovskaya, 2006, Study 1). People with mental illness may also harbor comparably negative biases themselves, suggesting internalized stigma (Teachman et al., 2006, Study 2). These latter findings (regarding implicit self-stigma) have been conceptually replicated by other investigative teams: Among people with mental illness, investigators have found, at the implicit level, decrements in self-esteem as well as effects of shame (Rüsch, Corrigan, Todd, & Bodenhausen, 2010; Rüsch, Todd, Bodenhausen, Olschewski, & Corrigan, 2010). Elucidating the causes and consequences of implicit associations in mental illness stigma—in social perceivers and the targets of stigma—warrants sustained and systematic research attention.

Ambivalence

A second core feature of stigmatizing reactions is the *ambivalence* inherent in their display (Hebl, Tickle, & Heatherton, 2000; Katz, 1981). A key argument is as follows: Social valuations of out-groups are inherently complex, balancing compassion on one hand ("people are down-and-out and have been mistreated") and harsh judgment ("but after all, they must not have displayed effort and hard work that we did") on the other. Moreover, many members of modern society hold two often-conflicting values: egalitarianism (the belief in the equal worth of all humans and the equal opportunities that should be available to all members of society) versus individualism (the belief that individual efforts are essential to personal advancement and are rewarded by social and monetary gains). Egalitarian views of members of disadvantaged out-groups should yield sympathy, identification with victims, and efforts to redress social injustices. However, individualistic views will turn this perception on its head, such that members of stigmatized groups will receive blame for insufficient efforts on their own behalf.

Thus, confrontation with an out-group member may well elicit ambivalence: the co-occurring or vacillating display of sympathy and castigation. As a result, reactions to stigmatized persons are likely to be unstable (oscillating between empathy and revulsion), extreme, and volatile across time. It may take only a small nudge—for example, witnessing one additional member of a stigmatized group—to shift an initially positive response to a hostile one, or vice versa (see Katz, 1981, for experimental evidence). This complexity makes for clear difficulties in investigating, much less reducing, stigma. Yet the presence of at least some initial compassion for stigmatized individuals provides reason for optimism.

With respect to racial/ethnic bias, as well as discrimination against women and sexual minorities, recent social changes have fostered new sets of social standards for the kinds of responses that are publicly acceptable to display. That is, current forms of racism or sexism (or even homophobia) may be far more masked than the overt, bigoted expressions that were formerly commonplace. Proponents of the concept of modern or symbolic prejudice or racism hold that such attitudes are expressed via conservative political views emphasizing individual responsibility or meritocratic beliefs, instead of direct antipathy toward an ethnic out-group. Pearson and colleagues (2009) described an important variant termed *aversive* prejudice or racism. Here, individuals consciously committed to nonstigmatizing views still hold overlearned, unconscious, negative attitudes that emanate from cultural exposure to negative stereotypes, which may leak when there is no clear set of cues to show egalitarian expression. Phenomena such as aversive racism reflect modern society's deep, even unconscious, ambivalence regarding out-groups, reflected in internally clashing attitudes and emotions.

Regarding mental health stigma, progress has been slow, meaning that it is still often permissible to explicitly stereotype and castigate persons with aberrant behavior patterns or mental illness. Yet as social mores and what are considered to be socially accepted responses change (i.e., when overt stigmatization is less and less tolerated), implicit and hidden attitudes may become the predominant means of castigating such individuals. These less-visible forms of aversive sentiments should predict greater display

of subtle exclusionary practices rather than overt bias. Given their complex interplay, both implicit and explicit attitudes and biases need to be assessed in comprehensive stigma research.

Motivations for Stigma: Cognitive Schemata, Self-Esteem Enhancement, and Institutional Supports

Why do members of in-groups stigmatize those in out-groups? As discussed by Allport (1954), in-group identification does not absolutely require out-group derogation. Nevertheless, several psychological and social tendencies often dictate that the two processes become intertwined.

Social Cognition

There is an overwhelming amount of information in our everyday social worlds. Humans have highly developed and efficient cognitive structures and processes for dealing with the deluge of social information that confronts them (see Myers, 2013, for a review). These methods include strong tendencies to categorize the social world through templates called *social schemas*. People make rapid judgments about individuals on the basis of these schemas.

Such modes of perceiving the world can quickly become stereotypes, preserving cognitive resources when perceivers are tired, pressed for time, or otherwise cognitively taxed. This kind of categorizing may lead people to see those from different social groups as all the same, exemplifying the out-group homogeneity effect (Ryan, Park, & Judd, 1996). Another cognitive tendency is to make linkages (or associations)—which become automatic—between negative attributes or events (e.g., violence, aggression) and socially determined categories, such as minority groups, including those with mental disorders (Greenwald & Nosek, 2008; Haghighat, 2001; Stroessner & Mackie, 1993). In short, some roots of prejudice and stigma do not require grossly unequal social conditions or discriminatory practices to be realized. Rather, they stem from normative aspects of social cognition. Note, however, that the presence of these tendencies does not imply that any resultant stigmatization is inevitable or immutable. Indeed, people can and often do invest the cognitive and emotional energy necessary for effortful social processing, integrating complex information to override stereotypes (see Devine, 1989).

Self-Esteem Enhancement

Evidence exists that derogation of out-group members serves to bolster not only social identity with the in-group but also one's self-esteem. In an intriguing series of studies, with troublesome implications, Fein and Spencer (1997) showed that individuals who had received information damaging to their own self-esteem made disparaging characterizations of members of stereotyped out-groups. Moreover, such negative evaluations of out-groups restored the disparagers' own self-image, at least temporarily. It is therefore tempting to posit that stigmatization can make one feel better about oneself, implying strong motivation to stigmatize.

Yet self-esteem enhancement cannot serve as the whole story regarding stigmatization. For instance, it does not explain the strong consensus that tends to develop within most cultures about who receives denigration and stigmatization. Moreover, it does not deal well with self-stigma—namely, the tendencies for out-group members to believe the stereotypes foisted on them and, at times, to display lowered self-worth in terms of the denigration they experience. Nonetheless, empirical findings that the putting down of devalued out-groups can at least temporarily bolster self-worth reveals at least some of the roots of the distressing tenacity of stigmatizing practices.

Institutional Supports

Cultures typically reveal *institutional supports* for discrimination. If segregation (or, indeed, slavery) is the law of the land, then system-justifying processes related to derogation of the disenfranchised group in question are likely. The reason is that such processes rationalize the officially sanctioned maltreatment. But other kinds of supports are part of cultural life. Dolls in the United States have also typically been white in color. During the middle of the last century, African American children were noted to prefer skin colors for drawings that were closer to the white norm than their own skin tone (Clark & Clark, 1950). Media portrayals provide another source of cultural modeling and strong institutional support for pervasive stereotypes. In this regard, the overwhelming portrayal of persons with mental disorders in the print and visual media is one of violence, unpredictability, and incompetence (Wahl, 1995, 2012). Clearly, societal and institutional factors motivate stigma.

An additional macro variable pertains to economics. In brief, it is likely that that there are harsher reactions to deviance during periods of difficult economic circumstances than during affluent times (Jones et al., 1984). In what is termed realistic group conflict theory, competition for scarce resources motivates high levels of out-group derogation (Sherif & Sherif, 1953; Stangor & Crandall, 2000). In a classic naturalistic investigation, Hovland and Sears (1940) found an inverse statistical association

between economic indicators (e.g., the price of cotton in the southern U.S.) and the number of lynchings of African Americans during corresponding periods. Lower prices (signifying economic downturns) were associated with a rise in such murders. Subsequently, Hepworth and West (1988) reanalyzed the same data with more sophisticated data-analytic techniques and concluded that, although the original findings may have exaggerated the magnitude of the relationship, the basic result held up. With respect to mental disorder, society provides sizable amounts of money and resources for individuals with serious mental illness as well as intellectual disabilities (although not to the extent of parallel expenditures regarding physical illness). During times of economic hardship, the willingness to provide such support may well wane.

A final macro variable to consider pertains to changes in the physical environment. A provocative, recent meta-analysis published in *Science* presented compelling evidence that climatic changes adversely affect intergroup conflict (Hsiang, Burke, & Miguel, 2013). A key implication is that rising temperatures related to anthropogenic sources may exacerbate tensions among a diverse array of social groups. These results are especially troubling to the extent that, across marginalized groups, people with mental illness might be considered the "lowest of the low," in the memorable phrase of L. T. Harris and Fiske (2006, p. 847). As global temperatures continue to climb, intergroup antagonism may intensify between neurotypical individuals and those with mental illness.

Evolutionary Origins of Stigma

It is increasingly evident that there could be a deeper, more fundamental way humans are universally predisposed to detect and shun fellow humans who show deviant behavior patterns. Specifically, evolutionary pressures may have hard-wired the capacity to stigmatize into the machinery of the mind (Kurzban & Leary, 2001). The near universality of the stigmatization of mental illness provides clear impetus to consider evolutionary processes as roots for such social exclusion. Furthermore, a preference for hierarchy—a feature of all primate groups, including humans—has specific neuronal underpinnings. Specifically, research implicates the left anterior insula and anterior cingulate cortices in such processes (Chiao, Mathur, Harada, & Lipke, 2009).

From an evolutionary theoretic point of view, humans have been selected over their history not only for prosocial tendencies but also for certain limitations on social interchange. Specifically, rampant sociability could foster exploitation. Framed somewhat differently, members of our species have always needed others for procreation, investment in parenting, and cooperation to achieve mutual goals. However, there are real costs to some social interactions, including (a) competition over shelter, economic resources, and mating partners; (b) the potential for aggression and violence; and (c) the contraction of parasites or contagious diseases. Underlying the evolutionary perspective is the assumption that humans require brakes on unbridled sociality because indiscriminate social contacts may compromise survival. Moreover, many other animal species display exclusionary strategies against conspecifics displaying certain forms of deviant behavioral patterns (Neuberg, Smith, & Asher, 2000).

The specific attributes most likely to engender naturally selected exclusionary mechanisms are those that presumably posed threats to early human societies. These include fellow humans who show parasitic infestation (revealing themselves through unsightly appearance or display of atypical behaviors), those who provide low social capital to or directly exploit social partners, and members of rival nationalities or cultures. Intriguingly, these three hypothesized types of social exclusion modules are isomorphic with the three kinds of stigmatized attributes originally posited by Goffman (1963): abominations of the body, character flaws, and tribal characteristics related to differences in skin color or place of origin.

Kurzban and Leary (2001) postulated that many characteristics of mental disorder can elicit the first two exclusionary tendencies. Specifically, behavioral and physical dishevelment (or even overly compulsive behavioral patterns associated with some forms of serious mental disorder) could trigger primitive fears of infestation or contagion. Birds and primates, in fact, signal parasites by excessive grooming. In addition, behavioral excesses and erratic behavior, along with poor inhibition, suggest both low social status and the potential for exploitation of others, putatively spawning the fear of being cheated. Yet the kinds of features related to tribal or nationalistic differences are not, on the face of it, linked to mental illness exclusion modules.

The specificity of implications from evolutionary models is noteworthy. First, emotional responses are postulated to differ across the three detection mechanisms. Those suspected of spreading parasites or disease will elicit disgust, violators of dyadic exchange are predicted to evoke anger (related to the violation of the social contracts), and members of tribal out-groups will tend to elicit fear and hatred (as a function of their threat to the home group or nation). Second, with respect to behavioral responses, the clear prediction is that those believed to be contagious will be shunned, those with character flaws will be punished for their social violations, and those in out-group tribes

will be economically and sexually exploited (Kurzban & Leary, 2001). In terms of mental illness—again, postulated to be linked to parasitic infection avoidance and social contract violations—the expected social responses would range from avoidance to punishment but not, presumably, the types of exploitative responses typical of national/tribal stigma.

Yet we urge further consideration. The surge of biogenetic research on the origins of mental illness yields strong evidence that many forms of mental disorder are moderately to highly heritable. Thus, as noted, there is advocacy for the explicit attribution of mental illness to reductionistic, biological medical models (such as brain disorder) by which mental disorders are assumed to be the product of defective genes or biochemistry (Insel et al., 2010; D. L. Johnson, 1989). Whereas attribution theory posits that such uncontrollable ascription should reduce blame, available experimental data suggest strongly that it can also induce punitive and distanced responses (see Mehta & Farina, 1997, and the meta-analytic review of Kvaale et al., 2013). One relevant mechanism may be that afflicted individuals come to be viewed not only as chronically diseased, and therefore beyond intervention, but also as a separate, inferior, and possibly even subhuman group (Haque & Waytz, 2012; Martinez, 2014; Martinez et al., 2011).

Indeed, when the issue at hand is irrational, potentially threatening behavior—along with a label (mental illness) that signals violence and incompetence (Ben-Zeev, Young, & Corrigan, 2010; Teachman et al., 2006)—attribution to a reductionistic, biological set of causes could fuel harsh and exploitative behavioral response. In other words, if the purveyor of threatening behavior has a genetic defect, he or she may now be branded as subhuman, even at the level of his or her very DNA (e.g., Dietrich et al., 2004; Phelan et al., 2002; Read & Harré, 2001; Rüsch et al., 2010; note that Corrigan & Watson, 2004, called for a balanced set of attributions, emphasizing biomedical and psychosocial risk factors for mental illness). Thus, one interpretation is that even though the tribal stigma module—initially theorized by Goffman (1963) and further elaborated by evolutionary psychologists (Kurzban & Leary, 2001)—does not initially appear related to mental disorders, it may be triggered by reductionistic, biogenetic accounts of mental illness, thereby fueling punitive and exclusionary tendencies.

Overall, although hard to test empirically, the evolutionary perspective represents an important effort to explain the apparent universality of many forms of stigmatization, particularly those related to mental illness. As currently proposed, it is not particularly developmental; understanding how children and adolescents come to their stigmatizing perspectives is an important research topic. Whereas the evolutionary theoretic viewpoint initially appears pessimistic—given its core tenet that human tendencies to exclude, shun, and even punish other persons with certain forms of behavioral deviance emanate from naturally selected tendencies—even advocates of evolutionary models agree that such proclivities do *not* mean that people must or should always act on these exclusionary modules (Kurzban & Leary, 2001). The presence of these potentially innate modules, however, deserves consideration when designing interventions to combat stigma, as overoptimism risks devolving into disillusionment (see Hinshaw, 2007). Indeed, regardless of the potency of evolved systems in shaping attitudes and behavior, the implication is *not* that they are correct or right in current times nor that they are inherently unmodifiable (see Mayr, 1974, for discussion of open programs). Even though stigmatization may in part be the product of evolutionary biological pressures, we need not succumb to the naturalistic fallacy—that is, the mistaken inference that an is requires deriving an ought, which in turn dictates social and moral action.

Summary

Stigma is multifaceted, complex, and overdetermined. The theoretical and empirical traditions of social-personality psychology have propelled understanding of basic stigma processes, the roots of which lie in social cognition, intergroup processes, and social hierarchies. In addition, natural selection may have shaped fundamental exclusion tendencies, some of which appear directly related to the propensity for the stigmatization of mental illness. Whereas the roots of stigma appear to lie deep within typical modes of functioning, the degrading, humiliating, and terrorizing aspects of prejudice and stigma are not predestined. Because stigma typically involves ambivalence—in which empathy and concern are intermingled with fear and hostility—promoting greater identification with, and compassion for, those with behavioral differences is an essential goal.

HISTORICAL PERSPECTIVES ON STIGMA: CHANGE AND CYCLICITY

Too often, historical accounts portray the past in sweepingly homogenous terms. For instance, the naturalistic, medical models of ancient Greece and Rome are juxtaposed with the chaos and ignorance of the Dark Ages; moralistic crusades against deviance in the middle of the seventeenth century (including witch hunting) are contrasted with the

humane treatment of the late Enlightenment or the current era. In fact, such global trends contain many distortions, as does the perspective that history moves inexorably toward increased progress. Closer to the truth are the presence of cycles of reform and retrenchment. Indeed, themes of biological versus environmental causation, personal control versus lack of control, and punitive treatment versus humane care have waxed and waned over time (Allderidge, 1979; Hinshaw, 2007). Despite the hope for linear models of progress, it is instructive to keep in mind the cyclic nature of social trends.

Still, the predominant theme across recorded history regarding the treatment of persons with mental disorder includes a strong tendency toward exclusion and punishment. Indeed, once people began to write down narratives of their cultural practices, descriptions of individuals with atypical behavior patterns soon followed. Ancient texts, such as the Bible, provide richly detailed accounts of mentally disordered behavior (Hinshaw, 2007).

Even though much unofficial history may have been characterized by attempts at home custodial care of persons with mental illness, official accounts are filled with cruelty and banishment as primary modes of response (Zilboorg, 1941). One fundamental theme is that views of and treatments for mental illness have lagged considerably behind mainstream scientific and humanistic advances. Moreover, the stigma surrounding the entire topic has greatly limited the spread of human knowledge (and scientific knowledge) on this subject (Hinshaw, 2007). During the Renaissance, for instance, the explosion of scientific and artistic advances was not matched by commensurate improvement in the understanding or care of those with mental illness. Instead, understanding of these individuals continued to be viewed with an amalgam of moralistic, superstitious, and deeply problematic biological perspectives (Zilboorg, 1941). When aberrant or threatening behavior was the subject matter, compassion did not always follow.

Adults with Mental Disorder

Across nearly all historical periods, a core perspective on disturbed behavior has involved the view that it emanates from demonic possession (see Zilboorg, 1941). Given their moralistic framework, such demonologic views have been associated with harshly punitive social responses. Yet in some instances, religious and moral perspectives have been linked to hopeful and humane care. Monasteries, for instance, were sometimes refuges during the Middle Ages, and the theory and practice of moral treatment in the early nineteenth century carried both humanitarian and religious overtones (Grob, 1994).

In terms of biological perspectives, one of the first recorded naturalistic views of mental disorder occurred in classical Athens with Hippocrates. He posited that mental illnesses originated from imbalances in one or more of the four major bodily humors. This theory was accompanied by his view that persons afflicted with such disturbances required careful diagnosis, compassion, and humane treatment that emphasized a restoration of bodily balances. Yet the lack of sophistication of the biological theorizing in such models meant that bloodletting and purging (through emetics) were primary treatments for the next two millennia. In addition, exclusively biological views have also been associated with the perception that mental illness is hopeless, chronic, and immutable, thereby fostering the belief that isolated custodial care in institutions should be the main treatment option.

History is replete with instances of cruelty and maltreatment toward persons with mental disorder. One of the predominant views of so-called insanity and lunacy in Western cultures has been that the afflicted individual had lost his or her fundamental abilities for exhibiting rational thought and reason, spurring the belief that he or she was less than fully human. Hence, many treatments involved terror and fright to spur the individual back to full mental faculties. At the level of physical sensation and pain, it was believed that such beatings, inductions of fright, or subjugation to extremes of cold in unprotected winter quarters did not affect "the mentally disordered" in the same ways as they would affect typical individuals (Zilboorg, 1941).

Institutional care, first in special wards of general hospitals and then in asylums created for the insane, spurred excursions by citizens of the nearby cities to observe (for an admission fee) the psychotic behavior of the inmates. Given the clear parallels with tours of zoos, the underlying belief was that the persons in the institutions were subhuman animals. Even some of the great liberators of those with mentally illness—Pinel in France, Tuke in England, Rush in the New World—held harshly authoritarian views of the childlike nature of persons with mental illness (Hinshaw, 2007).

A strong custom in many cultures was to force persons with mental illness outside of cities, towns, and villages to wander the countryside, begging for subsistence. Hence, shunning and exclusion were strong undercurrents of response to mental disorder (Zilboorg, 1941). As with institutional care in distant asylums, such banishment served to place mental disorder outside the everyday

awareness of most citizens, comprising another legacy of stigmatization.

The twentieth century was marked by the rise of increasingly secular—and increasingly scientific—views of mental illness, as demonstrated by the growth of the disciplines of psychology and psychiatry. Still, one important trend was the eugenics movement, which originated in the United Kingdom and rapidly spread to the United States (Black, 2003). The underlying belief in the genetic locus of intellectual disability and mental illness led to the passage of mandatory sterilization laws in a majority of states. This perspective set the stage for even more stringent measures in Nazi Germany, where hundreds of thousands of persons with mental illnesses (and intellectual disabilities) were not only sterilized but also annihilated (Kevles, 1985). Once again, reductionistic perspectives on biological loci of mental disorder have been associated with extremes of cruelty.

At the same time, psychological perspectives were emerging, most notably the psychoanalytic views of Freud and his followers. Although these perspectives (like the biological perspectives just discussed) tended to rid mental illness of demonologic overtones, for much of the century they directly implicated poor parenting as the cause of most forms of mental disturbance. In fact, conditions like autism and schizophrenia were held to result from faulty, cold, and unresponsive parenting. Such beliefs fueled decades of direct parental stigmatization regarding the mental disorders of their children (e.g., Bettelheim, 1967), representing a professionally sanctioned form of courtesy stigma.

We note the deinstitutionalization movement of the last 50 years. The advent of psychotropic medicine—plus the emergence of a community mental health model—led to the curtailing or closing of public hospital settings for children and adults with mental disorder from the 1960s through the present day (Grob, 1994). Whereas few would argue against the core tenets and intentions of this movement—including its goal of ending the dehumanizing, isolating conditions of mass institutionalization—the reality is that governments have often viewed deinstitutionalization as a means of cost saving. The absence of stable, long-term community-based services has allowed severely mentally ill individuals to exist in underfunded community residences—or in jails (or, far too often, on the streets). Tragically, these persons have become the face of mental illness in recent decades, in all likelihood fueling greater stigmatization.

Although it might seem self-evident that stigma has decreased in modern times—with its emphasis on science and reason instead of demonology—contrary views are worth considering. Indeed, Sartorius (1999) claimed that stigma has actually increased in the current era due to three key factors: (a) increased urbanization, which makes displays of deviance salient to more of the population; (b) increased educational and skill demands for technological and technocratic jobs, which renders failure in these domains due to mental disorder more noticeable; and (c) an extensive growth of a middle class in many societies, which intensifies social pressures toward behavioral standardization and conformity. Although speculative, this analysis gives reason for caution for those who assume linear reductions in stigmatization as modernization and Westernization proceed.

A key challenge for modern understanding is to appropriately blend current advances in neuroscience related to mental disorder with appreciation of social/contextual influences. These latter factors—which range from family interactions and school climate to neighborhood factors and the influence of the general culture—elicit and mold biological risk and vulnerability (Hinshaw, 2013). Even at the level of genetic risk, we must appreciate epigenetic factors and forces that shape gene expression (see Francis, 2009.) It is just as mistaken to retreat to the exclusively environmental views on causation from the middle of the twentieth century as it is to hold on to present-day biological reductionism—which at its worst can echo historical eras of humors, bloodletting, or phrenology. A balanced perspective may be difficult to turn into sound bites and 140-character Twitter feeds for public consumption, but (a) it has the advantage of scientific and clinically accuracy and (b) it may well have important implications for stigma reduction. Specifically, a transactional view may remove the personal or family blame for mental illness, emphasize biological vulnerability (but not inevitability or predetermination), and preserve the importance of personal and family responsibility for changing lifestyles, seeking treatment, and promoting strengths and resilience.

Children with Mental Illness

The plight of children—and, in particular, children with mental disturbances—across history is one that should elicit considerable shame. One sobering perspective is that relatively few children have survived childbirth, infancy, and childhood across most cultures and historical periods, limiting parental attachment to and investment in young children. Even as late as seventeenth- and eighteenth-century America and Europe, the clear majority of children did not survive until age 4 or 5 years (Donohue, Hersen, & Ammerman, 1995). Children have

also been viewed as miniature adults in many cultures, with childhood viewed as a brief period of time before youngsters were, of necessity, brought into the labor force (Aries, 1962). As a result, children's rights have been virtually nonexistent, with extremely high rates of exploitation, neglect, abandonment, and abuse (Phares, 2003). Indeed, a common practice throughout multiple cultures has been the practice of infanticide—the deliberate killing of babies and young children—when family size became too large and when providing for yet another mouth to feed was not possible. This practice was much more likely to occur when the child possessed physical or behavioral deviance. Short of the killing of deviant or disabled children, evidence is strong that such youth were stigmatized through treatment with scorn and derision (Donohue et al., 1995).

To assure economic well-being for families, youth were commonly put to full-time work by the age of 6 (e.g., in the fields) and marriages were arranged before adolescence. Children were often sold into slavery, and beatings were routinely accepted as discipline. As soon as children could provide labor in agrarian cultures, they typically did so (Donohue et al., 1995). With the advent of industry in the past several hundred years, children provided a cheap source of labor, until restrictions on such practices were recently instituted.

Only in the last several hundred years has childhood been viewed as a distinct developmental phase, and only in the last century and a half have there been movements to curtail child labor and mandate education. Furthermore, until only the past few decades, parents have had the right to physically and emotionally harm children—largely because of the views that family matters, such as discipline, are inherently private (see Helfer & Kempe, 1968). The brutalization of children has been such a part of many cultures that intergenerational patterns of maltreatment of children have been nearly endemic (Rhodes, 1999). Indeed, social institutions to treat emotional and behavioral problems are quite recent, dating only to the nineteenth century (Levine & Levine, 1992).

Whereas mental disorder has received banishment and harsh treatment throughout history, the plight of children and adolescents has been even worse, given the low status and utter lack of power afforded to youth. Parental blame for mental illness has been a mainstay of societal and even professional attitudes (see Lefley, 1992).

EMPIRICAL AND CULTURAL EVIDENCE FOR STIGMA

What do empirical research investigations reveal regarding the actual presence of stigma during our contemporary era? Moreover, what can we learn from a broader examination of cultural, linguistic, and institutional practices? We begin with attitudes of the general public, then highlight families and mental health professionals, and conclude with examination of less empirically rigorous, but nevertheless important, evidence stemming from everyday cultural practices.

Empirical Research

Researchers have gathered a wealth of empirical evidence in their efforts to understand the nature, mechanisms, and scope of mental health stigma. Below, we overview the contributions of this work.

General Public

Systematic research on mental illness stigma emerged in the 1940s and 1950s. Early investigators often utilized the methodology of presenting written case-history vignettes to probe respondents' abilities to identify whether mental illness was present and to appraise their attitudes toward mental disorder. Outcome measures typically included: (a) social distance scales (still common in contemporary research), whereby respondents appraised the degree of desired contact or distance from an individual so depicted; (b) informational and attitudinal measures; and (c) semantic differentials, for which respondents would choose between opposite pairs of adjectives, such as dirty versus clean, to describe the vignette (see, e.g., Nunnally, 1961). The overarching conclusion was the devastating nature of the stigmatization experienced by individuals with mental illness.

Indeed, once members of the public could identify a certain pattern of behavior as representing mental disorder, negative and rejecting responses were modal. The clearest explanations for such stigmatizing attitudes were the unpredictability and threat value of the behavior patterns in question (Rabkin, 1972). Stigmatizing attitudes characterized not only the general public but also family members and patients themselves. Furthermore, investigations revealed the presence of stigmatization even among mental health professionals and staff members, who had apparently internalized the general cultural messages of fear, distancing, and prejudice.

By the 1970s, however, some investigators noted that public attitudes, as revealed by questionnaire responses, had begun to shift toward a more empathic and altruistic stance toward people with mental illness (Crocetti, Spiro, & Siassi, 1971; Gove, 1982). Close examination reveals that such conclusions were premature. First, research in which direct comparisons were made between persons with mental illness and other stigmatized groups (e.g., physical

diseases, ex-convicts) consistently showed that mental disorder continued to be ranked last or nearly last in terms of social acceptance (e.g., Albrecht, Walker, & Levy, 1982; Tringo, 1970). Second, questionnaire responses may be influenced by social desirability (Link & Cullen, 1983), meaning that attitude scales may conceal or minimize the actual extent of stigmatization. Third, and crucially, research on the behavioral (as opposed to attitudinal) responses of the public to mental illness was strongly consistent in revealing tendencies toward shunning, devaluation, and discrimination. For example, the early work of Farina and colleagues (e.g., Farina, Allen, & Saul, 1968; Farina & Ring, 1965; Farina, Gliha, Boudreau, Allen, & Sherman, 1971) revealed that even a participant's *belief* that interaction partners knew of his or her mental illness negatively influenced a subsequent encounter, exemplifying a self-fulfilling prophecy effect. A classic and noteworthy example of behavioral—as opposed to attitudinal—research is the experimental work of Page (1995). Across three decades, data revealed that landlords were far more likely to deny housing opportunities to potential renters who disclosed a history of mental hospitalization, compared to those who did not present such a history.

More recent research, both attitudinal and behavioral, has confirmed that although the general public appears to have gained basic knowledge about mental illness over the past decades, attitudes and behavioral responses remain highly prejudicial and stigmatizing (e.g., Crisp, Gelder, Rix, Meltzer, & Rowlands, 2000; Hinshaw, 2007; Hinshaw & Stier, 2008; Link, Phelan, Bresnahan, Strueve, & Pescosolido, 1999; Pescosolido et al., 2010; Thompson et al., 2002; Wahl, 1999, 2012). Despite vigorous public awareness campaigns, levels of social rejection and stereotypes (e.g., perceived dangerousness) are pronounced across the diagnostic spectrum related to mental illness (Pescosolido et al., 2010; see also Pescosolido, 2011).

Which receives greater stigmatization: the behavioral displays characteristic of mental illness or the mental illness label itself? The answer is complex. When behaviors and the label are pitted against each other, the behavioral features of mental disorder receive more castigation and social distance. Yet when the label occurs alone, or in the presence of minimal behavioral disruption, stigmatization can be strong. The effects of the label are magnified greatly when respondents have pre-existing associations of mental disorder with dangerousness and violence risk (Link, Cullen, Frank, & Wozniak, 1987; see review in Hinshaw, 2007).

With respect to children, the bulk of research on stigma has focused on the effects of diagnostic labels with respect to the attitudes of social perceivers. A number of investigations reveal negative effects of labeling on stigma-related processes. For example, Farrington (1977) showed that the labeling, as delinquent, of youth displaying antisocial behavior had negative effects on eventual outcome (see Adams, Robertson, Gray-Ray, & Ray, 2003). Holguin and Hanson (2003) also demonstrated the negative consequences of the label of sexual abuse for individuals so termed. Furthermore, not only are children with behavioral and emotional disorders highly likely to receive peer rejection in response to the symptoms of their conditions (e.g., Erhardt & Hinshaw, 1994), but age-mates' perceptions of labels related to mental illness fuel denigration (M. J. Harris, Milich, Corbitt, Hoover, & Brady, 1992; Milich, McAninch, & Harris, 1992).

Labeling effects have considerable reach across the life span. Negative effects extend to infancy: Labeling videotapes of infants as cocaine exposed yielded more negative ratings of the behaviors displayed than did a no-label condition (Woods, Eyler, Conlon, Behnke, & Webie, 1998). Similarly, branding infants as depressed increases negative ratings, particularly if parents (fathers, in this case) show symptoms of depression themselves (Hart, Field, Stern, & Jones, 1997).

Other investigations, however, suggest that labeling of child behavior problems is not always pejorative and may well have positive effects. MacDonald and MacIntyre (1999) found that altering labels of intellectual disability and attention-disordered behavior did not influence participants' evaluations of the behavior patterns depicted. In addition, Klasen (2000) found that for parents of children with ADHD, the diagnosis of the child was actually salutary, as it reduced parental blame and increased the likelihood of obtaining treatment. Indeed, appropriate diagnosis and responsive treatment can be liberating, particularly if they facilitate the opening of opportunities for future independence and life satisfaction (Hinshaw, 2007).

Unfortunately, a substantial proportion of adults has stigmatizing attitudes toward treatment for children. This fact is critical, as the actions of adults may determine whether their children receive treatment that could alter their developmental trajectories. Distressingly, results from a nationally representative sample found that most respondents agree that physicians overmedicate children, that medicine has long-term negative developmental consequences, and that medicine turns children into zombies (Pescosolido, Perry, Martin, McLeod, & Jensen, 2007). Such findings do not bode well for increased treatment utilization.

Finally, research employing implicit measurement tools (using reaction time and bypassing self-report) has shed

important light on unconscious expressions of public stigma. Research applying these methods to mental illness stigma shows how attitudes in this domain may be automatic, unconscious, and reflexive. As noted, Teachman and her research team (2006) found evidence for implicit associations of mental illness labels with negativity and helplessness. Attitudes and beliefs that people with mental illness are vile and inept may thus reside below the threshold of conscious awareness and control. How such attitudes shape behavior and social interaction—along with potential moderators of this association—requires additional inquiry. In addition, explaining implicit internalized stigma, which may manifest as low self-esteem and/or increased shame (e.g., Rüsch et al., 2010), is an important area of future investigation.

People with Mental illness

Distressingly, persons with mental illness are highly likely to have internalized many of the negative stereotypes and prejudicial attitudes related to mental disorder that are part of the general culture. They frequently report being the victims of overt or covert discrimination as well as general prejudicial cultural practices (Brohan et al., 2010; Read & Baker, 1996; Wahl, 1999). The reported ubiquity of public stigma for those contending with mental illness is especially troubling. A survey of 1229 mental health services users in recovery from psychotic disorders from 14 European countries revealed that 69.4% experienced moderate or high levels of perceived discrimination (Brohan et al., 2010).

Furthermore, stigma and social rejection predict subsequent life adjustment problems for individuals with mental illness, over and above initial symptom levels (e.g., Hatzenbuehler et al., 2013; Wright, Gronfein, & Owens, 2000). Importantly, stigmatization predicts premature termination from therapy (Sirey et al., 2001). Among people with mental illness, two predominant mechanisms for coping with stigma are secrecy and withdrawal—behaviors that are likely to sustain, rather than diminish, stigmatization (Corrigan & Wassel, 2008; Wahl, 1999). We contend that timing is all-important with respect to disclosure of a history of mental illness, yet an automatic reversion to silence often perpetuates the core problem.

Largely unexplored (and unexplained) are the variety of coping styles and strategies deployed by persons with mental illness in response to the stigmatization they receive (Corrigan & Watson, 2002). Indeed, almost entirely unknown are the processes by which some persons internalize prejudice and stigma, others apparently ignore such castigation, and still others view it as a call to social action. Developmental factors are bound to be essential to such coping strategies, constituting a major area for future research. Why, for example, do some join consumer-oriented support groups or engage in advocacy (see Corrigan & Wassel, 2008), whereas others elect not to participate in such activism? Can changing social mores, and an enhanced sense of political mobilization, propel larger numbers of individuals to come out, demand justice, and work toward systemic change?

Families and Relatives

Two decades ago, research on family experiences of mental illness surged (e.g., Lefley, 1989, 1992; Tessler & Gamache, 2000; Wahl & Harman, 1989), although systematic research on this topic had begun during the 1950s (see Clausen & Yarrow, 1955). Early investigations documented stages of recognition of symptoms—analogous to those in reaction to the development of physical illnesses—with initial anxiety and denial giving way to adoption of a sick role and eventual rehabilitation.

As reviewed by Kreisman and Joy (1974), the early years of work in the field focused on (a) a variety of negative responses to relatives with mental disturbance, including fear and dislike; and (b) a host of reactions in such relatives themselves, such as sensitivity to criticism by others, a perception of marginality (with few resources available to help their plight), and self-disregard. Concealment was noted to be a predominant coping response. The enduring ramifications of having a relative with mental illness are considerable, encompassing Goffman's (1963) notion of courtesy stigma, in which social devaluation spreads to persons associated with a stigmatized group (see Struening et al., 2001). To take one example, family members of individuals with diagnoses of bipolar disorder continue to receive considerable stigmatization (Perlick et al., 2007). Qualitative research shows that family members too often experience rejection, avoidance, and blame (Karnieli-Miller et al., 2013). Moreover, a vignette experiment suggests that the siblings of people with mental illness are susceptible to social rejection because of genetic attributions (Phelan, 2005).

Mental Health Professionals

One might assume that those who work directly with persons with mental disorders would be immune to stigmatizing attitudes and practices. However, data reveal that the picture is actually quite complex (Schulze, 2007; Wahl & Aroesty-Cohen, 2010). Evidence began to be accumulated by pioneers in stigma research half a century ago (Nunnally, 1961). In investigations utilizing attitude

scales completed by staff of psychiatric facilities during the 1950s and 1960s, mental health personnel were found to be somewhat more accepting of mental disorder than members of the general community. However, additional attitudes, such as authoritarianism or benevolence—the latter signifying a belief in the childlike qualities of mental patients—were also prevalent and, when present, frequently associated with worse patient outcomes (Cohen & Streuning, 1962; see also review in Rabkin, 1972). Even as funding and models of care shifted to community-based rather than institutional settings, a continuing pattern of stereotypic beliefs and stigmatizing attitudes was found (see Keane, 1990, 1991; Scott & Philip, 1985). Fryer and Cohen (1988) found that staff of a Veterans Administration facility ascribed a host of negative traits—including apathy, hostility, immaturity, selfishness, and aloofness—to persons branded as psychiatric patients (as opposed to general medical patients). Mukherjee and colleagues (2002) provided evidence that, in London, half of surveyed medical students and physicians had beliefs in the dangerousness and unpredictability of individuals with schizophrenia and drug/alcohol problems. The general pattern appears to be one of continuing stigmatization from professionals and trainees.

Whereas a great number of those in the mental health field are genuinely committed to improving their clients' clinical status and fostering autonomy, training models (in psychology, psychiatry, and allied helping disciplines) often convey an attitude of superiority that promotes an us versus them mindset (Hinshaw & Cicchetti, 2000). In addition, the mental health professions have low status (in comparison with other medical subdisciplines), once again providing evidence for courtesy stigmatization. Medical professionals have often voiced disparaging attitudes toward clientele with mental illness (for historical information, see Nunnally, 1961; see also Wahl, 1999, with particular concern on the part of clientele that professionals have low expectations for improvement and change). Admittedly, working with patients who have serious mental illness can be stressful, especially when professionals receive relatively low pay and low status. Yet denigrating attitudes on the part of professionals will certainly undermine therapeutic outcomes. Indeed, there is an abundance of staff burnout, use of inappropriate humor, and scapegoating of particularly difficult clients and diagnostic categories (Wahl, 1999). Research into the current millennium continues to emphasize mental health professionals' propensity for stigmatization (Sadow & Ryder, 2008; Servais & Saunders, 2007). Indeed, Servais and Saunders (2007) found that a large percentage of clinical psychologists felt disidentified with their more severely disturbed clientele.

Overall, mental health professionals may inadvertently foster stigmatization through attitudes of superiority, paternalism, and separation from persons with mental illness. Stigmatization may also result from theoretical modes that fundamentally blame parents and family members for mental disorders of children and adolescents. Positive attitudes on the part of many clinicians certainly exist (Wahl & Aroesty-Cohen, 2010), but this is not uniformly the case.

In Hinshaw (2008), a number of mental health professionals, ranging from scientists and clinicians to trainees, disclosed their own personal and family histories of mental illness. These disclosures were an explicit attempt to break down barriers of silence and shame. Such efforts—along with different models of training that emphasize disclosure and honesty—may help to alter professional attitudes to the benefit of clients. It is difficult to discern who gains from postures of pseudo-strength, overconfidence in one's expertise, and denying the personal (and familial) roots of many professionals' interest in the very field in which they work. We advocate for closer self-examination of professionals' own attitudes, beliefs, and practices.

Summary

This section overviews research on stigmatization related to mental disorder. Although the general public is more knowledgeable about mental illness than a half-century ago, fundamentally negative attitudes abound. Moreover, research indicates that persons with mental illness are likely to be recipients of discrimination. Family shame and stigma regarding mental disorder are key issues. Especially pernicious is the notion that mental disorders result primarily or exclusively from poor parenting, a residue emanating from historical professional practices and scientific beliefs. In addition, when parents have mental disorders, the risk of transmission to their children is compounded by the presence of stigmatization and silence. Finally, many mental health professionals themselves are prone to display stigmatizing, patronizing, and sometimes hopeless attitudes toward the very persons they are entrusted to serve.

As a whole, has stigmatization toward persons with mental disorders increased or decreased in recent years? Although improvements in knowledge are apparent and although some reductions with respect to overtly expressed attitudes may be occurring (particularly in younger people), fundamental social attitudes have not sufficiently

improved in recent years (Pescosolido et al., 2010). One implication is that endorsement of a biologically-based, brain disease model to brand mental illness is not a panacea for stigma. In addition, insufficient research has examined the practical, behavioral consequences of perceivers' implicit, unconscious biases, a high priority for future research.

Beyond empirical evidence, less formal indicators of stigmatization are striking. We therefore include broader types of evidence for stigma, including indicators in the general culture and language of everyday life, depictions in the public media, and discrimination with respect to such areas as housing, employment, and fundamental social rights.

Broader Cultural Evidence for Stigma

The task of searching for general indicators of stigma in relation to mental illness is more difficult than one might expect. A key reason is that widely held attitudes and stances in a given culture are often so pervasive and grounded in everyday life that they are hard to detect (Goldhagen, 1996). In other words, the stigmatization of mental illness may be so deeply embedded in our culture's words, images, and practices as to escape easy capture. A fine-grained, more ethnographic approach may be required. Such an analysis may reveal that many cultural epithets, practices, and institutional structures are, in fact, stigmatizing toward—and discriminatory against—those coping with mental illness as well as members of their social networks.

Everyday Language

Many words in common use convey stereotyping and stigmatization about mental illness. During the course of an argument, if one makes a statement that disrupts the logic of the discussion, a common response from interaction partners may be "Are you insane?" Unpopular ideas are commonly dismissed as crazy or nuts; outlandish plans are described as madness. If someone does something deemed stupid, he or she is commonly called an idiot, imbecile, or moron—the formal terms used a century ago to designate gradations of intellectual disability. A panoply of disparaging terms emanate from depictions of mental disorder: Ideas are deranged, persons who behave outside the norms are lunatics, and strange or violent behavior is branded as psycho. A gift shop next to a contemporary art gallery in Los Angeles is even called WACKO, a naming choice that would be unthinkable for a racial/ethnic epithet. The frequency of use of terms like these betrays a preoccupation with the rationality and conformity of social partners.

Other linguistic practices are even more graphic. The institutions that are entrusted with the treatment and rehabilitation of people with mental disorders are termed loony bins or nut houses. This kind of language reveals fear as well as fascination—fear that the affliction could befall the perceiver and fascination with the illicit (and perhaps dangerous or bizarre) behavior patterns underlying the terms and labels. Children come to use such terms at early ages, signaling the pervasiveness of the cultural disparagement of persons with mental disorders. Indeed, the pejorative labels linked to mental disorders or developmental delays (cuckoo, crazy, retard) are among the initial terms used on the playground to denigrate socially rejected peers.

Media Depictions

Perhaps the most telling evidence in modern culture related to the stereotyping and stigmatization of mental disturbance is found through examination of media portrayals of those with mental illness (see Wahl, 1995, 2012). Although there are some signs that portrayals in public media are beginning to be less disparaging than has been the case for many decades, the pervasiveness of distorted media images is a major issue for anyone concerned with stigma. Negative depictions are frequent—of clients/patients as homicidal maniacs and narcissistic parasites, as well as mental health professionals as inept (see discussion in Schulze, 2007). Nunnally (1961) presented disheartening accounts of media practices from the 1950s, concluding that images from visual media were grossly negative, unflattering, stereotyped, and sensationalistic. Commercials, soap operas, prime-time dramas, advertisements, and newspaper/magazine accounts continue to portray persons coping with mental disorders as deranged, violent, and unpredictable (Coverdale, Nairn, & Claasen, 2002; Diefenbach, 1997; Wahl, 2012). Tellingly, children's cartoons are highly likely to depict mental illness in characters, and such portrayals are typically stereotyped and pejorative (Wilson, Nairn, Coverdale, & Panapa, 2000).

Even when portrayals do not include stereotyped depictions of violence and utter irrationality, they still often depict incompetence, unemployment, and grossly disturbed affect (Hinshaw, 2007). Despite an upturn in human interest coverage in recent years, still relatively absent are the perspectives and life stories of people with mental illness and their family members. What empirical evidence exists for change in media portrayals in recent

years? Surprisingly, and depressingly, the answer is not much. O'Hara, Ahmad, and Hinshaw (2015) examined U.S. and British newspaper headlines and stories related to mental health across a 25-year period from the 1980s through the past decade. The overall finding—from reliable, blinded coding of these accounts—was that little, if any, substantive change in tone and content had occurred. Although one can point to clear examples of greater humanization in coverage in some key instances—and a greater media-related awareness of mental disorder overall—the overall picture is not one of sustained progress. Indeed, whereas instances of sensational violence saturate the media landscape (see the introduction to this chapter), few stories of recovery and resilience are highlighted (Jamison, 2006).

Discriminatory Policies

A host of discriminatory policies linked to mental disorder are still in place. Several levels of discrimination can be differentiated: (a) *direct discrimination*, where, for example, housing or employment is denied based on knowledge of an applicant's mental disorder; (b) *structural discrimination*, entailing the curtailing of rights of those with mental illnesses because of long-standing policies and the formation of related societal barriers; and (c) *discrimination via self-stigmatization*, a subtle but pernicious form of limitation through which an individual's internalized stigma prevents his or her pursuit of important life opportunities (Angermeyer & Schulze, 2001).

Employment discrimination against those with mental disorder is a major concern. This is an important issue because gainful work can foster economic independence as well as benefit economies. Although the Americans with Disabilities Act (ADA) officially eliminated discrimination in public and work settings with its passage 25 years ago, persons with histories of mental illness still face substantial obstacles. Those contending with mental health issues know that disclosure of their pasts can be extremely problematic. Such disclosure may preclude their being considered for various jobs (or promotions within existing jobs) and can lead to diminution of status—or even precipitate job loss (Wahl, 1999, 2012). Distressingly, even though work-related accommodations linked to mental illness are often far less costly than those related to physical disability (e.g., a flexible work schedule versus the major rebuilding of an accessible workplace), only a tiny fraction of ADA-linked requests are for the purposes of accommodating mental illness. The reason is the underlying shame and discrimination involved (see review in Hinshaw, 2007).

Too few individuals make use of the legally mandated remedies that might mitigate problems. Moreover, persons with histories of mental illness face legal barriers with respect to obtaining or renewing a driver's license, maintaining child custody, or serving on a jury or running for office in a number of states (Corrigan, Markowitz, & Watson, 2004; see also Wahl, 1999, 2012). All such indicators of discrimination constitute prima facie evidence of persisting stigmatization.

Summary

A host of evidence from the general culture reveals pervasive and pernicious effects of stigmatization on the lives of persons with mental disorders and their family members. Coupled with the empirical research cited earlier, this evidence argues that stigma related to mental illness remains a central issue for the research and clinical fields as well as for the broader society. We admit to feeling puzzled by the current ambiguity in this field. On one hand, there appears to be considerably more openness and tolerance than in previous eras, given the greater number of memoirs and films depicting mental disorder in realistic fashion (e.g., *A Beautiful Mind* from 2001 and *Silver Linings Playbook* from 2012). Similarly hopeful is the reemergence of a national dialogue on mental health—spurred largely by recognition of huge mental health problems among war veterans (see Hoge et al., 2004) and horrific, widely reported acts of violence. On the other hand, however, fundamental change is proving elusive, given the flat nature of public attitude change (e.g., Pescosolido et al., 2010), the stereotype that mental illness is one and the same as acts of random violence, and the still-prevalent discrimination that exists across multiple layers of society.

We next consider the specific ways in which prejudice, discrimination, and stigmatization may manifest from childhood through adolescence and beyond. We underscore how considering core developmental principles and processes can benefit subsequent investigations of stigma.

DEVELOPMENTAL THEMES

Much current social psychological and evolutionary research on stigma is adevelopmental. Most investigations focus largely on adult manifestations of stigma processes without sufficient attention to (a) mechanisms related to stigmatization across the life span or (b) core principles from developmental psychopathology that could

enhance understanding of the causes and consequences of stigma. In this section, we discuss these essential points (for elaboration, see Hinshaw, 2006, 2007; and Hinshaw & Cicchetti, 2000).

Stigma Across the Life Span

Mental health stigma affects people across the life span. Below, we trace the trajectory of mental health stigma from infancy to old age.

Infancy and Toddlerhood

Although stigma pertaining to disorders of infancy and toddlerhood might not appear to be a major concern, given the young age of the children in question, stigma processes can have harmful implications when there is the possibility of mental illness in a very young child. Indeed, if the topic is expanded to include the entire family, the potential for diagnosis of mental dysfunction in a child of this age almost always incorporates implicit (if not explicit) blaming of parents. Such ascription—which has historically included the assumption of poor bonding/attachment as a function of parental unresponsiveness—can understandably spur parental reluctance to seek appropriate evaluation or treatment for the child. Of course, in some cases insecure or disorganized attachments may well be part of the diagnostic picture, and maltreatment of infants and young children remains a major clinical and public health issue (Kim-Cohen et al., 2006; Widom, Czaja, Bentley, & Johnson, 2012). Yet the automatic assumption that a young child's behavioral, emotional, and/or learning problems invariably emanate from insensitive parenting is a stigmatizing historical relic with major potential consequences for child and family mental health.

In the case of autism spectrum disorders, the causal attribution is increasingly made to genetic vulnerability given substantial evidence for the heritability of this class of conditions. This ascription may convey substantial stigma as well, as our previous discussion has illustrated. The absence of direct blaming of parents for having caused their child's serious emotional and behavioral disturbance (linked to such dated concepts as emotional refrigeration) may well propel appropriate referral and early intervention. Yet the potential for a family taint related to genetic transmission is a concern. This point is worth emphasis because of the need for accurate screening, diagnosis, and treatment of the earliest manifestations of childhood mental illness—such as autism spectrum disorders, early-onset depression, and ADHD. Ultimately, the stigma attached to having a young child with mental illness, regardless of the causal origin, often undermines early assessment and detection.

Preschool and School-Age Children

During the preschool and school-age years, parallel issues are salient, including ignorance of the possibility of mental illness, shame at admitting its presence, a lack of treatment options, as well as a historical lack of reimbursement in terms of insurance coverage. The confluence of these forces impedes needed intervention (for a conceptual framework related to child mental disorders, see Mukolo, Heflinger, & Wallston, 2010). Indeed, as noted previously, rates of treatment seeking for children with mental illness are abysmally low in the United States and are undoubtedly even lower elsewhere. The critical importance of academic achievement during childhood exacerbates this problem. In fact, the presence of a mental illness may disrupt the child's ability to focus on school curricula to attain mastery of educational material (see Hinshaw, 1992, for information on the complex associations among ADHD, aggressive behavior, and underachievement). If initial learning does not occur, this may set in motion a recursive cycle of school failure (see Cohen, Garcia, Apfel, & Master, 2006, on the importance of such feedback processes).

Under the Individuals with Disabilities Educational Act (IDEA), federal law guarantees the right to a school-based assessment and (if special needs are documented) appropriate accommodations under the concept of the least restrictive alternative (i.e., that the child is placed in settings that are as close as possible to mainstreamed classrooms). However, neither assessments nor accommodations can be implemented if stigmatization makes families reluctant to even acknowledge a child's emotional and behavioral difficulties. Also, at a structural level, IDEA's provisions involve only partial federal funding. In other words, it is an underfunded mandate, meaning that considerable debate and wrangling may well occur over a given family's contention that special educational services be implemented. Stigma may therefore derail development by limiting important life opportunities during years that are crucial for gaining academic, social, and emotional skills.

Therapeutic efforts with children nearly always require collateral work with parents, even if systemic intervention with the family is not primary intervention. Such work requires careful attention to stigma processes. Most saliently, related to our earlier discussion, clinicians must become familiar with current scientific literature that has largely debunked prior conceptions of psychogenic—and, in particular, child discipline–related—causation of most

childhood mental illness (e.g., Beauchaine & Hinshaw, 2013). At the same time, it is important that clinicians steer away from the other extreme of reductionistic, biogenetic causal factors as the sole determinants of child mental health issues. Psychoeducation about the complex array of biological predispositions *and* life stresses that converge to produce psychopathology might minimize blame, recrimination, and self-doubt among parents and family members, while at the same time motivating the seeking of needed intervention. Research underscores the reciprocal and transactional nature of child and family influence in child behavior disorders (Johnston, Mash, Miller, & Ninowski, 2012). Even for conditions with substantial heritability, psychosocial influences matter greatly in terms of outcome (see Nigg, 2013; Tully, Arseneault, Caspi, Moffitt, & Morgan, 2004).

For instance, related to ADHD, a condition with strong psychobiological underpinnings (Hinshaw & Scheffler, 2014; Nigg, 2013), socialization processes are predictive of impairments and comorbidities, and—if optimized—the potential for improvements over time (Hinshaw et al., 2000; see also Cicchetti & Hinshaw, 2002, for detailed accounts of how clinical and prevention trials can yield conceptually rich information on processes and mechanisms of psychopathology). The message for stigma reduction is clear: Whereas parents do not *cause* ADHD (or most other mental illnesses) in terms of direct effects of parenting styles per se, their socialization practices and ability to secure treatments are essential for affecting *outcome and course*. In the clinical enterprise, it is essential to remove blame, but not responsibility.

Adolescence

Adolescence is a time period during which identity is expected to consolidate and in which autonomy is gradually gained (see Dahl, 2004). Mental illnesses with onset (or continued presence) during adolescence may be particularly harmful for psychological and behavioral functioning. Mental disorders may impair identity consolidation, independent functioning, and a sense of fitting in or belonging with peers (Hinshaw, 2007). Indeed, adolescence is a time during which many symptoms are likely to emerge and during which female manifestations of psychopathology are particularly salient (Hinshaw, 2009). Experiences of acute symptoms during this developmental period may shape self-perceptions and the potential for independent functioning for years to come. With the addition of stigmatization—that is, when the adolescent and his/her family are ashamed to admit the presence of a mental illness or are banished to exclusionary treatment options—the opportunity for maintenance of intact self-esteem and a sense of personal agency is further diminished.

Furthermore, if the illness is severe and hospitalization is required, the dehumanizing settings, punitive procedures, and major restrictions on autonomy that ensue may exert profoundly deleterious effects on an individual's self-image (Hinshaw, 2002). Indeed, essential for destigmatization is that mental health staff and therapists show respect for the integrity and agency of their clientele and that treatment venues not confer derogation. Improvements in personnel selection, staff training, and pay scales may all be related to this essential effort, over and above enhanced attitudes toward mental disorder across society.

Adulthood

During adulthood, many persons with mental illness conceal information about their illness as a means of coping (see Link, 1987). Motivations for this strategy include shame as well as fear of losing employment or housing. However, such concealing may exacerbate the loneliness, isolation, and lack of social support that are frequent accompaniments of many forms of mental illness. To be clear, we are not advocating that individuals with a history of mental illness indiscriminately disclose their personal narratives. Indeed, given the pervasiveness of stigma, such a strategy could well result in backlash. We also recognize that there are individual differences in the degree to which people feel comfortable disclosing personal information. However, because of the potentially devastating consequences of a life filled with self-silencing and shame, opportunities for disclosure and support should be given greater consideration and pursued judiciously. Timing, along with adequate social supports, is crucial.

When adults with mental illness are also parents, the impact of stigma can be particularly harmful for the family. Specifically, when parents are not willing or able to disclose to their offspring that many of the erratic behaviors in the home are the products of mental illness, the children are highly likely to internalize blame. This often occurs because children do not understand the absences, unpredictable behavior, and deprivations they may well have experienced. To the extent that youngsters begin to comprehend that such experiences transcend their own personal control, they can be released from potentially disabling self-blame, guilt, and shame. Parental mental illness is clearly a risk factor for disordered functioning in children. A much-needed step is finding ways of encouraging productive discussion among family members. Such family

intervention requires honesty, frank disclosure, and a willingness to receive input from multiple sources of support (Beardslee, 2002).

Another core issue is the pervasive social attitude that mental illness permeates or encompasses all aspects of a person's being. Under the penumbra of such a view, the individual's identity may well become equated with the disorder. In other words, because having a mental illness is associated with the person's entire self-concept, the individual may begin to view himself or herself as a schizophrenic, a manic depressive, or an obsessive-compulsive (see Haque & Waytz, 2012). This practice may be perpetuated by professionals, who may come to perceive the individual as inextricably linked to—and defined by—his or her disorder. The underlying humanity of the person in question can be distorted by the diagnostic label, which connotes weakness, deviance, permanence, and a sense of fundamental flaw (see Martinez et al., 2011). Individuals with mental illnesses may well lose their basic sense of personhood when the diagnostic label is applied to who they are, rather than linked to a condition with which they must contend and manage (APA, 2013; Hinshaw & Cicchetti, 2000).

Finally, we note in passing that elderly persons with mental illness must struggle with the dual stigma of being old (and often disenfranchised financially as well as isolated from their families) and having a mental illness (see Hinshaw, 2007, for elaboration). Differential diagnostic issues related to cognitive decline versus mental illness (or their overlap) are paramount for many older adults with depressive features as well as memory loss. Yet efforts surrounding diagnostic clarity are often curtailed by the stigma that pertains to decrements in psychological functioning for elderly persons as well as by the potential for negative attitudes of staff and professionals.

Summary

Across the life span, stigma has important implications for a variety of life domains. These include the attainment of competencies; the development of a sense of self; the ability to gain independence and a sense of personal agency; the potential to receive social support and acceptance; and the struggle for families to acquire, and maintain, services for their children with mental illness. The pain and impairments that emanate from mental illness are often quite severe; when stigma and discrimination are superimposed on such symptoms, chances for life success become substantially diminished (Hinshaw, 2007). Only a life span perspective will yield a rich understanding of the pervasive consequences of stigma across multiple aspects of individual and family functioning. We call for developmentally oriented investigators to take up this topic more readily than has been the case heretofore.

Developmental Psychopathology Issues Related to Stigma

The enterprise of developmental psychopathology—the field that explicitly links normal and atypical development and that comprises the overarching topic of this entire series (see also Beauchaine & Hinshaw, 2013; Cicchetti & Cohen, 2006; Rutter & Sroufe, 2000)—embraces several core principles. We note some of the most salient and relevant themes and attempt to integrate them with the many considerations already raised regarding mental health stigma (for elaboration, see Hinshaw, 2013).

Continuities between the Typical and Atypical within Developmental Psychopathology

A core tenet of developmental psychopathology is that atypical, pathological behavior patterns represent aberrations in pathways that otherwise lead to normative development. Mental illness is not a fixed and static entity but rather the outcome of developmental processes, which are themselves characterized by flux (Cicchetti, 1993; Hinshaw & Cicchetti, 2000). Indeed, they represent fluid states that typically alternate with periods of more normative functioning and are best understood as disruptions in developmental processes that typically yield adaptation. Thus, persons with mental illness are not fundamentally different in type from other humans: They lie on the same continuum, even though they may have genetic propensities for emotional and behavioral disturbances that render them more susceptible to the influence of stressful or traumatic environments (spanning prenatal, familial, and sociocultural contexts).

Although it is possible that certain mental illnesses are best understood as taxa—that is, as discrete categorical entities different from the norm—evidence for this contention is quite slim (Beauchaine & Hinshaw, 2013). Indeed, most mental illnesses appear to be far more continuous in nature, representing extremes of distributions of underlying behavioral, cognitive, and emotional processes. (In actuality, categories of mental disturbance can be simultaneously continuous and categorical, depending on which criteria are used to examine their features, paralleling the way that light can be represented as both waves and photons; see Pickles & Angold, 2003, for lucid discussion). The upshot is that it is mistaken to view people with mental illness as qualitatively distinct, essentialistically demarcated, flawed, and inferior (see

Haslam & Ernst, 2002)—views that are bound to perpetuate beliefs in fundamental difference and thereby enhance stigma.

Ecological Models

Developmental psychopathology emphasizes the linkages between individuals and their environments and construes pathology and coping as residing at the interface of persons and settings (Bronfenbrenner, 1977). Thus, psychopathology does not lie exclusively within the individual or within the environment but rather within the fit (or misfit) between them. Stated somewhat differently, psychopathology constitutes an imbalance or disequilibrium between personal resources and environmental supports.

Intriguingly, stigma is a relational process too, as it comprises a mark of degradation conferred by society, related to membership in a group believed to be evil, flawed, or contagious. For children and adolescents, stigma processes occur in families, schools, and communities, with the concept of fit particularly relevant for conditions like ADHD, in which adaptation to classroom settings and pressure to perform academically is paramount (Hinshaw & Scheffler, 2014). Adults, as well, are judged by societal standards of appropriate deportment (e.g., in the work setting) in relation to decisions regarding mental illness. Although the impairments related to serious mental illness are undoubted, it is also important to understand that changing environmental standards may render certain behavioral tendencies more (or less) adaptive. Deviancies and flaws in one cultural context may well be adaptive in others. Fostering tolerance and acceptance of difference in behavior patterns (so long as they are not threatening to others) will require adapting contexts and environments—school, home, and workplace—to individuals to maximize the potential for productive behavior. At the same time, it is crucial to influence the biological substrates, underlying cognitive patterns, emotion-regulatory strategies, and other important features of the individual himself or herself. This is especially the case when intense personal pain and suffering are present, the ability to master key life transitions becomes disrupted, and fundamentally altering all life contexts is impractical or impossible.

Reciprocal Determinism, Transaction, and Multilevel Analysis

In developmental psychopathology models, mental illness results from interactive linkages between multiple levels of analysis. These include individual-level constructs (such as genotypes or temperament), relational variables (including attachment and parenting styles), and wider systemic influences (school or neighborhood settings and the general culture). We emphasize that these processes shape both typical and atypical development. Such multilevel, reciprocal influences unfold over time, reflecting the construct of *transaction* (Sameroff & McKenzie, 2003). The upshot of such transactional perspectives for stigma is that preconditions for psychopathology are at least potentially modifiable by environmental circumstances.

Along these lines, there is continuing interest in gene–environment interplay, including the process known as gene-by-environment interaction, in which both genotypes and crucial environmental circumstances synergize to yield risk for psychopathology. Although spurring considerable research across the past decade (see Dodge & Rutter, 2011), meta-analyses have challenged the robustness of this phenomenon (see Risch et al., 2009; but see also Karg, Burmeister, Shedden, & Sen, 2011). When operative, such gene-by-environment interactions reveal that psychopathology is not the fixed product of either biology or the environment alone but, rather, the interaction between the two. There are important implications for stigma, given that stigmatization is likely to intensify when people seek monocausal explanations. Stigmatization of families often occurs when parenting is viewed as *the* primary cause of mental illness; similarly, derogation and punishment of the individual are strong possibilities when deviant genetic makeup (or weak personal will) is believed to be *the* sole determinant of mental illness (e.g., Mehta & Farina, 1997). Understanding the inherently transactional nature of mental illness may help reduce blame for either parenting styles or flawed individual constitutions as the exclusive locus of mental disturbance.

Transactional models are not intuitively obvious, and communicating them may be difficult in a culture of quick Facebook posts and Twitter feeds. Yet promoting the notions of vulnerability, life stress, interaction, and transaction may help to reduce the stigmatization that is associated with extremes of exclusively environmental or exclusively biological perspectives. Such promotion may help to shape lay views of psychopathology as reflecting combinations of internal preconditions and external stressors that work in concert across time (Hinshaw, 2007).

Along the same line, media outlets might be able to help promote dual attributions (Hinshaw & Stier, 2008) for the treatment of mental illness. Rather than the perspective that causation and intervention involve either biological (e.g., genes/medicine) or psychosocial (e.g., life circumstances/psychotherapy), mental illness should be seen (as is quite often the case) as responsive to both. Such a dual

attributional perspective would imply that—beyond solely altering brain chemistry—efforts to seek treatment, family supports, and personal agency are also crucial ingredients to recovery. By invoking the psychosocial along with the biological, dual attributions may begin to alleviate the disempowerment and hopelessness that a diagnosis of mental illness may unwittingly trigger (Martinez & Mendoza-Denton, 2011).

Equifinality and Multifinality

Developmental psychopathology recognizes that there may be multiple causal pathways that lead to the same mental health–related outcome, signaling *equifinality*. For example, major depression may emanate from heritable risk, repeated experiences of stress, maltreatment, and/or overwhelming loss events (or, of course, combinations of some or all of the above). Alternatively, ADHD-related symptomatology, which is extremely heritable, may also result from low birthweight, exposure to prenatal alcohol, environmental lead (or even pesticides), or the experience of severe early deprivation, such as experienced in horrific Eastern European orphanages (for reviews, see Nigg, 2006, 2013). The presence of equifinality should caution us from reifying the nature of categorical diagnoses as representing single, essentialist, immutable psychiatric end states (Cicchetti & Rogosch, 1996).

Moreover, the same risk factor or vulnerability, relatively early in development, may well lead to a wide range of eventual outcomes, a process known as *multifinality*. Thus, an inhibited temperament in infancy and toddlerhood, although probabilistically linked to social isolation later in life, does not automatically do so, given the process of child-parent fit as well as key socialization experiences. Maltreatment is clearly a risk factor for a range of negative outcomes, but these are not inevitable, as they depend on the child's experience of protective factors (see Hinshaw, 2013, for elaboration). Multifinality reveals the complexity of causal pathways to mental health–related outcomes, revealing the importance of ongoing context. Moreover, multifinality also cautions against viewing risk-pathology linkages as invariant and inevitable. Recognition of both equifinality and multifinality should play a greater role in stigma-reduction research and intervention efforts, given that they signal the multitude of malleable influences that impinge on the individual regarding mental disorder and the potential for recovery.

Resilience

The pain and impairment related to mental disorder are beyond dispute, but it is also true that many people's mental illness symptoms wax and wane over time. Most people with mental illness experience periods in which relatively normal functioning is prevalent, and many such individuals can make unexpectedly good life adjustments. As noted, protective factors may intercede and eventually outweigh risk factors in producing healthy outcomes. In other words, *resilience* is a real possibility. Defined as the attainment of positive outcomes in the presence of risk for maladjustment (Luthar, Cicchetti, & Becker, 2000; Masten, 2001; Rutten et al., 2013), resilience provides a needed antidote to views of mental illness based solely on pathology and pessimism.

Resilience involves both individual characteristics (humor, intelligence, persistence, certain temperamental traits) and familial and community supports (presence of mentors or extrafamilial supports in childhood, healthy partners in adulthood). Stigmatizing attitudes may change when the general public comes to understand that mental illness does not inevitably or invariably result in despair and degradation. Indeed, views of mental illness that underscore its malleability—rather than immutability—should facilitate stigma reduction (see Jones et al., 1984; Martinez & Mendoza-Denton, 2011).

It would be a mistake, however, to apply overly optimistic approaches to depictions of mental illness. Indeed, many reform efforts have been derailed due to unrealistic, excessively positive views of the amenability of serious mental illness to community treatments or the latest round of reforms (see Grob, 1994). The promotion of realistic—rather than simplistic or sensationalistic—portrayals of mental illness is urgently needed at the level of public (and now social) media. Stigma reduction will have begun in earnest when we acknowledge that individuals with serious forms of mental illness can attend school and learn as children, can be sensitive and loving parents as adults, and can maintain their integrity despite, in many cases, tremendous challenges. The more human, realistic, and appropriately hopeful portrayals become, the greater the likelihood of stigma reduction.

Summary

The principles of developmental psychopathology—such as reciprocal determinism, transaction, equifinality, multifinality, and resilience—are important to consider when understanding the stigma of mental illness. Historically, however, mental health stigma researchers have tended to work in isolation from these principles. Future research and future stigma reduction intervention efforts may be strengthened by leveraging core developmental psychopathology concepts.

TOWARD AN INTEGRATIVE MODEL OF THE SOCIAL STIGMA OF MENTAL ILLNESS

We now attempt to synthesize the various concepts we have reviewed about the stigma surrounding mental illness. This model integrates principles from social-personality, evolutionary, and developmental psychology as well as sociology and developmental psychopathology, with particular emphasis on what is sometimes termed threat theory (Stangor & Crandall, 2000; see also Blascovich, Mendes, Hunter, & Lickel, 2000). Note that any accurate portrayal of stigma must acknowledge and address its overdetermined nature: Stigma processes operate at the levels of individuals, families, communities, and broader social and political contexts. Attempting to find which level of analysis is primary is futile because all such levels interact and transact. In spite of these myriad factors, we aim for clarity, economy, and coherence in our model. We highlight again that all too little is known about stigma's emergence across development, constituting a key research question for the future.

First, florid symptoms of the most severe forms of mental illness are threatening to social perceivers. Some of this threat may not require much in the way of cognitive mediation on the part of perceivers—for instance, psychotic behavior, with its irrational and unpredictable nature, may evoke felt threat to physical integrity that is automatically triggered. It may also signal to the perceiver a sense of the fragility of control over his or her own mental life, yielding an intense personal threat. Some of the symptoms may also, at a basic level, convey a sense of potential disease contagion or parasitic infestation (see Kurzban & Leary, 2001). Severely psychotic symptoms may also disrupt the perceiver's foundational belief in a stable, predictable world and engender fears of mortality.

Despite real variations across history and across cultures regarding response to such symptoms, these patterns of behavior tend to evoke powerful, negatively valenced emotion in social perceivers. Specifically, such displays predict anger (over the violations of social contracts and reciprocation) and revulsion/disgust (over the fear of contamination related to grossly disordered behavior and disheveled appearance). L. T. Harris and Fiske (2006) placed attributes of out-group members within a two-by-two array of warmth and competence (see also Rosenberg, Nelson, & Vivekananthan, 1968, and Fiske, 2013). Intriguingly (and depressingly), those individuals low on both dimensions (i.e., those believed to possess little warmth and poor competencies, such as homeless individuals, those with addictions, and presumably many with severe mental illness) activate perceivers' brain regions linked to disgust. Moreover, neural *de*activation of the medial prefrontal cortex (the brain region involved in social cognition) is implicated in perceptions of dehumanization—a process all too often inherent in the societal responses to the subject matter under consideration (i.e., serious mental illness).

Such responses are expectable from an evolutionary perspective when considering the development of automatic exclusion modules linked to fear of contagion, fear of being exploited, and tribal revulsion (Fishbein, 2002; Kurzban & Leary, 2001). In addition, the very label of mental illness has taken on a variety of meanings (as have many other poorly understood diseases throughout history; see Sontag, 1978), including depravity, weakness, filth, and loss of control (see Luhrmann, 2008). Again, these associations may well operate at implicit levels, below the threshold of conscious awareness (Greenwald et al., 2009; L. T. Harris & Fiske, 2006). In short, mental illness categories—even those that are not as intrinsically threatening as psychotic-level variants—carry semantically associated and sometimes automatically triggered baggage. Finally, when persons with mental illness are specifically seen as threats to the survival of a group's or nation's viability and/or as subhuman, extremely harsh responses (e.g., sterilization and even genocide) may follow. Recall the eugenics movements in the United Kingdom and United States early in the last century, as well as Hitler's direct linkage of persons with mental illness and developmental disorders as threats to the Aryan race.

Stangor and Crandall (2000) posited three stages to perceivers' reactions to threat: (a) an initial phase of real or symbolic threat; (b) the subsequent deployment of cognitive distortions (and stereotypes) to exaggerate differences from the out-group, serving as a fertile breeding ground for prejudice; and (c) the amplification of such distorted perceptions through societal communication (e.g., mass media). This latter process invokes system justification (specifically, blaming the victim) to promote the belief that the cause is not social inequity but rather weakness or deviance on the part of the stigmatized individual. In the second and third stages, we highlight once again that the target individual in question, in terms of ascribed humanity, is construed as "less than human" (Haslam, 2006; Haslam & Loughnan, 2014). This pernicious ascription may arise, as we noted earlier, because of perceivers' great fear of losing their own rationality, reason, and sense of control. In such cases, the harshest, most extreme, and even lethal responses may come to feel justified.

As noted, one of the hopes of recent decades has been that stigmatization will markedly decrease when mental

illness is finally seen from a naturalistic, medical-model perspective rather than as a volitional, morally censured, and depraved set of behaviors. Yet we have repeatedly highlighted that exclusive focus on (or overaccentuation of) biogenetic explanations of mental illness may actually increase punitive social responses (Dietrich et al., 2004; Martinez & Mendoza-Denton, 2011; Mehta & Farina, 1997; Read & Harré, 2001; for the definitive meta-analysis to date, see Kvaale et al., 2013). Factors other than attributions are clearly at play in this regard. Indeed, the threat value of disturbed behavior is twofold. First, the routinely media-promoted association of mental illness with violence means that the public seldom becomes exposed to the great numbers of people with mental health conditions who sustain strong recoveries (e.g., see Jamison, 1995). Thus, by default, people may construe mental illness as immutable, if not untreatable (Martinez & Mendoza-Denton, 2011). Second, general cultural norms assume personal responsibility for behavior and emotion, predisposing perceivers to shun and stigmatize those with mental illness, regardless of attributions to biological loci (Haslam, 2000, 2003).

What of the effects of stigmatization on its targets—that is, those who experience mental illness? In other words, how can we account for self-stigma or internalized stigma (see Corrigan & Watson, 2002)? Crucially, unlike ethnic characteristics or physical disabilities, a history of experiencing mental illness usually exemplifies a concealable mark (unless the individual is floridly symptomatic in the present moment). As discussed, such concealability leads to the perpetual dilemma of whether to reveal or mask such a history to social partners. Considerable anxiety, related to the potential for rejection and devaluation, is likely to accompany concealable attributes (see Quinn & Chaudoir, 2009). Furthermore, attempts to suppress symptoms (and relevant history, which may come to constitute a core aspect of personal identity) require great mental exertion. These attempts are likely to be peppered with intrusive thoughts about the concealed attribute in question and consequently deplete the individual's attentional/cognitive resources and mental bandwidth, further undermining social interactions and the fulfillment of life goals (see Mani, Mullainathan, Shafir, & Zhao, 2013; Mullainathan & Shafir, 2013; Smart & Wegner, 2000).

Thus, stigmatization of mental illness yields intense consequences for those who must cope with its effects on a day-to-day basis. Incessant, problematic coping attempts may engender a sense of low self-worth, hopelessness, and even despair in the target of stigma. Far greater understanding is needed of effective (and sustainable) coping strategies utilized by persons with mental illness in contending with prejudice and stigma, particularly in children and adolescents whose mental illness may be in its beginning stages. The responses of family members are crucial in the latter instance.

In closing, we note two key points. First, stigma exists only when social, institutional, and political power enforces the views of the dominant over those of the stigmatized group (Link & Phelan, 2001; Hatzenbuehler et al., 2013). In other words, individual differences alone, or social cognitions alone, do not fully explain stigma; only when the attributes in question are officially devalued are prejudice and stigmatization likely to occur. Thus, full consideration of stigma must integrate psychology with the investigation of structural aspects of social and institutional power, as well as the predominant culture's views of what are acceptable behavioral displays (see also Corrigan, 2004).

Our second point is that despite the fact that the lion's share of research in mental illness stigma relies on survey methods, important aspects of stigma are reflexive and automatic in nature. Theory and research must incorporate these implicit processes, in addition to deliberative, explicit processes (Systems 1 and 2, respectively, in Kahneman's framework, 2003). However, as we have indicated throughout this chapter, the automaticity of many forms of stereotyping and stigmatization does not mean that stigma is immutable or irreversible. Indeed, automatic schemas themselves may be highly malleable (see Foroni & Mayr, 2005, for a compelling empirical demonstration). Despite the pervasiveness and perniciousness of the stigmatization of mental illness, as well as its automatic activation in some instances, the situation can improve at both individual and structural levels. It will undoubtedly take sustained, well-organized, and multilevel intervention efforts to effect much-needed change (see Hinshaw, 2007).

KEY RESEARCH DIRECTIONS

Despite the great volume of research on stigma and stigma processes in recent decades, the vast majority of such work has focused on racial/ethnic or gender prejudice (Quinn & Chaudoir, 2009). A host of key questions remain to be addressed regarding the applicability of such models to the stigmatization of mental illness. We highlight several of the most salient of these in the current section.

Measurement and Appraisal of Stigma

The measurement and appraisal of stigma is a huge research area, dealing with such issues as basic definitions

of stigma (and the related constructs of stereotyping, prejudice, and discrimination) in relation to mental illness, attitude-behavior distinctions, and the explicit versus implicit nature of stigmatizing attitudes (for a review, see Link, Yang, Phelan, & Collins, 2004). Below, we discuss significant issues in this domain.

Defining Stereotyping, Prejudice, Discrimination, and Stigmatization in Relation to Mental Illness

Too often, investigators do not make clear distinctions among these core terms and processes. For example, much of the research reportedly dealing with the stigmatization of mental illness utilizes surveys of cognitions or attitudes as the chief (or only) measurement tool. Other investigators infer the presence of stigma from a single behavioral indicator. Although no one investigation can incorporate all potential measures of stigmatization, inclusion of a just few items signifying negative attitudes on a questionnaire is insufficient. State-of-the-art research on public stigma should include, when possible, at least some of the classic, theoretically informed (yet too often ignored) dimensions elucidated by Jones and colleagues from 1984 (concealability, course/chronicity, disruptiveness, aesthetics, peril/danger, and origin) in terms of defining stigmatized attributes. Future research should also consider examination of the impact of devaluation on the target of stigma himself or herself—self-stigma—over and above the documentation of negative attitudes and behaviors on the part of perceivers. Examining *reciprocal* processes of influence, both attitudinal and behavioral, is a priority. Investigators also need to elucidate the temporal unfolding of the cyclic (and bidirectional) nature of stigmatization. Unconscious or implicit measures are a welcome complement to the usual explicit attitude measures. Finally, structural processes and variables are a necessary adjunct to individual/psychological measures, and appraisal of courtesy (or associated) stigma is particularly relevant for family-level investigations. In brief, when stigma is characterized solely in terms of isolated negative attitudes (or a single behavioral indicator), important components of this crucial construct are bound to be overlooked. The task for the next generation of investigators should be to ensure that the elucidation of stigmatization is as multifaceted and comprehensive as the phenomenon itself.

Linking Attitudes and Behaviors in Relation to Stigmatization

Attitudes and beliefs on the part of perceivers do not translate automatically or directly into behavioral responses (see, e.g., the classic work of Azjen & Fishbein, 1980). In other words, negative attitudes may not always yield behavioral rejection and supposedly positive attitudes may sometimes be followed by harsh behavioral responses. Several points are salient with respect to this key issue.

First, attitude measures may be subject to social desirability as a key determinant of responses. That is, research participants may express kind or benevolent attitudes toward those with mental illness in terms of questionnaire responses, but those same attitudes may not be shown in terms of their behavioral responses. Investigators would do well to consider strongly the types of response biases, particularly social desirability, that may contaminate overt attitude surveys. However, this tide may be turning with the use of online samples in which participants may be more willing to reveal their authentic attitudes, perhaps because of anonymity (see Lowery, Unzueta, Knowles, & Goff, 2006).

Second, measures of attitudes of the general public need to utilize the types of large and representative samples evident in many early studies (see review of Rabkin, 1972). Convenience samples of undergraduates are far less than ideal in terms of representing the age, educational, and social class levels of the population. The external validity, or generalizability, of both attitude and behavioral research is dependent on the collection of data from diverse, representative samples.

Third, a major problem in reviewing research on public conceptions of mental illness is that attitude measures across different investigations and across time are quite difficult to compare. Indeed, on what basis can one assert with confidence that public attitudes have either improved or worsened across a given time period? Investigations in which respondents compare individuals with mental illness to other forms of disability or out-group status can be far more informative. In fact, studies forcing such explicit contrasts have shown that mental illness is typically the least (or nearly the least) preferred and most rejected among all social categories under consideration (e.g., Albrecht et al., 1982; Tringo, 1970). Thus, forced comparisons may be a valuable complementary research strategy, as they afford appraisal of the castigation of mental illness vis-à-vis other groups at a given assessment point. This strategy could serve as an ongoing metric for assessing mental illness stigma changes over time.

Fourth, we highlighted earlier that behavioral research reveals high levels of rejection and discrimination against persons with mental illness (e.g., Page, 1995). A basic disconnect, however, still exists between investigations of social cognitions (and attitudes) and those focused on appraising behavioral indicators. For example, it is difficult

to come up with many examples of studies in which respondents in behavioral, interactional research—that is, those in which participants interact directly with a person labeled as mentally disordered—have also been asked to provide responses on general belief and attitudinal measures toward mental illness. Admittedly, one risks undermining the experimental manipulation if attitude or social distance measures related to mental illness are administered to respondents immediately before they interact with persons suspected of having mental illness. Future research might employ two time-lagged occasions for measurement: one for attitude assessment (embedded with filler items) and another for recording a behavioral interaction. Although more time- and resource-intensive than a cross-sectional survey, such designs are eminently feasible and could yield considerable insight.

Implicit versus Explicit Expression of Prejudice and Stigma

Many investigators who study racial/ethnic prejudice have concluded that overt, explicit measures of attitudes and acceptance fail to tap underlying, implicit attitudes and biases—those that are the most likely to be exhibited in current times, when it is socially unacceptable to openly voice prejudicial sentiments (Pearson et al., 2009). A major tool for assessing unconscious biases is the Implicit Association Test (see Greenwald, McGhee, & Schwartz, 1998). Here, the outcome measure is response latency (or reaction time) as participants associate pairs of concepts with the attribute of interest. Interestingly, many individuals who claim to be without bias on explicit response measures show marked implicit biases on these types of measures. The assessment of implicit attitudes provides a unique window on the types of responses biases that exist below individuals' usual levels of awareness.

What if mental illness, by default, is the object of implicit bias? Research by Teachman and colleagues (2006) suggests that implicit bias against mental illness may be common, but studies with representative samples are sorely needed. Cheon and Chiao (2012) showed cross-cultural variation in implicit attitudes toward mental illness, an important finding given the barriers in performing such research via explicit attitude surveys (see also Wang, Huang, Jackson, & Chen, 2012). Also, at least some people with mental illness themselves may show similar biases against mental illness (Rüsch et al., 2010; Teachman et al., 2006, Study 2), perhaps due to implicit self-stigmatization. Furthermore, automatic shame associations to mental illness—among people with mental illness—may foster the acceptance of maltreatment by society and hence further perpetuate stigma (Rüsch et al., 2010). The prevalence of these effects, however, is unknown, as only small samples have been investigated thus far. Finally, O'Driscoll, Heary, Hennessy, and McKeague (2012) showed that normally developing youth showed different patterns of implicit versus explicit stigma toward peers with ADHD versus depression. Implicit stigma measures may therefore provide an aid to developmental research on the acquisition, and stabilization, of stigmatizing attitudes.

Even though much stigma may well operate at implicit levels, minimizing prejudice requires intentional, planned, effortful means or repeated exposure to counterstereotypic images (e.g., Dasgupta & Greenwald, 2001; Devine, 1989). Moreover, it may be the case that some measures of implicit bias gauge the level of exposure to—rather than the endorsement of—overlearned stimuli in positive or negative contexts. As such, these implicit associations would not inevitably portend discriminatory action. Overall, a key research priority is to formulate, and empirically test, models that make sense of the complex web of explicit attitudes, implicit attitudes, and actual behavioral responses toward people with mental illness.

Issues Regarding the Independent Variable of Mental Illness

What is actually stigmatized in the realm of mental illness: the symptoms themselves, particular diagnostic entities, the general labels of mental illness or ex-mental patient, or the associations commonly made to such terms? Whereas evidence exists that all of these may be the focus of stereotypes, prejudice, discrimination, and stigmatization, the lesson for investigators is that the independent variable—that is, the construct that is the potential subject of such denigration—must be specified clearly and precisely.

A key finding, highlighted earlier, is that when both behavioral depictions of symptoms and the label of mental illness (or ex-mental patient) are presented to research participants, symptom depictions are the more salient triggers of negative attitudes and stigmatization (see reviews in Hinshaw, 2007; Hinshaw & Stier, 2008). Yet when *normative* levels of behavior are branded or framed as related to mental illness, prejudice and stigmatization may well ensue. This is the case when labels are presented without accompanying behavioral symptoms. Importantly, when a given respondent carries in mind a strong preexisting association between mental illness and risk for dangerousness or violence, the label becomes a potent trigger for stigmatizing attitudes (Link et al., 1987). The flip side of this finding is that if individuals do not hold in mind an association between the label of mental illness and violence,

presentation of the label might lead to benign attitudes. Hence, the expectation that mental illness equates with violence is an important aspect of prejudice and stigma. In the end, labels *do* matter, and investigations of the effects of diagnoses or labels are still extremely viable as independent variables for future research efforts.

However, the world contains a great diversity of mental aberrations (see APA, 2013), belying the notion of a uniform or homogenous construct or label of mental illness. Indeed, considering mental illness to be undifferentiated may be not only ill-informed but also potentially stereotypic and stigmatizing, as doing so implicitly assumes that people with mental illnesses are all the same. Recognizing the great range of symptom levels and impairment has led investigators of recent large-scale public attitude surveys (in both the United States and abroad) to make distinctions among various forms of mental illness. Findings reveal that the different categories of mental illness are associated with unique profiles of misinformation and stigmatization, even though all forms receive some degree of stigma (e.g., Crisp et al., 2000; Pescosolido et al., 2010; Thompson et al., 2002).

At the same time, however, the global label of mental illness or mental illness should receive parallel attention, as media often use broad, global labels. For example, in a 2012 reelection debate the current U.S. president used the label mentally ill twice (Kliff, 2012). We thus recommend a two-pronged approach that investigates both the specific and the global labels of mental illness.

Three related issues are salient. First, as noted, belief in the immutability or chronicity of a stigmatizing condition is likely to be related to negative perceptions of that condition (Jones et al., 1984; Martinez & Mendoza-Denton, 2011). Thus, to the extent that mental illness is believed to be a chronic and permanent pattern of behavioral dysregulation—with little or no chance of successful rehabilitation—harshly stigmatizing responses are expectable. Even scientists and clinicians hold such stereotypes (Corrigan & Wassel, 2008; Schulze, 2007). However, evidence suggests that even schizophrenia is not chronically deteriorating in all cases or even in a majority of individuals (Harding, Brooks, Ashikaga, Strauss, & Breier, 1987). It is paramount that such information be explicitly imparted to the general public. Indeed, the term *schizophrenia* continues to retain a metaphoric linkage with despair, hopelessness, and devaluation (Finzen & Hoffman-Richter, 1999). In addition, the serious impairments of schizophrenia are often associated in the public mind as representing all forms of mental disturbance (or, far too often, misattributed to severe splits in behavior, which should more accurately be linked to dissociative disorders). In short, to erode common stereotypes, the malleability and treatability of many mental illnesses should be accurately underscored.

Second, viewing mental illness in its variegated manifestations, rather than as a homogenous and amorphous entity, prompts consideration of a crucial point: Not all forms of mental disturbance are utterly severe, and evidence-based treatments may yield real gains even with serious forms of mental disorder. Yet far too little is known about the responses of the general public, family members, mental health professionals, and patients themselves with respect to more prevalent but less severe forms of mental disturbance (Hinshaw, 2007). Although the severity and chronicity of mental disorders should predict the highest levels of stigmatization, less severe forms of mental disturbance may receive strong stigmatization precisely because of the expectation that the individual in question should have been able to control the periodic, aberrant behavior in question. It may well be, for example, that milder forms of autism spectrum disorders are particularly stigmatized (see, e.g., Norvitilis, Scime, & Lee, 2002; see also discussion in Hinshaw & Scheffler, 2014, regarding ADHD). A research priority is to extend work on prejudice, discrimination, and stigmatization to the full diagnostic and behavioral spectrum of mental health conditions.

Third, when considering the depictions of mental illness in typical research investigations, the portrayal is typically in the form of written vignettes that describe various symptom patterns. Alternatively, the manipulation may relate to the presence or absence of the label of mental illness or ex-mental patient. Although informative, such research should be complemented by other investigations that feature the direct exposure to behavioral and emotional patterns of mental illness. It would be extremely worthwhile to pursue research paradigms in which symptoms of mental illness are presented in videotaped, face-to-face, or virtual reality formats. Such encounters might yield the side benefit of enhancing empathy for the difficult experiences associated with mental illness if appropriate framing and contextualization are provided.

Overall, investigators need to exert care and thoughtfulness when depicting the independent variable of mental illness. Specific conditions, as well as the general label, require further investigation. Furthermore, the types of paper-and-pencil methods (or their present-day digital analogs) employed in many forms of attitude research should be supplemented with social interaction paradigms that feature actual, ongoing behavior.

Otherwise, investigators risk obtaining an incomplete, and potentially misleading, account of mental health stigma.

Extending the Attributional Analysis of Mental illness Stigmatization

We have made repeated reference to (a) the finding from attribution theory that ascribing deviant, threatening behavior to noncontrollable causes should lead to stigma reduction (Weiner, 1985, 2006) and (b) the counterpoint that there is a paradoxical risk of enhancing stigma by focusing on exclusive, reductionistic biogenetic attributions. Indeed, attributing mental illness to noncontrollable biomedical or genetic causal factors may not reduce punitive responses on the part of respondents and may, in fact, increase some key aspects of stigmatization, such as pessimism, social distance, and perceived dangerousness (Kvaale et al., 2013).

Accounting for this counterintuitive state of affairs should be a major research effort. First, many of the symptoms of mental disturbance are sufficiently threatening to observers that they may override or deactivate attributional processing (Haslam, 2003). The unpredictability of such symptoms—along with the symbolic threat they bring to the perceiver's beliefs in a rational world and his or her own sense of personal behavioral and emotional control—may evoke fear, castigation, and distancing. Such responses may be so rapid and automatic that they transpire prior to any mitigating effect of a causal explanation.

Second, when respondents are told that mentally disturbed behavior should be attributed to noncontrollable factors, such as aberrant genes or biochemistry, there may be initial resistance, related to the ubiquitous cultural belief that construes behavior as volitional. Maneuvers to foster a medical model of mental illness may thus be perceived as excuse-making or coddling, thereby engendering reactance. Many people may well believe that medical-model ascriptions are part of an overly disease-oriented culture that tries to absolve persons from personal responsibility.

Third, however, what if such biomedical, genetic ascriptions are ultimately accepted—particularly in relation to deeply disturbing behavior patterns that pose realistic or symbolic threat to perceivers? Again, intriguing behavioral evidence suggests that harshly punitive reactions may ensue (Mehta & Farina, 1997). This tendency may relate to the linkage of biomedical/genetic ascriptions to a deep sense of immutability and hopelessness regarding the sufferer's mental illness. In addition, if mental illness is believed to stem from a biogenetic defect, this belief may bolster essentialist views of its underlying nature as a separately caused, categorically distinct entity, which could invoke the forms of tribal stigma usually reserved for racial/ethnic or national minorities (Kurzban & Leary, 2001). Paradoxically, then, the medical model attribution might actually be an additional source of mental illness stigmatization, provoking exploitation and punishment rather than acceptance and inclusion.

Considering underlying mechanisms is provocative. We still do not fully know *how* persons in current society view mental illness and its biomedical attributions. It may be that there is a fundamental discounting of attempts to reattribute mental disturbance to biological and genetic causes: Many may continue to believe that the individual in question could *still* have controlled his or her behavior. Alternatively, some respondents may undergo a radical attributional shift, coming to the belief that the behaviors in question stem from a deep-seated, inborn flaw. Still other respondents may take a perspective parallel to demonological accounts of mental illness in former eras. Here, a supposedly uncontrollable causal factor—namely, possession by evil spirits or the devil—can be linked to the belief that the afflicted person is responsible for his or her *vulnerability* to the possession, perhaps through a moral weakness or lack of faith (Hinshaw, 2007; Zilboorg, 1941). Reductionistic medical-model/genetic perspectives may similarly convey the notion that the person displaying aberrant behavior still bears ultimate responsibility for being susceptible to the biological difference or vulnerability.

In terms of empirical investigations, open-ended/narrative responses need to complement the traditional rating-scale studies of attribution (see Weiner, 2006) to understand how members of society comprehend various explanations of mental illness. Uncovering the contents of such personal representations of, and attributions for, mental illness may require the intensive study of more diverse stimulus material: personal accounts, analyses of advertisements and media portrayals, and examination of cultural practices and language structures (e.g., jokes or common stories told in various cultures). Mixed-method research strategies may be crucial in this regard. The Web—with its social networks, crowd-sourcing, and weblogs (see Ito, 2004)—represents a novel data trove that may be mined for insights into these questions.

It will be particularly important to understand the cultural and linguistic representations of genetic ascriptions for mental disturbance. Indeed, in the coming years, genetic selection may become far more intentionally directed than has ever been the case in human history. Having deviant

genes may be viewed as an entirely controllable facet of one's makeup that is under the volitional control of parents. It will be important to understand societal messages regarding people who show the behavioral signs of a presumed genetic inferiority—and one that could have potentially been controlled or prevented through prenatal selection/termination or genetic manipulation. Overall, investigators must decode and explicate the content of current societal messages regarding ascriptions for mental illness—particularly in relation to genetic loci and their attributional consequences—to understand implications for stigma.

Responses of Persons with Mental illness to Social Stigma

Although research on the responses of the general public to mental illness has been plentiful for almost 60 years, far less is known about the targets or victims of stigma and about resultant self-stigma. That is, not enough is known about how people with mental illness comprehend, internalize, and/or cope with the devaluation and stigmatization they experience. As noted earlier, it was originally posited that stigmatized individuals would internalize the castigation foisted on them (see Allport, 1954). Later psychological perspectives, however, emphasized that lowered self-esteem and shame are far from universal consequences of being stigmatized (Crocker et al., 1998).

Still, however, individuals with mental illness may be particularly likely to experience shame and reduced self-esteem (Rüsch et al., 2014). This tendency may be related to the very symptoms of many forms of mental illness, which include demoralization and self-denigration, and to the lack of social cohesion compared to other stigmatized groups (such as racial/ethnic minorities). Along this line, self-advocacy and political solidarity have been a relatively recent occurrence with respect to mental illness. Throughout history, few have desired to disclose having to contend with or receive treatment for—let alone organize political movements around—this facet of identity. For such reasons, internalization of blame may be expected.

We note the taxonomy of personal coping responses described by Corrigan and Watson (2002). For one subgroup of persons with mental illness, shame and loss of self-esteem appear to be quite salient, over and above the symptoms of mental illness. Such individuals therefore display internalized or self-stigma. A second group shows active coping responses, including activism; this strategy appears to dissipate shame and self-blame. A third subgroup appears to ignore many stigmatizing messages, going on with their daily lives and personal goals. Unknown, however, are the proportions of such coping types among individuals with mental illness and whether these three tendencies are exhaustive of all potential coping responses. Also unknown are the social cognitive and emotional processes that enable people to sustain these strategies in the long-term. It may well be that developmental processes are sufficiently strong that individuals may shift across such types throughout the life course.

In addition, *stereotype threat* is a replicable phenomenon regarding members of stigmatized racial/ethnic and gender groups. In brief, when a particular societal stereotype is made salient (e.g., "African American individuals are inferior in terms of academic achievement" or "women are poor at math"), performance on relevant tests suffers accordingly for members of the group in question (once baseline differences in performance are controlled; McKown & Weinstein, 2003; Steele, 1997, 2010; see Inzlicht & Kang, 2010, for other consequences). Yet when tests are framed in ways that do not evoke stereotype threat—for example, the test items are described as problem-solving exercises rather than gauges of (presumably innate) ability—the performance of the stigmatized group does not suffer. Although challenges to the power of stereotype threat have been posed, it is a phenomenon of potential relevance here.

Specifically, an important question is how stereotype threats might influence at least some individuals with mental illness. Investigators will have to contend with the crucial issue of just what the relevant stereotypes are—and in what performance domains they might matter. Although there have been some initial forays into this area (see Quinn, Kahng, & Crocker, 2004), far too little is known. For example, does priming the common stereotype that persons with mental illness are unpredictable and incompetent impair performance during job interviews or in employment contexts? More ominously, does the stereotype that mental illness is inevitably and invariably associated with violence trigger self-fulfilling prophecies?

In all, the ways in which persons with mental illness respond to stigma and discrimination (successfully and unsuccessfully) constitute a crucial topic for future research. We have argued that self-stigmatization is likely to be particularly potent for individuals with mental illness, but there are too few data points on representative samples to state this assertion with confidence. Developing a comprehensive taxonomy of coping strategies would be an important initial step. Whether stereotypes related to mental illness (e.g., violence, incompetence, unpredictability, untreatability, and immutability) evoke threat and

performance decrements in crucial life tasks is a topic in need of programmatic investigation.

Families and Mental Health Professionals

Even more than objective types of burden—such as financial costs, finding housing, providing care, and taking time off from work—family members of persons with serious mental illness incur a strong sense of *subjective burden*. This process involves embarrassment, shame, and a host of related negative emotions related to the difficulties associated with caring for their afflicted relatives (Lefley, 1989, 1992). Beyond descriptive information about such burden, there is an important need to understand the following: Which types of families stay silent about a relative's mental illness, and which types exhibit openness? Do certain forms of mental illness predict one or the other stance with any specificity? What are the kinds of extra-familial supports that successful families utilize? At which points in the life cycle of the relative's mental illness do families show the greatest chance of engaging in open dialogue with one another and with relevant professionals? For important background, see Larson and Corrigan (2008).

The subjective experiences of family members are inextricably linked with professional and scientific views on mental illness. As discussed earlier, some professionals in the field convey stereotypic views of and stigmatizing attitudes toward people with mental illness. Yet most information about attitudes comes from explicit attitude measures or from selected personal accounts (Wahl, 1999). Obtaining information on the actual behavioral responses of professionals to persons with mental illness is an important objective. Equally crucial is obtaining a rich database on how the *implicit* associations of mental health workers and professionals affect persons with mental illness and how these biases may shape treatment adherence and clinical interactions and outcomes. Finally, it may well be that the majority of current and recently trained mental health professionals hold positive or nonstigmatizing attitudes toward persons with mental illness. However, relevant research that could shed light on this topic has simply been lacking.

Developmental Issues Regarding Stigma

Research on racial/ethnic bias has taken on a decidedly developmental perspective, with efforts made to ascertain the ages at which children become aware of prejudice and bias toward people of color (e.g., McKown & Weinstein, 2003). More should be known about the parallel topic of bias and stigma regarding mental illness. In fact, however, developmental considerations have been sorely missing from most research on this topic.

Space limitations preclude a full exploration of this issue, but we propose several key questions that require greater elucidation. First, how do stigmatizing attitudes in society (and from mental health professionals) explain parental rejection versus acceptance of a diagnosis of mental illness in their child? Also, how does the age of the child relate to such family response? In other words, what are the distinct (and common) issues for families of infants/toddlers, preschoolers, grade-schoolers, and adolescents in contending with a child's mental illness? Second, what are children's own reactions at different ages to receiving a mental illness diagnosis? Can such a label be a source of strength in that one can begin to attribute negative experiences to an outside entity (an illness) rather than to one's flawed sense of self? Or does the stigma attached to mental illness make the receipt of a diagnosis a trigger for lowered self-esteem? Even more fundamentally, how do children of various ages understand what mental illness signifies, both in general and for themselves in particular?

At a broader level, how do cultural messages about mental illness—from the media, from school-based lessons, from peer networks, from social media—influence the thoughts and attitudes of typically developing children and adolescents toward peers with mental disorders? As noted earlier, even children's cartoons have contained frequent, and disparaging, images of mental illness (Wilson et al., 2000), and some of the first words young children use to denigrate disliked peers are slang words for mental illness. A host of research questions emerge from consideration of the ways in which visual images and verbal messages regarding mental illness are communicated to, and processed by, children. We noted earlier the important investigation of O'Driscoll et al. (2012) regarding implicit versus explicit attitudes displayed by children versus adolescents with respect to two different mental disorders (ADHD and depression). Such research, particularly if carried out longitudinally, would represent a major advance.

At present, the field is ripe for developmentally oriented investigators to probe both basic and applied questions about the origins, and manifestations, of stigma in children and adolescents. A systems approach is critical, given the need for providers of children's services to be aware of potentially stigmatizing messages and practices (see Heflinger & Hinshaw, 2010). All such work would simultaneously enhance knowledge of social cognitive processes across development and facilitate interventions

aimed at reducing mental health stigma in its earliest manifestations.

Current Social Issues in Relation to Stigma and Mental illness

A number of political and social events and issues appear to have important implications for the stigmatization of mental illness. We list these briefly in the hope of stimulating relevant empirical inquiries. First, nearly all state budgets across the United States have become awash in red ink during the early years of the twenty-first century. Education, welfare, and mental health are often the first targets of defunding and disinvestment. Will stigmatization of persons with mental illness, including children and adolescents, show increases in economic downturns and anemic economic recoveries? Will the willingness to engage in treatment be affected? Admittedly, linking public attitudes temporally with economic trends and current events is difficult. Yet investigations of this topic area could shed light on important macro-level variables in relation to stigmatization.

An immediate concern is the implementation of the Affordable Care Act, the landmark legislation that brings the United States closer to universal health coverage. Political and ideological rancor might still be successful in derailing this public policy. Alternatively, if implemented with fidelity to its goals—which is now more likely given the Supreme Court decision of June 2015—the Affordable Care Act could result in greater access to mental health care and thereby destigmatize participation in mental health care services.

Further, immigration is a major issue confronting Congress and could render the United States more ethnically and culturally heterogeneous, potentially stoking the flames of hatred and xenophobia. It is unknown whether intolerance will spread to persons with mental illness. Yet two reasons make such an occurrence probable. For one, the persistent media-driven stereotype that mental illness equals violence would clearly tend to intensify rejection and marginalization of people with mental illness. For another, recall the fascinating linkage, as previously noted, between (a) fears of mortality and (b) intolerance of those who are different (e.g., Solomon et al., 1991). Some theorists posit that anxiety over death or annihilation may lead the perceiver to become acutely aware of the fleeting nature of life, thereby spurring stereotyping and castigation of individuals who seem to imperil community norms and safety. Given threatening, high-profile acts of violence that saturate the media, discrimination against those with mental illness may intensify.

Summary

A host of research questions emerge from analysis of the literature on stigmatization. Indeed, the bulk of empirical work on stigma pertains to the important topics of racial/ethnic and gender-based prejudice, but the applicability of such research to mental illness remains uncertain. Important issues pertain to the specification of the dependent variable of stigma (including more focus on measurement of observable behaviors, rather than attitudes and beliefs per se) and parallel specification of the independent variable of mental illness (in terms of its inherent variability and specificity). Also important are high-granularity attributional analyses related to personal control versus biogenetic ascriptions and their impact on stigma. Finally, more research needs to address questions about family issues, developmental factors, and the impact of macro-level sociopolitical and economic events on stigma in this domain.

STRATEGIES FOR OVERCOMING STIGMA

Finding effective strategies to overcome stigma is a difficult yet achievable task. Although knowledge must replace ignorance as a starting point, increased literacy regarding mental illness does not always translate into improved attitudes. Knowledge may be particularly helpful for youth, but *contact*, which can lead to empathy and modeling of equitable interactions, is especially important across the life span (for data and relevant discussion, see Corrigan & Kosyluk, 2013). Intervention must be multilevel and operate on psychological, structural, and cultural processes, as single-focus anti-stigma efforts are bound to fail to address the array of factors necessary for lasting change (Hinshaw, 2007). Efforts to reduce self-stigmatization are gaining in ascendancy (e.g., Corrigan, Kosyluk, & Rüsch, 2013; Corrigan, Sokol, & Rüsch, 2013). A major, multifaceted anti-stigma program in the United Kingdom, called Time to Change, was recently evaluated (see Henderson & Thornicroft, 2013), with some evidence of national-level success but limited evidence for maintenance of gains. System-wide change with respect to stigma reduction is bound to be a challenging objective. In the limited space available, we describe several promising strategies.

Social Policy and Culture-wide Levels

Beginning with broad levels of intervention in the realm of policy, general health care reform is a priority in light

of the large numbers of uninsured in the United States. As just noted, the funding and sustained implementation of the Affordable Care Act is a key long-term priority. Even if it survives full-frontal political attacks and becomes established in the long-term, it still could eventually be defunded in practice, as were community mental health centers after deinstitutionalization occurred. Moreover, enforcing existing legislation mandating nondiscrimination in employment and housing is also crucial. Yet beyond such enforcement, new initiatives will be required to help promote education and occupational skills (and, hence, income levels) of persons with mental illness.

Regarding children and adolescents, strengthening the provisions of the IDEA will help to ensure adequate academic attainment for youth with mental illness. An additional suggestion with potentially far-reaching implications is to include behavioral and emotional functioning as part of the medical checkups that children receive each year from health care providers. Such a preventive approach could bring discussion of children's social and behavioral functioning into the everyday language of doctors and families. Importantly, this dialogue could help address the precursors of mental illness before symptoms escalate (Hinshaw, 2007; Institute of Medicine, 2009) and potentially curtail future suffering as well as violence-laden tragedies. Such efforts are controversial, however, particularly given fears that early detection would lead, in too many cases, to overmedication as opposed to preventive intervention.

In terms of public media, a far different kind of message about mental illness needs to be transmitted. Information about mental illness in the print, visual, and electronic media continues to pertain largely to danger, violence, and utter irrationality. Protest by consumer groups may lead to consciousness raising among writers and producers, even though protest movements have the potential (in some instances) to lead to a counterproductive rebound of the very messages that are targeted (Corrigan & Penn, 1999; Wahl, 1995). Furthermore, promotion of poignant disclosures by individuals and families who deal with mental illness provides a different set of images and a different cultural dialogue than the typical depiction of persons with mental illness as either heroes or incompetents. For developing youth, portrayals of the realities of such conditions as child autism and ADHD—as well as adolescent mood disorders and eating disorders—can set the stage for openness and discussion instead of silence and shame. It is important to avoid demonization *and* glorification from such accounts; everyday struggles and triumphs are likely to promote identification and empathy.

Communities

At a community level, the predominant empirically based strategy for overcoming discrimination and stigma has stemmed from the contact hypothesis (Allport, 1954). From this perspective, changes in attitudes and behaviors are most likely to occur through direct behavioral contact with members of out-groups. A major meta-analysis by Pettigrew and Tropp (2006) confirmed that sheer contact is an important, and even necessary, condition for alleviating prejudice and stigma across multiple out-groups (as for the effectiveness of contact with people dealing with mental illness, see Corrigan & Kosyluk, 2013). The *conditions* of contact are crucial for success: Specifically, contact is most likely to lead to improved attitudes when in-group and out-group members have regular, informal contact on an egalitarian basis. Thus, visiting patients in a mental hospital is not nearly as likely to facilitate enhanced attitudes as is regular interchange in the mainstreams of the community and the workplace (but see Pettigrew & Tropp, 2006, who contended that contact per se transcends such conditions with regard to reducing prejudice). Clearly, improvements in mental health care, enhanced employment opportunities, and housing availability are needed for contact to be more egalitarian than it often is today (see review in Hinshaw, 2007).

Other aspects are important for successful contact. Adequate treatment and social supports are essential aspects of such community intervention. Also, stigma is particularly likely to diminish when in-group and out-group members work toward common, superordinate goals that foster expanded in-group identity (Gaertner & Dovidio, 2000; Sherif & Sherif, 1953). Advocacy and support groups in which persons with mental illness, their family members, and the general public interact provide a clear example of such collaboration.

Importantly, provocative new social psychological research has shown that contact effects are not restricted to this kind of direct contact. Specifically, *indirect contact* has been shown to be effective in some intergroup contexts as well (Hewstone & Swart, 2011). Indirect contact comes in at least two flavors, including *extended contact* and *imagined contact*. In the former, one might have a friend who has a friend with mental illness. This type of contact can shift attitudes in the initial, more distantly related person. Thus, extended social networks might help decrease mental illness stigma. In addition, *imagined contact* research has shown that the sheer act of imagining contact with out-groups can positively change attitudes about them. Although it is presently unknown whether this kind of intervention would ameliorate stigma

in the domain of mental illness, future research should systematically explore this possibility, especially given that imaginative engagement causally affects empathy (Kidd & Castano, 2013).

Moreover, because contact effects with a specific out-group can shift attitudes toward out-groups more generally (in what are termed secondary transfer effects—see Pettigrew, 2009), reducing mental illness stigma via contact may reduce patterns of prejudice at a broad level. As Allport (1954) maintained over 60 years ago, if the in-group's boundaries can be stretched to include wider numbers of individuals, we all stand to benefit. Still, as noted in Henderson and Thornicroft (2013, introducing a supplement to the *British Journal of Psychiatry*), even carefully thought-out, well-funded multipronged strategies at a national level do not always yield large effects. Considerable work remains to be done.

Families

For families, a number of procedures and interventions may serve to decrease subjective burden and bolster coping resources. These include education about the causes and realities of mental illness, social support from other families grappling with similar issues, and engagement in (plus reimbursement for) family-based therapies that provide strategies for dealing with the difficult life issues presented by serious mental illness. Furthermore, when a parent has a mental illness, families need to engage children in treatment in ways to help them understand that they themselves are not to blame—and that their parent is getting help (Beardslee, 2002). Openness and communication are crucial in this regard. Self-help and advocacy groups can reduce isolation, provide needed information, and aid in family coping. In addition, theoretical models in the field must emphasize reduction of parental blame for the mental illnesses of their children yet simultaneously promote family responsibility for ameliorating the course of the disorder. At the same time, the reality is that some families promote maladjustment via physical or sexual abuse or child neglect. Preventive strategies along these lines are also essential for optimal mental health care and, ultimately, stigma reduction.

Youth in the Community

From all appearances, young people in the general population appear eager to discuss behavioral differences, are far more likely to accept a variety of expressions of sexuality than older individuals, and may be more accepting of mental illness. These cultural trends provide grounds for optimism about a future that features far less mental health stigma than the past. Yet is there any evidence that active promotion of youth-based discussion actually helps? In an intriguing model, Let's Erase the Stigma (LETS) features a simple premise: High school (or even middle school) students can form a school club rather than a support group with mental health professionals during which active discussion of differences, acceptance, and ideas for reducing stigmatization is the priority. In an initial, quasi-experimental evaluation of the LETS model, benefits of participation were noted with respect to improved attitudes and knowledge (about mental illness stigma), enhanced behavioral intentions to combat stigma, and reduced social distance toward individuals with mental disorders (Murman et al., 2014). Such contact- and peer-based programs are likely to be preferable to top-down knowledge enhancement alone as a strategy for community-wide stigma reduction among youth. LETS has recently merged with the antistigma organization known as Bring Change 2 Mind, and further evaluations are ongoing.

Persons with Mental Illness

Finally, for individuals with mental illness (including children and adolescents), engagement in evidence-based treatment is absolutely crucial. Participation in such intervention can reduce symptoms and facilitate competent academic, social, and vocational performance as well as enhance social welfare (see Marcotte & Markowitz, 2011, for policy implications)—all of which can serve to reduce stigma. To the extent that interventions diminish threatening and maladaptive symptoms, perceivers in society will have less *apparent* justification to stigmatize those with mental illness (Hinshaw, 2007). More simply stated, there may be few more effective means of combating stigma than ensuring access to well-funded, responsive treatments.

Yet there is potential peril in this line of reasoning. It is dangerous to advocate for the position that all responsibility for stigma reduction falls on the shoulders of persons with mental illness, who must eliminate any sign of disturbance. This kind of blaming-the-victim mentality could be perceived as tantamount to arguing that the solution for ending racial/ethnic prejudice is to have all members of minority groups blanch their skin. Obviously, such a solution is irrational and immoral. Thus, there is need for systemic change, not just adjustment on the part of persons with mental illness to conform to social norms.

However, mental illness is unlike ethnicity and race in an important and undeniable respect: It is indeed a form of illness—albeit a complex form, comprising all of the developmental psychopathology principles and processes discussed throughout this chapter. Relatedly, the symptoms of mental illness are undeniably maladaptive and cause suffering. The evidence-based treatment of such symptoms, and related impairments, can enhance autonomy and flourishing in the individual in question. Thus, successful treatment is clearly a crucial aspect of stigma reduction. But just as clearly, it cannot be the sole component.

Beyond participation and engagement in evidence-based intervention, finding means to bolster coping resources of persons with mental illness is needed. For example, if individuals encounter prejudice, it will be important that they attribute such stigma appropriately to the biases of society instead of to inherent defects within themselves. At the same time, individuals should retain motivation to remain in their particular forms of treatment. Because, however, many forms of mental illness serve to erode self-confidence, as well as personal value and agency, teaching such coping strategies is a formidable objective. Finally, even successful interventions will not be likely to reduce all signs of behavioral difference, nor should this be their goal. Thus, greater societal tolerance for and appreciation of the diversity of behavioral and emotional expressions is a simultaneous cultural objective for stigma reduction.

Summary

The ultimate goal of mental illness stigma research is to find means of promoting change strategies that span levels of the person, family, community, media, and social policy. Again, there is a danger that ameliorating stigma processes at any one level will leave untouched the pernicious problems at other levels, leading to fragmented and unsustainable change (Hinshaw & Stier, 2008; Link & Phelan, 2001). Moreover, stigma is a process with social, cultural, and even moral dimensions (Kleinman & Hall-Clifford, 2009; Yang et al., 2007), meaning that change is likely to be slow. Yet concentrated efforts must begin in earnest. A major intellectual, clinical, and policy-related challenge is to apply the basic principles of stigmatization—across the multiple levels of influence that are operative—to design, implement, evaluate, and refine stigma reduction practices for children, adolescents, adults, and their families and communities. Importantly, elucidating mental illness stigma in particular will also add to a more comprehensive general theory of stigmatization, potentially benefiting other socially marginalized groups.

Citizens and interventionists face particularly complex challenges. These include the pervasive shame and silence surrounding mental illness, the cyclic nature of reform and retrenchment throughout history, and the automatic (and perhaps naturally selected) stigmatizing tendencies toward behavioral deviance, all of which we have discussed in this chapter (Hinshaw, 2007; Kurzban & Leary, 2001). All human societies, however, require variability and diversity, so long as the behavioral manifestations are not threatening to fellow humans. Thus, at the largest level, successful stigma reduction will require promoting greater tolerance for a wider range of behavioral and emotional styles, thereby allowing *all* individuals to actualize their potential. Although severe forms of mental illness—which can include highly irrational and erratic forms of behavior—may always receive some degree of castigation, this does not mean that reducing stigma is impossible. All members of society will gain when compassion and understanding supplant shunning and shame and when access to evidence-based treatments becomes a reality. Understanding relevant developmental processes that contribute to stigma formation—and that may therefore illuminate pathways to its undoing—is an urgent priority for basic science, informed public policy, and forging the kind of humane society to which we all should aspire.
