These volumes are dedicated to Marianne Gerschel in recognition
of her great vision and staunch support of the field
of developmental psychopathology.

Contents

Preface to Developmental Psychopathology, Third Edition ix
Dante Cicchetti

Contributors xi

1 **CHILDHOOD ADVERSITY AND ADULT PHYSICAL HEALTH** 1
Katherine B. Ehrlich, Gregory E. Miller, and Edith Chen

2 **COMMUNITY VIOLENCE EXPOSURE AND DEVELOPMENTAL PSYCHOPATHOLOGY** 43
Patrick H. Tolan

3 **SOCIAL SUPPORT AND DEVELOPMENTAL PSYCHOPATHOLOGY** 86
Ross A. Thompson and Rebecca Goodvin

4 **POVERTY AND THE DEVELOPMENT OF PSYCHOPATHOLOGY** 136
Martha E. Wadsworth, Gary W. Evans, Kathryn Grant, Jocelyn S. Carter, and Sophia Duffy

5 **DETERMINANTS OF PARENTING** 180
Marc H. Bornstein

6 **RESILIENCE IN DEVELOPMENT: PROGRESS AND TRANSFORMATION** 271
Ann S. Masten and Dante Cicchetti

7 **VULNERABILITY AND RESILIENCY OF AFRICAN AMERICAN YOUTH: REVELATIONS AND CHALLENGES TO THEORY AND RESEARCH** 334
Margaret Beale Spencer and Dena Phillips Swanson

8 **SOCIAL INEQUALITIES AND THE ROAD TO ALLOSTATIC LOAD: FROM VULNERABILITY TO RESILIENCE** 381
Robert-Paul Juster, Teresa Seeman, Bruce S. McEwen, Martin Picard, Ian Mahar, Naguib Mechawar, Shireen Sindi, Nathan Grant Smith, Juliana Souza-Talarico, Zoltan Sarnyai, Dave Lanoix, Pierrich Plusquellec, Isabelle Ouellet-Morin, and Sonia J. Lupien

9 **COMPETENCE AND PSYCHOPATHOLOGY IN DEVELOPMENT** 435
Keith B. Burt, J. Douglas Coatsworth, and Ann S. Masten

10 **THE DEVELOPMENT OF COPING: IMPLICATIONS FOR PSYCHOPATHOLOGY AND RESILIENCE** 485
Melanie J. Zimmer-Gembeck and Ellen A. Skinner

11 **TEMPERAMENT AND DEVELOPMENTAL PSYCHOPATHOLOGY** 546
Cynthia Stifter and Jessica Dollar

12 **INTERPARENTAL CONFLICT AND CHILD ADJUSTMENT** 608
Ernest N. Jouriles, Renee McDonald, and Chrystyna D. Kouros

13 **RELATIONAL AGGRESSION: A DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE** 660
Dianna Murray-Close, David A. Nelson, Jamie M. Ostrov, Juan F. Casas, and Nicki R. Crick

14 **CULTURE, PEER RELATIONSHIPS, AND DEVELOPMENTAL PSYCHOPATHOLOGY** 723
Xinyin Chen and Cindy H. Liu

15 **CLASSROOM PROCESSES AND TEACHER–STUDENT INTERACTION: INTEGRATIONS WITH A DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE** 770
Robert C. Pianta

16 **ADVANCES IN PREVENTION SCIENCE: A DEVELOPMENTAL PSYCHOPATHOLOGY PERSPECTIVE** 815
Sheree L. Toth, Christie L. M. Petrenko, Julie A. Gravener-Davis, and Elizabeth D. Handley

17 **CULTURALLY ADAPTED PREVENTIVE INTERVENTIONS FOR CHILDREN AND ADOLESCENTS** 874
Nancy A. Gonzales, Anna S. Lau, Velma M. Murry, Armando A. Pina, and Manuel Barrera, Jr.

18 **THE EFFECTS OF EARLY PSYCHOSOCIAL DEPRIVATION ON BRAIN AND BEHAVIORAL DEVELOPMENT: FINDINGS FROM THE BUCHAREST EARLY INTERVENTION PROJECT** 934
Charles A. Nelson, Nathan A. Fox, and Charles H. Zeanah

19 **PREVENTING SENSITIZATION AND KINDLING-LIKE PROGRESSION IN THE RECURRENT MOOD DISORDERS** 971

Preface to Developmental Psychopathology, Third Edition

A decade has passed since the second edition of *Developmental Psychopathology* was published. The two prior editions (Cicchetti & Cohen, 1995, 2006) have been very influential in the growth of the field of developmental psychopathology. The volumes have been highly cited in the literature and have served as an important resource for developmental scientists and prevention and intervention researchers alike. In the present third edition, we have expanded from the three volumes contained in the second edition to four volumes. The increased number of volumes in this current edition reflects the continued knowledge gains that have occurred in the field over the past decade.

A not insignificant contributor to this growth can be found in the very principles of the discipline (Cicchetti, 1984, 1990, 1993; Cicchetti & Sroufe, 2000; Cicchetti & Toth, 1991, 2009; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). Theorists, researchers, and prevention scientists in the field of developmental psychopathology adhere to a life span framework to elucidate the numerous processes and mechanisms that can contribute to the development of mental disorders in high-risk individuals as well as those operative in individuals who already have manifested psychological disturbances or who have averted such disorders despite their high-risk status (Cicchetti, 1993; Masten, 2014; Rutter, 1986, 1987, 2012). Not only is knowledge of normal genetic, neurobiological, physiological, hormonal, psychological, and social processes very helpful for understanding, preventing, and treating psychopathology, but also deviations from and distortions of normal development that are seen in pathological processes indicate in innovative ways how normal development may be better investigated and understood. Similarly, information obtained from investigations of experiments of nature, high-risk conditions, and psychopathology can augment the comprehension of normal development (Cicchetti, 1984, 1990, 1993; Rutter, 1986; Rutter & Garmezy, 1983; Sroufe, 1990; Weiss, 1969).

Another factor that has expedited growth within the field of developmental psychopathology has been its ability to incorporate knowledge from diverse disciplines and to encourage interdisciplinary and translational research (Cicchetti & Gunnar, 2009; Cicchetti & Toth, 2006). In keeping with its integrative focus, contributions to developmental psychopathology have come from many disciplines of the biological and social sciences. A wide array of content areas, scientific disciplines, and methodologies has been germane. Risk and protective factors and processes have been identified and validated at multiple levels of analysis and in multiple domains.

The increased emphasis on a multilevel, dynamic systems approach to psychopathology and resilience, the increased attention paid to gene–environment interplay in the development of psychopathology and resilience, and the application of a multiple levels of analysis developmental perspective to mental illnesses that have traditionally been examined nondevelopmentally (e.g., bipolar disorder, schizophrenia, and the personality disorders) not only have contributed to a deeper understanding of the dysfunctions but also have educated the public about the causes and consequences of mental disorder (see Cicchetti & Cannon, 1999; Cicchetti & Crick, 2009a, 2009b; Miklowitz & Cicchetti, 2006, 2010; Tackett & Sharp, 2014).

Advances in genomics, GxE interactions, and epigenetics; growth in our understanding of neurobiology, neural plasticity, and resilience; and progress in the development of methodological and technological tools, including brain imaging, neural circuitry, hormone assays, immunology, social and environmental influences on brain development, and statistical analysis of developmental change, pave the way for interdisciplinary and for multiple levels of analysis research programs that will significantly increase the knowledge base of the development and course of maladaptation, psychopathology, and resilience. Moreover, randomized control prevention and intervention trials are being conducted based on theoretical models and efforts to elucidate the mechanisms and processes contributing to developmental change at both the biological and psychological levels (Belsky & van IJzendoorn, 2015; Cicchetti & Gunnar, 2008).

Despite the significant advances that have occurred in the field of developmental psychopathology, much important work lies ahead. Undoubtedly these future developments will build on the venerable contributions of the past; however, as work in the field becomes increasingly interdisciplinary, multilevel, and technologically sophisticated, it is essential that even more emphasis be directed toward the process of development (Harter, 2006; Sroufe, 2007, 2013). It is not only genes and environments but also the cumulative developmental history of the individual that influences how future development will unfold (Sroufe, 2007, 2013).

Developmental psychopathologists have incorporated concepts and methods derived from other disciplinary endeavors that are too often isolated from each other, thereby generating advances in knowledge that might have been missed in the absence of cross-disciplinary dialogue. The continuation and elaboration of the mutually enriching interchanges that have occurred within and across disciplines interested in normal and abnormal development not only will enhance the science of developmental psychopathology but also will increase the benefits to be derived for individuals with high-risk conditions or mental disorders, families, and society as a whole.

REFERENCES 34

A consensus in the developmental psychopathology literature is that the experience of early adversity—particularly the experience of chronic, uncontrollable stress—is a risk factor for a diverse set of poor outcomes across development (e.g., Appleyard, Egeland, van Dulmen, & Sroufe, 2005; Poulton et al., 2002; Shonkoff et al., 2012). In the last three decades, a growing number of studies have provided convincing evidence to conclude that adversity in childhood has a lasting influence on adult physical health, particularly chronic diseases associated with aging, like cardiovascular disease, diabetes, arthritis, and some cancers (Gluckman & Hanson, 2006; Miller, Chen, & Parker, 2011; Repetti, Taylor, & Seeman, 2002). This susceptibility to the chronic diseases of aging resulting from early adversity has been identified in diverse samples with a range of adverse risk factors, including socioeconomic disadvantage, maltreatment, and chaotic family environments. These findings suggest that these early stressful experiences leave a "biological residue," manifesting in physical health problems in adulthood.

This chapter provides a review of the current knowledge linking childhood adversity to adult physical health. We first provide a discussion of childhood adversity and the varied ways that children encounter stressful experiences in their daily lives. Then we review evidence for links between childhood adversity and chronic diseases of aging, with a focus on cardiovascular disease and metabolic disorders, where most of the research to date has occurred. We then describe conceptual models that help guide empirical investigation of the processes through which early adversity influences later health. We also review biological mechanisms that might play an intermediary role in translating psychosocial stress into health problems, which can help explain how early adversity "gets under the skin" and influences the onset of disease in adulthood. Our goal is to highlight the advantages and limitations in the conclusions

we can draw from research on these biological processes. Finally, we end this chapter with a series of important research questions that should be a focus in the next generation of empirical investigation on early adversity and adult physical health.

DEFINING CHILDHOOD ADVERSITY

There are a number of ways that children could experience significant adversity. In this chapter, we focus on adversity that is both chronic and severe in nature. We define *chronic* adversity as one that remains present in the child's life over a significant period of time (e.g., lack of material resources due to poverty). Adversity can also be chronic when children experience lingering threat over the possibility of a repeated stressful experience (e.g., stress resulting from a traumatic experience, such as abuse, that could reoccur) or aftereffects of adversities that create severe disruptions to daily life (e.g., long-term displacement resulting from a natural disaster). Adversity is considered *severe* when it results in a profound unsettling of normative childhood experiences and threatens the well-being of the child (e.g., exposure to gang violence while living in poverty).

Studies that have attempted to estimate the prevalence of adverse life experiences in childhood have found that these stressors actually are fairly common. Kessler and colleagues (Kessler, Davis, & Kendler, 1997) categorized early-life adversities into four domains, including (a) interpersonal traumas (e.g., rape, physical attacks); (b) loss events (e.g., death of a parent); (c) parental psychopathology (e.g., parental depression, antisocial personality disorder); and (d) a miscellaneous category of stressful life events (e.g., life-threatening accidents, man-made disasters). Using the National Comorbidity Survey, a nationally representative sample of families in the United States, Kessler et al. found that by the age of 16, nearly 75% of children have experienced at least one significant adversity and approximately 50% of children have experienced multiple adversities. In this sample, the most frequent adversities that children faced were maternal depression, paternal verbal abuse, paternal substance abuse, and parental separation or divorce.

Further, a startling number of children currently face adversity in impoverished or economically stressed conditions. According to the Children's Defense Fund (2012), 22% of children in the United States were living in poverty in 2010, meaning that a family of four earns less than $22,350 a year (U.S. Department of Health and Human Services, 2011). An additional 22% of children live in low-income families, defined as less than 200% of the federal poverty level (or less than $44,700 for a family of four). Children in low-income families may be exposed to many of the same stressors that children living below the poverty line face, including dangerous neighborhoods, material deprivation, parental underemployment, and familial mental health problems, all contributing to strained family relationships.

Overwhelmingly, research on the links between early adversity and later physical health has focused on two types of adversity: child maltreatment and socioeconomic disadvantage. Although these experiences of early adversity fall under the definition of adversity proposed above, they differ from each other in some critical aspects, including the *nature* and *source* of threatening experiences; the duration, frequency, and severity of those experiences; and the opportunities for coping. Yet maltreatment and socioeconomic disadvantage share several overlapping qualities, which may include cold, insensitive parenting; harsh discipline; exposure to conflict and violence; limited access to resources; and uncertainty of future environmental stability (Repetti et al., 2002). Next we take a closer look at several forms of adversity that are thought to be particularly detrimental for later physical health.

Child Maltreatment

A fundamental component of attachment theory is the notion that individuals develop representations (or internal working models) that reflect the extent to which a caregiver serves as a *secure base* for exploration and as a *safe haven* when needed for comfort and support (Bowlby, 1969/1982, 1973). These representations are experience-based, and they are developed over the first year of life in response to repeated interactions with a caregiver. When these caregiving experiences include neglect or abuse, children learn that their caregiver is not an available secure base or safe haven. Further, these children may develop unusual behaviors, characterized by odd, fearful, and disorganized patterns of interactions with a caregiver—characteristics that emerge when the caregiver becomes their primary source of fear *and* support (Lyons-Ruth & Jacobvitz, 2008). These behavioral responses reflect the child's inability to cope with a chaotic environment. Importantly, children who are maltreated by caregivers grow up without the experience of knowing that a reliable caregiver is available when needed—an aspect of the family emotional climate that plays a fundamental role in children's abilities to regulate distress and cope with negative emotions (Bowlby, 1988).

Child maltreatment is a serious public health concern that poses significant mental and physical health burdens on its victims (Cicchetti & Toth, 2005) as well as substantial economic burdens on society as a whole (Fang, Brown, Florence, & Mercy, 2012). Estimates suggest that almost 700,000 children were victimized in the United States in 2011, almost half of whom were under 6 years old at the time of the abuse (U.S. Dept. of Health and Human Services, 2011). Of course, because a large number of cases are unreported and a third of reported cases are not investigated (Cicchetti & Toth, 2005), the actual rate of child maltreatment may in fact be higher. The vast majority of cases (78%) included children suffering from neglect, but each year, hundreds of thousands of children are also victims of physical, sexual, or psychological abuse. Alarmingly, childhood maltreatment is perpetrated most often by primary caregivers, with over 80% of cases involving abuse by one or more parents.

Explanations for the causes of child maltreatment widely recognize that the phenomenon is multiply determined. Attempts to characterize the contexts of maltreatment have cited parental factors (e.g., mental illness, substance abuse), child factors (e.g., difficult temperament, disruptive behavior), interactional factors—that is, the dynamic transactions that take place between parents and children that might incite abuse (e.g., a child's aggressive behavior elicits physical punishment from parents that subsequently escalates to abuse), and environmental factors (e.g., cultural attitudes, poverty; Belsky, 1993; Cicchetti & Toth, 2005).

Socioeconomic Disadvantage

Children growing up with socioeconomic disadvantage have a higher probability of being exposed to stressful conditions across virtually every domain of daily life. Many of these stressful conditions center on the lack of security for basic resources, such as food and housing. For example, over 10% of children live in "food-insecure" families who struggle to provide enough food to meet children's daily nutritional needs, and over 20 million children receive free or reduced-cost lunches at school—meals they are eligible to receive because of their family's scarce financial resources (Children's Defense Fund, 2012). Children in poverty often do not have adequate access to medical care, resulting in infrequent visits to the doctor and risk for serious complications from untreated illnesses. Children growing up in poverty are at risk for low educational attainment, meager job success, and incarceration (Duncan, Kalil, & Ziol-Guest, 2008). Notably, children in poverty also face neighborhood stressors, and they are at increased risk for becoming victims of violence, theft, and other crimes (Ross & Mirowsky, 2001). Further, their caregivers are burdened by numerous demands, such as multiple part-time jobs, unaccommodating schedules, and psychosocial stress brought on by their lack of resources, making it more difficult for them to serve as sensitive sources of support for their children. The accumulation of deficits in resources—both material and psychological—cluster to create an environment that is ill-equipped to foster children's healthy development. Children living in disadvantaged families can face daily threats to their basic needs and be exposed to additional stressors that can jeopardize their mental and physical well-being.

Presumably, other adverse experiences in childhood (including many of the factors that Kessler et al. [1997] identified) have repercussions for adult health. To date, however, these links between exposure to other early adversities besides poverty and maltreatment and adult health have not been a primary focus in the literature. For example, with the exception of a handful of studies, we know very little about how the loss of a parent, the experience of severe interparental conflict, or exposure to neighborhood stress plays a role in shaping chronic disease outcomes in adulthood. Children are exposed to a wide array of adverse experiences, and it will be important to understand the extent to which each of these adversities is associated with long-term physical health outcomes.

Summary

Chronic adversity is a problem for many children in the United States. So far, the literature on health consequences has focused mainly on maltreatment and disadvantage. But an important question for future studies to consider is the impact of other significant adversities (e.g., interparental conflict, long-term separations from parents, natural disasters) on adult physical health. One challenge to this line of research, however, is that many forms of adversity—and socioeconomic disadvantage and maltreatment in particular—co-occur more often than would be expected by chance alone (Crouch, Hanson, Saunders, Kilpatrick, & Resnick, 2000), thus creating a unique challenge to parsing out the effects of different forms of adversity on later physical health outcomes. The use of a variety of statistical techniques (e.g., variable-centered and person-centered approaches to data analysis) as well as comprehensive models (described in more detail later in this chapter) offer opportunities to circumvent the

challenges associated with identifying the complex connections between early adversity and adult physical health.

DEFINING HEALTH OUTCOMES

Studies documenting the link between early adversity and adult physical health have assessed everything from the frequency of minor physical symptoms like headaches and constipation to rates of disorders and death from various conditions. As much as possible we focus on disease morbidity (the diagnosis of a disease or a clinical manifestation of it) and mortality rather than symptom reports. The advantages of focusing on disease endpoints and death are that they can be ascertained objectively and are viewed as reflecting differences in an underlying disease process. Further, these outcomes are much simpler to interpret than symptoms reported by patients, which tend to be heavily shaped by individual differences in symptom perception, labeling, and reporting (Feldman, Cohen, Doyle, Skoner, & Gwaltney, 1999).

Our focus in this chapter rests on the major chronic diseases associated with aging, including studies of risk for cardiovascular disease, stroke, cancer, diabetes, and metabolic syndrome, which is a precursor of cardiovascular disease and diabetes (Grundy et al., 2005). These diseases account for the vast majority of suffering and disability in the United States (and well over 1 million deaths in the United States each year; Murphy, Xu, & Kochanek, 2012). Further, the economic burden associated with health care costs for treating these chronic diseases—which amounts to more than three-quarters of the nation's health care spending—accounts for approximately $300 billion annually (DeVol & Bedroussian, 2007).

CHILDHOOD ADVERSITY AND LATER DISEASE: EPIDEMIOLOGICAL EVIDENCE

Mounting evidence suggests that early childhood adversity is associated with a number of chronic health problems later in life, including cardiovascular disease, diabetes, cerebrovascular disease, and even some cancers (Adler & Rehkopf, 2008; Gluckman & Hanson, 2006; Shonkoff et al., 2012). This quickly growing body of research has implicated psychosocial stress as a primary mediator of adversity's association with morbidity and mortality from chronic diseases of aging (Matthews & Gallo, 2011; Shonkoff, Boyce, & McEwen, 2009). In the sections that follow, we review epidemiological evidence for the role of early adversity in contributing to later disease. We focus mainly on the role of maltreatment and socioeconomic disadvantage, two forms of adversity that have been studied extensively in relation to later health problems. Where applicable, we review available literature documenting other forms of early adversity that have been linked to chronic diseases of aging. When possible, we selected studies that used nationally representative studies with large sample sizes, assessment of possible confounds, prospective study designs, and objective measures of health outcomes in adulthood. In some domains, these criteria could not be met within any single study, so we review available evidence and note the methodological concerns. Further, our discussion is restricted to studies that link childhood adversity to *adult* physical health. Although a growing body of research has documented links between exposure to stress in childhood and childhood disease outcomes, these studies are beyond the scope of this chapter.

Maltreatment and Later Disease

Studies of the long-lasting sequelae resulting from maltreatment in childhood have identified robust links between childhood abuse and chronic diseases of aging, including cardiovascular disease and diabetes. Evidence for these links comes from studies that focus on different forms of maltreatment, including physical abuse, sexual abuse, and neglect (e.g., Anda et al., 2006; Goodwin & Stein, 2004). The vast majority of these studies used retrospective reports about maltreatment, which presents some methodological concerns about the accuracy of the reports. Next we review a selection of studies that have examined links between maltreatment and specific disease outcomes.

Maltreatment and Cardiovascular Disease

Links between early maltreatment and cardiovascular disease are well documented (e.g., Batten, Aslan, Maciejewski, & Mazure, 2004; Dong et al., 2004; Draper et al., 2008; for meta-analytic findings, see Irish, Kobayashi, & Delahanty, 2010; Wegman & Stetler, 2009). For example, using data from the National Comorbidity Survey, Goodwin and Stein (2004) found that recalled sexual abuse in childhood was associated with increased risk for cardiovascular disease, including heart attacks. Similarly, findings from the Nurses' Health Study revealed links between women's recollections of childhood physical and sexual abuse and cardiovascular disease (Rich-Edwards et al., 2012). In this study, severe physical abuse was associated with a 46% greater risk of having a cardiovascular

event (e.g., heart attack, stroke). Similarly, sexual abuse was associated with 56% increased odds of having a cardiovascular event.

Links between maltreatment and cardiovascular disease have been found even in complex analyses that include possible alternative explanations, including adult health risk behaviors (e.g., smoking), stressors in adulthood (e.g., daily stress, low educational attainment), depression, and childhood stressors other than maltreatment (e.g., parental divorce). Even after accounting for these potential confounding variables, Fuller-Thomson, Brennenstuhl, and Frank (2010) found that recalled childhood physical abuse was associated with 45% greater likelihood of being diagnosed with heart disease. Felitti and colleagues (1998) have suggested that some of these confounding variables may serve as mediating mechanisms in the progression of heart disease (e.g., the experience of maltreatment may lead individuals to engage in unhealthy lifestyles), but the findings from many of these studies indicate that maltreatment still accounts for some of the risk for cardiovascular disease even after accounting for health behaviors, which may point to other mechanisms linking early maltreatment to cardiovascular disease.

Several investigations have identified gender-specific links between maltreatment and cardiovascular disease (e.g., Batten et al., 2004; Draper et al., 2008; Fuller-Thomson, Bejan, Hunter, Grundland, & Brennenstuhl, 2012; Goodwin & Stein, 2004). For example, Fuller-Thomson et al. (2012) found that childhood sexual abuse was associated with a greater risk for heart attacks for men but not for women. In contrast, in the National Comorbidity Survey, Goodwin and Stein (2004) and Batten et al. (2004) found connections between maltreatment and cardiovascular disease for women but not for men. Unfortunately, insufficient evidence exists currently to make broad conclusions about gender-specific risk for cardiovascular disease resulting from early maltreatment. Nevertheless, it will be important for future research to examine whether the link between maltreatment and cardiovascular disease differs for men and women. It may be that certain forms of maltreatment (e.g., sexual abuse or neglect) are associated with unique risk outcomes for men versus women.

These findings suggest that exposure to early maltreatment is linked to adult cardiovascular disease, but the studies' methodological limitations make it difficult to conclude that maltreatment *causally* contributes to heart disease. For example, these studies rely exclusively on retrospective self-reports of maltreatment (often with a single question about whether participants were ever abused or neglected), which calls into question the accuracy of the assessment due to possible memory errors or informant biases. In addition, most of these studies use participant reports about their medical diagnoses, which are less trustworthy than medical records. These study weaknesses are not easily discounted, and they limit our ability to make strong conclusions about the role of maltreatment in contributing to disease outcomes. To address these concerns, future studies will need to identify and control for factors that could give rise to spurious associations between maltreatment and subsequent cardiovascular disease (e.g., neuroticism). The use of strong methodological designs, including studies from administrative databases that can utilize objectively verified records of maltreatment and cardiovascular disease, would help assuage skepticism about the link between child maltreatment and adult cardiovascular disease.

Maltreatment and Metabolic Risk

Childhood maltreatment has been found to be predictive of diabetes and other metabolic abnormalities in adulthood (e.g., Danese et al., 2009; Felitti et al., 1998; Goodwin & Stein, 2004; Rich-Edwards et al., 2010; Thomas, Hyppönen, & Power, 2008). In recent investigations, researchers have examined a cluster of metabolic abnormalities known as the metabolic syndrome (Cornier et al., 2008; Grundy et al., 2005; previously known as Syndrome X). Metabolic syndrome is increasingly viewed as a precursor to cardiovascular disease and diabetes and reflects sedentary lifestyles and overnutrition. Its connection to potentially fatal cardiac events (e.g., heart attacks, strokes) and high prevalence in modern society (estimates suggest that around 30% of adults in the United States meet criteria for metabolic syndrome; Cornier et al., 2008) make it a promising predisease marker for individuals who have not yet developed chronic diseases.

In the first study of links between early maltreatment and diabetes, Felitti et al. (1998) found that diabetes was more prevalent when individuals reported four or more indicators of childhood risk (including maltreatment and family dysfunction). Similarly, in a community sample of women in New Zealand, Romans, Belaise, Martin, Morris, and Raffi (2002) found that childhood abuse was associated with increased diabetes prevalence. Further evidence for a link between maltreatment and metabolic risk comes from the National Comorbidity Survey (Goodwin & Stein, 2004). In this sample, recalled childhood neglect (but not physical or sexual abuse) was associated with increased odds of having diabetes. Despite variations in definitions of maltreatment (e.g., neglect versus abuse), these studies suggest that the experience of poor caregiving conditions

in childhood is a risk factor for diabetes in adulthood. Interestingly, Goodwin and Stein's (2004) findings of the specific type of maltreatment experience that was associated with metabolic risk suggests that certain types of maltreatment may be particularly influential in shaping diabetes onset.

To date, only a handful of studies have examined whether maltreatment in childhood is a predictor of prediabetes metabolic risk in adulthood, but preliminary evidence provides some support for this link. Midei, Matthews, Chang, and Bromberger (2013) examined connections among emotional, physical, and sexual abuse and the onset of metabolic syndrome in a sample of women in middle adulthood. In this study, childhood physical abuse, but not sexual or emotional abuse, was associated with the onset of metabolic syndrome over a 7-year span.

In one of the only prospective studies of maltreatment and metabolic risk, Danese et al. (2009) examined the separate predictive roles of child maltreatment, social isolation, and socioeconomic status (SES) as well as the cumulative exposure to adversity across these domains. Using the Dunedin Multidisciplinary Health and Development Study, Danese et al. grouped participants into three categories according to their exposure to maltreatment in childhood: (a) no maltreatment; (b) probable maltreatment—meaning that children experienced one out of five indicators of maltreatment; and (c) definite maltreatment, wherein children experienced two or more indicators of maltreatment. Although low SES and social isolation were independently predictive of metabolic risk, child maltreatment was not reliably associated with higher rates of metabolic risk factors. Somewhat surprisingly, adults who were categorized as "probable maltreatment" had elevated risk for metabolic abnormalities, but adults who were categorized as "definite maltreatment" were not at increased risk. This finding is particularly noteworthy, as it is the only study to our knowledge that has multiple informant ratings of maltreatment assessed when participants were children and does not rely on retrospective reports. Given that participants were still relatively young (32 years old) and healthy at the time of assessment of metabolic indicators, it is not entirely surprising that maltreatment was not a reliable risk factor for metabolic disruptions. It may be the case that maltreatment takes longer to manifest itself in metabolic disruptions that will be seen when these participants are older. Yet it is also possible that other studies that have used retrospective self-reports of maltreatment have overstated the link between early maltreatment and adult metabolic risk. Thus, although it appears that early maltreatment is a risk factor for both diabetes and prediabetes metabolic risk, additional research with multiple informants and prospective study designs will be important for shedding light on the extent to which harsh caregiving experiences and maltreatment are predictive of later metabolic disruptions.

Maltreatment and Cancer

Compared to the well-established literature that examines early maltreatment and cardiovascular disease and diabetes, much less is known about the extent to which maltreatment in childhood confers additional risk for cancer. A handful of studies have studied this link using retrospective study designs, with mixed findings (e.g., Brown et al., 2010; Draper et al., 2008; Felitti et al., 1998; Fuller-Thomson & Brennenstuhl, 2009; Morton, Schafer, & Ferraro, 2012). In the first reported examination of this link, Felitti et al. (1998) found that individuals were at increased risk for cancer when they experienced four or more adverse childhood risk factors. Similarly, in the National Survey of Midlife Development in the United States (MIDUS), Morton and colleagues (2012) examined links between childhood abuse and cancer and found that emotional and physical abuse were associated with increased risk of cancer at midlife. These links remained significant even after controlling for potential confounding variables, including age, race, SES, and health-related behaviors (e.g., smoking). Additional evidence for a link between childhood maltreatment and cancer comes from a sample of over 13,000 Canadians who took part in the Canadian Community Health Survey (Fuller-Thomson & Brennenstuhl, 2009). In this sample, recalled physical abuse was associated with 47% higher odds of cancer, even when adjusting for risk factors, such as childhood stressors, adult health behaviors, and adult SES. Morton et al. and Fuller-Thomson and Brennenstuhl (2009) relied on studies that used self-reports of abuse and cancer, which raises interpretational ambiguities, as we noted earlier. However, self-reports about cancer diagnosis may be less subject to false reports than other disease outcomes or symptom reports. Prospective studies and studies utilizing administrative databases with objective measures of maltreatment and disease diagnoses will bolster support for the notion that child maltreatment is a risk factor for adult cancer diagnosis.

Other studies, however, have not found links between early maltreatment and later cancer risk. In a sample of over 21,000 older adults, Draper et al. (2008) examined links between childhood physical and sexual abuse and adult mental and physical health outcomes. In this study, although adults who had been abused reported worse

mental and physical health, abused participants were not at greater risk for experiencing cancer in adulthood. Similarly, Korpimäki, Sumanen, Silanmäki, and Mattila (2010) did not find a link between maltreatment and cancer in a large epidemiological study in Finland. A number of factors could account for these inconsistent findings. For one, researchers vary in their definitions of maltreatment: Some studies include a range of harsh parenting indices, whereas other studies take a more explicit approach by asking participants if they had been abused as children. Moreover, there is considerable variability across studies in sample characteristics and analytical approaches (e.g., the extent to which possible confounding variables are included in statistical models, whether maltreatment is considered as a continuous or binary variable). Another difficulty is that cancer prevalence rates are lower than the rates of heart disease and diabetes, thus making it a more difficult outcome to predict. Further, cancer is a much more heterogeneous disease compared to diabetes and cardiovascular disease; this heterogeneity may explain some of the inconsistent findings, particularly if studies vary in their focus on particular cancers versus all cancer diagnoses. Additional investigation into the connections between maltreatment and cancer risk will provide insight into whether the experience of maltreatment in childhood is a risk factor for later cancer diagnosis.

Summary of Research on Early Maltreatment and Later Disease

Consistent with the notion that early exposure to adversity is linked to many of the chronic diseases of aging, preliminary evidence suggests that maltreatment in childhood may be a risk factor for poor health outcomes in adulthood. In the vast majority of these studies, however, researchers have relied on retrospective reports of maltreatment, which are subject to significant reporting biases. Moreover, these reporting biases might not be random: It is possible that individuals with poor health remember their prior experiences in negatively biased ways. Further, many of these studies use self-reports of physician diagnoses of diseases. Although we prefer these markers of physical health over informants' own symptom reports, these assessments are nevertheless vulnerable to inaccurate reports.

Additional research will be useful for shedding light on the specific contexts in which maltreatment is likely to be a serious risk for later health problems. For example, it is possible that certain forms of maltreatment are more likely to contribute to health problems for women but not for men, or for people from particular racial or ethnic backgrounds. Another lingering question concerns the relative weight of various forms of maltreatment in the progression of long-term health problems: Do all forms of maltreatment pose risk for health problems, or are certain forms of abuse or neglect especially likely to have a negative effect on later physical health? Moreover, the experience of a particular type of maltreatment (e.g., physical abuse) and its impact on later health may depend, in part, on the cultural context in which it occurs. For example, in cultures that condone corporal punishment, links between childhood physical abuse and later health may be less identifiable. These research questions await empirical examination.

Socioeconomic Disadvantage and Later Disease

The literature on the role of childhood socioeconomic disadvantage in shaping risk for later disease and mortality risk is extensive and suggests that, like early maltreatment, it is a risk for poor health outcomes in adulthood. In particular, low SES in childhood is a risk factor for early mortality, cardiovascular disease, diabetes, and some cancers (Cohen, Janicki-Deverts, Chen, & Matthews, 2010; Galobardes, Lynch, & Smith, 2004, 2008; Kumari, Head, & Marmot, 2004).

When studying the long-term health outcomes associated with childhood socioeconomic disadvantage, an important factor to consider is that SES tends to be stable across the lifespan (Hertzman, 1999). Such stability makes attempts to disentangle the effects of early versus adult SES on health particularly difficult. Given that adult SES is a robust predictor of morbidity and mortality from chronic diseases of aging (Adler & Rehkopf, 2008; Lynch & Smith, 2005), many studies of early childhood SES statistically control for adult SES in analyses, thus allowing for better insight into the role that early-life experiences play in influencing the risk for later disease. In order to avoid multicollinearity issues associated with highly stable childhood and adult SES estimates, recently researchers have developed statistical modeling techniques to better account for early and adult SES (e.g., Nandi, Glymour, Kawachi, & VanderWeele, 2012).

Socioeconomic Disadvantage and Cardiovascular Disease

In their systematic review of the literature on SES and cardiovascular disease, Galobardes, Smith, and Lynch (2006) concluded that low SES in childhood is a significant risk for cardiovascular disease in adulthood. Even when adult SES was controlled in statistical analyses, the link between childhood SES and disease risk was still significant, accounting for 20% to 40% of the risk for cardiovascular

disease. In a large-scale investigation of socioeconomic disadvantage and cardiovascular disease, Claussen, Smith, and Thelle (2003) found that cardiovascular disease-related mortality was associated with childhood SES. Similarly, researchers found evidence for the role of early socioeconomic disadvantage in predicting cardiovascular disease in the British Whitehall II study (Singh-Manoux, Ferrie, Chandola, & Marmot, 2004). Another study tracked the onset of coronary heart disease over a period of 40 years in a sample of physicians who graduated from medical school at Johns Hopkins University (Kittleson et al., 2006). Even among these educated, affluent physicians, childhood adversity was associated with worse health in adulthood. The rates of cardiovascular disease by age 50 were 2.4 times higher in physicians who were raised in households that were low versus high in SES. These findings offer dramatic evidence in support of a link between socioeconomic disadvantage and cardiovascular disease.

Socioeconomic Disadvantage and Metabolic Risk

A number of studies have examined the role of early socioeconomic disadvantage and risk for metabolic abnormalities, including the metabolic syndrome and diabetes (e.g., Agardh et al., 2007; Brunner et al., 1997; Kumari et al., 2004; Parker et al., 2003). Support for this link has been somewhat mixed, although the majority of studies have found at least some evidence of a link between early low socioeconomic standing and greater risk for metabolic disruptions later in life. For example, in the British Whitehall II Study, Kumari and colleagues (2004) found that low SES predicted higher incidence of diabetes relative to individuals with higher social standing. Using the same sample, Brunner and colleagues (1997) identified a link between SES and the metabolic syndrome. Similarly, in the Panel Study of Income Dynamics, a nationally representative prospective longitudinal study in the United States, Johnson and Schoeni (2011) found that poverty in childhood was predictive of diabetes almost 40 years later.

In one of the few prospective studies of socioeconomic disadvantage and metabolic risk, Melchior, Moffitt, Milne, Poulton, and Caspi (2007) found that low SES in childhood was associated with a cluster of risk factors at age 32 (e.g., elevated blood pressure, adiposity, glycated hemoglobin). This finding remained significant, even when accounting for familial liability, childhood IQ, adolescent health behaviors, and adult SES.

Recently researchers have incorporated sophisticated analytical techniques to separate the effects of early versus adult SES in the prediction of metabolic disorders. Using prospective data from the Health and Retirement Study, Nandi et al. (2012) used marginal structural models, a statistical approach that allowed them to estimate (a) the direct effect of early SES, (b) the direct effect of adult SES, (c) effects of early SES that are mediated by risk factors (e.g., blood pressure, smoking, alcohol consumption), and (d) the effect of early SES that is mediated by adult SES (referred to as a social trajectories model). By separately estimating these effects, Nandi and colleagues were able to test the relative contributions of early and adult SES on adult diabetes. Using this modeling approach, Nandi et al. found that early-life SES was associated with adult diabetes—an effect that was not accounted for by adult SES. Interestingly, when Nandi et al. used traditional regression analyses to compare the role of early and adult SES on later diabetes, the effects of early status were largely attenuated by adult SES. In other words, comparison of the findings across the two statistical strategies suggests that studies that employ commonly used regression-based approaches for estimating effects (e.g., Agardh et al., 2007) may have significantly underestimated the effects of early-life SES. Future studies should take advantage of these advancements in analytic techniques in order to more accurately estimate the relative contributions of childhood and adult risk factors.

Although these studies offer convincing evidence for a link between low SES and metabolic abnormalities, recent evidence suggests that certain protective factors might play an important role in buffering children from the deleterious effects of early-life adversity. For example, low SES in childhood was associated with higher prevalence of metabolic syndrome at midlife in the MIDUS sample (Miller, Lachman, et al., 2011). However, for individuals who recalled high levels of maternal support, low SES was not associated with metabolic syndrome at midlife. Interestingly, this pattern was not explained by upward social mobility, suggesting that maternal nurturance, and not the addition of material resources, served as a buffer against low SES. These findings are encouraging, as they suggest that early adverse experiences might be offset by protective factors; continued examination of protective factors will be an important area for future research.

Socioeconomic Disadvantage and Cancer

A small but growing body of evidence suggests that early-life socioeconomic disadvantage may play a role in the development of cancer in adulthood (e.g., Lawlor, Sterne, Tynelius, Smith, & Rasmussen, 2006; Power, Hyppönen, & Smith, 2005; Pudrovska, Anishkin, & Shen, 2012). In the Wisconsin Longitudinal Study, which prospectively studied individuals over the course of 50 years, low early-life

SES was associated with breast cancer. Similarly, in a prospective study of women in Great Britain (Power et al., 2005), trend-level associations between childhood social class and lung and stomach cancers emerged, even after controlling for health behaviors and adult social class. Additional research will be important to add further insight into the extent to which low SES in childhood is a predictor of cancer diagnosis in adulthood.

Summary of Research on Early Socioeconomic Disadvantage and Later Disease

The studies of socioeconomic disadvantage on later health outcomes have notable strengths compared with the maltreatment literature. They make use of large and representative samples across countries, use prospective designs, often have objective indicators of SES, and measure outcomes through medical records and health care databases (rather than self-report measures). Many of these studies control for plausible alternative differences in lifestyle factors, such as smoking, diet and exercise, and adiposity. The consistency of findings across countries suggests some universalism in the phenomenon and makes it unlikely that culture-specific factors (e.g., class-related differences in access to health care) are driving the findings.

Despite these more rigorous study designs, the literature linking early SES with adult physical health has some weaknesses that complicate interpretation and conclusion. For instance, these studies largely make use of observational data, which is understandable, given that individuals cannot be randomly assigned into poor environmental conditions. Further, the possibility remains that the observed links are due to unmeasured confounds, such as a common genetic liability that predisposes offspring to low SES and poor health. An additional limitation is that most of the studies are not fully longitudinal in that they do not assess childhood health during exposure to low SES (Cohen et al., 2010). Given that many of these disease endpoints (e.g., cardiovascular disease, stroke) are not observed in young children, assessment of the same health measures would not add incremental value to the study designs. Nonetheless, assessment of general physical health would help address the possibility that poor children start out life sicker than more affluent children, affecting both their parents' earning potential and their own long-term health.

A handful of studies have capitalized on naturally occurring fluctuations in societal economic conditions to examine the impact of early-life resources on later physical health outcomes (e.g., van den Berg, Doblhammer, & Christensen, 2009; van den Berg, Doblhammer-Reiter, & Christensen, 2011). One advantage of these naturalistic experiments is that researchers can be fairly confident that a genetic liability is unlikely to be the cause of any observed connections between the adverse experience and physical health outcomes. Further, these studies still can be useful in documenting links between adverse experiences and later health problems, particularly when there are children from the same cohort who were not directly affected by the event (e.g., Heijmans et al., 2008). Moreover, given that the unusual event is due to random and external forces, these studies minimize the likelihood that unknown spurious factors (e.g., personality traits) explain the link between early exposure to adversity and later physical health problems.

For instance, children who were born under adverse economic conditions in Denmark between 1873 and 1906 had higher mortality rates from cardiovascular disease than their peers who were born during more prosperous economic cycles (van den Berg et al., 2011). Further, van den Berg and colleagues (2011) reported that individuals who were born during a recession (and survived until at least age 40) lived, on average, *11 months* less than other individuals born during an economically prosperous time, providing evidence that economic circumstances early in life may have a lasting effect on health outcomes.

Not all studies of fluctuating economic conditions and long-term physical health have found support for this hypothesis, however. Cutler, Miller, and Norton (2007) did not find evidence of a link between economic fluctuations and physical health outcomes later in life in a sample of Americans who were born during the Great Depression. The detailed analysis of the Danish sample might shed light on why links between early-life economic circumstances and long-term health were not found in the U.S. study. In Denmark, the negative impact of economic adversity varied as a function of the community size: It was substantially less dramatic in major cities, such as Copenhagen, relative to smaller towns, where fewer resources were available. Similarly, individuals who lived in rural areas—with smaller communities of individuals who might take a more proactive approach to caring for each other—were similarly less affected than individuals who lived in midsize towns. It may be that a lack of early-life economic resources can be offset by community-level support systems, just as early-life socioeconomic adversity within the family appears to be mitigated by maternal support (e.g., Miller, Lachman, et al., 2011). Cutler et al. (2007) did not examine whether the link between early economic adversity and adult health varied based on the degree of urbanization in U.S.

communities, which may have obscured these possible community effects.

Other Forms of Adversity and Later Disease

To date, the epidemiological literature has provided some evidence that maltreatment and socioeconomic disadvantage may set the stage for a range of health problems in adulthood. Much less is known, however, about the extent to which other forms of adversity in childhood are risk factors for chronic diseases in adulthood. Of course, maltreatment and socioeconomic disadvantage are not the only forms of adversity that many children face that may shape the course of their long-term health trajectories. Next we briefly review evidence from several studies that have identified connections between other childhood adversities and later health outcomes. We note that these findings should be viewed as preliminary and will require further investigation in large, representative samples.

Parental Death and Later Disease

The death of a parent—resulting in the loss of an attachment figure—is widely regarded to be a profound stressor for children (e.g., Bowlby, 1980; Luecken & Roubinov, 2012). Studies have documented the risk for immediate and long-term mental health problems following parental death (e.g., Kivelä, Luukinen, Koski, Viramo, & Kimmo, 1998), but only recently have investigations studied the physical health consequences associated with parental loss in childhood. In an epidemiological study of women, Jacobs and Bovasso (2000) found that women who experienced the death of their mother in childhood were at increased risk for breast cancer. In another study, Krause (1998) examined early parental loss as well as recent life stressors in a national study of older adults. Although early parental loss alone was not associated with later disease, the interaction between parental loss and *current* stress levels predicted self-reported health and reports of acute conditions, including cancer, diabetes, and cardiovascular disease. In this case, the loss of a parent served as a vulnerability factor, and the addition of a current stressor increased the likelihood that individuals would have poor health outcomes. As we discuss in the next section, diathesis–stress models can add insight into links between early adversity and physical health, and they can shed light on specific contexts (e.g., stressful periods of life) and specific individuals (e.g., those who lost a parent in childhood) who might be especially prone to early onset of disease. Other studies, however, have not found links between early parental loss and later physical health (e.g., Maier & Lachman, 2000). When main effects do not emerge, it may be informative to examine whether there might be moderating factors that specify which individuals are most at risk, as Krause (1998) found.

Interparental Violence and Later Disease

To date, most studies examining the aftereffects of interparental violence on children's long-term outcomes have focused on emotional and behavioral problems (e.g., Hammen, Henry, & Daley, 2000), and little is known about how these early experiences might be associated with long-term physical health problems. The large-scale Adverse Childhood Experiences study (Felitti et al., 1998) included interparental violence in the cumulative risk assessment for adverse childhood experiences, but they did not examine the unique role that interparental violence played in contributing to long-term physical health problems. Several studies have reported links between individuals' exposure to interparental violence as children and self-rated health problems in adulthood. In a large-scale European sample of adults (Roustit et al., 2011), the odds of having poor self-reported physical health were 2.3 times greater if participants reported exposure to interparental violence in childhood. This preliminary evidence suggests that exposure to interparental violence in childhood may be a risk factor for the early onset of disease in adulthood, but additional research is needed to better understand the role of interparental violence in contributing to later disease. Further, studies that incorporate disease diagnosis rather than self-reports of health will be helpful for establishing support for a link between intimate partner violence and chronic disease.

Evidence from the study of children's short-term health outcomes associated with exposure to severe interparental conflict adds support to the idea that interparental violence may also be a risk factor for chronic health problems in adulthood (see Troxel & Matthews, 2004, for a review). Like much of the research on links between maltreatment and later physical health, this literature relies heavily on cross-sectional study designs and self-reports of physical health. Nevertheless, the evidence is compelling enough to warrant further examination of the role of interparental conflict in violence in contributing to long-term physical health problems later in life.

Extended Parental Absence and Later Disease

Some children encounter periods when their parents are absent for an extended period of time (e.g., military families where parents are deployed, families where a parent is imprisoned). Such long-term separations from

parents in childhood have been associated with long-term mental health problems, such as depression (Pesonen et al., 2007). Less is known about how these extended separations might be linked to later disease outcomes. Some naturalistic evidence from World War II suggests that long-term parental separation may be associated with physiological stress activity in late adulthood (Pesonen et al., 2010). During World War II, approximately 70,000 children were separated from their parents and sent to live in foster care to escape the dangers of war. Many of these children were separated from their parents for several years. Pesonen and colleagues (2010) found that adults who had been separated from both parents as children had higher average salivary cortisol and greater salivary cortisol reactivity during a laboratory stress task relative to adults who had not experienced long-term parental separation in childhood. Given the large numbers of children who experience lengthy parental separations due to ongoing military deployments and divorce, there is a need to examine what impact, if any, such disruptions in the parent-child relationship will have on long-term health outcomes.

Natural Disasters and Later Disease

Natural disasters, including hurricanes, tsunamis, tornadoes, earthquakes, and drought, result in dramatic disruptions to daily life. These disruptions range in severity from temporary setbacks to major transformations, including displacement and loss of one's home, inadequate access to food and other basic necessities, and uncertainty about the future. In some ways, natural disasters differ from exposure to some of the other adversities that have been a focus of this chapter, in that the cause of the distress is often not traceable back to poor parental care or disparities in resources. At the same time, however, the aftereffects that could result from living through a natural disaster may resemble the consequences of stressors that co-occur with poverty and maltreatment.

Several studies have documented the ways in which physical health can be affected in the short term by exposure to natural disasters. For example, in 1995, Japan experienced a 6.8-magnitude earthquake near Kobe, resulting in the loss of over 6,000 lives and leaving over 300,000 homeless. Following this disaster, there was a threefold increase in heart attacks and twofold increase in strokes, particularly for individuals who lived close to the epicenter (Kario, McEwen, & Pickering, 2003). These findings offer compelling evidence suggesting that natural disasters create enormous stress for individuals that might have serious health implications. To date, however, evidence for the long-term health impacts for individuals who endured natural disasters as children has been lacking. Further, although evidence suggests that children experience physical health problems in the months following a natural disaster (Datar, Liu, Linnemayr, & Stecher, 2013), the long-term effects of these stressful experiences still are largely unknown.

War and Later Disease

The immediate effects of war cause significant stress on children and their families. Children may face daily threats of violence, loss of loved ones, and fears about the future. In some cases, the effects of war have long-ranging influences on daily life, including reduced access to resources and basic necessities. For example, during World War II, a German blockade cut off the food supply to a large area of the Netherlands during the winter of 1944–1945. This tragic event provided the rare opportunity to examine the connection between starvation during pregnancy and long-term health outcomes of offspring affected by the war-induced famine (de Rooij, Wouters, Yonker, Painter, & Roseboom, 2010). Exposure to famine and malnutrition prenatally has been linked to Type 2 diabetes, cardiovascular disease risk, other metabolic abnormalities, and even breast cancer in adulthood (Barker & Clark, 1997; de Rooij et al., 2010; Painter et al., 2006; Painter, Roseboom, & Bleker, 2005; Rich-Edwards et al., 1999).

Findings from survivors of World War II suggest that exposure to wartime stressors may be associated with elevated rates of cancer. In one study, cancer rates were elevated in European-born immigrants who immigrated to Israel before or during the war (Keinan-Boker, Vin-Raviv, Liphshitz, Linn, & Barchana, 2009). The largest effects emerged for people born between 1940 and 1945, who would have been exposed to horrific conditions before age 5. Their cancer risk was elevated 3.5-fold relative to same-aged immigrants who arrived in Israel before the war.

Like the experience of socioeconomic disadvantage and maltreatment, these adversities described are likely to expose children to chronic, stressful circumstances, with lingering threats of repeated exposure to the stressor (e.g., lasting concerns of repeated interparental violence) and aftereffects resulting from the stressor (e.g., loss of all resources as a result of a natural disaster). To date, these adversities have not been examined extensively in relation to long-term health outcomes. As we develop a better understanding of the ways in which early adversity predicts later health outcomes, it will be important to understand the characteristics and contexts of early adversity that are most likely to contribute to poor health. Increased

specificity about the types of adversities that influence health will help researchers and policymakers focus efforts on mitigating the risks that are most likely to contribute to chronic disease.

Limitations and Alternative Explanations

Although the evidence linking early adversity to physical health is provocative, there are a number of weaknesses to this research that preclude a definitive interpretation. For example, many of the studies rely on one-time assessments, during which early stress and later health are measured via retrospective self-report. Understandably, this methodology raises concerns about the reliability of reporting, which would be particularly problematic if reporters are systematically biased in their assessments of early adversity and adult health. Some evidence suggests, however, that adults underreport negative experiences from childhood (Dill, Chu, Grob, & Eisen, 1991). Another concern is that these studies may reflect differences in the *reporting* of health problems as a function of early adversity, rather than real differences in the manifestation of disease. Notably, however, many studies—particularly studies linking socioeconomic disadvantage to later health outcomes—utilize medical records and physician diagnoses, thereby eliminating informant bias in symptom reports (e.g., Felitti et al., 1998; Rich-Edwards et al., 2012).

Yet another possibility is that genetic confounds might play a large role in creating the observed connections between early adversity and physical health. For example, there could be a familial genetic liability that contributes to abusive parenting and disease vulnerability. Or it could be the case that the direction of effects is wrong. For instance, a sick child can accumulate enormous medical bills, not to mention chronic stress on caregivers and other family members. The net effects of expensive medical care and lost earnings due to time spent caring for sick children might result in low SES in adulthood. A handful of studies have controlled for child sickness (e.g., Caspi et al., 2002), but this practice needs to be adopted more widely before we can definitively rule out this alternative explanation.

Using Animal Studies to Supplement Epidemiological Evidence

In light of the fact that it would be unethical and impractical to experimentally manipulate early human experiences or exposure to pathogens in adulthood, it is difficult and perhaps impossible to evaluate whether early adversity causally influences adult disease in humans. However, studies of this nature can be done with animals, and it is useful to consider how these studies have informed our understanding of connections between early adversity and adult physical health. In this section, we describe some of the findings that have emerged from experimental studies with animals that bolster support for the findings from epidemiological studies with humans.

Evidence from studies using experimental manipulations with animals suggests a causal link between early adversity and health outcomes. Animal models often provide good mechanistic evidence relating psychosocial risk factors to physical health. Unlike humans, animals can be randomly assigned to psychologically difficult circumstances and monitored over time to determine whether these stressful experiences influence disease outcomes. Further, questions about the effects of the relative timing of adverse experiences (e.g., early infancy versus later childhood) can be addressed by manipulating the onset of the stressor and examining differences in later health consequences associated with these timing differences. Often findings from animal studies converge with correlational evidence from human epidemiologic research.

Hofer's (2002) observations that rat pups responded with significant distress when separated from their mothers—similar to distress signals in humans—raised questions about the mechanisms of separation distress in nonhuman mammals. To explore this question, Hofer conducted a series of experiments to identify what physiological subsystems become disrupted when mothers were removed from their pups (for a review, see Hofer, 2002). These studies revealed a number of hidden regulators that no longer functioned properly if rat pups were separated from their mothers. Hofer found that when rat pups were removed from their mothers, they showed a dramatic decline in multiple physiological and behavioral systems, such as those controlling heart rate, body temperature, food intake, movement, and exploratory behavior. Hofer argued that maternal separation resulted in the removal of the important regulatory functions that the mother serves for her offspring, and the absence of these regulatory components resulted in rat pups' visible behavioral distress. These studies led Hofer to conclude that mother-infant interactions have embedded within them a number of vital physiological regulatory functions that are negatively affected by separation from maternal care.

In this regard, animal studies have some parallels to the experiences of children in poverty or unsupportive caregiving environments. On the whole, children exposed to these stressors receive less sensory, cognitive, and emotional stimulation and are more likely to be deprived of basic necessities, such as food and heat, than children growing up

without extreme adversity (e.g., Evans, 2004). That said, it is difficult to know how closely these deprivation studies in animals actually resemble human experience. Permanent maternal separation and extreme sensory deprivation are relatively uncommon in humans, even in families where maltreatment and disadvantage are present. At best, what these animal studies model is extreme and unusual human stress. Species differences in developmental growth are another major challenge in translating conclusions from animal studies to meaningful information for human development. At the time of birth, rodents are much less mature than humans. As a result, their physiology may need external regulation by caregivers in a manner that is not comparable to full-term human newborns.

These caveats aside, a number of studies indicate that premature separation can have long-term effects on animals' susceptibility to disease. In one study, mice pups were separated from their mothers for 6 hours a day over the first 2 weeks of life (Avitsur, Hunzeker, & Sheridan, 2006). As adults, the mice were challenged with intranasal exposure to an influenza virus. Compared to controls that remained with their mothers until weaning, the separated mice had greater viral replication and worse symptoms of infection, which was a result of an overly aggressive inflammatory response to the virus. Moreover, the proinflammatory response was present 9 days after the infection, a time when viral particles had declined to the point of being almost undetectable. These findings suggest that early stress calibrated the immune system to mount overly aggressive and extended inflammatory responses to the virus.

In another study, rats endured a stressful situation at 100 days of life (corresponding to early adulthood in humans). In order to obtain food and drink over a 4-day period, rats incurred electric shocks (Ader, Tatum, & Beels, 1960). Nearly all of the rats developed gastric ulcers following this stressful experience. However, the density of these ulcers was fivefold greater in rats that had been prematurely separated from their mothers at 15 days of life. In a follow-up study, a third group was added to evaluate whether nutritional disparities accounted for the health effects of the maternal separation manipulation. To test this hypothesis, rat mothers were removed from her offspring at 15 days, had their nipples cauterized to prevent nursing, and then were returned until 21 days. The median number of ulcers in this group was similar to the control condition. Because both groups in which the mother remained present had significantly fewer ulcers than the prematurely separated and weaned rats, these findings suggest that the effects were due to the absence of maternal nurturance rather than nutritional deficiencies per se (Ader, 1962).

There also has been mounting interest in early-life influences on asthma in animal models. In one study, mice were randomized into one of three conditions: In one condition, they received regular footshocks for 1hr on 3 days during the fourth week of life; in another condition, mice watched and heard other mice undergo this experience but were not shocked themselves; and in the third condition, the mice were undisturbed in their home cages (Chida, Sudo, Sonoda, Hiramoto, & Kubo, 2007). When the mice reached young adulthood (at 8–10 weeks of life), they were sensitized to ovalbumin, a protein in eggs that causes allergic reactions. At 11 weeks, all mice were given airway challenges with ovalbumin. Relative to controls, those mice that received or observed footshocks showed greater airway inflammation and more bronchial reactivity to the challenge. Similar patterns were observed in another study of rats that, over the first month of life, were either separated from their mothers daily for 2 hours and then reunited or remained undisturbed in their home cages (Kruschinski et al., 2008). When the rats were adults, asthma was induced by sensitizing subjects to ovalbumin, and airway tissue was collected. Analyses revealed striking differences. Adult rats that had been repeatedly separated from their mothers early in life showed more severe airway pathology than adult controls, with increased numbers of eosinophils, T-cells, and other proinflammatory mediators found in their lungs upon dissection.

Summary

Collectively, these studies provide evidence to support the notion that early adversity has long-term effects on physical health. To be sure, more work needs to be done to definitively rule out alternative explanations and clarify what the associations reflect in terms of underlying pathophysiology. But the weight of the evidence, from observational data and natural experiments in humans and randomized studies in animal models, leads us to conclude that there is evidence indicative of a causal effect. With that said, increased precision in the definition and assessment of early adversity and adult health will aid in our understanding of how and under what conditions early adversity leads to later health problems. This increased specificity in measurement will provide insight into what characteristics and contexts of early adversity prove to be most detrimental for physical health outcomes. Further, increased attention to whether there are protective factors that can mitigate the risk associated with early adversity and what mechanisms put people on a trajectory from

early adversity to poor health across development will be an important direction for future research.

CONCEPTUAL MODELS LINKING CHILDHOOD ADVERSITY TO ADULT PHYSICAL HEALTH

Researchers have long recognized that no single risk factor can account for all chronic diseases of aging, and research on the early origins of adult physical health outcomes has supported the notion that there are multiple pathways linking early experience to adult disease (e.g., Felitti et al., 1998; Miller et al., 2011; Taylor, Repetti, & Seeman, 1997). Yet to date, much research on the experience of early adversity and adult health has explored risk factors in isolation without consideration of the broader context in which the risk factors occur. Moreover, despite an interest in the impact of early adverse experiences on later health, existing studies have not thoroughly examined the relative timing of adverse experiences. Evidence from other areas of developmental research suggests that meaningful critical and sensitive periods constrain the impact of early experience on later outcomes (e.g., Knudsen, 2004), and it stands to reason that similar sensitive periods may constrain the impact of early adversity on long-term physical health outcomes as well.

Given that chronic disease is a multiply determined phenomenon, it is useful to clarify the complex pathways from childhood adversity to adult physical health by testing larger conceptual models that integrate multiple risks across multiple time points. In this section, we review several theoretical models that can be used to guide the investigations of connections between early-life adversity and adult physical health. Many of these models take into account the notion that multiple factors contribute to physical health outcomes; further, these models describe processes through which intervening factors (e.g., buffers, vulnerability factors) can alter individuals' health trajectories over time, leading to endpoints that may not have been expected, given individuals' starting points. These models provide a foundation for clear, testable hypotheses about the processes through which early adversity contributes to disease risk.

Cumulative Models

In contrast to models that examine a single risk factor in isolation, cumulative risk models provide a testable framework for studying how risk factors operate in the context of other risk factors to influence later health outcomes. Cumulative models of risk focus on the accumulation of risk factors and on how an increase in the number of risk factors an individual is exposed to might translate into an increase in risk for poor functioning (Sameroff, 2000). In other words, cumulative models predict that as the number of risk factors increases, there is an increase in the likelihood of poor outcomes. Two types of cumulative risk models, described next, offer variations in the hypotheses about how the presence of additional risk factors might be associated with poor physical health outcomes in adulthood.

Linear Risk Models

One type of cumulative risk model is a *linear* model, which emphasizes that each increase in early risk is associated with significantly greater risk for later disease. Two key assumptions go along with this model. First, one must assume that each adverse experience conveys more or less equal risk in shaping health. Linear models do not place any weight on the *relative severity* of risk factors. Instead of focusing on the characteristics of the risks, linear models focus on the *quantity* of risk factors. The second assumption of this model is that the various adverse experiences are nonredundant in their ability to predict later health. In other words, each risk factor creates additional strain or burden on individuals in a way that leads to worse health in adulthood. Although some early adverse experiences, such as neglect and poverty, may lead to the same specific deficit in access to resources (e.g., poor or neglected children may struggle to receive adequate food and health care), according to a linear risk model, an individual who is poor *and* neglected would have worse health outcomes than an individual who is poor but *not* neglected.

Support for a linear risk model comes from a recent study by Evans and Kim (2012), who examined the role of cumulative risk exposure as a predictor of markers of physiological wear and tear (i.e., allostatic load, a biological marker described in more detail in the next section). In this study, researchers created an index of cumulative risk exposure score by summing across items about physical risk (e.g., noise, housing problems) and psychosocial risk (e.g., violence in the home). Evans and Kim found that cumulative risk exposure at age 13 was a predictor of allostatic load at age 17. These findings are particularly notable because the markers of wear and tear (including measures of endocrine, cardiovascular, and metabolic functioning) were measured while participants were still young (i.e., during adolescence), so it will be important to examine whether cumulative risk exposure predicts individuals' accelerated aging and chronic disease later in life.

Threshold Risk Models

Threshold risk models, like linear risk models, focus on the number of risk factors present. Unlike linear risk models, however, threshold models predict that only after people experience a certain number of adverse experiences will their risk for poor health increase. Once people pass this threshold, they are likely to experience health problems. In this way, threshold models allow for the experience of some adversity without necessitating that each exposure to stress must lead to later health problems, as is the case in linear models. In other words, for every health outcome, there is some tipping point at which early adversity poses a serious risk for poor health. Moreover, at this tipping point, risk factors may have synergistic properties, such that the combined effect of the risk factors is much worse than the sum of each risk factor in isolation.

Some of the best evidence for threshold risk models comes from the Adverse Childhood Experiences study, which examined over 9,000 individuals who were enrolled in a large insurance health maintenance organization (Felitti et al., 1998). Participants completed self-report assessments about 17 adverse experiences that may have occurred in childhood, including abuse, violence, and parental mental illness. These experiences were categorized into seven domains of adversity, and participants received a total score indicating the total number of domains in which they were exposed to risk. This cumulative risk score was then used to predict physician-diagnosed diseases. As predicted, early adversity was associated with heart disease, cancer, and strokes. Interestingly, however, individuals were at increased risk for these diseases only when they reported four or more adverse experiences. When participants reported three or fewer adverse experiences, they were not at increased risk for these diseases.

Notably, in many studies, adverse experiences cluster together more than one would expect by chance (Crouch et al., 2000). This pattern of clustered risks may explain some of the observed threshold findings. For example, one risk in isolation might reflect circumstances that are beyond the control of caregivers (e.g., single parents in poverty may have limited abilities to raise their social status). Children who experience poverty but not maltreatment, parental psychopathology, or other serious risks may grow up in an environment that is lacking in material resources but otherwise stable and conducive to healthy development. These children may in fact be shielded from some of the most toxic aspects of poverty. Despite their economically stressed conditions, they would have access to a supportive caregiver who is reliable and responsive to their needs. In contrast, children who are exposed to many adverse experiences might endure chaotic, unsupportive family contexts that are ill-equipped to meet the needs of growing children. For these children, who face a multitude of risks, it is quite possible that their total exposure to stress is well beyond the sum of each stress alone; such multiplicative effects can be identified with threshold models.

In summary, both linear and threshold cumulative models offer a heuristic for explaining the role of early adversity in shaping later health. These models suggest that risk is best captured at the level of total exposure to risk, with the general framework that greater exposure to adversity will translate to more physical health problems in adulthood. These models do not differentiate between different *domains* of risk exposure (e.g., abuse from primary caregivers, neighborhood violence, access to resources); instead, these models posit that adverse experiences across domains will exert a negative influence on long-term health outcomes. In addition, these models typically do not take into account the timing of exposure to adversity, which limits researchers' ability to examine whether there are sensitive periods in which the experience of early adversity is most likely to translate into health problems in adulthood. Further, cumulative models explicitly ignore the relative severity of risk factors; as such, these models can be viewed as relatively crude approaches to defining risk. Yet despite this somewhat unsophisticated approach to quantifying adversity, many researchers have found strong evidence for cumulative risk models in the prediction of chronic disease outcomes in adulthood.

Diathesis–Stress Models

One question of great interest to developmental psychopathologists focuses on why some individuals seem to be at greater risk than others for poor functioning (Shonkoff & Phillips, 2000). One popular approach to answering this question is through testing of diathesis–stress models (e.g., Ingram & Luxton, 2005). In these models, a particular risk factor (e.g., poverty) is associated with poor outcomes only for individuals who have some sort of vulnerability, which might include a genetic risk factor, temperamental quality, or other personality characteristic. These vulnerability factors increase individuals' susceptibility to the negative effects of adversity. This model can be useful in examining connections between early exposure to adversity and adult health by focusing on whether there are specific individuals for whom stressors might be most likely to lead to poor health outcomes as a result of their early experiences.

To date, most diathesis–stress studies of vulnerability to early adversity have focused on adult mental health outcomes (e.g., Moffitt, Caspi, & Rutter, 2006). Recent evidence suggests that diathesis–stress models will be useful in future examinations of the links between early adversity and physical health. Brody and colleagues (2013) examined the family emotional climate in early adolescence and two gene polymorphisms (the short allele of the 5-HTTLPR gene and 7+ repeat of DRD4) as predictors of allostatic load in early adulthood. These two genetic polymorphisms were of particular interest because they have been suggested to confer sensitivity to family environments (e.g., Bakermans-Kranenberg & van IJzendoorn, 2011; Belsky, Bakermans-Kranenberg, & van IJzendoorn, 2007). Brody et al. found that individuals who had the short allele for 5-HTTLPR and 7R allele for DRD4 and who were exposed to less supportive family environments had greater allostatic load (a composite measure that included body mass index (BMI), blood pressure, and neuroendocrine functioning) relative to individuals without both "sensitivity" alleles. Individuals with these same alleles but living in supportive family environments did not have elevated allostatic load. Further, the quality of the family environment was not directly associated with allostatic load. These findings are provocative in suggesting more nuanced ways that family experiences might confer risk for allostatic load for certain individuals with particular genetic vulnerabilities. This line of research is still in its infancy; additional work is needed to better understand what vulnerability factors (e.g., genetic liabilities, temperament) best identify individuals for whom early adversity is most likely to be associated with poor health in adulthood.

Differential Susceptibility

In contrast to diathesis–stress models, models of differential susceptibility posit that vulnerability sources actually are better viewed as *plasticity* factors that magnify the risk for poor outcomes in adverse conditions and amplify the likelihood of positive outcomes in more supportive environments (Belsky, 1997; Belsky et al., 2007; Ellis, Boyce, Belsky, Bakermans-Kranenberg, & van IJzendoorn, 2011). Theories of differential susceptibility, including Belsky's (2005) differential susceptibility theory and Boyce and Ellis's (2005) biological sensitivity to context theory, are similar to diathesis–stress models in that they predict that certain individuals with particular characteristics (e.g., genetic predispositions, temperaments) will be more negatively affected by unsupportive environments relative to other individuals who have different genetic or temperamental characteristics. At the same time, however, differential susceptibility models assert that the traits that put some individuals at risk for exponentially worse outcomes also predispose the same individuals to better-than-expected outcomes given supportive contexts, leading researchers to argue that these individuals are both "for better and for worse," depending on their environment (Belsky et al., 2007, p. 300). Like diathesis–stress models, differential susceptibility models may be useful as a way of documenting why some individuals are more adversely affected than others by exposure to harsh conditions in early life. Differential susceptibility models take this idea a step further, however, by suggesting that the same individuals who flounder in adverse conditions may be ones who would thrive in more supportive contexts.

Evidence for differential susceptibility has been found for the prediction of a variety of outcomes, including mental health and behavior (for a review, see Belsky & Pluess, 2009), but to our knowledge, no evidence has been documented for differential susceptibility in studies of early adversity and adult physical health. Notably, however, it was Boyce et al.'s (1995) observations of children's illness rates that motivated the theory of biological sensitivity to context. In this study, highly reactive children had the *lowest* rates of illness in supportive environments and the *highest* rates of illness in unsupportive environments. Thus, it seems reasonable to predict that similar models of differential susceptibility will be evident in the study of early adversity and adult physical health.

Buffering Models

Similar to diathesis–stress models, buffering models help clarify the specific contexts in which risk factors are associated with poor outcomes. The main difference, however, is that buffering models uncover *protective* factors that can help mitigate the negative effects associated with early risk (e.g., Chen Miller, Kobor, & Cole, 2011; Miller, Lachman, et al., 2011). These models offer great starting points for the development of interventions; once a protective factor has been identified, interventions can target this domain with the goal of minimizing the negative outcomes associated with risk.

For example, as mentioned earlier in this chapter, Miller and colleagues (2011) examined the connection between early SES and metabolic syndrome at midlife and found that maternal care served as a buffer, such that individuals from poor backgrounds who experienced high levels of maternal nurturance were not at risk for metabolic syndrome. Given that many of the early

adversities that children face are difficult to resolve quickly (e.g., poverty is a chronic and pervasive form of adversity), efforts to uncover buffers that can lessen the negative impact of adverse experiences may prove to be particularly instrumental from a public health perspective.

Developmental Trajectory Models

One of the core themes of development is the notion that individual differences exist across development (Shonkoff & Phillips, 2000). Waddington (1957) argued that early in development, organisms have a range of possible developmental pathways (what Waddington called the epigenetic landscape). Over time, these pathways become more constrained and deterministic as a function of increasing constraints and limitations on the developing system. Further, the developing behaviors and systems become more canalized and resistant to change over time. According to Waddington, changes in the developmental trajectory are most likely to occur at decision points—transition periods with multiple options for the subsequent course of development. This theory proposes that major deviations from normative development early in life (e.g., child neglect) would lead to major changes in expected outcome (in this case, physical health) relative to minor deviations that take place at later points in development. Waddington's ideas about developmental pathways became the foundation for many theories that sought to explain variation in developmental trajectories.

Developmental trajectory models posit that there is a progressive pruning of possible pathways across development, an idea that is consistent with other developmental theories that emphasize the importance of early critical or sensitive periods in development (e.g., Bowlby, 1973; Shonkoff & Phillips, 2000). The issue of sensitive periods has been relatively unexplored in relation to early adversity and adult physical health. There is an assumption that early childhood represents a sensitive period in which adverse experiences have a disproportionately large influence on health trajectories, but empirical tests of this idea have been lacking. Is early childhood a unique time for the development of long-term health problems? Might there be other periods of development—such as adolescence—in which exposure to adversity is likely to confer greater risk for health problems?

Some evidence suggests that each exposure to adversity at different developmental periods confers risk for poor health outcomes (e.g., Singh-Manoux et al., 2004). Other evidence, however, suggests that experiences in infancy and early childhood are particularly potent for the long-term risk for infectious disease (e.g., Cohen, Doyle, Turner, Alper, & Skoner, 2004). For example, Cohen et al. (2004) examined adult participants' reactions to virus exposure as a function of early-life socioeconomic conditions. Following intranasal exposure to rhinovirus, participants were monitored for cold symptoms. As hypothesized, childhood SES was associated with cold systems. Notably, the strongest effects were found for SES at the earliest ages of measurement (12–24 months), with a progressive decline in the strength of the connection between SES and susceptibility to colds when examining later-childhood and adolescent family SES.

Evidence from some animal studies suggests that there may be windows of development in which stressful experiences lead to biological tendencies (e.g., Meaney & Aitken, 1985) and health outcomes (e.g., Ackerman, Hofer, & Weiner, 1975). These kinds of developmental timing studies are difficult to conduct in humans; intervention studies and the use of naturalistic experiments can help identify whether there are particular periods in development during which individuals are especially sensitive to exposure to adverse conditions.

Waddington's epigenetic landscape can be used to explain the processes involved in two developmental trajectory models (described in the next two subsections). These models document the processes through which development unfolds over time in a nonlinear pattern and can help explain how (a) individuals with different backgrounds and risk exposure experience the same physical health problems later in life and (b) how individuals with the same risk exposure ultimately experience dramatically different outcomes in adulthood. These models can serve as useful guides for understanding the complex ways in which early childhood adversity can contribute to adult physical health.

Equifinality

As we have already discussed, there is evidence linking early adversity to cardiovascular disease, diabetes, and a number of other chronic diseases of aging. One question that arises when looking at the links between adversity and health is: How do different adverse experiences—many of which are nonoverlapping experiences—lead to the same poor health outcomes? What happens across development that leads individuals with different backgrounds ultimately to share the same chronic diseases? Models of *equifinality* document the process through which different starting points in development may lead to the same outcome (Cicchetti & Rogosch, 1996). As Waddington (1957) theorized, individuals will vary in their developmental

trajectories, in part because of variations in choices and conditions at key decision points that shape subsequent experiences. As such, it is possible that a complex series of decisions made across the early years of life will set into motion a series of developmental trajectories that share a common endpoint (e.g., diabetes, cardiovascular disease). It may be that even though individuals from impoverished or abusive backgrounds experience different day-to-day stressors in childhood, the consequences of such stressful experiences may have the same effect on physiological regulatory systems, coping and regulation of emotional distress, and health behaviors that shape the course of disease.

For example, early adversity—whether such adversity includes maltreatment or poverty—may cause individuals to be vigilant toward threatening information in the environment and mistrusting of others. These characteristics shape the manner in which people engage their social worlds, making them more likely to elicit conflict and rejection and less likely to garner warmth and support. The experience of early adversity may shape success in forming and keeping long-term, high-quality relationships. Early adversity also is associated with poor self-regulation and coping skills, wherein the future is highly discounted in favor of immediate gratification, including engagement in risky or unhealthy lifestyle behaviors (e.g., high-fat diets, excessive alcohol consumption, drug use). Over time, these proclivities and experiences exert wear and tear on the body, with potential repercussions for disease outcomes. Thus, even though two individuals may have had unique starting points and sources of adversity (e.g., poverty versus abuse), they may come to share the same chronic health problems in adulthood because of a series of events across the life span that constrained their development and shaped their progression toward disease (Cicchetti & Rogosch, 1996; Miller et al., 2011).

Multifinality

Like models of equifinality, the focus of multifinality models is on the trajectories that explain developmental processes and how unique experiences can change the long-term path toward health or disease. Of course, not all individuals are affected in the same way by the experience of early adversity. Multifinality models help explain how individuals with similar starting points (e.g., growing up in poverty) develop varied outcomes over time (Cicchetti & Rogosch, 1996). These models can be particularly informative for understanding the different mechanisms that explain how individuals who share common adverse experiences in childhood face unique health problems decades later.

Individuals can take different trajectories for a number of reasons. For example, intervening factors can offset negative trajectories, as illustrated in tests of buffering models (e.g., Miller, Lachman, et al., 2011). In these cases, individuals who experience adversity do not go on to develop poor health outcomes because something in their development (e.g., a supportive parent, a new role model) changed the course of their trajectory. Similarly, as discussed in models of diathesis–stress and differential susceptibility, individuals might possess vulnerability or plasticity factors (e.g., genetic liabilities, temperamental traits) that explain why some individuals are more adversely affected by negative environments than others (e.g., Brody et al., 2013). Further, evidence for multifinality can emerge when individuals who are exposed to the same adversity go on to face different disease outcomes in adulthood (e.g., heart disease versus cancers versus autoimmune disease). In this case, the nature of the disease endpoint may differ across individuals for a variety of reasons (e.g., genetic predispositions), but disease morbidity can be traced back to the same initial stressor.

Developmental Cascades

Another model of development emphasizes the possibility that early experiences may influence the development of subsequent systems or domains (Masten & Cicchetti, 2010; Rutter & Sroufe, 2000). These developmental cascade models are particularly useful in depicting the connections between early experience and later adaptation (or maladaptation), particularly when the causal explanation for such a link is unclear. These models explain how problems in one domain of functioning (e.g., physical abuse in the parent-child relationship) can spill over into other areas of functioning (e.g., poor lifestyle behaviors) across development. Methodologically, researchers measure multiple domains of functioning across several time points (usually at least three of each; Masten, Burt, & Coatsworth, 2006). Analytically, cascade models control for the longitudinal stability of each domain while also including the cross-lagged paths across domains to test the extent to which one domain of functioning is influencing another. Developmental cascade models might provide insight into how it is possible that detrimental effects resulting from early experiences of childhood adversity might lie relatively dormant for decades, only to emerge as experiences of chronic disease in mid- and late adulthood. For example, the experience of adversity in childhood is unlikely to transform immediately into cardiovascular disease or other chronic diseases of aging. Nevertheless, as

described earlier in relation to individuals' developmental trajectories, exposure to early stressors might influence children's health behaviors, interactions with others, and outlook for the future. These subtle intervening steps along the path from early adversity to adult health would represent instances in which early exposure creates a cascade of aftereffects, which reverberate biologically across numerous systems and ultimately lead to chronic diseases in adulthood. In this way, cascade models can identify the steps along the progression from early adversity to later physical health problems.

Although these models have become quite popular in identifying spillover effects associated with mental health problems and social functioning (e.g., Bornstein, Hahn, & Haynes, 2010), cascade models have been underutilized in investigations of early adversity and adult physical health, in part because longitudinal studies are needed with multiple waves of assessments of adversity and health. Another difficulty with these study designs is that the same measure of health across ages might be impractical. For example, disease outcomes such as diabetes and cardiovascular disease are less likely to emerge before adulthood, so equivalent health measures across time points may not be available.

One study examined the cascading effects from family adversity and poverty in childhood to self-reports of health in adulthood (Herrenkohl et al., 2010). In this study, childhood family adversity was associated with adolescent internalizing symptoms, which in turn were associated with poor self-reported health in adulthood. These findings demonstrate that cascade models can be useful in identifying mechanisms that explain the progression from early adversity to later health. Research is needed using these types of models in samples with more objective measures of adult health.

BIOLOGICAL INTERMEDIARIES LINKING EARLY ADVERSITY TO ADULT PHYSICAL HEALTH

Now that links between early adversity and adult physical health have been clearly identified, the next step is to identify what biological processes translate the stressful experiences into the physical environment of disease pathogenesis (i.e., what biological mediators carry the effects of early adversity under the skin). In the last several decades, significant progress has been made in understanding the biological correlates of stress. This burgeoning area of research is due, in part, to Campbell and Fiske's (1959) long-standing calls to conduct multitrait-multimethod research, as well as directives to conduct research at multiple levels of analysis (e.g., cellular, molecular, individual, family, and societal levels; Cicchetti & Dawson, 2002). These data provide new insights and establish a conceptual approach for future studies mapping relations between early adversity and physical health. Yet at the same time, there are limits to what these biological mechanisms can tell us about why early adversity is an important determinant of physical health and disease.

In this section, we provide a nonexhaustive review of several of the most widely studied biological processes thought to translate early adverse experiences into chronic diseases of aging. These biological mediators have received considerable theoretical and empirical attention for their potential role in explaining how early adverse experiences contribute to disease and accelerated aging. We provide a critical review, highlighting the strengths and weaknesses of each mechanism and documenting the limits of conclusions that can be drawn when evidence is found for a link between biological processes and early adversity. We note that other biological mediators have been examined in relation to early adversity and later health outcomes (e.g., sympathetic and parasympathetic nervous system activity), but our focus is on mediators that have been, and continue to be, the major thrust of research in this area.

Hypothalamic-Pituitary-Adrenocortical Axis

One potential mechanism that has received widespread attention is the HPA axis. This hormonal response system is present in organisms ranging from birds to humans and can be activated by a broad range of mental and physical stressors (McEwen, 1998; McEwen & Stellar, 1993; Weiner, 1992). Next we provide a review of the HPA axis and common measures used to capture HPA axis activity. After that, we review evidence supporting the notion that HPA axis activity functions as a biological mechanism linking early adversity to adult health outcomes. We then discuss some important caveats that should be taken into consideration when evaluating the role of HPA axis functioning as a mechanism linking early adversity with health outcomes.

Cortisol: Background and Measurement

Activation of the HPA axis occurs when neurons in the paraventricular nucleus of the hypothalamus secrete corticotropin-releasing hormone (CRH). This molecule travels to the anterior pituitary gland, which responds by secreting a pulse of adrenocorticotropin hormone (ACTH). The ACTH signal is carried in the blood to the

adrenal glands, which synthesize and release cortisol into the bloodstream. Cortisol then travels throughout the body through the bloodstream and acts on a wide range of tissues. Of all the hormones released in this cascade, cortisol has gained the most notoriety, probably because of its widespread regulatory influences. Cortisol is a steroid hormone belonging to the glucocorticoid family, and it is thought to play a key role in the biological stress response system. In addition, cortisol plays an important role in the central nervous system, where it is involved in learning, memory, and emotion; in the metabolic system, where it regulates glucose storage and utilization; and in the immune system, where it regulates the magnitude and duration of inflammatory responses and the maturation of lymphocytes (Sapolsky, Romero, & Munck, 2000). Cortisol's role in regulating such a wide range of physiological systems has helped motivate research focused on its possible role in linking early adversity to adult physical health.

Cortisol levels in the body exhibit a diurnal rhythm, characterized by high levels upon waking, proceeded by a rapid increase in cortisol after approximately 30 minutes (a feature known as the cortisol awakening response [CAR]), followed by a progressive decline in cortisol levels across the day (Kirschbaum & Hellhammer, 1989). Thus, cortisol research tends to incorporate one or more of the following indices of cortisol: (a) the size of the CAR; (b) the slope of the cortisol diurnal rhythm; (c) reactivity to naturalistic or laboratory-based stressors; and (d) metrics reflecting total cortisol output over some unit of time, typically the day, as reflected by area under the diurnal curve or urinary cortisol output (Adam & Kumari, 2009; Miller, Chen, & Zhou, 2007). These measures of cortisol output are thought to provide distinct information about HPA axis functioning. For instance, the CAR, which is regulated in part by the suprachiasmatic nucleus (Clow, Thorn, Evans, & Hucklebridge, 2004), is thought to play a role in mobilizing energy stores for the demands of the day (Hucklebridge, Mellins, Evans, & Clow, 2002). Further, an increase in the CAR is thought to reflect an increase in life stress, whereas a reduced or blunted awakening response is indicative of a failure to recruit the resources needed to tackle the day's demands (Chida & Steptoe, 2009). Normatively, cortisol has a diurnal rhythm that is characterized by a pronounced decline from morning through evening, although there appears to be substantial intra- and interindividual variability in this pattern, even among healthy persons (e.g., Stone et al., 2001). Nonetheless, flat rhythms that lack the typical diurnal decline often are seen in persons exposed to chronic stress (Gunnar & Vazquez, 2001) or with chronic psychiatric disorders, such as posttraumatic stress disorder (e.g., Yehuda, Golier, & Kaufman, 2005). Indices of total cortisol output are thought to provide a cumulative estimate of how much of this hormone bodily tissues get exposed to over some defined period of time, such as a day. Levels that are either too high or too low are thought to be detrimental for health (though via different pathways; see Heim, Ehlert, & Hellhammer, 2000; Raison & Miller, 2003; Miller et al., 2007; Sternberg, Chrousos, Wilder, & Gold, 1992).

Evidence for the Role of Cortisol as a Biological Intermediary

Evidence from a number of studies on stress-related changes in the output of cortisol has helped shape the notion that the HPA axis may serve as a biological intermediary linking early adversity to adult physical health. Meta-analytic findings of studies linking chronic stress to cortisol activity suggest that there is considerable variability (Miller et al., 2007), however. For example, connections between chronic stressors and HPA activity varied dramatically as a function of the timing of the stressor, whether the stressor involved trauma, whether the stressor was controllable or physically threatening, as well as individual emotional responses to the chronic stress (e.g., feelings of shame, loss). For example, individuals who faced physical stressors, such as war, and traumatic, uncontrollable stressors had high volumes of cortisol output over the day. In contrast, individuals facing chronic or controllable stressors did not differ from controls in their total daily output of cortisol. These findings suggest that cortisol is perhaps not best viewed as a generic marker of stress; it may, however, be a marker of stress under certain contexts and conditions (e.g., when experiencing traumatic and uncontrollable stressors). This view reinforces the findings of an influential meta-analytic study of cortisol responses to acute stress, which showed that levels of the hormone rise only in experimental settings that evoke uncontrollable social-evaluative threats (Dickerson & Kemeny, 2004).

Notably, the best predictor of cortisol levels is the timing of a chronic stressor (Miller et al., 2007). Studies that focused on temporally distant stressors found lower-than-normal cortisol, whereas studies that focused on individuals' current experience of stress found elevations in cortisol levels. This finding suggests that stress might initially trigger a burst of cortisol, eventually leading to adaptations to the HPA axis that are meant to limit the damage that might result from sustained periods of heightened cortisol levels. In other words, it may be that the body mounts a counterregulatory response such

that cortisol output rebounds below normal levels. This rebound effect makes sense in light of the fact that the HPA axis is regulated by a potent negative feedback circuit, in which elevated levels of cortisol suppress the output of CRH and ACTH by acting on glucocorticoid receptors in the brain.

Consistent with these meta-analytic findings, a number of studies have found that exposure to a wide range of early adversities, including socioeconomic disadvantage, neglect, abuse, and the loss of caregivers, is associated with later hypo-activation of the HPA axis. For example, in a prospective sample of adopted children, those who experienced severe neglect and abuse prior to the adoption (as reported by the adoptive parents) had lower morning cortisol values and flatter diurnal slopes in adulthood compared to individuals who did not experience neglect or abuse prior to the adoption (van der Vegt, van der Ende, Kirschbaum, Verhulst, & Tiemeier, 2009). Similarly, in a sample of older adults, Gerritson et al. (2010) found that the experience of any early adversity (e.g., abuse, poverty, parental divorce, loss) was associated with reduced morning cortisol levels and flatter diurnal slopes.

Further, several studies have found evidence for a long-term effect of parental separation and loss on HPA axis functioning. In a small study of adult men, the loss of a parent in childhood was associated with greater cortisol levels throughout the day compared to men who did not lose a parent (Nicolson, 2004). Additional evidence suggests that prolonged separations from parents could be connected to adult HPA axis functioning (Kumari, Head, Bartley, Stansfeld, & Kivimaki, 2013). Using data from the British Whitehall II study, Kumari and colleagues (2013) found that the experience of prolonged maternal separation before the age of 16 was associated with flatter diurnal slopes compared to adults who did not experience prolonged maternal separation. Notably, these effects did not differ as a function of the reason for the separation (e.g., maternal death, wartime evacuation). Further, individuals who experienced parental separation exhibited larger cortisol awakening responses relative to individuals who did not experience parental separation.

Some evidence suggests that socioeconomic disadvantage is associated with adult HPA axis functioning (e.g., Li, Power, Kelly, Kirschbaum, & Hertzman, 2007). For example, using data from the 1958 British cohort study, Li et al. (2007) examined participants' SES at birth and ages 7, 11, and 16. For men (but not women), low SES in childhood was associated with greater cortisol output as indexed by area under the curve, even when controlling for adult SES.

Cortisol as a Biological Intermediary: Considerations and Caveats

Although cortisol has regulatory influences on many bodily systems, these dynamics are highly complex. The result is that it is often difficult to interpret the biological significance of adversity-related differences in cortisol. Here we discuss these complexities in some detail, with the goal of facilitating more probative research on cortisol's role as an intermediary linking early adversity and later disease.

We begin by noting that a number of steps must take place before the presence (or absence) of cortisol can begin to influence one of the body's tissues or organs. First, cortisol must bind to a specific receptor located inside a cell. Most cortisol that is released into the bloodstream, however, is attached to carrier proteins, such as cortisol binding globulin (CBG) or albumin. When cortisol is attached to these proteins—which is about 90% of cortisol that is produced—it is unable to traverse cell membranes. Consequently, it cannot get inside the cell to bind to receptors. The other 10% of cortisol making its way through the bloodstream—which is free, or unattached to carrier proteins—must go through several steps before it is capable of modifying tissue. First, the hormone must traverse cell membranes and avoid being excreted by a structure called the multidrug resistance (MDR) pump, which expels molecules that threaten homeostasis. Further, it must avoid being converted to its inactive form by an enzyme called 11-β-hydroxysteroid dehydrogenase. Then it must bind to either a glucocorticoid or mineralocorticoid receptor, once those receptors shed some accessory molecules known as heat-shock proteins (see Raison & Miller, 2003, for a review of the mechanisms behind glucocorticoid signaling). Once cortisol has progressed through these steps, the newly formed receptor-hormone complex must translocate to the nucleus, where it is then capable of modifying the cell's program of gene expression.

Clearly, several (often overlooked) steps must take place between the release of cortisol and the ultimate effect of cortisol on tissues of interest. An important implication of this multistep progression of cortisol activity is that even if a particular psychosocial factor of interest can be linked to the release of cortisol, the signal may not be heard downstream in the tissues of interest. One reason for this is that, as already discussed, most tissues are equipped with a host of counterregulatory mechanisms, such as carrier proteins (e.g., CBG) and the MDR pump that potentially can intervene in this process to ensure that acute changes in cortisol do not drastically disrupt homeostasis. This means that even if cortisol levels are increased markedly by a stressor, the tissues that are regulated by cortisol may

not be affected because counterregulatory mechanisms may alter how loudly cortisol's signals are heard. For example, cells may alter the characteristics of the receptors to which cortisol binds. In addition, cells can reduce the density and activity of their receptors. Receptors that are downregulated or desensitized will pass on fewer signals to the nucleus of the cell, where gene expression occurs (Cole et al., 2007). Even in the absence of connections between a given stressor and cortisol, however, it is quite possible that there is ongoing activity at the level of the receptor that has important implications for physical health. In other words, the sheer volume of unbound cortisol in the body (and the amount that cortisol levels change in response to stressors) does not provide enough information to explain how the HPA axis could be involved in shaping physical health outcomes.

One study nicely illustrates these complexities. In a sample of adult participants who varied in early-life SES (Miller et al., 2009), participants with low-status backgrounds had modestly elevated cortisol relative to high-status participants. Importantly, however, examination of gene expression profiles in leukocytes indicated that individuals from low-SES backgrounds had decreased glucocorticoid signaling relative to people with high early-life SES. In other words, the leukocytes of individuals from low-SES backgrounds were registering *less* cortisol signal. These findings are provocative because examination of cortisol levels alone would have suggested that low early-life SES confers risk for elevated circulating cortisol in adulthood, with the corresponding assumption that this extra cortisol could have a damaging effect on tissues and organs. Yet the gene expression findings suggested that individuals from low-SES backgrounds had cells that were hearing less signal from cortisol, not more—a finding that indicates that examination of circulating levels of cortisol alone is an insufficient assessment of HPA axis activity. Thus, the study of cortisol in isolation—without also considering glucocorticoid signaling—does not provide an accurate picture of the ways in which HPA axis activity might serve as a biological intermediary linking early adversity and later health outcomes.

An additional concern centers on the extent to which cortisol values exhibit within-person stability over time. Some recent studies highlighting cortisol's lack of temporal stability (Ross, Murphy, Adam, Chen, & Miller, 2014; Shirtcliff et al., 2012) call into question its plausibility as a mediator of the lengthy underlying pathologic processes that give rise to most chronic diseases of aging. For example, one recent study showed that only 13% of the variability in cortisol values over a 6-year period was attributable to a stable, traitlike component (e.g., Shirtcliff et al., 2012). Instead, over half of the variability in cortisol values could be explained by situational, or statelike, factors at the time of the assessment. Thus, even over relatively short periods of time, cortisol activity shows very little stability. In other words, if individuals' cortisol levels are not stable over relatively short intervals and appear instead to reflect dynamic changes in situational experiences of close temporal proximity, then it is unlikely that chronically dysregulated HPA axis activity is a mechanism that causally contributes to diseases such as cardiovascular disease, which evolves over decades.

In summary, the HPA axis has been a popular target for mechanistic research on early adversity and adult disease over the last several decades. This explosion of research has led to a greater understanding of how responsive the system is to stressful experiences. Important features of cortisol, however, often have been overlooked in this research (e.g., glucocorticoid receptor availability and sensitivity, counterregulatory mechanisms that influence cortisol's actions in tissue, temporal stability and dynamics of cortisol). These features are important details that cannot be ignored, particularly if researchers want to develop a biologically plausible understanding of cortisol's role in explaining how early experiences influence chronic disease outcomes.

Allostatic Load

Allostatic Load: Background and Measurement

Some of our physiological systems, such as body temperature and blood pH, are tightly regulated, such that they operate within a narrowly specified range of functioning, with *homeostatic* set points around which the body attempts to achieve stability. Other systems, however, operate under much more flexible states, and they can change adaptively in response to the demands of the environment. In these circumstances, the systems operate under conditions of *allostasis* ("stability through change"). The main difference between allostatic systems and homeostatic systems is that allostatic systems have dynamic and adjustable mechanisms in place that are responsive to the environment, whereas homeostatic systems operate to achieve a specific set point *despite* the environmental demands. For example, during exercise, our bodies achieve thermoregulation through perspiration (thus achieving a fairly static temperature despite changes in behavior), but our heart rate adjusts to the increased physical demands by beating faster.

Another way of viewing allostasis is as a measure of plasticity. This ability to adapt to environmental demands enables temporary adjustments in physiological systems that allow for the ultimate goal of overcoming stressful or challenging situations. This plasticity in physiological systems, however, is thought to come at a cost: When these systems repeatedly are required to adapt to meet the demands of the environment—as in cases when individuals are exposed to chronic, repeated stressors—the systems may become inefficient or less flexible in their ability to adapt. The systems may not shut off completely, or there may be delays in the return to baseline functioning as a result of repeated environmental stressors. McEwen and colleagues (McEwen, 1998; McEwen & Seeman, 1999; McEwen & Stellar, 1993; Singer, Ryff, & Seeman, 2004) developed the concept of allostatic load, which refers to the wear and tear that results from repeated stressors that activate the body's regulatory controls in an attempt to achieve a new level of stability (and recovery from stress). Over time, this wear and tear manifests itself in the dysregulation of multiple physiological systems. Measures of allostatic load, therefore, sometimes are viewed as reflecting the number of physiological systems that are experiencing disruption in optimal functioning.

A number of physiological systems are thought to be regulated under allostatic control, including the neuroendocrine, metabolic, cardiovascular, immune, and autonomic and sympathetic nervous systems (Singer et al., 2004). Accordingly, frequently a variety of biomarkers are included in measures of allostatic load. Neuroendocrine measures of allostatic load often include cortisol and catecholamines, such as epinephrine, norepinephrine, and dopamine. Immune measures often include markers of inflammation, including the cytokines interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) as well as C-reactive protein (CRP), an acute phase protein that promotes inflammation by enhancing phagocytosis. Indicators of metabolic dysfunction include high-density lipoprotein cholesterol (this value is reverse-scored so that low values indicate risk), low-density lipoprotein cholesterol, triglycerides, glycosylated hemoglobin, and blood sugar. Cardiovascular components of allostatic load frequently include systolic and diastolic blood pressure and heart rate. Finally, waist-to-hip ratio or BMI usually are included in measures of allostatic load as indicators of adiposity. Researchers frequently create quartiles for each index, assigning individuals into dichotomous categories depending on whether their values are in the top high-risk quartile. These categories are then summed across indices to create a total composite score for allostatic load.

One question related to this method of creating a composite score is whether the indicators of physiological dysregulation reflect a single underlying construct or if they are better conceptualized as separate components of physiological dysregulation. To answer this question, McCaffery, Marsland, Strohacker, Muldoon, and Manuck (2012) tested the factor structure of allostatic load indices. In this study, researchers found support for a single factor underlying the allostatic load indices, including measures of metabolic, inflammatory, and cardiac vagal activity measures. These findings lend support to the practice of using one composite score for the wide range of physiological systems that are included in assessments of allostatic load.

With that said, McEwen and others (e.g., McEwen & Seeman, 1999) have sorted allostatic load markers into categories, including primary mediators, secondary outcomes, and tertiary outcomes, in a way that is conceptually and methodologically useful. Primary mediators include chemical messengers, such as cortisol, dehydroepiandrosterone (DHEA), and catecholamines, which are thought to relay messages from the brain to organs and tissues that mobilize resources for coping with stress. Secondary outcomes are hypothesized to reflect the impact that repeated signaling from primary mediators has on target organs and tissues. These outcomes include tissue- and organ-specific indicators of health, including waist-to-hip ratio, blood pressure, glycosylated hemoglobin, and cholesterol. Finally, tertiary outcomes (which currently are not included in most measures of allostatic load) include actual diseases hypothesized to result in part from allostatic load (e.g., cancer, dementia, heart disease). The basic premise of this model is that primary mediators influence the development of secondary and finally tertiary (disease) outcomes. This hierarchical organization of allostatic load indicators offers a conceptually grounded approach to understanding how a stressor could contribute to wear and tear on the body and ultimately lead to the accumulation of chronic diseases. As far as we are aware, however, longitudinal studies have not yet been done to confirm the theorized progression from primary mediators to secondary and finally tertiary outcomes. Prospective studies of this sort will be useful for improving our understanding of the role of allostatic load in translating early adversity into disease.

Evidence for the Role of Allostatic Load as a Biological Intermediary

Allostatic load has been proposed as a biological intermediary linking early adversity to adult health (e.g., Repetti,

Robles, & Reynolds, 2011; Taylor, Way, & Seeman, 2011). For example, in a prospective study of individuals in Sweden, Gustafsson, Janlert, Theorell, Westerlund, and Hammarstrom (2012) found that the experience of social stressors (e.g., loss of a parent, social isolation) and material adversity (e.g., parental unemployment, poor standard of living) in adolescence and early adulthood were uniquely predictive of allostatic load in midlife. Similarly, using data from the MIDUS study, Gruenewald et al. (2012) found that low SES in childhood and adulthood predicted allostatic load in adulthood. Notably, low SES at each developmental period was associated uniquely with later allostatic load. Further, Gruenewald and colleagues found evidence of a cumulative effect: Individuals who were persistently low in SES across childhood and adulthood had greater allostatic load relative to individuals who were consistently high in SES or who were upwardly mobile. Interestingly, these effects remained significant even after controlling for health behaviors and psychosocial variables in adulthood. Evidence from studies with children and adolescents suggests that these processes might start early in life (e.g., Evans & Kim, 2012).

Allostatic load, in turn, has been shown to be predictive of cardiovascular disease and mortality (Seeman, McEwen, Rowe, & Singer, 2001; Seeman, Singer, Rowe, Horwitz, & McEwen, 1997). These links are not particularly surprising, given that the index includes measures of blood pressure and central adiposity, two of the most established risk factors for cardiovascular disease and health. Reductions in allostatic load have been associated with lower 7-year mortality risk (Karlamangla, Singer, & Seeman, 2006). These findings have led researchers to suggest that allostatic load may be a pathway through which exposure to early adversities can lead to greater health problems in adulthood (e.g., Danese & McEwen, 2012; Gruenewald et al., 2012). Indeed, one strength of the allostatic load model is that the composite score reflects the extent to which multiple physiological systems are operating under strained conditions. If early adversity results in different biological cascades across individuals, leading to a wide variety of endpoints with possible dysregulation, then a single biological marker might not always be linked to adverse experiences. By creating a composite measure of allostatic load, researchers are better positioned to capture the connection to early adversity. Thus, in a way, the practice of creating a composite measure of allostatic load provides a simplified way of testing for multifinality in the links between early adversity and long-term health outcomes by creating a single outcome variable that reflects a diverse array of physiological systems.

Allostatic Load as a Biological Intermediary: Considerations and Caveats

One of the concerns about allostatic load, as it has typically been operationalized in this literature, is that its components vary in how proximal they are to actual disease. As McEwen and Seeman (1999) emphasize, primary mediators, such as cortisol, probably are quite distal causes of physical health problems, which act through more proximal secondary outcomes, such as insulin resistance, to cause disease. Yet most studies to date group all of these components into a single aggregate, making the implicit assumption that they are equally powerful and equally detrimental in terms of long-term health. We recognize that there is factor-analytic evidence to support a single composite score for allostatic load (McCaffery et al., 2012). However, it still seems likely that allostatic load components vary considerably in how proximal, necessary, and sufficient they are in the disease process. Indeed, allostatic load might foreshadow cardiovascular disease not because individuals are elevated on a diverse set of physiological measures but because they have high blood pressure and excess central adiposity, which are well-established risk factors for this condition. This lack of clarity in the utility of allostatic load indices makes it difficult to know whether this measure provides incremental value over already established stand-alone risk factors for poor health and whether some components may be more powerful contributors than others for poor health outcomes. Moreover, the practice of creating nonstandardized cut points for dichotomizing the indicators raises several methodological issues. For one, this practice often is done using sample-specific cutoffs, such as top quartiles, which makes it difficult to compare across studies and increases the odds of chance findings. Another problem with the cutoff approach is that it ignores the fact that functioning and risk within each domain may follow a more linear gradient. If domains have validated cutoffs with prognostic significance (e.g., blood pressure, cholesterol), then these established criteria may be more meaningful indices to use when sorting individuals into high- and low-risk categories.

One final concern relates to the choice of measures included in allostatic load composites. As described earlier, indices of allostatic load are categorized into primary mediators, secondary outcomes, and tertiary outcomes. Yet this level of categorization is not reflected in the single composite measure of allostatic load. Instead, these markers are aggregated across the different stages without consideration of the relative importance of each indicator or acknowledgment that primary mediators should prospectively predict secondary outcomes, which

should in turn shape the onset and progression of diseases. Given that the hierarchy is so fundamental to the theory behind allostatic load, it is unclear why these indicators are treated equally. In fact, some measures in and of themselves may pose no clear health risk, or do so in only a very distal manner, whereas other indices (e.g., blood pressure) are actually measures of damage already done to the system. For example, having higher-than-average levels of dopamine is not considered a risk factor on its own, but elevated blood pressure and cholesterol are risk factors for cardiovascular disease. Based on the theoretical model, early adversity should be related most closely to the primary mediators of allostatic load, and these changes should presage the onset of secondary outcomes. This kind of cascading model has not been tested to date, however.

In summary, allostatic load has been implicated as a potential biological mechanism linking early adversity to later disease and early mortality. We look forward to the next generation of research on this construct, which we hope will clarify some of the complex issues surrounding conceptualization and measurement of allostatic load. Future studies that can clarify the clinical significance of allostatic load and the processes through which allostatic load contributes to disease will be especially useful.

Telomeres

Telomeres: Background and Measurement

Recently there has been an active interest in the ways in which psychosocial stressors might accelerate cellular aging through changes in telomere structure (Aubert & Lansdorp, 2008; Aviv, 2008; Mather, Jorm, Parslow, & Christensen, 2011; Price, Kao, Burgers, Carpenter, & Tyrka, 2013). Telomeres are nucleoproteins located at the end of chromosomes. Telomeres act like caps that prevent DNA degradation when cells divide and in doing so ensure the stability of chromosomes and the cells themselves. Briefly, when cells divide, replication enzymes are unable to function at the very end of chromosomes (an issue known as the end replication problem; De Lange, 2009). Without telomeres, each cell division would result in segments of chromosomal DNA being lost to replication, meaning that as time went on, progressively more of genetic code (DNA) would disappear. The presence of telomeres slows the progressive erosion of genetic material. Telomeres serve as a kind of buffer for the chromosome, which can absorb successive losses of material with each replication. Because telomeres are comprised of noncoding DNA, or material that is not essential for building proteins, their degradation does not have significant consequences for cellular function in the short term. Moreover, as telomeres shorten with successive replication cycles, cells produce an enzyme, known as telomerase, which acts to restore their length. However, most cells do not contain enough telomerase to maintain telomere length indefinitely. So, with time, telomeres degrade. When this occurs, healthy cells enter a phase known as senescence, where they cease replication and can have limited functional capacity. Thus, cellular senescence is the endpoint of a lengthy process involving repeated cell replications and waning telomerase activity to counterbalance it.

Evidence for the Role of Telomere Degradation as a Biological Intermediary

Telomere length has been viewed by some as a biological marker of aging (Aubert & Lansdorp, 2008; Epel, 2009; Mather et al., 2011). Indeed, health-compromising behaviors, such as smoking, have been related to shorter leukocyte telomere lengths. And to the extent people have shorter leukocyte telomeres, their risks for morbidity and mortality from various conditions increase (e.g., Kimura et al., 2008; Valdes et al., 2005). Some researchers argue that shorter telomeres (relative to telomeres of other individuals of the same age) are an indication of accelerated aging, with the potential for long-term health consequences.

Emerging evidence suggests that early exposure to adversity may be associated with telomere degradation (Drury et al., 2012; Kananen et al., 2010; Tyrka et al., 2010). For example, Tyrka et al. (2010) found that recalled emotional and physical neglect in childhood were associated with shorter telomeres in white blood cells. Similarly, Kananen et al. (2010) reported a connection between early adversity (e.g., parental unemployment, parental mental health problems) and telomere length in white blood cells in a sample of anxious and nonanxious adults. Further, in a sample of Romanian children, Drury and colleagues (2012) found a link between buccal cell telomere length in middle childhood and time spent in early institutional care. Additional evidence for a link between early exposure to adversity and later telomere attrition comes from Kiecolt-Glaser and colleagues (2011), who found that older adults who had experienced multiple childhood adversities had shorter telomeres in white blood cells compared to adults who were not exposed to early adversities in childhood.

Some evidence suggests that supportive parenting experiences may play a role in buffering children from telomere degradation associated with early adversity. In a cross-sectional study, Asok, Bernard, Roth, Rosen, and

Dozier (2013) found that children from high-risk families who experienced responsive parenting had greater buccal cell telomere length than children from high-risk families whose parents were less responsive. These findings offer some insight into the ways in which telomere length may be influenced by both supportive and unsupportive environmental contexts, although longitudinal studies will be needed to lend support to the notion that these environmental inputs play a causal role in affecting telomere length.

Telomere Degradation as a Biological Intermediary: Considerations and Caveats

The studies just reviewed consistently find linkages between early adversity and telomere length, which suggests the provocative hypothesis that accelerated cell aging might be a mechanistic pathway to later disease. However, as is the case with the broader literature on telomeres, several features of these studies complicate interpretation. First, all of the studies were based on a single measurement of telomere length. There are significant individual differences in telomere length across the population (Aviv, Valdes, & Spector, 2006; Geronimus et al., 2010; Takubo et al., 2002). Thus, with a single time point measure, we cannot be certain whether the disparities in telomere length are a consequence of the earlier adversity or are simply a correlate. For example, it could be that the same children who are exposed to adversity are born with relatively short telomeres, for partly or fully unrelated reasons. To sort this complexity out, multiwave studies or natural experiments are needed.

Along these lines, some of the most convincing evidence that exposure to adverse conditions in childhood accelerates telomere degradation comes from the Environmental-Risk Longitudinal Twin Study, a nationally representative sample of children in Great Britain (Shalev et al., 2013). Researchers assessed children's exposure to violence in childhood, including domestic violence, bullying and victimization, and maltreatment from an adult. Telomere length in buccal cells was assessed at baseline (age 5) and 5 years later (age 10). Shalev and colleagues (2013) found that children who were exposed to two or more types of violence had accelerated telomere erosion across the 5 years compared to children who were exposed to one type of violence or who were not exposed to violence.

These are provocative findings from a methodologically rigorous study. They represent an important starting point for mechanistic research on early adversity. Nevertheless, there is some uncertainty about the clinical relevance of telomeres in buccal cells for the kinds of chronic diseases of aging we are concerned with in this chapter. For those conditions, telomere length at the site of disease pathogenesis—for example, in the heart for cardiovascular disease, the pancreas for diabetes, the immune system for virally mediated cancers and infectious diseases—would be more germane. It is possible that buccal cells, or other easily accessed specimens, such as white blood cells, can serve as a proxy for telomeres in these tissues of interest. But given the degree of tissue specificity seen in most cellular processes, this seems like a dubious assumption to proceed on, at least until the field has accumulated sufficient evidence to justify it. Indeed, recent studies indicate that the correlations between telomere length in buccal and immune cells are modest at best (Gadalla, Cawthon, Giri, Alter, & Savage, 2010).

This problem is not limited to buccal cells. As an alternative, researchers often measure telomere length in leukocytes, based on the quite reasonable presumption that immune cell aging could have deleterious consequences for host resistance to infections and cancers. But even when leukocytes are collected, most studies assess telomere length in bulk populations with heterogeneous cellular content. Peripheral blood contains a number of different types of leukocytes, including granulocytes, lymphocytes, and monocytes. These cell types differ significantly in their telomere profiles (Aubert & Lansdorp, 2008). What makes this methodological decision even more problematic is that people vary in the relative proportion of these cell types in peripheral blood, and adversity is known to shift that balance (Segerstrom & Miller, 2004). Thus, any linkage between adversity and telomeres could reflect individual differences in the balance of cell types present in the assay rather than cellular aging per se. To rule out this possibility, researchers need to account for cellular heterogeneity through statistical controls, or, even better, physically sort cells into different phenotypic clusters prior to telomere analysis (e.g., see research on stress and telomeres by Cohen et al., 2013; Damjanovic et al., 2007).

Aside from the heterogeneity in cell types used for telomere assessment, it is important to consider the fact that not all cells in the body replicate. Of the major immune cells, only lymphocytes do so routinely. This fact raises the question of what telomere length means in samples that are mainly composed of nonreplicating cells. (This is the case with most whole blood analyses of telomeres, where roughly 50% to 80% of the cells are nondividing granulocytes or monocytes.) Some researchers have argued that in nondividing cells, such as granulocytes, telomere length might index senescence of the parent cell—the cell

that divided to form the granulocyte. If so, these measures would take on significant new meaning. But until this issue and others are settled, we remain cautious about the interpretation of the telomere data.

Epigenetics

Epigenetics: Background and Measurement

All cells within an individual carry an identical DNA sequence, which is established at conception and fixed for life. (Lymphocytes and cells that have acquired mutations are exceptions to this rule.) The DNA sequence serves as a blueprint for transcription, the process whereby cells synthesize ribonucleic acid (RNA) molecules—a process known as gene expression. RNA molecules are later translated into proteins, which cells use for structural and functional purposes. Epigenetics describes stable changes in gene expression activity that arise without changes to the gene's DNA sequence (Jaenisch & Bird, 2003; Jirtle & Skinner, 2007). A primary function of epigenetic alterations is to allow cells to develop and maintain specialized functions. For example, epigenetic alterations can modify a cell's ability to transcribe a particular gene into RNA. Because RNA serves as a template for translation of proteins, these epigenetic alterations have downstream influences on how much of the gene's protein ultimately is synthesized. When this process takes place across many different genes, it can give rise to significant phenotypic diversity in cells. This variability is thought to play a role in the long-term development of physical disease (e.g., Rakyan, Down, Balding, & Beck, 2011), although the nature of these pathways is still largely unknown.

Epigenetic modifications to DNA typically occur in one of two ways (Whitelaw & Garrick, 2006). The first modification is DNA methylation, which involves the attachment or removal of a methyl group to cytosine residues in a gene's promoter. The methyl groups prevent transcription factors from interacting with DNA to modulate gene expression, which makes the gene inactive. The second form of epigenetic modification involves changes to the chromatin structure that packages the DNA. This process occurs by attaching or removing chemicals from the histone proteins that hold DNA within the cell's nucleus. These proteins cause the DNA near the gene to become more or less tightly coiled, which makes it more or less difficult for RNA polymerase and transcription factors to access its promoter (Whitelaw & Garrick, 2006). These epigenetic modifications can be quite stable over the life span, and sometimes they are passed along to daughter cells during mitosis. As such, it is possible for early experiences—such as early exposure to adversity—to create lasting epigenetic modifications that persist over the life span, which may help explain how early experiences become embedded in the epigenome and contribute to chronic diseases many decades later. Measurement of epigenetic modifications typically relies on DNA microarray analysis. This process assesses the presence of methylation at multiple promoter sites in each of many thousands of different genes (e.g., these analyses can quantify the proportion of sites that are methylated).

Evidence for the Role of Epigenetic Modifications as a Biological Intermediary

Recent evidence suggests that epigenetic processes might serve as pathways through which early experiences can bring about long-term changes in the activity of genes, thereby contributing to the pathogenesis of disease (e.g., Roth, Lubin, Funk, & Sweatt, 2009). Much of the early work in this area centered on animal models, including the work by Meaney and colleagues (see Meaney, 2001, for a review). Meaney found that, in rats, certain caregiving experiences early in infancy were associated with long-term changes in rat pups' stress response physiology (Liu et al., 1997). Specifically, rat pups that received high levels of maternal licking and grooming and arched-back nursing showed attenuated cortisol responses to threat and increased exploratory behavior—effects that lasted into adulthood (Caldji et al., 1998; Liu et al., 1997). In a series of elegant mechanistic studies, Meaney and his colleagues discovered that these lasting differences in stress responsivity arose through epigenetic changes to glucocorticoid receptor genes in the hippocampus of the offspring (Weaver et al., 2004)—in other words, in the rat pups that received more licking and grooming. In essence, maternal nurturance in the early days of life led to epigenetic changes in the offspring's hippocampus including demethylation of DNA and acetylation of histone proteins, which facilitated expression of the glucocorticoid receptor gene across the life span (Weaver et al., 2004). Greater expression of this receptor, in turn, enabled tighter regulation of the HPA axis, the hormonal system that controls the release of cortisol in response to stress. Notably, Weaver et al.'s (2004) findings revealed that the epigenetic modifications that took place during the first week of the rat pups' lives persisted into adulthood, suggesting considerable stability in these early programming effects.

Recent work with humans suggests that early experiences—including adversity—also bring about epigenetic changes that affect gene expression (e.g., Bick et al.,

2012; McGowan et al., 2009; Oberlander et al., 2008). In one study, hippocampal tissue from suicide victims was assessed postmortem (McGowan et al., 2009). Epigenetic modifications varied as a function of whether participants had been abused as children: Individuals who had been abused had greater methylation at sites in the glucocorticoid receptor gene promoter. In a prospective study of maternal depression and infant cortisol reactivity, Oberlander and colleagues (2008) found that exposure to prenatal maternal depression led to epigenetic changes in infants' gene expression that were associated with elevated stress reactivity in the HPA axis. Specifically, prenatal exposure to depression during the third trimester was associated with increased methylation at sites in the glucocorticoid receptor gene promoter. Further, methylation at this location was related to heightened cortisol reactivity when the infants were 3 months old, suggesting that this epigenetic alteration may have functional implications for HPA axis regulation. Additional evidence for lasting epigenetic modifications as a result of early adversity comes from a sample of adults who were exposed to famine prenatally as a result of wartime food scarcity and their unexposed same-sex siblings (Heijmans et al., 2008). Compared to their unaffected siblings, prenatal exposure to famine was associated with reduced DNA methylation in the promoter of the insulin-like growth factor II gene, which plays a role in insulin- and growth-related activities.

Additional evidence from studies of early adversity and epigenetic modifications also supports the notion that adverse experiences are biologically embedded in the epigenome (Borghol et al., 2012; Essex et al., 2013; Tyrka, Price, Marsit, Walters, & Carpenter, 2012). For example, Essex and colleagues studied DNA methylation in the buccal cells of 109 adolescents from a larger longitudinal study. In this sample, the extent to which adolescents' buccal cells were methylated varied as a function of their parents' stressors years earlier. The timing of stress influences differed for mothers and fathers. Specifically, methylation during adolescence was related to maternal stress during infancy but paternal stress during preschool. These findings are consistent with those of Tyrka and colleagues (2012), who found connections between early-life familial adversity (e.g., parental death, maltreatment) and methylation of the glucocorticoid gene promoter in white blood cells. Adults who, as children, experienced early familial adversity had increased methylation of the promoter region relative to adults who experienced more stable and nurturing care in childhood. Borghol and colleagues (2012) similarly identified connections between early SES and methylation of white blood cells in 40 participants from the 1958 British cohort study. In this detailed microarray analysis of approximately 20,000 genes, over 1,200 gene promoters were differentially methylated as a function of early-life SES—over twice as many regions that were differentially methylated as a function of adult SES. Lam et al. (2012) posed similar questions about early SES in a sample of healthy adults aged 25 to 45 but found a more modest association with methylation patterns.

These findings suggest that early adversity may leave an epigenetic residue in the genome of some cells. Based on basic research in model systems, there is reason to suspect these residues may be durable and persist over lengthy periods of time. This stability could help explain how early experiences can develop into diseases decades after the exposure to adversity has subsided. With that said, we do not yet have the prospective, longitudinal evidence in humans to know whether the findings reflect this kind of lasting biological imprint versus some other process or methodological artifact.

Epigenetic Modifications as a Biological Intermediary: Considerations and Caveats

Like the other biological mechanisms we have discussed, the study of epigenetic modifications to DNA poses some important methodological challenges that will need to be addressed in future studies. For example, in trying to extend Meaney and colleagues' findings (Weaver et al., 2004) to humans, research has made use of cord blood cells, white blood cells, and buccal cells. These approaches make sense logistically. Hippocampal tissue cannot be noninvasively acquired in living humans, whereas cells from the blood, mouth, and umbilical cord can be extracted noninvasively. With that said, it is important to keep in mind that very little is known about how well these tissues can serve as a proxy for the extent of methylation in the hippocampus. Many researchers believe the epigenetic processes exist mainly to allow tissues to functionally specialize. If that is true, we need to be cautious about assuming cross-tissue consistency in epigenetic marks, at least until there is evidence to support doing so. Further, the use of heterogeneous pools of cells for measuring DNA methylation raises some concerns. As was the case with telomeres, people vary in the relative proportion of cell types that make up their immune systems and their cord blood, and stress can shift the balance of cell types. And as was the case with telomeres, the degree of methylation varies across cell types (Lam et al., 2012; Ohgane, Yagi, & Shiota, 2008). Together, these issues complicate interpretation of the existing epigenetic data in humans—any disparities linked to adversity

could reflect differences in the cellular composition of samples or the degree of methylation. Some studies have addressed the issue of cellular composition in their analyses. Lam and colleagues (2012), for example, found that white blood cell methylation was correlated with the relative amount of lymphocytes and monocytes present in individuals. Thus, assessments of DNA methylation may need to take into account the relative proportion of cell types in the sample.

Finally, it will be important for future studies to explore the functional implications of adversity-related changes in methylation. Much work in this area proceeds on the assumption that epigenetic changes will have consequences for gene expression, as they do in the animal studies. But this assumption is not always borne out in studies of humans, which rely on large heterogeneous pools of cells from the buccal cavity or the immune system. For example, in the study by Lam et al. (2012), associations between methylation and transcriptional profiles were very modest, and this has been the case in other studies too. These findings suggest that methylation is likely to be one process among many that are important in regulating gene expression patterns. Thus, future epigenetic research in this area would be most helpful if it supplemented methylation data with studies of the functional consequences of methylation for gene expression or other relevant outcomes (e.g., see Oberlander et al., 2008, study). Also important in future research will be consideration of other epigenetic mechanisms—such as histone modifications and microRNA expression—that can work in concert with methylation to influence patterns of gene expression.

Inflammation

Inflammation: Background and Measurement

Inflammation occurs when cells of the innate immune system, including neutrophils, dendritic cells, monocytes, and macrophages, gather at the site of an infection or injury. These cells attempt to eliminate the pathogen, rid the body of infected tissue, repair any damage the pathogen caused, and begin the process of healing. The inflammatory response is essential for survival. Without it, minor injuries or infections would be lethal. However, the inflammatory response must be regulated carefully; otherwise, inflammation can become persistent and contribute to the emergence of multiple diseases of aging.

Inflammation is orchestrated by signaling molecules known as cytokines, which are released by immune cells and the damaged tissue. The major cytokines involved with inflammation are interleukin (IL)-1, IL-6, and TNF-α. Researchers sometimes use concentrations of these molecules in circulation as a rough estimate of ongoing inflammatory activity. However, these cytokines are fairly unstable in blood, so a more common approach is to measure CRP, a molecule produced by the liver during inflammation. CRP provides a reliable index of low-grade chronic inflammation over the preceding month or so and is prognostic of morbidity and mortality from a number of chronic diseases of aging, such as diabetes, obesity-related problems, cardiovascular disease, autoimmune disease, and cancer (Danesh, Collins, Appleby, & Peto, 2000; Libby, Ridker, & Hansson, 2009; Ridker, 2007; Yeh & Willerson, 2003). CRP's role is particularly well established in the progression of cardiovascular disease, where in apparently healthy individuals, it presages disease risk in a roughly dose-response manner. The role of inflammation in such a broad array of diseases, along with the relative ease of assessment, has prompted researchers to consider it as a mechanism linking early adversity to later disease.

Evidence for the Role of Inflammation as a Biological Intermediary

Mounting evidence supports the idea that exposure to early adversities is linked to measures of chronic inflammation. For example, in a prospective study of 12,000 adults from diverse backgrounds, early-life SES measured in childhood was inversely associated with CRP, independent of current SES (Pollitt et al., 2007). Similarly, in the British Women's Heart Health Study, evidence for a cumulative effect of SES was found: Lower status across development was associated with increases in CRP (Lawlor, Smith, Rumley, Lowe, & Ebrahim, 2005). Further, links between childhood SES and inflammation were examined in a sample of adults who took part in the Coronary Artery Risk Development in Young Adults study (CARDIA; Taylor, Lehman, Kiefe, & Seeman, 2006). In this study, Taylor, Lehman, Kiefe, and Seeman (2006) found that childhood SES was associated prospectively with measures of psychosocial functioning (e.g., depression, social contacts), which in turn predicted CRP.

Additional evidence suggests that early-life socioeconomic disadvantage confers risk for immune system profiles characterized by proinflammatory responses (Miller et al., 2009). In this study, researchers examined healthy adults who were either low or high in childhood SES (as defined by the prestige of their parents' occupations). Participants' white blood cells were cultured in vitro with a series of microbial products, and the magnitude of the cell responses to these stimuli was indexed by subsequent production of IL-6. Participants who were exposed

to socioeconomic disadvantage as children showed more pronounced IL-6 production in response to bacterial challenges relative to participants from families of high SES. Notably, participant groups in this study were balanced on the prestige of their adult occupations, which removed the possibility that these findings were attributable to adult SES.

Similar evidence has been found for the role of the early family emotional climate on adult inflammation. In the Dunedin longitudinal study, for instance, multiple assessments of early maltreatment and harsh parenting were predictive of CRP at age 32 (Danese et al., 2009; Danese, Pariante, Caspi, Taylor, & Poulton, 2007). For example, Danese and colleagues (2007) reported that adults who had been maltreated as children had a threefold higher level of CRP at age 32 relative to individuals who had not been maltreated. Similarly, those who came from poor backgrounds and were socially isolated as children were also more likely to show high CRP; notably, these risk factors were independent of each other.

Several other studies have assessed inflammation in samples of adults who were asked to report retrospectively on experiences of childhood abuse. In one study, adults who had been abused as children had higher circulating IL-6 and TNF-α levels relative to adults who did not report being abused as children (Kiecolt-Glaser et al., 2011). In the Nurses' Health Study II, Bertone-Johnson and colleagues found a link between retrospectively reported sexual abuse in adolescence and CRP and IL-6 in adulthood (Bertone-Johnson, Whitcomb, Missmer, Karlson, & Rich-Edwards, 2012). Interestingly, however, this pattern did not emerge when examining the link between inflammation and reports of physical abuse.

In the MIDUS sample, Slopen and colleagues (2010) examined a range of adverse early-life experiences as predictors of inflammation. In particular, adversity in childhood and adolescence was measured across three domains, including stressful life events (e.g., parental alcohol or drug problems, school failure), parent-child relationship quality (including relationships with mothers and fathers), and the frequency of verbal and physical abuse. Scores across each of these domains were standardized and then summed to create a composite of early-life adversity. This composite measure was associated with five different biomarkers of inflammation for African-American participants but not for participants of European descent (Slopen et al., 2010).

In summary, emerging evidence suggests that to the extent that individuals are exposed to early adversity, as adults they display evidence of mild, chronic inflammation. Further, many of the chronic diseases of aging (e.g., cardiovascular disease, strokes, autoimmune diseases, some forms of cancer) are widely recognized to involve chronic inflammation. Thus, inflammation could play a mediating role in the links between early adversity and adult physical health.

Inflammation as a Biological Intermediary: Considerations and Caveats

Converging evidence suggests that early adversity may contribute to later disease through inflammatory processes. Despite these encouraging findings, we note that there are several limitations that will need to be addressed in future studies. Like the studies of other biological mechanisms, many of the studies linking early adversity to inflammation rely on a single assessment of inflammation, which limits our ability to conclude that exposure to adversity causally shapes inflammatory activity. Longitudinal studies, with multiple assessments of inflammation, will help clarify the extent to which early stressors lead to changes in inflammation over time. These types of studies also will help to clarify the chronicity of the inflammation. To be plausibly involved in accelerating disease, the inflammation would need to be long standing. Only via multiwave studies can we ascertain whether inflammation is transitory or chronic. Another issue to be addressed in future studies is the fact that most existing studies of inflammation capture ongoing inflammatory activity in peripheral blood rather than inflammation in tissues or organs. Thus, it is unclear whether these measures of inflammation reflect activity happening in the tissues that are directly relevant for chronic diseases (e.g., coronary arteries, pancreas). Finally, nearly all studies focus on proinflammatory processes, but anti-inflammatory signals play an important role in regulating the balance of inflammatory activity. Going forward, researchers should examine both pro- and anti-inflammatory signals to capture a more comprehensive picture of how the immune system responds to adversity.

CONCLUDING COMMENTS AND DIRECTIONS FOR FUTURE RESEARCH

Over the last 30 years, researchers have made considerable progress in identifying links between early adversity and adult physical health outcomes. Findings from epidemiological studies, animal studies, and naturalistic experiments converge on the idea that exposure to early adversity is a risk factor for cardiovascular disease, metabolic disruptions, some cancers, and even early mortality. Great strides

have been made in formulating hypothesis-driven, conceptually based models that set out to test the processes by which early stressful experiences become embedded in the body only to emerge as physical health problems, early aging, and chronic disease several decades later.

Yet despite this wave of exciting research progress, we are only beginning to understand the pathways linking early adversity and health. Many of the studies to date, including retrospective reports and cross-sectional study designs, have significant methodological limitations, which limit our ability to draw strong conclusions about causality. Similarly, our knowledge about the biological mechanisms that might explain the progression from early adversity to accelerated aging and disease in adulthood is considerably lacking. Next we identify several key research areas that will be important to explore in the next generation of studies linking early adversity to adult physical health. The list of research priorities is far from exhaustive; nevertheless, advancements in each of these areas will increase our understanding of how and under what contexts early adversity shapes long-term physical health outcomes.

Expanding Research to Other Periods of Development

The large majority of the research reviewed in this chapter focuses on the impact of adversity that occurs during the early childhood years. There is good reason for this emphasis: During these early years, many biological systems are especially sensitive to environmental effects, and many organ systems and tissues are undergoing a rapid period of development, expansion, and specialization. At the same time, however, these early years capture only a brief glimpse of development, and we believe that other developmental periods as well as transitions across developmental periods may be particularly sensitive to the effects of adversity in ways that can make individuals susceptible to physiological disruptions and progression toward disease. We describe several of these opportunities for future research next.

Prenatal Period

The *fetal-programming model* (Lucas, Fewtrell, & Cole, 1999) posits that in utero experiences shape infants' development by exposing them to maternal signals about environmental conditions to be expected at the time of birth. From an evolutionary perspective, the ability to send signals to the developing fetus has a number of advantages for survival: The fetus, in response, can alter its development in preparation for the demands of the environment. Cottrell and Seckl (2009) have suggested that prenatal overexposure to glucocorticoids might be one mechanism through which prenatal stress results in greater risk for health problems, such as cardiovascular disease and metabolic abnormalities. Evidence from animal studies lends support to this hypothesis, but whether such an effect is present in humans remains to be seen.

Findings from a number of studies suggest an important link between prenatal experiences and subsequent outcomes in infants (e.g., Field et al., 2004; Oberlander et al., 2008; Sandman, Davis, & Glynn, 2012; Sharp et al., 2012) and adults (Heijmans et al., 2008). Using a sample of mothers who varied in their levels of depression during and after pregnancy, Sandman and colleagues (2012) examined the hypothesis that infants are calibrated in utero for postnatal environmental conditions. As predicted, infants with the best performance on measures of mental development (e.g., sensory-perceptual acuity) and psychomotor development (e.g., body control) were ones who had similar pre- and postnatal environmental experiences—even when those experiences included maternal depression. In other words, infants who experienced maternal depression pre- *and* postnatally fared better than infants whose mothers were depressed at only one time point. These somewhat counterintuitive findings suggest that infants receive important programming signals in utero, and when these signals do not correspond with the external environment, infants show early delays in motor skills and mental development. Evidence about the long-term deficits related to the incongruence between prenatal and postnatal environments is lacking, however. It is possible that these effects disappear by childhood or have little long-term health relevance. Nevertheless, continued research in this area will be useful for determining the extent to which prenatal exposure to adversity confers risk for long-term physical health problems.

Adolescence

Adolescence is a developmental period of multiple transitions, characterized by fundamental changes in biological, cognitive, social, and psychological processes (Holmbeck, 1994; Lerner & Castellino, 2002). Researchers now widely consider adolescence to be the second critical period of development, and experiences during this period are thought to have an unusually strong influence on long-term health outcomes. This plasticity confers unique sensitivity to environmental and contextual experiences that can have a lasting impact on health. Indeed, from a health perspective, adolescence represents a critical time in which long-term health trajectories are set in motion, and the precursors of chronic disease often emerge during this period (Lule, Rosen, Singh, Knowles, & Behrman, 2006).

Further, recent estimates suggest that a growing number of adolescents show symptoms that are indicative of metabolic disruption (Cornier et al., 2008).

Compared to the extensive body of research on pediatric and adult health, adolescent health has received far less attention, which is surprising given that adolescents represent 25% of the world's population (Sawyer et al., 2012). The World Health Organization, UNICEF, and the *Lancet* (Sawyer et al., 2012; United Nations Children's Fund, 2012; World Health Organization, 2014) recently highlighted the importance of investing in adolescent health research in order to address significant gaps in knowledge about determinants of health across the life span. The growing prevalence of health problems in childhood and early adulthood, including obesity and diabetes, has both immediate and long-term social, economic, and medical consequences. Although adolescent mortality rates are quite low, the precursors of chronic disease often emerge during this period (Balagopal et al., 2011; Berenson & Srinivasan, 2005). For example, risk for heart disease, including the early formation of atherosclerotic plaques, becomes apparent in adolescence. Thus, attempts to identify the processes that set adolescents on trajectories that culminate in health problems across the life span are of significant public health and economic importance. Moreover, identification of early-onset predisease processes has the potential to identify individuals for whom targeted interventions may be most beneficial.

An additional question about the connection between stressors and health outcomes in adolescence relates to the fact that the onset of puberty corresponds with many of the transitions that take place during this developmental period. We know little about how puberty and the corresponding shifts in stress hormones interact with stressful experiences to shape physical health outcomes—both in adolescence and into adulthood. These questions will be important to address in future research.

The Study of Transitional Periods Across Development

Transitional periods in development, such as the transition from elementary school to middle school and the transition to adolescence, have the potential to be stressful periods for children (Graber & Brooks-Gunn, 1996). These periods often are marked by dramatic shifts in behavior, responsibility, rules, and opportunities. Given the sweeping changes across social, cognitive, affective, and biological domains and the onset of new stressors that take place around developmental transitions, researchers should examine how transitions may create stressors that put children at risk for health problems. Transitional periods that affect social and emotional functioning also may engender changes in physiology and risk for poor health. To study biological changes that co-occur with transitional periods, longitudinal studies will be necessary, an issue we discuss in more detail later.

Strengthening Study Designs

Throughout this chapter, we have noted some of the important methodological limitations that limit our ability to make definitive conclusions about the extent to which early exposure to adversity leads to chronic diseases of aging in adulthood. Next we review a few of the main study design limitations and offer some solutions for stronger research designs that can be used to test research questions about how early adversity becomes biologically embedded in the body and translates into physical disease in adulthood.

To date, cross-sectional and retrospective studies make up the bulk of studies on early adversity, biological intermediaries, and later health outcomes. Although there certainly is merit in identifying connections at the cross-sectional level, our ability to draw conclusions about the causal nature of these links is substantially limited with these study designs. For one thing, retrospective reports have significant weaknesses (as discussed earlier in the chapter), which call into question the validity of the reports. Further, cross-sectional study designs cannot shed light on whether exposure to adversity contributes to dysregulation and disease or is simply a correlate of these outcomes. Future research needs to incorporate longitudinal study designs with multiple assessments of biology to allow for stronger statements about the direction of effects. These study designs can be costly and time-intensive, but they are important for researchers who wish to take a developmental approach to understanding the processes through which early adversity influences health. Of course, it is not necessary for researchers to conduct decades-long research investigations focused on experiences from infancy through adulthood in order to add to our understanding of adversity and health. For researchers who wish to test mediational models and developmental cascades models, at least three time points are preferable, with sufficient time between assessments for measures of interest to change during that period. Longitudinal designs that are conducted over relatively short time frames still can add insight into the intermediary processes that take place on the road from early adversity to chronic disease.

Another concern focuses on the nature of various proposed biological mediators of the link between early adversity and adult health. Many of the biological

mechanisms that we have described in this chapter are thought to serve as intermediate phenotypes, and they should be assessed at multiple time points to examine change over time. Research that can map the trajectories of these biological markers across time would greatly add to our understanding of how these mechanisms eventually lead to disease. Moreover, researchers studying these biological mediators should be aware of the strengths and weaknesses of the mechanistic concepts and methods used to measure them. They also should be aware of the untested assumptions about the clinical relevance of a number of proposed biological mechanisms (e.g., telomeres in nonreplicating cells, circulating cortisol).

Another way to strengthen future study designs is to conduct experimental and quasi-experimental studies. Given that some environmental experiences cannot be assigned randomly for ethical reasons, intervention studies may be a useful way to evaluate changes that result when reducing environmental exposure to adversity. Some evidence suggests that interventions designed to address socioeconomic disadvantage may lead to improvements in physical health. In the 1990s, the United States Department of Housing and Urban Development undertook a large-scale randomized intervention study in five large U.S. cities to examine the health outcomes associated with moving out of poverty (Ludwig et al., 2011). Families were randomly assigned to one of three groups: One group received housing vouchers to move to a low-poverty area, another group received the vouchers without the low-poverty location restriction, and a third control group did not receive vouchers or counseling. Approximately 10 years later, Ludwig and colleagues measured a variety of metabolic outcomes, including glycosylated hemoglobin and BMI. Women who moved to low-poverty neighborhoods had decreased rates of extreme obesity and glycosylated hemoglobin relative to women in the control families. These findings suggest that reducing exposure to adverse neighborhood experiences may have long-term health implications. This study was focused on health outcomes of adult women, but it is possible that similar intervention programs will have beneficial effects for children living in poverty. In fact, these types of intervention programs may have a stronger influence on children compared to adults if such an experience can create a lasting change in children's developmental trajectories.

Buffers and Protective Factors

As described earlier in this chapter, epidemiological findings suggest that exposure to stressful adverse experiences is a significant risk factor for poor health outcomes. Nevertheless, not all individuals who experience adversity get sick (e.g., Chen et al., 2011; Miller, Lachman, et al., 2011). Research focused on buffers against the negative mental health outcomes associated with adversity has uncovered key variables that might help explain why some individuals thrive despite early experience with adversity. Researchers have identified intrapersonal characteristics (e.g., temperament, emotion regulation capacities), family characteristics (e.g., sensitive caregiving), and neighborhood factors (e.g., connections to adults in the community, access to support services) that serve as buffers and help protect children from some of the negative consequences associated with exposure to socioeconomic disadvantage and maltreatment.

To date, most of this research has focused on protective factors for mental health outcomes, and only recently have researchers studied whether there might be buffers that mitigate the negative physical health outcomes associated with exposure to early adversity (Chen, Lee, Cavey, & Ho, 2013; Miller et al., 2011). For example, in a sample of healthy adolescents, low SES was associated with higher circulating markers of inflammation, but only for adolescents who did not have a supportive role model (Chen et al., 2013). Similarly, in a sample of adults who experienced low SES in childhood, high levels of maternal warmth buffered adults against a phenotype characterized by proinflammatory signaling (Chen et al., 2011). These findings are notable because they offer insight into the reasons why not all individuals exposed to early adversity go on to experience poor health in adulthood.

Another related question concerns the timing of these buffers. Recent empirical evidence for the positive outcomes associated with protective factors has focused on buffers that are temporally connected to the experience of adversity (e.g., receiving supportive caregiving or having a role model while living in poverty). Research on the effects of these buffering factors also should examine the extent to which buffers at other important periods of development might play a role in mitigating risk. For example, adolescents who experience adversity in early childhood may benefit from supportive caregivers or role models in adolescence. It may be, however, that support systems need to be in place at the time of exposure to adversity to offset the negative experience. These questions will be particularly important to explore in order to shed light on what factors are most effective at ameliorating the negative health outcomes associated with exposure to adverse experiences.

Translational Implications

After identifying the protective factors that shield children from the negative health effects associated with early adversity, clinicians and researchers should use this information to develop testable interventions to examine whether the programs that foster behavioral changes also shape biological intermediaries in ways that have long-term implications for physical health. For example, programs designed to provide mentors and supportive role models to at-risk children may alter biological pathways that ultimately could improve long-term physical health outcomes. Similarly, parenting interventions that reduce children's exposure to harsh parental caregiving could shape biological processes in ways that minimize risk for accelerated aging and early mortality. For example, evidence from an intervention study suggests that children whose foster parents received a positive parenting intervention showed declines in basal cortisol levels relative to control children whose foster parents did not receive the intervention (Fisher, Gunnar, Chamberlain, & Reid, 2000). Although this study had a small sample size (just 10 children in each condition), the findings offer some indication that parenting interventions might affect predisease pathways in ways that are beneficial to health. Community programs that are designed to improve family socioeconomic conditions may provide opportunities for researchers to examine whether a modest change in the experience of early adversity shapes epigenetic modifications, HPA axis activity, and inflammation. These kinds of translational studies will require researchers and community advocates to work together to advance our understanding of how early adversity shapes physical health.

Linking Research on Developmental Psychopathology and Health Psychology

Throughout this chapter, we have noted a number of instances in which exposure to early adversity has been associated with long-term mental health but not physical health outcomes (e.g., effects of exposure to interparental violence, natural disasters). This trend is not entirely surprising, given that programs of research often are focused on a narrow set of outcomes (e.g., mental health *or* physical health). Yet this tradition of focusing on a restricted range of outcomes ignores the fact that researchers interested in developmental psychopathology and health psychology often are motivated by a similar set of research goals. Going forward, we believe that a more integrated and interdisciplinary approach to research on mental and physical health is warranted. To the extent that researchers in these fields can share theories, methods, and work together collaboratively, scientific progress on all fronts will be much more rapid. Indeed, there are some exciting questions at the intersection of these fields, which we hope researchers will soon answer. For example, researchers across these disciplines frequently seek to understand the long-term developmental effects of early exposure to adversity and whether there are intrinsic or extrinsic buffers that can offset the negative outcomes associated with stress. These questions—and many others—will be of central interest in the years to come.

Conclusions

We look forward to the next generation of studies on early adversity and adult physical health. In the coming years, more research on the biological intermediaries linking early adversity and adult physical health will help uncover the processes by which stressful life events translate into chronic disease and accelerated aging. This research should take a developmental approach, using prospective studies and incorporating multiple levels of analysis, from molecular studies to large-scale epidemiological studies. The use of comprehensive models (e.g., models of equifinality and multifinality, developmental cascades, differential susceptibility) will help shed light on questions about (a) the relative timing of events in development (e.g., sensitive periods, transitional periods), (b) the complex interconnections among risk and protective factors, and (c) the biological consequences associated with early adversity. Findings from these studies will offer new ideas that can help inform public policy and clinical practice.

INTRODUCTION: VIOLENCE IS COMMON BUT PROBLEMATIC

Violence is a ubiquitous human behavior, occurring across human societies, economic and social positions, and the life span. Yet, for the vast majority of people, direct exposure is rare and is a high impact experience. Similarly, every community has violence, but exposure to violence in the community is exceptional in all but a few locations. Most people are violent at some point in their life and

accordingly have some victimization or witnessing experience. Yet even among individuals exhibiting violence at a relatively high rate and for those residing in our most dangerous neighborhoods, violence is still rare during conflict, when facing frustration, or when intending to aggress. Similarly, experiencing violence as a witness or direct victim, while it occurs at alarming rates for some portions of the population, remains in almost each instance an experience that stands out as remarkable. Thus, the experience and impact of violence exposure, even while having limited direct involvement, has substantial impact on development and warrants careful attention of developmental psychopathologists. This chapter focuses on the impact of exposure to one form of violence, community violence. However, in order to understand the subcategory of community violence, it is important to consider violence more generally and violence in other forms as a human behavior and environmental experience/condition more generally.

Evolutionary biology and archeological research explain violent behavior as an adaptive or protective response to compete for resources and power in the social hierarchy and to fend off similar threats from outside the group (Eisner, 2011). Folk and formal literature reveal a long-standing reporting of violence as an undesirable but complex part of human nature dating back to some of the earliest writings (James, 2011). For example, James (2011) notes a record from AD 24 of a trial of Plautius Silvanus for killing his wife by pushing her out a window. His defense was that he was asleep at the time and that she must have leapt. He committed suicide while awaiting trial. Also, his prior wife subsequently was tried for having driven him insane with potions and incantations leading to the murder of his second wife. In this example and in multiple historical accounts from the earliest times, two seminal controversies can be found that persist about the meaning of violence particularly in regard to psychopathology. Is violence a willful criminal act to be treated as a justice issue, or is it an outcome of emotional loss of control or other forms of psychopathology? Is it an inevitable part of human behavior? Are those who commit violent acts psychopathological or simply evil, and if sometimes one and sometimes the other, how do we distinguish these? Is use of violence and harm from it the result of pathological upbringing, or is the developmental course one of less proneness and impact as we mature, such that adults are expected to have full control over that behavior? Is use of violence the result of goading and provocation or a reflection of character and personality makeup? Are there times when violence is appropriate, perhaps even desirable? Is violence exposure inevitably harmful, or does that depend on the type and extent of exposure? What can be done about violence and to help those most vulnerable to its influence?

While these considerations fill volumes of legal, philosophical, and social analyses, and violence and related aggressive behavior have received as much attention as any subject in psychology, most of the controversies that are the subject of this scholarly attention remain unresolved. Understanding violence remains of critical interest in understanding psychopathology and is in need of more study. Violence is of continuing interest to those attempting to understand its pernicious role in the developmental course of psychopathology (Cicchetti & Toth, 1995). Violence is implicated regularly in theories about developmental psychopathology, whether as a symptom of some psychopathologies, a putative cause, or the conduit through which psychopathology can be imposed or promoted (e.g., violence causing traumatic anxiety in a witness or victim; Tolan & Gorman-Smith, 2002). In addition, violence occurs in many forms, from a variety of sources, and with differing levels of injury (including death; Tolan, 2007). Capturing the many roles, features, and meanings of violence for developmental psychopathology and organizing them into a coherent explanation can be challenging, because different aspects can seem pertinent depending on the specific interest (Elliott & Tolan, 1999). However, coherently relating the many aspects of violence is essential in order to understand community violence and violence as a whole and to advance knowledge about its role in psychopathology.

This chapter focuses on one form of violence, which is often cited as particularly pernicious: community violence. Still, there is limited understanding of this particular form of violence exposure and its effect on developmental psychopathology. Adequate understanding of the state of knowledge rests on integrating important work from a developmental psychopathology perspective on community violence, on other forms of violence, and on related descriptive and intervention studies. Therefore, this chapter begins with an overview of the multiple definitional challenges in determining what violence is, in general, and how it relates to the common view and framework of community violence. This general-to-specific relation is pertinent in the ensuing sections on patterns of violence exposure, causes of exposure, effect of exposure, interventions and policy related actions, and suggested further research and actions.

VIOLENCE PERPETRATION AND EXPOSURE ARE IMPORTANT BUT POORLY DEFINED DEVELOPMENTAL PSYCHOPATHOLOGY CONSTRUCTS

Because almost all people are violent at some point in their life and almost all are exposed to some form of direct violence, it is noteworthy that violence nevertheless is seen as dramatic and/or problematic in all but a few instances (e.g., minor physical aggression among young children, righteous war, self-defense, fighting injustice). Also, the harm is not seen as limited only to direct exposure or to whether that exposure is experienced as victim or perpetrator. Indeed, there is little disagreement that violence is almost always problematic and that abating it is positive. However, beyond that matter, consensus drops quickly about how it is understood and what to do about it. Much of the disagreement is tied to how violence and violence exposure are defined. In addition to carrying differential assumptions and connotations, the definitional variations make scientific comparison and certainty difficult. Moving to a useful scientific understanding of violence requires a balance between precision and consistency in definition and a consideration of the differential interests in research, practice, and policy related to violence exposure. That tension needs identification and articulation to facilitate sustained shared meaning and related action.

What Constitutes Violence for Understanding Developmental Psychopathology?

Among the controversies related to violence are these questions: What is considered violence? How is violence differentiated from nonviolent aggression and other forms of interpersonal disregard or insult (Elliott & Tolan, 1999; Tolan, 2007)? Variations in these boundaries carry important implications for the role of violence in psychopathology, how patterns are identified, what and how risk factors are related, and which interventions and policies seem appropriate. Moreover, different definitions can create variations in data, testimony, and other information that are the bases for scientific and public understanding, variations that in turn can lead to divergence in implications (Loseke, Gelles, & Cavanaugh, 2005). The lack of consensus hinders scientific progress by obstructing coordination and comparison between epidemiological and risk/causal studies, obscuring the meaning of trials of program and service procedures effects, and undermining standards of judging effectiveness. A lack of a consistent shared definition of violence impedes scientific interests such as generalization, replication, and robustness of knowledge. This vagueness of definition also degrades the respect given to such evidence in comparison to opinions and how policies designed to address violence define expertise.

Common and Differentiating Features of Violence

The common feature of most violence definitions is intent to injure from a perpetrator's point of view and physical harm or fear from threat of such harm from a victim's point of view (Krug, Dahlberg, Mercy, Zwi, & Lozano, 2002). Forms of violence are distinguished along dimensions that also form legal distinctions about violence: intentionality of action and a level of notable harm. This definition differentiates violence from injury that may result from an accident (no intention), negligence (failure to show due caution that results in harm), and recklessness (acting in such a manner as to greatly increase the potential for injury), not by the harm that may result by criminial intention (mens rea). Mens rea is legally an essential component of crime perpetration.

This definitional base also emphasizes physical harm or the threat of such harm (e.g., the threat to hit if someone does not do as the perpetrator insists) as an essential determinant that violence has occurred. Violence can be narrowly defined as an act of intentional physical aggression inflicted in order to cause and resulting in physical injury of self or another. Constraining the definition in this way has the advantage of making determination of what is violence easy and tracking violence patterns and effects more straightforward. Such clarity may enable criminal and civil codes to guide legal procedures more easily. It also may be more important for tracing epidemiological patterns than including less certain acts and intentions (Tolan, 2007). However, these benefits may come at the cost of excluding many important nuances of violence experience. Such a narrow definition simplifies three components that vary across violence definitions: (1) role of intent, (2) what constitutes an aggressive act, and (3) how harm to the victim(s) should be considered. For example, violent intentions may not result in injury. Recklessness, while a less intentional condition leading to harm, can be as injurious as other forms of violence and can appear intentional to the victim. Similarly, violence may not always be expressed directly or experienced directly. It can come in the form of intimidating gestures or verbal threats of violence. Participants in a conflict may have quite different perspectives on whether violence

was present, using different thresholds of what is termed physical threat and what needs to be explicit or can be implied to constitute violence. For example, a group of young men on a city corner may see as a threat another group of young men from a different neighborhood moving physically closer to them. They may be correct if the groups are organized gangs competing for drug sales turf. They also may not see such a move as violence, as no one was actually attacked or hurt, or no direct threats were made. Similarly, a couple bickering loudly within earshot of neighbors may induce fear and worry about the female's safety for some, but others may see the encounter as dramatic but insubstantial. The arguing couple may each experience the conflict as imminently at risk for violence or not.

Are Physical Harm Threat andlor Intent Necessary for an Act to Be Violent?

There is less certainty, and substantial disagreement, about how fully intentional the expression to cause physical harm must be for the act to be considered violent. The extent to which intent is seen as required for violence to occur is important for understanding how violence arises in relation to psychopathology. Similarly, the likelihood or imminence of intentional harm can affect how violence exposure is tied to trauma. It may be that traumatic impact is significantly dependent on actual harm (compared to threat or witnessing violence) or it may not be. Similarly, it is an unsettled debate whether, for violence to be present, the intention must be to cause physical harm or merely to coerce another (Tolan, 2007). For example, most would agree that threatening to hit someone unless he or she does as you demand is violent. However, in a given study, there may be important variations in impact and basis for effects depending on whether threat is treated the same as physical injury and how matters such as perceived intent and imminence are considered. At present, most of the difference in inclusion and exclusion across studies and reviews is not based on careful definitional comparison or empirical tests of the role of intention, actual harm versus fear of harm, and/or imminence of harm. Instead, variation in measurement makeup often is overlooked. Also, frequently a measure shows that a particular perspective was applied without the basis of the theory being clearly acknowledged (Chalk & King, 1998). Stakeholders vary widely on where such boundaries should be drawn (Jackman, 2002; Jouriles, McDonald, Norwood, & Ezell, 2001; World Health Organization [WHO] Summit on Violence, 2002). For example, while some definitions restrict violence to imminent threat of harm, others expand it to include direct attempt to oppress or coerce, and others go further, including where it might be implicit or would be considered so by an outside observer. These boundaries have been debated most when violence is occurring in a relationship and there is differing power and ability to cause harm (e.g., domestic violence, child abuse).

In regard to a recipient or victim's perception of potential harm or threat of injury as part of the definition of violence, some argue that acts, orientations, or statements that are experienced as intimidation, coercion, oppression, or creating undue insecurity are violent, even if they do not involve actual physical aggression or specific verbal threats. From this viewpoint, if the "victim" feels threatened or afraid or identifies some act as violent, it is considered violent. Although this definition incorporates the experiencing of violence and informs about behavior during conflict, it also introduces unspecified variation in responses within samples and across studies. Moreover, we cannot see any differences among the contribution of violence, the perspective about violence, and personal reaction when they are all collapsed into defining any interaction as violent.

Others suggest that violence should be differentiated from the victim's perception of threat even if only to permit more careful empirical testing of the relation between acts and perceptions (Johnson, 1995; Malley-Morrison & Hines, 2004). For example, in such an approach, the act would be defined as violent by intention to injure or to directly intimidate through threat of violence. Typically, some determination is made about what is a reasonable or common basis for concluding that threat has occurred (akin to the legal criterion of "reasonable person standard" for perception and expectation). This is done so that variations in labeling and reaction can be studied and understood as important but distinct components. When defined with objective criteria rather than personal determination, it can be argued that more sensitive consideration of variations in what is threatening also can be better considered because the perception and the conventional/objective definitions can both be considered. In addition, proponents of such a distinction would note that it also helps in offering perspective in explaining violence and the effects of the relationship between the involved persons, such as ongoing high levels of interpersonal conflict, contemptuous attitudes, or neglect of expected care. It is argued that limiting the definition of violence to the act itself and by using a "reasonable person" standard of threat/harm, research can disentangle violence and its affects from co-occurring problems. Research also can differentiate

between related but distinct contributors to functioning, susceptibility to trauma or other pathology effects, and best interventions.

Cultural and Societal Variations in What Is Considered Violence

Another important challenge in defining violence is that cultural differences may affect the meaning of the terms *violence* and *injury* (Hudley & Taylor, 2006; Walters & Parke, 1964). For example, injury in some cultures is broadly defined as an attempt to harm or manipulate the well-being of others. Alternatively, in other cultures, injury is reserved for serious physical harm, and minor assaults may not be considered violence. Similarly, behavior that is considered very offensive in one culture may be considered acceptable, even expected, in another. Even if physical force is clearly evident, such acts may not be seen as violent, or they may not be treated as similar to other acts of violence. For example, if two friends are teasing each other in a display of relative dominance during a group gathering of adolescents, one might smack the other upside the head. This action would not be seen as violence by anyone familiar with the exchange; it would be seen as part of group hierarchy competition in certain contexts. If asked about violence exposure, neither the perpetrator nor the victim would report this event.

Outside observers might say that this exchange was clearly violent, even if the adolescents involved did not view it that way. Whether cultural acceptability and commonality of occurrence should be considered criteria for violence remains controversial (Tolan, Dodge, & Rutter, 2013). For example, in a state of armed struggle, exposing children to violence may be seen as unavoidable. Therefore, those responsible for their safety and well-being may focus on how that exposure is managed and how the child might learn to avoid such exposure. Similarly, outsiders may view increasing empathy for an enemy and trying to train youth not to act violently toward members of the enemy's group as virtuous. However, within the culture, such actions may be seen as confusing and harmful to the children. Turning the other cheek may diminish children's vigilance, which risks their safety and/or distracts from allegiance to a religious cause or patriotic interest (Garbarino, 1996). A more common example of violence as part of developmental psychopathology is the question of how violence by parents affects youth when it is a part of routine discipline (Lansford et al., 2005). Although studies provide mixed results, a trend shows that cultural variation in harm of corporal punishment is related to how typical such practice is and how acceptable or normative it is perceived to be. It may be that acceptance of minor forms of punishment vary by culture whereas severe physical punishment may not be. The lesser forms of punishment also may be part of what is viewed as parental responsibility (or hierarchically, by teachers to students or older children to younger children).

Cultural considerations in the definition of violence also apply to understanding community violence, particularly how fear and perceived safety are related to actual levels of harm. For example, in the United States, there is a belief that violence in schools is increasing in the form of sudden violent rampages resulting in multiple victims. Each such horrific incident receives wide attention in the media, but it is important to recognize that such incidents still are extremely rare. At the same time, other types of school violence, which in fact causes more victims per year, do not receive such attention. These acts include student-to-student, student-on-teacher, and teacher-to-student violence. This violence often is concentrated in schools that serve lower-socioeconomic-status (SES) and ethnic minority populations. And, while some schools account for a higher percentage of overall violence, most schools are safe and in fact remain among the safest environments for children across neighborhoods. These variations in what affects the perception of school safety means that actual and believed threat may diverge, to the point that concern could be diverted to circumstances where violence victimization is actually unlikely (Tolan, 2001a).

Similarly, fear of strangers abducting children led to an infusion of funding and programming to teach children about "stranger danger," even though such occurrences are much less common than abduction by a person known to the child and is much less likely than harm from family members. Such emotionally charged responses seem to misdirect from acknowledging violent threats by family and acquaintances in favor of a much less likely threat of violence from strangers. For example, it may be presumed that violence exposure is not an issue in middle- and upper-middle-income communities because such communities have lower nonfamily assault and homicide rates than poorer and urban counterparts. Yet victimization, witnessing, and awareness of violence occurs within such communities. Conversely, it does not accurately characterize the daily experience of most urban, lower-SES residents (Horney, Tolan, & Weisbourd, 2012). These examples indicate that the perception of a setting as violence prone or violence ridden can induce fear, hypervigilance and

mistrust, attitudes that affect the definition of violence and how it may affect development.

Gender and Defining Violence

Related to the cultural and societal variation in violence perceptions is the understanding of the role that gender plays. Evidence clearly shows that males perpetrate violence at greater rates and are exposed to greater levels of violence than females (Farrington, Langan, & Tonry, 2004). Gender differences, particularly in physical aggression, are present early in life and remain throughout development (Tremblay et al., 2005). Further, it is widely recognized that male aggression includes more violence, ability to harm, intimidation, and other threatening aspects than female aggression. Also, community violence disproportionately occurs by and to males, although the extent of difference is hard to determine from existing research.

Yet among community samples of male-female couples, overall rates of violence do not differ by gender, and most violence is rare and minor (Tolan, Gorman-Smith, & Henry, 2006). A key consideration is that male relationship violence is more likely to be part of a pattern of coercion, intimidation, or contempt. This difference in relationship power is considered important in defining violence and in locating concerns about battering, political and economic inequities, and social resources when characterizing gender-based violence (American Psychological Association [APA] Presidential Task Force on Violence and the Family, 1996; Jouriles et al., 2001). Whether attempting to incorporate status differences in defining violence overtly or noting this contextual determinant of how violence and threat of violence might be related to gender, it is evident that the relation of exposure to psychopathology is dependent at least in part on this variation. These considerations have been central in research and policy debate about partner violence but have received much less attention in the study of community violence. In part, this is because much of the interest in violence emanates from study and policy related to domestic violence. Also, domestic violence is differentiated from what is considered community violence, treated as different in regard to likely effects on witnessing and with different treatment legally (likelihood of legal intervention and seriousness of potential charges). Whether status difference is literally less pertinent for community violence or not, partner violence is overheard regularly by neighbors. Thus, partner violence can also be community violence. It spills into the community experience, bringing to light gender and related power and threat differences for measuring and evaluating community violence exposure.

Moreover, there is controversy about how cultural variations and how gender should be incorporated into violence definitions. For example, even if actions that are violent, if violence is defined as physical harm or threat of such harm, are legal or sanctioned, should they be treated as violence in studies identifying patterns and rates and relating outcomes to risk factors? Should acts that seem to diminish the rights or status of others be treated as violence, even if they are labeled "not violent" in a given culture (Fagan & Browne, 1994)? When an act seriously harms the viability and safety level of a community, even if the act is legal or sanctioned, should it still be considered violent? Is the failure to care for those in pain or the imposition of prolonged neglect an act of violence? Not surprisingly, some argue for culturally based definitions of violence, whereas others argue for absolute definitions that focus on physical harm or imminent threat of harm. Some believe variations should be measured consistently and then interpreted within cultural contexts and other potential influences (Farrington et al., 2004; Krug et al., 2002). One argument for such an approach is that the relation of gender to violence and other cultural and societal variations that affect how a given act is perceived, experienced, and viewed by others needs to be considered. The best way to do that is to differentiate these variations from what is called violence. A second argument is that these effects are marked through legal codification, traditions, social structures and other engrained beliefs, so translation of scientific findings using this differentiation is more in line with social policies and existing norms. A third argument is that these considerations are always present, albeit in varied importance and prominence, and as such they should be measured separately for full consideration even if they are not implicated in a specific experience of a given individual (Chalk & King, 1998; Tolan et al., 2006). These arguments seem to permit due accounting of the role of gender in violence without conflating gender with violence.

Defining Violence Exposure for Developmental Psychopathology

These variations in what is considered violence and how it is measured affect studies of violence exposure and its impact, yet specifics of measurement formulation are rarely described in empirical studies. While giving due consideration to these variations in perspective, concerns, and empirical basis, there is consistency across studies that

points to the experience or imminent threat of physical harm as the hallmark of violence. This does not mean other forms of aggression and threat are not harmful or can be neglected, or that corollaries and corresponding problems are not worthy of consideration in understanding violence as a developmental psychopathology issue. However, focus on this central distinguishing feature seems important to permit differentiation and organization of the relation of violence exposure to closely related experiences and to conditions, covariates, and group differences in effects. Thus, there is increasing agreement that violence should be limited to referring to intentional physical harm or immediate threat of such harm to coerce another.

Even these basic considerations could lead to definitions that may vary in what is considered violence exposure. Because violence is a politically, socially, and culturally determined construct, there is an unavoidable compromise required between interests such as definitional precision and replication comparability and encompassing varying applications for policy and other actions (APA Presidential Task Force on Violence, 1996; Chalk & King, 1998; Office of the Surgeon General, 2001; WHO, 2002). For purposes of this chapter, the definition rendered by the *World Report on Violence and Health* (*WRVH*; WHO Summit on Violence, 2002, p. 5) seems to capture the variations in violence forms and sources while distinguishing it from other related behaviors. It is also suggested here as a definition for future work in the field:

> the intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment, or deprivation.

The WRVH Typology of Violence

The *WRVH* also provided a typology of violence and categorized it into four modes of injury: physical, sexual, psychological, and deprivation. As is evident from this differentiation, there is interest in discerning when the injury is through sexual violence. The categorization also shows that in addition to physical injury, there can be injury that is psychological or that occurs by depriving the victim of basic needs or safety. These details help to define more specifically the forms of harm or likelihood of harm that are important in understanding violence and differentiating it from other potential risk influences.

WRVH also differentiated violence into three subtypes based on the victim-perpetrator relationship. *Collective violence* refers to violence committed by large groups of individuals, connoting the role of the group in precipitating the violence of the individual members. Collective violence includes acts that can be *social group*, *political*, or *economically* based. *Self-directed violence* refers to violence in which the perpetrator and the victim are the same individual, with distinction between *self-abuse* and *suicide*. *Interpersonal violence* refers to violence between individuals, and can be further differentiated into *family/intimate partner violence* and *community violence*. The former category includes child maltreatment, intimate partner violence, and elder abuse, while the latter is differentiated into *acquaintance* and *stranger* violence. With these categorizations and differentiation of forms of harm, this WHO definition brings into relief the complex variations that violence exposure can take and some systematization of how to measure and compare variation impact by type and relationship of victim and perpetrator. By these categorizations and in most writing, community violence includes: youth violence; assault by strangers; violence related to property crimes; and violence in schools, workplaces, and other institutions.

Considering Neglect or Deprivation as Violence

The word *power*, sometimes used in defining violence perpetration, refers to use of power in relationships and in relative social standing as a basis for imposing physical harm, threat of loss of safety or essential care, or deprival of resources (neglect). This view of coercive use of power as violence has focused most on relating gender to understanding violence impact. The inclusion of the use of power also incorporates treating acts of omission or deprivation/neglect as being violent. In order to understand violence as part of developmental psychopathology, this inclusion is important; it allows consideration of how coercion and harm can arise from lack of expected care or concern. However, this inclusion seems to suppose that effects of deprivation of care or regard are similar in extent and process as physical threat or harm rather than being based in empirical support. This relation is far from clear. In part, this is because many samples in studies to identify effects on maltreatment included children exposed to neglect as well as those physically or sexually abused. In most such cases, the large majority of such children have been neglected as well. These two limitations prevent understanding of how effects of neglect relate to other forms of victimization (Trickett & McBride-Chang, 1995). However, when differentiation permits comparison, results are mixed about whether neglect and violence have the same pathology-inducing and function-impairing effects (Trickett & McBride-Chang, 1995; Twardosz & Lutzker, 2010).

The way in which neglect relates to actual physical harm is relevant to community violence because community violence often includes exposure that is indirect or that induces fear. From that view, the absence of a safe environment is implicated as one form of violence exposure. For example, does failure to provide children with a safe route to school constitute the same harm as witnessing violence during that route?

This WRVH definition also includes a broad range of violence effects that stretch beyond variations in physical harm to include an increase in frequency of psychological disorders, elevated susceptibility to such disorders, and failures in development. While not stated explicitly, the definition also permits considerations in alteration of developmental pathways and sensitivities that can evince diminished functioning at key transitions or specific situations and at other points in the life span. Thus, consequences can be immediate as well as latent and can last for years after the initial violence. Also, it is important to consider not only the effects of violence on victims but also to examine the effects on perpetrators, those emotionally connected to the victim or perpetrator, and those witnessing the violence either directly or indirectly (e.g., child experience of partner violence between parents).

Defining Community Violence and Exposure

If violence is defined as imposing intentional physical harm or as the imminent threat of such harm, then community violence is the form of these actions that occur in one's community. Community violence is often differentiated from other violence in that it is something other than family or partner violence or violence between friends or acquaintances. It is also differentiated by where it occurs (or actually by where it does *not* occur). Community violence usually is defined as exclusive of violence in the home or at work. Violence at school is sometimes differentiated from community violence but most often is treated as a subset of community violence or separate therefrom. A third differentiating characteristic of community violence is that it includes a broader set of experiences than most other forms of violence. It is thought to include not only direct injury and threat of such injury but also knowledge or witnessing it. Often simply residing in a neighborhood with elevated rates of crime and violence is considered to be exposure to violence—growing up in an unsafe neighborhood with elevated opportunities to witness violence or know persons affected by violence can potentially affect development. Community violence is differentiated from family violence by the relationship between the perpetrator and the victim or witness. Also, as family violence means violence between persons who are also often responsible for care and affection toward each other or the child, the emotional and relationship complexities are differentiating. Similarly, serious injury or death of a family member caused by someone other than the family is usually distinguished from community violence. It should be noted that while these definitional differentiations are increasingly considered in measuring impact of different forms of violence, measurement of community violence varies considerably from study to study in what is included, how well it is differentiated from other forms of violence, and to what extent community violence is considered along with other forms (often only one form is considered in any given study).

Therefore, community violence exposure refers to a broad range of experiences related to violence and should be considered on a study-to-study basis. For example, violence exposure may refer to living in a high-crime community in one study, or it may be limited to serious violence that community members have heard about. Or it may be measured as personal experience of being the victim of physical aggression or witnessing it. Because community violence is often of interest as much for its direct effects as for its impact on creating an unsafe environment, many studies collapse varied contact with violence, such as victimizations of friends and families, witnessing or learning/knowing of violence in the surrounding community, with firsthand victimization. Thus, to some extent, community violence can refer to some subset or a variety of forms of violence that do not occur between family and friends and are not the result of war or political actions. Also, a given study may not distinguish, in measurement or in calculation of variable relations, the differences among direct victimization from exposure due to being a perpetrator of violence from witnessing violence as a bystander, from merely knowing about recent violent events, or a perception of low safety personally or of the school overall (Tolan, 2001a).

Differentiating Types of Community Violence Exposure

There is increasing agreement regarding the need to measure each of these types of exposure and to test for differentiation of effects (Tolan, 2001a). For example, Shields, Nadasen, and Pierce (2009) reported that direct victimization had more substantial and sustained effects on children's social and psychological distress than witnessing or hearing about violence, but the latter two forms were not significantly differentiated in regard to effects. However, the pattern of findings suggests it is not merely a matter

of extent of exposure or proximity to victimization that accounts for impact. Along that line, Schwartz and Proctor (2000) found that violent victimization was associated with negative social outcomes whereas witnessing violence was related only to subsequent aggressive behavior. Moreover, victimization effects on outcomes were mediated through emotion dysregulation. In a study with a related but different focus, Gorman-Smith, Tolan, Sheidow, and Henry (2002) tracked the link between family violence involvement and community violence and found that it was rare that community violence perpetration occurred without concurrent or preceding violence at home. Yet family violence did not simply account for effects of violent behavior in the community.

Empirically tracing the role of violence exposure to youth development and psychopathology patterns, causes, and course can entail extensive complexity. In fact, measurement detailed enough to make all the differentiations noted here as potentially relevant is impractical even for large studies with considerable resources. Also, as initially noted, it is unlikely for a given person to engage in violence even if subjected to it over substantial amount of time. Serious incidents of violence are rare enough to strain statistical reliability and validity assumptions for accurate interpretation of patterns even in high-crime communities. For these and other reasons most of the literature has focused on violence exposure overall, with a few instances in which differentiation of community violence from family violence is incorporated. What is known about demographic patterns, relation of forms of exposure, correlates, risks and protective factors, and effective interventions is often about exposure as generally defined or if there is more differentiation of type, role in the violence, or extent of exposure it is specific to the interest of the particular research project. There is little consistency across studies in such differentiation.

RATES AND PATTERNS OF EXPOSURE TO COMMUNITY VIOLENCE

Exposure to community violence came to the fore as a public health issue because surveys evidenced high rates of violence victimization and witnessing among youth residing in low-economic inner-city communities (Gorman-Smith & Tolan, 1998). These reports coincided with empirical verification of traumatic stress in veterans due to exposure to violence of war conditions and independent reports of posttraumatic stress symptoms, similar to what was seen in war veterans, among children exposed to terrible events. These events, such as kidnapping, produced interest in the conditions of a community, particularly violence levels, might potentially harm children (Tolan & Guerra, 1998). A third coincident influence was the emerging literature documenting effects of child abuse and neglect on developmental psychopathology (Cicchetti & Toth, 1995, 2005). As with traumatic impact of war and disaster, the finding of links between abuse and psychopathology susceptibility and developmental course helped to persuade many scientists and policy makers that violence in the community could have direct effects on child development.

Many of the initial reports about community violence rates, while useful in marking such violence a risk factor of importance, were dependent on questions that often were general, did not make clear the time frame for response, and did not provide ways for children to differentiate types of exposure. Moreover, there was considerable reliance on convenience samples via one-time surveys and limited attention to population representation and variations (Margolin & Gordis, 2004). Only a few of these studies differentiated questions about community violence exposure from familial or acquaintance violence and that which was a by-product of perpetration of violence from exposure due to victimization (Gorman-Smith & Tolan, 1998). Nevertheless, what was shown was that some children, particularly those residing in impoverished inner-city communities, experienced community violence at alarming levels, with reports as high as 70% reporting violence exposure (Thompson & Massat, 2005). For example, several studies published in the early to mid-1990s estimated that about 25% of inner-city youth have witnessed someone shot and/or killed during their lifetime (Groves, Zuckerman, Marans, & Cohen, 1993). The shock of one in four children witnessing such serious violence as well as documentation of related psychopathology led to much interest in rates of violence exposure of youth in the United States. As with child deaths due to violence, the United States stood out from other countries in the rates of children exposed to serious violence (Tolan, 2001b).

National Surveys

More careful assessment and sampling, although they documented for lower rates overall, seemed to verify the exceptional level of community violence exposure of U.S. youth. It also verified elevated rate of exposure in economic poor urban (inner-city) communities. For example, a recent national sample of U.S. adolescents found that 55% reported some type of violence exposure (McCart

et al., 2007). Similarly, another national sample study estimated that 17.6% of children and adolescents are direct victims of an assault in the community (Finkelhor, Turner, Ormrod, Hamby, & Kracke, 2009). One of the most extensive surveys has been by Finkelhor and colleagues (Finkelhor et al., 2009; Finkelhor, Turner, Shattuck, & Hamby, 2013), who reported on exposure to multiple sources of violence. Utilizing an extensive questionnaire, the Juvenile Victimization Survey, on a national sample of children ages 2 to 17 (adult reported for those under 10), found that 33% reported witnessing violence in the past 12 months, with 69% reporting some exposure to violence during their lifetime. In another report from the same data, Finkelhor et al. (2013) found that 22% of children had witnessed violence in their homes and schools in the past year and 39% had witnessed violence against another person during their lifetime. Specifically, 16.9% reported witnessing an assault of another in the community in the past year, with a lifetime prevalence of 27.5%, and 3.4% reported indirect exposure to community violence in the past year, with a lifetime prevalence of 10.1%. Notably, these rates are higher than for witnessing violence toward a family member or in the home. Other studies that have differentiated community violence from other exposure led to national estimates of witnessing community violence that range from 19.2% to 37.8%, with rates in inner-city communities of 30% to 50% directly experiencing violence and over 70% witnessing some form of serious violence (Finkelhor et al., 2009; Stein, Jaycox, Kataoka, Rhodes, & Vestal, 2003; Tolan, Gorman-Smith, & Henry, 2004;).

Among the major finding from this survey was the pattern of polyvictimization—that is, children exposed to violence were often exposed to more than one form. As the number of forms of violence they were exposed to increased, so did reported distress and problems in functioning. The results may suggest that the harm that results from multiple exposures does not increase linearly as exposure increases but may have qualitative increases in harm. However, this study leaves undifferentiated the extent to which effects from exposure overall differs from overall and component types of exposure. Repeated exposure and exposure to multiple types of violence are rare but are strongly related. In addition, multiple exposures may be attributable to additional risk factors also related to psychopathology. Thus, while documenting that multiple exposures occur and may have a nonlinear impact on functioning, this correlational survey study cannot authoritatively provide understanding about how exposure across types might impact psychopathology.

The Centers for Disease Control (CDC) has used the Youth-Risk Surveillance Survey to track exposure to and engagement in violence in school and the community. Although it does not differentiate fully community versus school or in-home/familial violence, the questions utilized permit reasonable estimates of community violence exposure. The most recent report, for 2013, indicated that nationwide, 24.7.8% of students had been in a physical fight one or more times during the 12 months before the survey, with the rate higher among males (30.2%) than females (19.2%) and higher rates by ethnicity (CDC, 2014). Blacks had a higher rate (34.7%) than Whites (20.9%) and Hispanic youth (28.4%). Also, Whites and Hispanics differed significantly. Within gender, the ethnic differences were maintained, but within ethnicity, the rate difference for males to females was similar. As with many violence exposure indicators, the rate has decreased since 1991 from 42.5% to 24.7%, with a significant drop between 2011 and 2013 (32.8%). The number of youth who reported having been threatened or injured with a weapon on school property one or more times during the preceding 12 months was 6.9%; 8.1% of youth reported being in a physical fight at school. Each indicator followed the same pattern of higher rates among Black than White or Hispanic youth as well as higher among males than females. In most cases, the differences between Hispanic and White youth were significant as well. The same ethnic group pattern was found for forced sexual intercourse (7.3% overall), but women reported rates of about twice to three times what males reported (10.5% to 4.2% overall respectively). Also, unlike most other physical attacks, significant differences in rates between 2001 and 2103 were found.

Being bullied at school (the only setting asked about) showed a different ethnic and gender pattern. Overall, this was reported by 19.6% of students with females reporting higher rates than males (23.7% versus 15.6%) and a higher rate among non-Hispanic White students than Black or Latino students. Similarly, with an overall rate of 7.1% indicating they had not attended school at least 1 day during the 30 days before the survey due to feeling unsafe at school, females had a higher rate than males. This rate was higher among Blacks than Hispanics. Both rates were higher than for non-Hispanic white students. Notably, the rates of such behavior increased from 1993 to 2013 rather than decreased, as has experience of violence at school and overall.

Across indicators, irrespective of gender or ethnicity trends, there was considerable variation in exposure by state and among similar communities. For example, across 37 states, the prevalence of having been in a physical fight ranged from 16.7% to 31.0% with a median of 22.8%.

Across 19 large urban school districts in the survey, the median prevalence rate was 26.3% with rates ranging from 17.2% to 37.6%. Although not summarized here, comparisons do tend to find urban-suburban differences in violence exposure rates.

Estimates from Youth Self-Report of Violence Involvement

Another way to estimate exposure to community violence, particularly of youth, is to consider how youth report weapon carrying, which suggests either likelihood of violence or concern for victimization. Notably, the vast majority of weapon-carrying youth say they do so for protection against attack rather than as intention to harm others (Tolan, 2001b). The CDC Youth-Risk Behavior Study (2014) reported 17% of youth had carried a weapon at least 1 day in the past 30 days, (more than 1 in 4 males; only 1 in 12 females). The highest rate was for White males (33.4%) followed by Black Hispanic males (23.8%) and Black males (18.2%). Female rates did not differ significantly by ethnicity. Gun-carrying patterns mimicked the overall weapon-carrying rate (5.5% overall; the highest rate, 10.7%, was for White males). There was no significant difference between Black and White males (Black males 9.8%, White males 10.7%)]).

Variations in Exposure by Gender and Ethnicity

These patterns reveal consistency in greater exposure for males than females for most types of violence, particularly community violence. Similarly, minority ethnic groups tend to have higher rates of community violence exposure, a fact that seems to be closely related to differences in likelihood of residing in a community marked by concentrated poverty and other associated problems, including higher violence rates. Therefore, it seems that differences in exposure rates are mostly accounted for by community economic levels and related resources. However, these covarying neighborhood conditions also represent a complex pattern of elevated risk, lesser opportunities, and scarce resources for avoiding exposure and for managing exposure (Tolan, Guerra, & Montaini-Klovdahl, 1997). These conditions constitute a differential risk ecology that may well relate to differential bases for exposure, impact of exposure, and ability to mitigate exposure and impact.

The gender differentiation seems to cut across ethnic groups and economic levels (to the extent studied). In this case, the greater exposure does not correlate with the group that has greater social status or access to more resources for coping. In addition, as with other forms of violence, serious community violence is more likely to emanate from males than from females. Thus, the differential exposure seems to reflect differences in proclivity for involvement in settings and antisocial behavior that is related to violence. Notably, the few studies that have made gender comparisons show consistency in relation to symptoms and impact on functioning, although exposure rates tend to be higher for males (Fowler, Tompsett, Braciszewski, Jacques-Tiura, & Baltes, 2009; Pinchevsky, Wright, & Fagan, 2013). Yet in one of the most thorough comparisons of forms of exposure, Pinchevsky et al. (2013) reported that direct (victimization) and indirect (witnessing or hearing about) community violence proved to have limited relation to substance use for males (alcohol or marijuana use) but significant relation to use for females. The effect was more robust for indirect exposure than direct exposure. Notably, all of the relations were small, and many relations were not significant.

Age and Exposure

Exposure to violence in general and to community violence in particular is usually related to age, with adolescence marking a time of substantial increase in both time spent in the community and unsupervised time there. This means that youth not only have greater opportunity for exposure to violence, but violence also may occur in part because adult supervision that could quell it is not present (Tolan & Guerra, 1998). The exception to this general trend is for physical assault when violence (abuse) from family members is not differentiated. However, Finkelhor et al. (2013) state that across maltreatment sources, rates of maltreatment reported for children ages 2 to 5 was 10% ; ages 10 to 13, 17%; and ages 14 to 17, 21%. Physical assault rates did not increase over time. Witnessing violence increased from a rate of 8% of those ages 9 and under, to 26% for those ages 10 to 13 and 43% for those ages 14 to 17 (Finkelhor et al., 2009). Indirect exposure increased from a rate of 2% for ages 9 or younger to 4% for ages 10 to 13 and 6% for ages 14 to 17.

Another trend evident across studies is that severity of violence exposure increases with age. For example, in the Finkelhor et al. survey (2013), those under 9 years of age were most commonly exposed to assault without a weapon or without injury and assaults by a sibling, with 10- to 13-year-olds reporting more assault with a weapon, sexual harassment, and kidnapping and reporting more witnessing of domestic violence in the home involving their parents and assaults by other family members. Fourteen- to 17-year-olds had the highest rates of any age

group for the most serious forms of violence victimization. Among this age group, the most common types of exposure were injurious assaults, gang violence, sexual assaults, physical and emotional abuse, and witnessing violence in the community. They also reported more sexual violence victimization than younger children.

Community Violence and Residing in Low-Socioeconomic-Status Urban Neighborhoods

Implicit in results of the CDC surveys and others is that exposure to community violence is related to residing in urban neighborhoods with concentrated poverty, or what has been termed the inner city (J. Wilson, 1987). These neighborhoods are marked not just by elevated rates of violence, but low home ownership, the absence of middle-income residents, and many other social and political problems. There is now considerable evidence that living in such neighborhoods is associated with exposure to a host of risk factors, reduced protective factors, and many other poor outcomes for children, including aggression, violence, substance use, depression, and academic failure (Gorman-Smith et al., 2002; Leventhal & Brooks-Gunn, 2000; Sampson, 1997). Surveys of children and adults reporting about children sampled from lower-SES urban neighborhoods routinely report high levels of exposure (40%–70%) to the most serious forms of community violence, setting these neighborhoods apart from most other U.S., communities regarding child risk for exposure to community violence (Tolan & Gorman-Smith, 2002).

The juxtaposition of patterns evident in the CDC survey and others—which show greater rates among those residing in low-SES, urban neighborhoods—seems to explain much of the difference in exposure for minorities, who reside disproportionately in these neighborhoods. It is not clear how much of the difference is due to the compilation of risk factors, such as urban residence and lower economic status and the concomitant dearth of resources, or how much is the confluence or coincidence of these factors for given neighborhoods. However, most studies to date have not systematically compared what might differentiate exposure across such communities or compared them with communities that differ on one but not other risk characteristics. Most of the literature focused on community violence has used samples from communities that are urban and have low socioeconomic levels. As such, this population has comprised a large proportion of minority ethnicity samples, but without due recognition that these characteristics might differentially relate to violence exposure and impact. Nor is adequate consideration given to how the conflating of these two demographic characteristics may lead to unjustified conclusion that it is both ethnicity and low income prevalence that promotes community violence. Because the majority of studies also focus on the variation of exposure for individuals within high-risk communities, the focus tends to be on how individual and family variables explain exposure and impact rather than on how community differences and demographic differences might explain them. Thus, the understanding based on current findings is constrained to documenting that rates drawn from such neighborhoods are high and that relations to psychopathology can be found in many studies, some of which are focused on youth from urban, poor communities. For example, in a study of youth receiving mental health services, community violence, domestic violence exposure, and maltreatment effects were differentiated. Community violence and maltreatment contributed uniquely to conduct disorders, whereas domestic violence did not. Community violence, but not maltreatment and domestic violence, predicted externalizing behavior (McCabe, Lucchini, Hough, Yeh, & Hazen, 2005). However, the sample was not systematically differentiated or stratified by community of residence, limiting implications to how individual variation in exposure affects these relations and differ by forms of violence.

WHAT ARE THE MENTAL HEALTH AND BEHAVIORAL EFFECTS OF COMMUNITY VIOLENCE?

The majority of research on community violence has focused on documenting a relation to psychopathology symptoms. Primary interest has been about the effects on externalizing symptoms (aggression, antisocial behavior) and disorders (conduct disorder), internalizing symptoms and disorders (primarily depression but more recently an increased focus on anxiety) and posttraumatic stress disorder (PTSD). Studies have increased in sophistication over the past two decades from convenience samples with cross-sectional correlations to consideration of longitudinal tracking and modeling of how variations in exposure, psychopathology measurement, and covariates and moderators interact in affecting the patterns. Although there are studies that have controlled for exposure to other forms of violence, looked at other risks for psychopathology, and applied careful measurement of type and extent of exposure, these tend to be the exception. For example, a school-based study examining school, home, and neighborhood violence exposure reported that school

and home exposure predicted internalizing symptoms, whereas only home exposure predicted delinquency and overt aggression (Mrug, Loosier, & Windle, 2008).

As in the other areas of interest, the considerable study of violence exposure due to maltreatment also seems informative about likely effects of community violence (Paolucci, Genuis, & Violato, 2001). In addition, there has been considerable attention to effects of witnessing and being involved in parental domestic violence (Evans, Davies, & DiLillo, 2008; Kitzmann, Gaylord, Holt, & Kenny, 2003). For example, in a sample of youth identified by child protective services as neglected/abused, harsh physical discipline was associated with externalizing whereas witnessing home violence was associated with internalizing behaviors (Maikovich, Jaffee, Odgers, & Gallop, 2008), suggesting that different types of violence exposure may have different effects. These studies could be informative about different levels of exposure.

Studies also vary considerably in how recent the exposure was, how carefully chronology of exposure is considered (lifetime versus recent exposure), and correspondingly how time is considered in measuring psychopathology effects (e.g., current status, recent functioning, lifetime occurrence). Also, most studies focus on relative differences in level of psychopathology symptoms, not on presence or absence of disorder. In many cases, the relative differences, although statistically significant, are modest in size between two nonclinical range scores. Yet results from studies that have relied on diagnostic criteria or cut scores thought to correspond to clinical problems are generally consistent with those utilizing symptom scale score comparisons. Similarly, few studies have considered the impact of community violence exposure on practical functioning indicators, such as school functioning, relationship quality, or economic well-being. The few that are available suggest some substantial effects.

Most of the existing studies have at least one of the limitations mentioned. These methodological considerations mean that interpretations are best focused on relative risk increase and probability of disorder than on suggesting direct causal role in mental illness. Similarly, the overall trends across studies provide a more reliable guide than any given study. Methodic reviews have been provided over the past 10 years, including a recent thorough meta-analysis of studies of community violence exposure relation to psychopathology (e.g., Fowler et al., 2009; Lynch, 2003). In addition, a substantial literature has been produced about potential protective factors (Gorman-Smith, Henry, & Tolan, 2004) and about related topics, such as children witnessing domestic and other violence (Evans et al., 2008; Kitzmann, Gaylord, Holt, & Kenny, 2003). These related studies can also inform about the psychopathology effects that seem attributable to community violence exposure.

Meta-Analysis of Effects of Exposure to Community Violence

In 2009, Fowler and colleagues reported a thorough meta-analysis of studies of the relation of community violence exposure to psychopathology symptoms. Of the 110 studies and 116 samples (n = 39,667) published before 2005 that had adequate documentation to permit effect size calculation, Fowler and colleagues found that total level of exposure (however measured) predicted mental health symptoms significantly and substantially. The reported effect size averaged $d = .63$ for externalizing symptoms and $d = .45$ for internalizing symptoms. In addition, because PTSD symptoms were commonly considered as a distinct outcome in many studies, Fowler et al. examined effects on PTSD symptoms and reported an average effect of $d = .79$.

Effects for Different Levels of Exposure

Fowler et al. (2009) were able to examine effects for different levels of exposure. It had often been speculated, and some studies suggested, that those who were direct victims of violence were more at risk for psychopathology effects than those who merely witnessed and/or had heard about violence near where they resided (Martinez & Richters, 1993; Nader, Pynoos, Fairbanks, & Frederick, 1990). For example, Nader et al. (1990) reported that children who were on a school playground during a shooting at that school had more severe symptoms than children inside the building, and both showed more symptoms than children who were not at school that day. Fitzpatrick and Boldizar (1993) found victimization but not witnessing related to depressive symptoms. For externalizing symptoms, direct victimization ($d = .78$) and witnessing ($d = .72$) effects did not differ from each other, but both were greater than hearing about community violence ($d = .42$). For internalizing symptoms, the effects differed by direct victimization ($d = .45$) compared to witnessing ($d = .32$) or hearing about community violence ($d = .27$) but the latter two exposure types did not significantly differ. PTSD symptom effect sizes did not differ by level of exposure ($d = .65$ for direct victimization, .60 for witnessing, and .63 or hearing about).

Effects for At-Risk versus Other Samples

Fowler et al. (2009) reported that effects of exposure were not significantly different for externalizing or internalizing

problems for samples identified as at-risk by virtue of residence in high crime communities in comparison to effect for those not having this risk status. However, the relation was significant for both groups on each outcome. When PTSD was the outcome, stronger effects were found for the samples not residing in high risk neighborhoods. Notably, only samples in which the neighborhood risk could be identified were so rated, meaning that some of those samples not so rated simply lacked enough information about where the sample was from to determine if crime was elevated in those communities.

Age Patterns in Effects

Fowler et al. (2009) reported that some age patterns were significant, comparing adolescent-only to child-only to mixed child and adolescent samples. For externalizing symptoms, correlations were greater for adolescent samples ($d = .99$) than for mixed child and adolescent samples ($d = .53$), which were greater than for child-only samples ($d = .35$). For internalizing, mixed-age samples had the largest effect ($d = .51$), which was greater than for adolescent samples ($d = .45$), and which was greater than found for child-only samples ($d = .33$). For PTSD comparisons, a similar pattern to internalizing symptoms was found, with mixed samples having stronger effects ($d = 1.02$) than for adolescent-only ($d = .66$) or child-only ($d = .63$), but with the latter two not significantly different.

Gender and Ethnicity Variations in Effects

Gender comparisons in the meta-analysis of Fowler et al. (2009) did not show significant differences in effect sizes for externalizing or PTSD but did find stronger effects for females than males for internalizing symptoms. Ethnicity comparisons showed significant effects for all ethnic groups, with some suggestion of lower effects for internalizing and PTSD for African American and larger effects for PTSD for Latinos when compared with each other and non-Hispanic White samples. However, Fowler et al. noted that relatively few studies had female-only samples or effects reported in a way that could be separated; likewise, there were not enough studies of Latinos or non-Hispanic Whites to permit sensitive comparisons. Thus, any conclusions need to be drawn with caution.

Example Studies Linking Exposure to Psychopathology

Studies Relating Externalizing Problems to Community Violence Exposure

Within the overall significant relation between community violence exposure and externalizing symptoms reported by Fowler et al. (2009), there was significant variation in quality of studies and in strength of findings. The interest in violence exposure promoting aggression, conflict with authority, involvement in delinquency, and exhibition of violence has been long-standing (Gorman-Smith & Tolan, 1998; Lambert, Ialongo, Boyd, & Cooley, 2005; Lynch & Cicchetti, 1998). Many of these studies focused on variations in symptomology among those residing in high-risk communities. For example, Gorman-Smith and Tolan (1998) demonstrated that among young men residing in high-poverty, high-crime Chicago neighborhoods, the length of community violence exposure related to level of aggression, even if exposure to family violence and exposure to other life stress were controlled for. As with many other studies, family functioning (parenting practices, quality of family relationships) explained likelihood of exposure and effects of exposure. Other studies focused on how neighborhood violence level might help explain externalizing symptoms, with residing in such communities considered as representing more exposure. For example, Plybon and Kliewer (2001) differentiated urban neighborhoods using cluster analyses of indicators or relative poverty and crime levels. Children (ages 8–12) living in high-crime, high-poverty neighborhoods exhibited more externalizing behaviors than those living in low-crime, low-poverty neighborhoods. Neighborhood type was mediated by family stress level; and family cohesion moderated the relation of neighborhood type to externalizing. Other studies have examined the relation of community violence exposure to personal behavior. For example, Lynch and Cicchetti (1998) reported that externalizing behavior among urban 7- to 12-year-olds predicted increased exposure to community violence one year later, even when prior exposure was controlled. Gorman-Smith and Tolan (1998) found similar effects but also showed that when controlling for prior behavior, community violence exposure predicted increased aggression. Lynch and Cicchetti also demonstrated that family violence increased likelihood of community violence exposure. Gorman-Smith, et al. (2002) reported similar results for their inner-city male sample. However, in both studies and as examined in some detail by Gorman-Smith et al., the overlap of patterns suggested much variation in likelihood of exposure to violence in the home and also in the community.

Not only do these examples show consistent linkage of violence exposure to occurrence of and growth in externalizing symptom levels; they also suggest several aspects of understanding that relation. First, both child behavior and family circumstances contribute to differentiating the

likelihood of exposure and effects of exposure. Second neighborhood social relation are important for understanding effects (Sampson, Raudenbush, & Earls, 1997). However, there is still a gap in studies that examine how neighborhood conditions might predict exposure and how such exposure translates to increased aggression and antisocial behavior.

Studies Relating Internalizing Problems to Community Violence Exposure

Multiple studies have shown that violence effects are not specific to externalizing but usually also affect internalizing problems (e.g., Gorman-Smith & Tolan, 1998; Schwab-Stone et al., 1999). In many cases, the internalizing symptoms were measured broadly, not differentiating anxiety and depression or other internalizing effects. Others focused on one specific type of internalizing disorder. For example, Fitzpatrick & Boldizar (1993) linked depressive symptomology to violence in the community. Lynch and Cicchetti (1998) found that direct victimization (but not witnessing) of violence related to depression symptoms. That study controlled for victimization from child abuse. These findings are in line with the overall finding in the Fowler et al. (2009) meta-analysis showing that effects on internalizing may be more specific to community violence victimization than to overall exposure or merely witnessing violence.

Studies Relating Posttraumatic Stress Symptoms to Community Violence Exposure

As noted by Fowler et al. (2009), the largest average effect size of the three psychopathologies considered in the meta-analysis was the relation between exposure and PTSD. As with externalizing, the investigations have gone beyond documenting increased symptomology as a correlate of violence exposure. For example, Garrido, Culhane, Raviv, and Taussig (2010) examined foster care youth to explore the relation between community violence exposure and family violence exposure in predicting trauma symptoms. Community violence was associated with trauma symptoms controlling for family violence exposure, but family violence was not related once community violence was considered. Similarly, in a sample of youth from Cape Town, South Africa, Fincham and colleagues reported that both community violence and child abuse and neglect significantly predicted PTSD symptoms in children. Notably, personal resilience via coping skills moderated the relation of abuse and neglect but not community violence exposure. Gapen et al. (2011) examined how neighborhood processes that are linked to community violence might relate to PTSD symptoms. In their sample of low-income, urban African Americans, perceived neighborhood disorder (a measure of self-reported perceptions of the physical environment) and community cohesion (a measure of perceived social ties) related to self-reported PTSD symptoms even after controlling for previous trauma exposure. Although both neighborhood disorder and community cohesion related to PTSD symptoms, cohesion also partially mediated the relation between disorder and PTSD symptoms.

Studies Relating Other Outcomes to Community Violence Exposure

Studies Relating Substance Use to Community Violence Exposure

Effects on substance use have also gained some attention, although they are usually secondary to another primary interest, such as effects on PTSD. Significant positive associations have been reported in some but not all studies that tested the relation between exposure to community violence and alcohol and/or other substance use by teenagers (Fagan, Wright & Pinchevsky, 2014; Farrell & Sullivan, 2004; ; Kliewer, 2006; Schwab-Stone et al., 1995; Zinzow, Ruggiero, Hanson, Smith, D., Saunders, & Kilpatrick, 2009). Kaufman (2009) reported a difference in habitual drinking for victimization but not indirect exposure and also no difference for drug use. Similarly, Pinchevsky et al. (2013) assessed direct and indirect exposure to community violence (approximating victimization and witnessing as well as proximity as one combined category) in relation to alcohol and marijuana use. They found each type significantly predicted the use of alcohol and marijuana and binge drinking. However, the effects were weaker and less robust for consideration of covariates for males. In a nationally representative sample, Zinzow et al. (2009) reported that witnessing community violence was associated with substance use, although witnessing parental violence was not. Among those who had witnessed community violence, the chronicity of violence exposure also related to substance use. What may be important, but is often not considered, is that violence exposure is more prevalent in communities in which substance use is less prevalent for adolescents. For adolescents, there is a lower rate of substance use among inner-city adolescents than is found in less-violent suburban communities (Tolan & Morris, 2005). Thus, it may be that among those residing in a given community, there is a positive correlation of substance use and violence exposure, but this effect may occur within a community-level relation of relatively lower rates of use.

Studies Relating Community Violence Exposure to Practical Functioning Effects

In addition to the psychopathology symptom effects reviewed by Fowler et al. (2009), it is thought that community violence can affect practical functioning as represented by outcomes such as academic functioning, relationship quality including marital stability, and economic and work functioning (Schwartz & Gorman, 2003).

In regard to academic functioning, several studies report lower academic skills and performance related to community violence. For example, Schwarz and Gorman (2003) correlated academic functioning and community violence, noting the relation was partially mediated by depression score. Bowen and Bowen (1999) reported that school danger predicted declines in grades among middle school and high school students and also predicted lower attendance. A specific study of community violence exposure in a large urban sample found that the degree of exposure affected school achievement and engagement (Perkins & Graham-Bermann, 2012; Ratner et al., 2006). Exposure to community violence negatively correlated with IQ and reading ability in a sample of first graders (Ratner, Chiodo, Covington, Sokol, Ager, & Delaney-Black, 2006).). However, in at least one study of inner-city children, controlling for other stress exposure, community violence did not independently explain school performance (Attar, Guerra, & Tolan, 1994). One longitudinal study noted that poor academic skills predicted earlier exposure to community violence, which related to later level of aggression (Lambert, Bettencourt, Bradshaw, & Ialongo, 2013). Sharkey, Tirado-Strayer, Papachristos, and Raver (2012) reported that children assessed within a week of a homicide that occurred near their home showed lower levels of attention and impulse control and lower preacademic skills than was found otherwise in the community. Parental distress was also elevated, suggesting one mechanism by which this community violence "exposure" could affect child functioning.

This smattering of findings suggests there are several ways that such exposure might affect school performance, engagement, and attainment. It might be that violence exposure compromises self-control, attention management, and the executive functioning critical for achievement. It might be that if travel to and from school is perilous, the ability to attend school is decreased. Similarly, it may be that motivation to achieve is lowered when life expectancy is shorter and life is threatened and uncertain. Further basis for expecting such effects can be found from studies of learning processes related to violence (not specifically community violence). De Bellis, Hooper, Spratt, and Woolley (2009) reported lower vocabulary, language processing, and attention control scores related to such violence exposure. Macmillan and Hagan (2004) reported lower academic attainment among adolescent violence victims. Others have shown the same relation for abused children (e.g., Currie & Widom, 2010; Herrenkohl, Sousa, Tajima, Herrenkohl, & Moylan, 2008; Lansford et al., 2005).

Not surprisingly, given the consistent relation between community violence exposure and increased aggression, there is a positive association between community violence exposure and involvement in the criminal justice system. For example, McGee and Baker (2003) reported that victimization by community violence correlated to juvenile offenses in a sample of 12- to 18-year-old African Americans, with a stronger relation for males than females. Among youth already in the juvenile justice system, those previously exposed to community violence were four times more likely to have committed serious criminal behaviors (Preski & Shelton, 2001). In a longitudinal study, Eitle and Tuner (2002) controlled for prior antisocial behavior, other stress, and demographic characteristics and found that exposure to violence as an adolescent predicted young adult crime. Notably, witnessing and direct victimization each independently added to the explanatory capability of this relation.

Violence exposure on stability and quality of later relationships has not been studied much. Most of the attention has been on documenting greater violence in personal relationships (Gorman-Smith et al., 2002). Covey, Menard, and Franzese (2013) reported that witnessing community violence correlated to marital status quite modestly ($r = .12$ to not having married). The relation was at a level comparable to experiencing abuse ($r = .14$). There has been documentation that adults with histories of child abuse have greater rates of divorce and less stable premarital relationships (Currie & Widom, 2010).

One area that has not received much attention is the long-term effect of community violence exposure on employment and income. Prior studies found such relations for exposure to childhood abuse and neglect (Currie & Widom, 2010; Zielinski, 2009) and adolescent victimization (Macmillan & Hagan, 2004;). For example, adolescent violence victimization was associated with adulthood wages averaging over $1 per hour less than those not victimized. Covey, Menard, and Franzese (2013) tracked the relation between adolescents' exposure to physical abuse, witnessing parental violence, and neighborhood violence in a nationally representative sample of adolescents. Controlling for parental education and

SES level, Covey et al. reported that of the three forms of exposure, only community violence exposure related to employment ($r = -.08$) and income level.

Differentiating or Specifying Effects of Community Violence Exposure

As noted throughout this chapter, much of what has been studied about violence exposure has not been focused on community violence or has not differentiated exposure to community violence from other forms. Lynch and Cicchetti (1998) and Tolan et al. (2006) reported that community violence and other forms of violence are associated, meaning those exposed to one form are more likely to be exposed to another. However, both reports emphasize it is a transactional relation, not merely coincidence that is of interest. This means that among those residing where community violence is more prevalent, those with family violence are more likely to be exposed and susceptible to the effects of community violence. It is also likely that there is some increased acceptance and use of family violence when violence is more frequent or normative in the community (Tolan et al., 2006).

For example, Cichetti and Toth (1995) compared maltreated and nonmaltreated children in a longitudinal study in which exposure to community violence was also considered. They found that maltreated children were more affected by community violence, with specific impact depending on type of maltreatment. Others have compared violence effects from home and school to community exposure. For example, Morales and Guerra (2006) examined the relation of internalizing and externalizing symptoms to exposure in community, school, and at home. After controlling for several risk factors for exposure, community exposure was differentiated from home and school exposure in not relating to internalizing or externalizing symptoms. Community violence attenuated the relation between home violence and internalizing and between school violence and externalizing problems. Similarly, there is evidence that exposure across different contexts is not independent, with those more likely to be exposed in one context likely to be affected in another (Laub & Lauritsen, 1998). These studies point out the value of differentiation of violence exposure from other potential sources in identifying potential risk and protective factors. They also highlight the importance of understanding how risk and protective factors may differentially relate to risk for exposure than to exposure impact as well as by extent or type of exposure. Most fundamentally, these findings point to the need to consider interactive dependencies of influence and to trace the transactional patterns that are the basis for community violence exposure effects.

RISK AND PROTECTIVE FACTORS ASSOCIATED WITH COMMUNITY VIOLENCE EXPOSURE AND EFFECTS

Multiple risk and protective factors have been related to the likelihood of exposure to violence and to the variation in effects of such exposure (Gorman-Smith & Tolan, 1998). These factors range from within-individual characteristics, such as impulsivity and prior aggression level (Lynch & Cicchetti, 2002); to parenting and family relationship characteristics, such as parental monitoring of child behavior and family support and cohesion in managing life challenges (Sheidow, Gorman-Smith, Tolan, & Henry, 2001); to peer influences, such as gang involvement (Thornberry, 1998); to elevated life stress (Attar et al., 1994); to community characteristics related to social functioning of neighborhoods and resources for child development (Tolan et al. 2003). As in other areas of research on this topic, much of what is understood is drawn from inferences from studies of other forms of violence exposure or of community violence considered without controlling for or distinguishing from other forms of violence exposure (Tolan, 2001a). However, there have been empirical investigations of community violence exposure related to indicators within each level of systems of influence in the developmental ecology and also study of the relation of impact if exposed to indicators across several levels. The latter studies often seek to identify protective factors that might mitigate effects or to understand how these additional risk factors might differentially affect those exposed to community violence.

Most studies of community violence exposure draw samples from communities that have elevated crime levels. Often these communities are also impoverished because exposure likelihood is also elevated there. In addition, most of the studies available consider how individuals within such neighborhoods differ in likelihood of exposure or in effects from exposure rather than in how variations in neighborhood conditions systematically relate to group risk. Thus, results inform about individual differences among those residing in communities or attending schools where violence exposure is elevated rather than in the vast majority of communities. Also, as is the case for other topics within community violence effects, often exposure to other forms of violence is controlled for or collapsed into

a single indicator. Thus, there is limited information about how community characteristics affect populations residing in communities where violence is elevated, about how community violence specifically might affect those youth, and about how community violence may affect youth residing in communities without elevated violence rates.

Individual Characteristics Linked to Community Violence Exposure

Studies of individual differences have concentrated on documenting effects of violence and identifying what differentiates impact among exposed individuals. The most documented individual risk factor is prior exposure (often measured as direct victimization) due to other forms of violence and/or community violence. For example, in a national survey, Finkelhor et al. (2009) reported that children who experienced one type of victimization in the past year had double or even triple the risk of other types of victimization. These risks held true for lifetime exposure as well.

Empirical reports of individual differences suggest greater risk for exposure as well as greater impact from exposure for youth with lower self-regulatory capabilities (Lambert et al., 2010; Salzinger, et al., 2002), social-cognitive processes biased toward aggression acceptance and use (Bradshaw, Rodgers, Ghandour, & Garbarino, 2009; Guerra et al., 2003), and higher prior aggression level (Gorman-Smith & Tolan, 1998; Lambert et al., 2005). Hill and Madhere (1996) tested for violence exposure related to social-cognitive features; they determined that perceived level of violence, not outwardly identifiable exposure, that related to social-cognitive features and that this perception mediated the impact of exposure.

Overstreet and Braun (2000) demonstrated that perceived exposure may mediate impact of actual level of exposure, suggesting that social-cognitive features may affect not only exposure but also the impact such exposure has on adjustment. Schwartz and Proctor (2000) and Guerra et al. (2003) each reported effects of violence exposure on social cognition (beliefs about aggression use, norms for violence, problem solving when facing conflicts) and that the effects mediated impact on peer relations and subsequent aggression in the respective studies. Notably, in both cases, the correlations were small but significant, despite the studies taking place over some significant length of time. However, neither study tested how these characteristics might affect risk for exposure.

Accumulating evidence suggests that exposure to community violence compromises central organizing behaviors (i.e., self-regulatory capacities), such as emotion regulation, and impulse control (Attar et al. 1994; Overstreet & Braun, 2000; Schwartz & Proctor, 2000). Impairments in self-control or behavioral control may limit access to social support or increase likelihood of victimization (Pope & Bierman, 1999; Schwartz & Proctor, 2000). Low and Espelage (2014) found that impulsivity related to more exposure and exacerbated exposure effects by increasing involvement with antisocial peers.

In addition, there are indications that prior psychopathology symptom levels relate to greater likelihood of exposure. Gorman-Smith and Tolan (1998) reported that prior depression and prior aggression related to subsequent violence exposure among a sample of inner-city high-risk males. Kliewer (2006) and Overstreet and Braun (2000) reported a similar relation to trauma symptomology. All of these studies noted that psychopathology did elevate risk for exposure but also that greater exposure related to a relative increase in symptoms as well. Thus, similar to the transactional model suggested by Lynch and Cicchetti (1998) for the relation between child maltreatment and community violence exposure, it appears that aggression and depression relate both to greater exposure and also to greater effect if exposed.

Similar but more complex findings were reported by Boyd, Cooley, Lambert, and Ialongo (2003). In that study of urban students from economically disadvantaged schools, teacher and parent reports of aggression at baseline each predicted subsequent exposure to violence, but only for boys. In addition, impact on later behavior was dependent on the boys' anxiety level, with an effect only for low-anxiety boys. In longitudinal follow-up with this urban student sample, Lambert, Ialongo, Boyd, and Cooley (2005) reported that among males, aggression, anxiety level, and depression each related to subsequent victimization but not exposure due to witnessing. However, for females, the relations held across type of exposure. Overall, the reports suggest that effects of exposure, including variation in exposure type effects, immediacy of effects, and psychopathology symptoms affected, may be different by gender.

Studies of the impact of moderators of violence exposure have identified coping skills as a potential mitigating factor (Tolan et al., 1997). Dempsey (2002) showed that violence exposure relates to reliance on aggression and other negative forms of coping. Edlynn, Gaylord-Harden, Richards, and Miller (2008), found methods used for effectively coping with violence exposure may be considered maladaptive in other contexts (e.g., the use of avoidance). In a study of anxiety impact of violence exposure, Edlynn

et al. found that direct problem solving had no moderating effect for young men residing in high-violence, high-poverty urban communities. Other studies suggest that the benefits of coping may be dependent on adequate social support, particularly from adults (Hammack, Richards, Luo, Edlynn, & Roy, 2004)). Tolan and Grant (2009) summarized the research on coping for youth residing in inner-city communities—the communities where violence exposure is most elevated—as often requiring strategic use of methods such as avoidance and reliance on others for protection and guidance largely because personal control over one's own circumstance may be limited. Direct action and individual problem solving may lead to decreased safety and/or engulfment in social challenges that are developmentally beyond what is manageable by children and adolescents. For example, if faced with an unfolding violent situation, trying to stop it may increase the likelihood of victimization. At the same time, reputation and subsequent safety might rest on not opposing the violence.

Others have suggested that coping skills for violence exposure need to be understood from a critical consciousness framework in which the political and social forces thought to be the reason for elevated violence exposure in a given community are discussed and utilized to help support productive coping (Bentley, Thomas, & Stevenson, 2013; Watts, Abdul-Adil, & Pratt, 2002). From this framework, coping is based in cultural identity, awareness of inequities, and positive alternatives to frustration and aggression or depression.

Parenting and Family Characteristics

Exposure to community violence has been related to family structure (Martinez & Richters, 1993), although inconsistently (Fitzpatrick & Boldizar, 1993). Miller et al. (1999) noted that younger siblings of delinquents were more likely to be exposed to community violence. When differentiated from family violence exposure, there is no relation of family structure (e.g., one-parent family) and violence exposure (Hanson et al., 2006).

Some studies have shown a relation between parenting skills and violence exposure as well as impact of exposure (Low & Espelage, 2013). However, the majority of studies that have differentiated particular parenting practices or qualities of family relationships find no significant relation to exposure and show inconsistent relation to impact of exposure (Gorman-Smith & Tolan, 1998; Miller et al., 1999), except as related to maltreatment (Lynch & Cicchetti, 1998).

Risk for exposure to community violence has been related to family alcohol or drug problems (Hanson et al., 2006; Stevens et al., 2005). Similarly, children from families where there was intimate partner violence showed increased risk for community violence exposure (Lynch & Cicchetti, 1998; Rumm et al., 2000). These findings suggest that a breakdown in parenting may result in greater exposure risk for children, and they may incur additional accompanying risk for effects due to similar lack of access to family as a resource (Tolan et al., 2013; Tolan, Sherrod, Gorman-Smith, & Henry, 2004;).

Some have suggested that apart from the effects attributable to parental and family violence exposure, family influence on risk for exposure may be better understood as violent events causing a disruption in parenting support and resources (Tolan & Gorman-Smith, 2002; Trentacosta et al., 2009). From this perspective, violence in the community creates challenges that strain family capabilities, imposes threats that overwhelm or exacerbate other stress faced by families in these communities, and/or occurs along with many other risk factors such as violence-involved peers that also challenge parental efficacy (Overstreet & Mazza, 2003; Salzinger, Feldman, Stockhammer, & Hood, 2002; Tolan & Gorman-Smith, 1997). A study by Gorman-et al., (2004) showed an exception to limited indication of parenting and family relationship correlates to exposure. That study examined person-based patterns of combined parenting practices (monitoring, discipline consistency, use of positive parenting) and family relationship characteristics (cohesion, support, organization) to classify families into four groups: exceptionally well-functioning (high on all scales); typical families (midrange on all scales); struggling families (low on all scales); parenting-focused families (mid to high on parenting scales but not on family relationship scales). Struggling families were more likely than the other types to have sons with greater exposure to violence, but both struggling and parenting-focused families showed greater impact of such exposure than the other two types. The results suggest that children from typical and exceptional families were protected from the effects of exposure on subsequent aggression and depression. This difference in findings for the person-oriented configuration of characteristics from that obtained from variable-based correlations seems to reflect how patterns of characteristics might represent family risk that are not captured in variable-based studies. Specifically, these results suggest that overall functioning of the family and the cumulative impact of different configurations of family relations are important, not just specific, characteristics. In addition, this study suggests subtle differences in what might relate

to exposure and what might relate to effects. Spano, Rivera, and Bolland (2010) recently reported a similar approach and found that particularly vigilant monitoring was related to less exposure of urban impoverished youth but that it had a less clear protective effect for impact. These results are consistent with the studies of Gorman-Smith et al. (2004) and others of family relationship qualities as protective of violence exposure effects (Hammack et al., 2004; Hardaway et al., 2012). In particular, the prevailing findings seem to be that family functioning that includes strong monitoring and warm relationships between parent and child can moderate effects of violence exposure even if it is unable to prevent such exposure (Kliewer, Murrelle, Mejia, Torres, & Angold, 2001).

Peer Influences

Multiple studies have documented a positive relation between involvement with delinquent or violent peers and victimization from community violence (Fagan, Piper, & Cheng, 1987; Felson, 1997; Lauritsen & Davis-Quinet, 1995; Tolan et al., 2003). Affiliation with delinquent peers is related to likelihood of witnessing community violence (Halliday-Boykins & Graham, 2001). Children who associated with more deviant or delinquent peers in one year have greater exposure to community violence in the next year (Lambert et al., 2005; Salzinger et al., 2002). Such association seems to promote risk particularly for high-risk youth. For example, Lambert et al. (2005) reported that deviant peer affiliation moderated the association between aggressive behavior and exposure to community violence. It would be important to disentangle how community violence exposure is related to engagement with delinquent or violent peers (Thornberry, 1998). One important distinction is to differentiate how antisocial tendencies may lead to affiliation with peers who are more violent, thus increasing community violence exposure, from how such exposure may spur peer affiliations with deviant youth. For example, it is evident that violence perpetration increases as youth get involved in gangs and decreases if they leave gangs (Thornberry, 1998). The theoretical explanation is that by being affiliated with violent youth gangs, use of violence is promoted and the youth tend to exhibit violence they might otherwise not perpetrate to. It seems likely that community violence exposure could have similar processes of effects, but it is also plausible that such violence has less direct and immediate influence than that related to peer relationships.

More recently, studies of protective factors for violence exposure effects have identified social support and in particular engagement with peers for social support. For example, Hammack et al. (2004) found that social support (mostly from peers) emerged as a protective-stabilizing force for witnesses of violence both cross-sectionally and longitudinally. Similarly, Hardaway, McLoyd, and Wood (2012) reported that engagement in prosocial activities moderated violence exposure, an effect they thought might be related to support from prosocial peers. Notably, these findings indicate that support, not only from peers but also from family and the family-peer network, serves to mitigate exposure impact (Kaynak, Lepore, & Kliewer, 2011).

Neighborhood Social Relations and Structural Characteristics

Community violence exposure is defined in part by proximity to where the violence occurs. Also, it is well documented that violence exposure is greatest in the lower-SES communities in large cities. Therefore, it seems likely that much of the risk for exposure, and potential solutions to reduce exposure, rest in understanding neighborhood or community characteristics like these (Tolan, Sherrod, Gorman-Smith, & Henry, 2004).). What is now emerging is a theoretical framework for understanding neighborhood characteristics and processes affecting development that can be applied to understanding violence effects (Henry, Gorman-Smith, Schoeny, & Tolan, 2014; Sampson et al., 1997; Tolan et al., 2004). This framework focuses on how community structural characteristics, such as economic resources, income level of residents, and single-parent family prevalence, can affect social problems, such as high crime rates and limited opportunities for conventional achievement. These issues are in turn related to social processes of neighborhoods, such as collective efficacy, informal social control, shared norms, and felt responsibility for the neighborhood safety level.

The interest in how neighborhood differences in economic and social resources and problems relates to crime and particularly to crime inducement has been longstanding (J. Wilson, 1987). For example, community-level variations in population makeup, home ownership, mobility, and housing density positively relate to variations in community-level crime (Bursik, 1988; Byrne & Sampson, 1986). In these and subsequent studies, structural characteristics were differentiated from social characteristics or processes (Sampson et al., 1997; Tolan et al., 2004; J. Wilson, 1987). The term *structural characteristic* refers to demographic, economic, and political differences that mark communities economically and politically and are related to resource limitations and problematic outcomes

(Tolan et al., 2004). Structural characteristics tend to be examined in terms of the average economic status of residents and the range of income levels within the community, the crime rate, and the opportunity for employment and adequate housing and education. Other structural characteristics, such as quality of schools and social and health resources, can also be related to violence (Henry et al., 2014). Theoretically, structural limitations affect the opportunity for neighborhood social processes that are thought to be important for healthy development. The term *neighborhood social processes* refers to relations among residents (Sampson et al., 1997; Tolan et al., 2004). These include processes such as informal social control or how much neighbors regulate each other's behavior through expectations, behavioral norms, and interaction. The classic example of informal social control is the extent to which youth in a community might be subject to control of deviant behavior by the adults in the community (Sampson et al., 1997; Tolan et al., 2004). These processes have been incorporated into an overall construct referred to as collective efficacy (Sampson et al. 1997), which refers to a felt, shared ability among residents to manage issues and problems facing the community. Multiple studies have tracked the combined and interdependent effect of these different aspects of community ecology to violence perpetration, including increased exposure to violent peers in the community (Chung & Steinberg, 2006; Tolan et al., 2003). Recently, Henry et al. (2014) validated a set of scales that measured three neighborhood processes commonly referred to in the literature and that relate to child development outcomes: norms (type of behavioral expectations and extent shared), informal social control (regulation of neighbors by group expectations and felt responsibility for community safety and order), and social connection (extent to which residents organize to manage the neighborhood, spend time together, feel connected). Notably, these sets of scales were validated using neighborhood-level scale construction and also focusing on child development as well as crime outcomes. Many prior measures actually were constructed and validated as individual level measures, even though they were used and interpreted as representing community-level constructs.

Although violence exposure seems to be concentrated in high-poverty urban neighborhoods, the extent of violence and exposure of youth can vary substantially among those with similar structural characteristics (Tolan et al., 2004). Browning, Gardner, Maimon, and Brooks-Gunn (2014) reported that exposure to community violence that was life-threatening had effects on psychopathology for those youth in neighborhoods with low collective efficacy but not when efficacy was elevated. Tolan et al. (2004) showed that while neighborhood processes could be predicted by structural characteristics, structural characteristics also mediated the relation of neighborhood processes to exposure of violent peers and subsequent risk for violence perpetration. Sheidow et al. (2001) found that neighborhood social process level had a small effect on violence exposure among young men residing in poor urban communities, but youth from families with a combination of lower parenting skills and less supportive family relationships had particular risk. The most direct test of neighborhood processes related to youth community violence exposure was a study by Fagan, Wright, and Pinchevsky (2014) that showed that collective efficacy moderated the relation between community violence exposure and substance use by adolescents. This finding suggests that neighborhood processes can serve a protective role against the structural characteristic of high levels of violent crime. However, the limited number of studies points to how little we know about what neighborhood characteristics, beyond poverty, relate to risk and how social processes might help mitigate exposure and effects from exposure. These initial studies suggest that a critical area for empirical investigation is how crime rates that may drive exposure to community violence are related to neighborhood social characteristics within those communities with structural characteristics that also relate to crime rates.

THEORIES ABOUT HOW COMMUNITY VIOLENCE EXPOSURE CAUSES OR INCREASES INDIVIDUAL RISK FOR PSYCHOPATHOLOGY

Varied explanations have been offered regarding how community violence exposure is harmful. Most explanations have not differentiated community violence exposure from violence exposure in general, or they are drawn directly from formulations of how family violence might affect a child (Margolin & Gordis, 2000). However, an additional thread of reasoning compares residing in communities with high violence rates to exposure to war conditions, natural disasters, or horrific accidents and maltreatment (e.g., kidnappings) (Fitzpatrick & Boldizar, 1993). These explanations tend to emphasize a trauma process of impact that either precipitates pathology or exacerbates prior risk into expression of syndromes. Other theories have focused on attachment disruption, similar to what is thought to be an effect of neglect and abuse (Cichetti & Toth, 2005). Social-cognitive theories have been offered that suggest the impact is to shift normative expectations about behavior and of rewards or functionality of violence. Still others

have suggested that violence exposure is often part of an overall ecology of exceptional stress and unpredictability and so is best understood as one of many challenges faced by children and families residing in impoverished urban communities. In this approach, violence exposure is considered as distinct from, but one of many, stress-inducing experiences affecting risk (Tolan & Gorman-Smith, 1996). Explanations framed using this perspective tend to see the effects as cumulative and linear, with more exposure and less stress-coping resources equating to more symptomology.

Explanations Emphasizing Trauma Process

Trauma-focused explanations rest on the concept that severe fright and disgust caused by witnessing violence, being directly victimized, or residing in an unsafe community overwhelms and perverts neurophysiological functioning—particularly attention regulation and inhibition of impulses. Further, this traumatic exposure also impedes or misdirects further development of these key systems that increases susceptibility to other psychopathology risk factors or sets overactive or underactive attention and arousal management and the relation between emotion and behavior. Overdeveloped fear conditioning is seen as a key process, with additional effects on hypothalamic-pituitary-adrenocortical (HPA) axis regulatory systems. Both processes are thought to either lead to hypervigilance about threat (and related anxiety, depression, or aggression) or problematic habituating and underreactivity to violence (and related aggression and depression) (Horowitz, McKay, & Marshall, 2005; Perry, 2008). Children who are still developing are particularly susceptible to these effects and also suffer from the ongoing unpredictability of the environment, including a lack of ability to rest secure and safe (Garbarino, Dubrow, Kostelny, & Pardo, 1992). At too early an age and in an ongoing, clearly unhealthy way, these children must be always on alert. As a result, psychological functioning and underlying neurobehavioral regulatory systems are compromised, analogous to the impact of war exposure found in veterans and survivors of disasters. This may lead to anxiety, depression, as well as use of aggression as a means of intended self-protection (Tolan et al., 1997).

A related theory is that violence exposure in the community disrupts attachment because it brings into acute awareness the inability of caregivers to provide safety and belonging, which are so critical to healthy development. Most essentially, the precariousness of a safe environment and dependable care is thought to disrupt secure attachment capability, which acts as a trauma to undercut relationship engagement, trust, and communication with parents and other caregivers and the ability to properly depend on others. All of this exacerbates risk for psychopathology and/or is thought to cause it (Lieberman, Chu, Van Horn, & Harris, 2011; Perry, 2008). This approach is different from the framework that says experience overwhelms neurobehavioral regulatory systems. Instead, it posits that the mechanism of psychopathology is disruption of social relationships through effects on personal attachment and relationship skills. Although these trauma frameworks provide important ideas and potentially critical insights about how community violence affects children, they are primarily based on evidence accumulated about child abuse and neglect or domestic violence. An exception is a study by Farrell and Bruce (1997) that tracked community violence exposure to emotional distress features related to trauma. That study focused on individual differences in exposure and found a modest positive link. However, the authors did not focus on documenting a traumatic process as the cause of behavior change, but rather to correlate how extent of symptoms thought to represent post traumatic stress disorder corresponded to violence exposure extent.

Thus, it seems likely that the same processes implicated for other forms of violence exposure might be at work when people are exposed to community violence. However, as with many other theories, there has been almost no tracking of these effects specific to community violence exposure. In part this is because the needed studies would entail comparing samples defined as community violence exposed to counterparts who have only had traumatic events or family violence experiences or to nonexposed children who are otherwise similar (e.g., also reside in low-SES urban communities). Creating such a study and garnering the resources to enable measuring the neurobiological effects and related symptomology presents numerous challenges. This lack of empirical studies has limited how much can be inferred from findings of violence effects from abuse, witnessing domestic violence, or disaster experiences (Cicchetti & Toth, 2005).

Social-Cognitive Impact Theories of Community Violence Exposure Effects

Social-cognitive theory has also been offered as an explanation of community violence exposure but almost exclusively in relation to subsequent aggression levels. Within this framework, violence exposure promotes aggressive reactions but also supports the use of aggression as a method

of managing fear, frustration, and conflict (Dodge & Somberg, 1987). Growing up in a community where violence exposure is more likely means that it is more likely to be seen as normative, acceptable, and useful (Guerra, Huesmann, & Spindler, 2003). For example, Guerra et al. (2003) reported that community violence exposure had a significant effect in increasing aggression, normative beliefs about aggression, and aggressive fantasy. In older children it showed effects on social-cognitive processes. Additionally, this study showed that these changes in social cognition mediated the effects of exposure on aggression exhibition. While emphasizing the role of exposure in increasing an expectation of violence from others and to form a bias toward viewing motivations of others as hostile (which increase use of violence), these social-cognitive processes have also been tied to depression symptoms (Dodge, 1993).

Social cognitions related to conflict, frustration, and self-control are shaped by imitating others (who are also likely to use and approve of violence) by the utility of violence in enabling development (e.g., creating status, reducing threat, accessing rewards) and shifting what is considered normative or acceptable behavior. In turn, this misdirected form of self-control, self-image, and consideration of others in forming behavioral responses leads to a more limited arsenal of alternatives to aggression, more use of aggression, lack of impulse control over life span, and less reward or reward orientation related to nonaggressive behavior (Morales & Guerra, 2006). Notably, this approach has been based on empirical studies that suggest correlation among the components and some moderating and mediating relations (Attar et al., 1994; Guerra et al., 2003)). For example, Chaux, Arboleda, and Rincon (2012) corelated residence in more or less violent communities in Bogota, Columbia to aggression. The 1,235 fifth- to ninth-grade students studied reported a relation between exposure to community violence and levels of proactive and reactive aggression (aggression used to solve a problem versus used in reaction to immediate threat). Moreover, normative beliefs supporting use of aggression, hostile attributions of intent, positive expectations from use of aggression, and low guilt about using aggression each partially mediated that relation.

Notably, much of the theorizing about violence effects has been formulated through studies of youth residing in high-risk communities and through measurement of variation in individual behavior based on extent of exposure (Guerra et al., 1995; Guerra, et al., 2003). These theories also correspond to stress models in that exposure to violence is seen as one of many forms of environmental challenge that might affect normative beliefs about behavior, particularly the role of aggression in conflict management (Cooley-Quille et al., 2001; Guerra et al., 2003). Thus, some models link social-cognitive processes to a developmental-ecological model that characterizes exposure as inducing stress in parallel, linked, or contributing to a confluence of pathology-promoting process (Morales & Guerra, 2006).

Stress Models of Community Violence Exposure Effects

The primary supposition of this approach is that violence is one form of life stress, a particularly powerful and potentially virulent form (Gorman-Smith & Tolan, 1998). Based on the observation that community violence exposure is often based on residence within communities that are marked by many other stressful conditions and families facing these also have limited social and economic resources for managing stress, it is suggested that violence exposure may result in anxiety, depression, PTSD symptoms, and aggression (Tolan et al., 1997). This theorizing has focused at the level of individual coping skills and resources, such as social support, parental guidance, and protection from places and situations that might increase community violence exposure. Linkage to neurodevelopmental processes in stress-regulatory systems has been limited, and most of these studies have not considered other forms of stress. An exception is a study by Sharkey et al. (2012), who assessed children within a week of when a homicide occurred near their homes to test for its effects on child behavior, utilizing a stress framework. They found lower levels of attention and impulse control and lower preacademic skills than found otherwise in the community. Parental distress was also elevated, suggesting that one mechanism by which this community violence exposure could affect child functioning is that it renders violence-exposed parents less able to help to provide needed regulation and care.

Only a few studies have examined the impact of community violence exposure on physiologic markers of stress response in children (Kliewer, 2006; Wilson, Kliewer, Teasley, Plybon, & Sica, 2002;). For example, Kliewer (2006) examined the association between salivary cortisol levels and exposure to violence in 101 African American youth. Witnessing community violence was associated to lower baseline cortisol and increased cortisol in response to a mild stressor (e.g., watching a video showing scenes of community violence).

Much of the theorizing about violence exposure treats it as a life stress that can overwhelm coping mechanisms

and support resources and strain the physiological systems involved in managing stress; in doing so, it induces distortions in psychological functioning that characterize posttraumatic stress (anxiety), depression, and aggressive tendencies. For example, Attar et al. (1994) showed that exposure to violence and threats exacerbated the effects of more minor stress. In a related study, Gorman-Smith and Tolan (1998) documented that for inner-city youth, violence exposure has a distinct effect on level of externalizing and internalizing symptoms, over and above that attributable to general life-stress level. Although it helped explain symptoms from other forms of stress, it was distinct from being just another form of stress. In that study, the effect was found even after accounting for individual variations in behavior that might have prompted different levels of exposure to violence. White, Bruce, Farrell, and Kliewer (1998) reported a similar set of effects, with community violence promoting additional effects over and above those found from other forms of stress.

Common to these diverse theoretical explanations is a recognition that exposure to violence is related to larger developmental context characteristics, such as residing in inner-city communities, or transactional confluence processes, such as low parental monitoring. Similarly, residing in such communities may increase opportunity for proximity to violence or affiliating with those likely to perpetrate violence (Lynch & Cicchetti, 1998; Tolan, Guerra, & Kendall, 1995). These developmental-ecological models emphasize that multiple risk processes, with interdependencies among the processes, are implicated in both the risk for exposure and the impact a given level of exposure may have. For example, violence exposure is more likely to occur to families with fewer economic and social resources and in neighborhoods with fewer social connections among neighbors but also to those youth with more impulse problems and more antisocial friends. The limited evidence does not suggest that risk is explained simply by the accumulated adverse experiences in life; rather, it may be due to some particular interactions and may vary substantially by the type of community in which one resides. At the same time, there is growing interest and basis for understanding how violence exposure gets under the skin to affect psychopathology through neurodevelopmental processes.

NEURODEVELOPMENTAL PROCESSES THAT MIGHT BE IMPLICATED IN COMMUNITY VIOLENCE EXPOSURE

Neurodevelopmental explanations of community violence exposure are essential to translate the social and behavioral nature of these experiences to individual developmental psychopathology effects. As with all areas of developmental psychopathology, the relation includes a dual consideration: neurodevelopmental functioning and processes that differentiate susceptibility to environmental conditions and experiences and determination of how the environmental experience (in this case community violence) affects brain and neural physiology, systems, and functioning. Much work has been conducted to identify the impact of violence on neurodevelopment, but little has focused on community violence specifically (Cicchetti & Toth, 2005; Mead, Beauchaine, & Shannon, 2010). Most understanding of neurodevelopmental effects from violence exposure has come study of abused and neglected children. These samples often included a mix of children who were exposed to violence and those neglected but not exposed to violence. In addition, as exposure to abuse and neglect are also related to probability of community violence exposure and other failures in care and safety, it is difficult to parse what might be effects of abuse/neglect, community violence exposure and attendant failures in care, attachment, other stress, and co-occurring insults to the neurodevelopmental systems and course (Lynch & Cicchetti, 1998; Malik, 2008). Yet it may also be that violence exposure source or type does not significantly affect the neurodevelopmental processes or susceptibility to pathological effects on development. Thus, while providing many potential clues to the likely processes of and effects from community violence, the applicability of neurodevelopmental understanding gained from studies of violence impact is not yet determinable.

Genetic Contributions to Violence Exposure Susceptibility

Gene–Variant Contributions from Other Forms of Violence Exposure

Genetic contributions might relate to violence exposure in many ways, but these can be grouped into two main ways (Tolan et al., 2013). First, genetic differences related to tendency to be aggressive or to be antisocial may lead to greater likelihood of being involved with community violence (Raine et al., 2005). Second, there may be genetic differences in disposition that are affected differently by violence exposure. Several studies have suggested that genetic polymorphisms (e.g., monoamine oxidase A [MAOA]) moderate the relation between violent abuse as a child and violence and aggressive outcomes (Caspi et al., 2002; Kim-Cohen et al., 2006). Others have traced genetic variations (serotonin transporter; 5-HTT) in response

to stress (Cicchetti, Rogosch, & Sturge-Apple, 2007). Therefore, it is likely that there are some genetic variations in response to community violence and in the outcome of such exposure.

However, since specific genetic studies of community violence exposure effects have not been conducted, it could also be that the process and the genes involved are not analogous to that of direct victimization through abuse (Huizinga et al., 2006). Other gene variants and genes might be involved. It is likely that not only will there be multiple genetic variations implicated but also that those identified as most likely candidates may not prevail. It seems likely that gene variants will help explain the differential effect of violence exposure and may help explain the differential likelihood of exposure. It is also likely that networks rather than specific gene variants will be implicated in this effect and that a confluence of genetic contributors and other developmental influences will also contribute.

One possibility is that exposure to community violence is not interactive in the sense of only having influence in the presence of certain genetic variants but that there are two main effects or a gene–environment (G×E) correlation. For example, a very severe level of abuse exposure is the environmental moderator implicated in several G×E interaction demonstrations of violence effects on aggression (Kim-Cohen et al., 2006). Below that level, the effects seem to be additive, not interdependent. For example, Foley et al. (2004) utilized a lower threshold of violence exposure in a G×E interaction study of violence effects, including exposure to witnessing domestic violence, which may be more analogous to community violence exposure. They report a main effect for this exposure on conduct disorder in addition to moderation by genetic vulnerability. The relation also could be a passive or evocative correlation. Those with the tendency to be violent or to engage in social relations with other aggressive individuals may be more likely to be exposed to violence. Those with a genetic disposition toward antisocial personality characteristics may be more likely to evoke parental hostility or other risk, thereby exacerbating related environmental responses related to exposure. Since these studies are related to family-based violence (maltreatment), the coalescence of multiple methods of genetic influence are also present, which may not transfer to how community violence exposure and effects occur (Tolan et al., 2013).

Similarly, maltreatment and abuse have been related to depression likelihood through polymorphism studies, primarily in the promoter region of 5-HTT, the serotonin transporter gene (Cicchetti et al., 2007). This study also reported that different allele variations had a G×E effect depending on the type and extent of maltreatment exposure (e.g., neglect, sexual, physical). The effect also related to stress level. More generally, studies of depression have focused on life-stress experience, including violence exposure, showing stress exposure moderates a genetic tendency for depression, increasing risk more for those with heritable risk than those without (Kendler, Kuhn, Vittum, Prescott, & Riley, 2005). For example, Kaufman et al. (2004) found that among a sample of maltreated children, the short/short allele variant related to greater probability of current depression than either the short/long or long/long variant. However, they also noted that this relation was moderated by social support, which is often viewed as protective against stress. The trend across these G×E interaction studies of maltreatment and stress and depression suggests a more complex set of interactions than implicated in studies of antisocial behavior outcomes. These findings seem consistent with a stress interpretation of violence impact on developmental psychopathology (Gorman-Smith & Tolan, 1998).

The G×E interaction studies suggest two processes for community violence exposure effects. Exposure leads to greater likelihood of aggression for those with the at-risk allele MAOA pattern and to depression and other internalizing problems for those with the risk allele for 5-HTT. Susceptibility to type of effect also could have some variability by gender. Some have speculated that MAOA and aggression relation and 5-HTTT and depression relation moderated by violence exposure differs by gender, with males primarily affected by the MAOA and females by the 5-HTTT (Mead et al., 2010). Whether this is borne out in additional studies of violence exposure or is tested and found applicable to community violence exposure remains to be seen. A dual neurodevelopmental process of violence impact is suggested: increasing aggressive tendencies by breaking down self-regulation systems and increasing depression by overwhelming stress management systems (Crockett, Clark, Hauser, & Robbins, 2010). It may well be that rather than two distinct G×E interactions that affect impact of community violence exposure, the interactions could act together. It may be that, if moderated by genetic susceptibility, the effects of violence exposure act through stress systems and also through threat-impulse control systems. Thus, effects may vary from internalizing and externalizing to the extent that both self-control and self-regulation of emotion are susceptible.

What is not determinable is how applicable the results of these studies are for community violence when the evidence for G×E effects are only from exposure to family

violence, usually as direct victim, and with substantial levels necessary for interaction. In addition, the evidence of the MAOA polymorphism and family violence exposure has been replicated only for White samples, although many studies have been limited in ethnic diversity. For example, Widom and Brzustowicz (2006) failed to find this moderation for the non-White portion of their sample. Also, 5-HTT polymorphism relating abuse to depression has been inconsistent in findings across genders and age groups. Given that community violence exposure disproportionately occurs for minority persons, this finding suggests that further caution be exercised on generalizing from these findings. Although samples used in these gene expression studies have been more diverse ethnically than those demonstrating MAOA interaction, there has not been the type of comparison that might permit consideration of how ethnic group differences in gene variants might affect impact. Moreover, although there have been demonstrations of poverty relating to cortisol differences, it is not clear how this relates to G×E interaction (Lupien, King, Meany, & McEwen, 2001). Since violence exposure is related to poverty and residence location and since it is also a correlate of ethnic group in our current society, these contextual differences may substantially shift the relation of environment and genetic susceptibility. Given that community violence exposure disproportionately occurs to non-White persons, this finding suggests further caution in any generalizations from these findings.

Genetic Variation in Environmental Sensitivity

An alternative to a polymorphism variation risk susceptibility model is the formulation that emphasizes sensitivity to environment as a key genetic difference: that some persons have a tendency to be more affected by environmental conditions, good or bad, than others (Belsky & Pluess, 2009). One relevant example noted by Belsky and Pluess (2009) in support of this formulation of G×E effects is that toddlers who scored high in proclivity to get angry at 15 and 28 months were more likely than other children to manifest behavior problems at age 5 if provided ineffective parental guidance and were less likely to display such problems than others if parental guidance was effective. It may be that those most affected by community violence are those most sensitive to environmental disorder, fear-inducing threats, or the shock of experiencing, seeing, or living with violence. Although each of these models might be quite important in understanding how individual differences in reaction to violence exposure occurs, at present, a G×E study of community violence exposure has not been conducted. Thus, little is known about how G×E relations should be considered in psychopathology formulations of community violence exposure.

Epigenetic Explanations of Violence Impact

Another genetically informed area of study of violence effects might show the importance for studies of community violence impact. This is the rapidly developing area of telomere science. This field focuses on cellular and molecular processes affecting telomere length, particularly related to stress and stress-related aging processes over the life span. Shorter telomere length is associated with advancing chronological age and also increased disease morbidity and mortality. Thus, interest has been stimulated in how stress might accelerate erosion of telomeres, even early enough in life to affect newborn setting of telomere length. Shalev et al. (2013) tested for relation stress to telomere erosion or aging in a prospective-longitudinal study in children and found that children who experienced multiple forms of violence exposure (either exposure to maternal domestic violence, frequent bullying victimization, or physical maltreatment by an adult) showed significantly more telomere erosion in buccal cells in measurements between ages 5 and 10. This effect remained even with controlling for multiple potential confounds. This finding suggests that perhaps violence exposure acts to age or to deteriorate telomere length, which is thought to explain susceptibility to psychopathology.

From the findings of G×E relations and apparent interactions, it can reasonably be concluded that there may be genetic variations in susceptibility to community violence and genetic impact that is analogous to what has been demonstrated for other forms of violence exposure. Moreover, it appears that exposure can have effects through stress regulation and self-control or aggressive tendencies in the face of threat influence. In addition, G×E models (or gene network and multiple environmental contributors) that emphasize specific risk susceptibility may provide understanding. Or these models may affect relative sensitivity to environmental conditions. These studies may provide important models, suggested processes, candidate gene and environmental precipitants, and insight about brain plasticity related to psychopathology effects and therefore guide helpful preventive and treatment interventions (Cicchetti & Curtis, 2006). However, most fundamentally, studies are needed that explicitly and distinctly consider community violence.

Alteration of Neural Networks, Brain Areas, and Regulatory Systems

Violence exposure effects on psychopathology and functioning are presumed to occur through some alteration of neural physiology, processes, and regulatory systems that affect symptom occurrence and functioning. Most essentially, it is believed that shocking, threatening, unpredictable, and sensory-overloading experience through violence disrupts healthy developmental processes for adaptation by altering brain systems that manage threat-reaction and stress responses. Exposure to violence, particularly early in development, is seen as potentially altering formation, efficiency, and proper functioning of important areas of the brain. These inferences are drawn from studies of direct victimization, usually from caregivers. However, some studies of exposure to domestic conflict and violence have been influential on this conceptualization.

Unlike neglect, which is viewed as failure to consistently stimulate in order to promote organization and relative stability in emotional functioning, violence exposure is unregulated, unpredictable overstimulation, with harm resulting from repeated and extreme overstimulation. As suggested by G×E interaction studies, this overstimulation can occur through multiple systems and can affect orienting and regulatory functions of the cortex (cognition), limbic system (affect regulation), diencephalon (e.g., fine motor regulation, startle response), and brainstem (heart rate, blood pressure regulation). Since each system is affected by experience-dependent neurochemical signals and each has different periods of sensitivity, the impact can vary as to which system is compromised and how that affects development. Also, since many of these systems can be affected by in utero experience, children may be born with substantial variation in sensitivity to disruptions such as violence exposure (Perry, 2008). For example, in animals, experimental inducement of prenatal and perinatal stress can alter hippocampal organization and the HPA axis and have lifelong effects (Plotsky & Meaney, 1993).

Lower Areas of Brain (Brain Stem, Diencephalon, Hypothalamus)

Lower areas of the brain are the portals for neural/sensory input and relay sensory information to the primary sensory receptive areas of the cortex into a feedback process of sorting and actions related to threat experience. The reticular activating system (RAS), the hypothalamus, and the thalamus are brain regions most likely to be affected through violence exposure. The RAS is a network of arousal related neural systems through which neurotransmitters, including epinephrine (EPI), norepinephrine (INN), dopamine (DA), and serotonin (5-HT), orient and set regulation of arousal, fear, stress response, and threat reaction. The hypothalamus and thalamus receive input from various afferent sensory systems and transmit arousal information from the RAS to the limbic, other subcortical, and cortical systems (Castro-Alamancos & Connors, 1996).

Violence exposure could affect the lower brain areas through affecting orientation sensitivity, with primary focus and evidence to date on startle response. For example, several studies have identified exaggerated startle responses among people with PTSD related to war (Morgan, Grillon, Southwick, Davis, & Charney, 1996) and among female sexual assault survivors (Morgan, Grillon, Lubin, & Southwick, 1997). Not all studies have shown this link, however. In some cases, the startle response is blunted. The implication is that exposure to violence affects orientation to threat. There is some suggestion that earlier and more chronic exposure might blunt response, after an initial effect of heightening the startle response. For example, Klorman, Cicchetti, Thatcher, and Ison (2003) found such a pattern when they examined electromyograms in response to acoustic startle in maltreated children 3 to 11 years old.

The Limbic System

The limbic system is a subcortical network regulating emotion, stimulation, and memory. Along with the amygdala, this system processes, interprets, and integrates emotional experience and information (Clugnet & LeDoux, 1990). The system interprets positive versus negative emotional experience, initial organization of an experience affectively and cognitively, and response tendency for socially relevant stimuli. As the seat of emotional memory, it also is implicated in activation of motor behavior and neuroendocrine (stress) response. Within this system, the hippocampus is potentially affected by violence exposure because it is involved in storage of sensory information and in stress activation (Phillips & LeDoux, 1992). Threat may affect the nature of emotional storage as well as the efficiency. Studies of abused children suggest no difference or only marginal effect in hippocampal volume among maltreated children with PTSD (De Bellis, 2005). Hippocampal volume has not been shown to relate to violence (De Bellis, 2005). However, as hippocampal atrophy relates to impairment in memory functions and is implicated in HPA axis dysregulation, some suggest it may be an important effect through which violence exposure contributes to psychopathology (Mead et al., 2010). This view emphasizes

perceptual and response bias over impulsive responding in understanding how community violence might affect psychopathology and behavior.

Cortical and Subcortical Areas

In concert with the limbic system, cortical areas of the brain serve to modulate, organize, and moderate emotional and behavioral impulses for adaptation and goal-directed activity (Perry, 2008). Since the cortex takes the longest to develop and is the site of complex decision making, it is thought that violence impacts cortical physiology in part through harm to lower areas that affect the "input." Also, severe challenges, such as environmentally harsh or under- or overstimulating experiences, might impair development of cortical areas that are the neural substrates of important executive functions (Cicchetti & Toth, 2005; Perry, 2008). Perry (2008) reported that rats raised in an environmentally enriched setting have 30% higher synaptic density in the cortex than rats that were raised in an environmentally deprived setting and suggested that this effect process is analogous to the effects of exposure to violence and neglect. Magnetic resonance imaging and other brain scans in children exposed to abuse and violence have shown differences in white and gray matter volumes and gray matter thickness in cortical areas (e.g., Choi, Bumseok, Rohan, Polcari, & Teicher, 2010; De Bellis, 2005). Mead et al. (2010) provided an extensive review of diverse studies that might together provide a basis for formulating the neurodevelopmental impact of violence exposure, particularly family violence victimization, on cortical development. Although the majority of studies focus on abused and/or neglected children, some focus on media violence exposure. This latter focus may be informative as it is a form of violence exposure that has similarities to community violence. Media violence is not direct victimization but instead is tantamount to being in a violent and violence-accepting environment or as a witness. Also, the violence exposure is not due to perpetration by a caregiver. That the findings seem consistent across media- and abuse-based exposure lends some credibility to looking for similar effects due to community violence exposure.

Neurotransmitter Systems

Studies of violence in relation to psychopathology have focused mostly on three neurotransmitter systems: dopamine (DA), norepinephrine (INN), and serotonin (5-HT). The DA system has been implicated through its linkage to differences in novelty seeking, reward responding, approach motivation, and emotion; and through the cortical effects on cognition, working memory, self-regulation, and planning. Thus, much of the work on understanding the role of the DA system in psychopathology has been related to externalizing problems, such as attention-deficit/hyperactivity and conduct disorder. The theoretical linkage from violence exposure to these empirical findings is that substantial and sustained exposure could induce long-term downregulation of central DA activity (Mead et al., 2010). Behaviorally, this would translate to more impulsive and aggressive behavior with related changes in motivation, cognitive processes of aggression, and self-control.

Elevated INN has been related to trauma symptoms and violence exposure in numerous studies (De Bellis, 2005). It has been shown to differentiate children with such symptoms and history from those without such history. It also has been shown to relate to duration or trauma and predicted symptom levels posttrauma (De Bellis, 2005; Delahanty, Nugent, Christopher, & Walsh, 2005). INN is one of the few neurotransmitters studied in relation to exposure to community violence (Wilson et al., 2002). In that study, victimization that was related to community violence predicted INN level for both males and females. There was a significant relation between witnessing or hearing about violence and INN level across the day for males but not females. Although the study used a small sample ($n = 56$) of a single ethnic group (African American), it is one of the few studies to document neurotransmitter effects related to violence exposure. Since selection screening was for healthy youth, members of this sample probably had little or no abuse histories, so these results may represent a linkage of findings about community violence empirically to those observed in studies of maltreated children. Across studies, including Wilson et al. (2002), the primary hypothesis has been that INN functioning is changed by stress exposure and that the effect is to lower the behavioral inhibition system, which may not lead to more impulsive and aggressive behavior. Additionally, it is thought that this exposure will reduce aversion to violence through blunting the stress response.

There has been substantial documentation of the relation of 5-HT depletion and impulsive and aggressive behavior (Duke, Bègue, Bell, & Eisenlohr-Moul, 2013; Pine et al., 1997). Depletion of 5-HT has been linked to lessening of harm avoidance and to greater likelihood of anxiety and depression. Animal studies indicate that regulation of the 5-HT system is affected by the animal's early rearing environment, particularly abusive rearing environments. These patterns are taken to imply that 5-HT functioning can be affected by violence exposure and may

be one way of affecting brain development and functioning. As with INN and DA systems, there is no compelling evidence of what effects, if any, community violence has on the 5-HT system. However, there is substantial indication of the relation of functioning of these systems and violence exposure or psychopathology. Thus, there is good reason to investigate how these might be affected by community violence.

Cortisol and Cortisol Regulation

The area of brain functioning that has received the most attention in relation to violence exposure, particularly related to maltreatment, has been cortisol regulation and the HPA axis (Cicchetti & Rogosch, 2001; Gunnar & Vazquez, 2006). The primary hypothesis is that stress, particularly traumatic or overwhelming stress, leads to increased cortisol levels and/or impaired regulation of cortisol levels such that reactivity patterns (more reactive, longer to return to baseline) and diurnal patterns are affected. During acute stress, the HPA axis is activated and cortisol serves to downregulate hormonal secretions and to stop many metabolic and neuronal defensive and immune reactions in order to mobilize coping with stress. Thus, cortisol as a catabolic hormone activates energy mobilization, focused attention, vigilance, and memory formation. The effect is to distort emotions related to threat and cortical processes essential in processing, evaluating, and managing threat (Gunnar & Vazquez, 2006). Ongoing and particularly shocking stress (such as violence exposure) is seen as potentially permanently affecting this system, perverting brain functioning, and perhaps affecting physiology. The behavioral effect is threat-focused anxiety, depression, and/or aggression (Twardosz & Lutzker, 2010).

Although a large number of studies have marked a relation among cortisol level, reactivity, and/or diurnal patterns and violence exposure, the results have varied across studies. Sometimes variations show complex patterns that vary by type of maltreatment or violence exposure, gender, and which cortisol regulation characteristic was implicated (Cicchetti & Rogosch, 2001). Also, in many studies, it is difficult to disentangle what might be psychopathology basis for cortisol regulation differences and what is attributable to violence exposure that might also explain psychopathology occurrence. As with other areas of neurodevelopmental violence effects, the vast majority of studies focus on maltreatment as the source of violence exposure, often sampling children with severe and chronic abuse histories. The next largest set of studies in this area did not differentiate source of violence exposure. These latter studies often summed up types of violence experiences to relate overall exposure. One exception was a study that showed negative relations for both peer victimization and witnessing violence and basal cortisol levels among children living within urban neighborhoods with high rates of violence (Kliewer, 2006). These effects were found after controlling for stressful life events, gender, and age. Recently Aiyer, Heinze, Miller, Stoddard, and Zimmerman (2014) examined the longitudinal relation of cumulative violence exposure of an African American sample residing in a low-income, high-crime community. A cumulative exposure to violence effect on cortisol was found for males, with those exposed having a more attenuated response pattern. Notably, the effect of cumulative exposure to violence on cortisol was moderated by the presence of fathers' support during adolescence. This study did not limit focus to community violence, but it was part of the cumulative violence exposure index.

The relation of cortisol patterns and psychopathology among violence-exposed children has been stronger for depression or internalizing disorders, with the relation primarily to higher levels of cortisol (Cichetti & Rogosch, 2001; Mead et al., 2010). Lower levels have shown relation to aggressive tendencies among maltreated and nonmaltreated children, albeit inconsistently and with gender variations in any effect and type of effect (Cicchetti & Rogosch, 2001; Gunnar & Vazquez, 2006). Also, there is evidence that cortisol regulation effects related to abuse may be influenced by entry into nonabusive care and may be responsive to targeted intervention (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Fisher, Gunnar, Chamberlain, & Reid, 2000). Other studies have shown long-term effects of violence exposure on cortisol regulation (e.g., Peckins, Dockray, Eckenrode, Heaton, & Susman, 2012). However, the promising findings in some studies show a pattern of inconsistencies across studies that have raised questions about how much cortisol patterns may reflect the current situation more than developmental effects of prior experience (see Gunnar & Vazquez, 2006, for an excellent review of the issues). Moreover, how community violence exposure may compromise cortisol regulation in a manner that could reasonably be interpreted as contributing to psychopathology remains relatively unexplored.

In a study not of violence exposure but of "neighborhood disorder related to residence in impoverished urban communities," Dulin-Keita, Casazza, Fernandez, Goran, and Gower (2010) reported that neighborhood disorder was predictive of lower serum cortisol levels. The number of years spent living in poverty related positively to overnight

cortisol level and extent of dysregulation of cardiovascular response (i.e., muted reactivity). A similar finding was reported by Evans and Kim (2007), which tracked poverty status, cumulative life stress, and health and reactivity to an acute stressor. The cumulative stress measure appears quite similar to the neighborhood disorder indicators used by Dulin-Keita et al. (2010). Evans and Kim reported that the more years one lived in poverty, the more elevated overnight cortisol was and the more poorly regulated was the cardiovascular response (i.e., muted reactivity). These studies suggest that studying the effects of community violence on cortisol regulation would be very useful.

Arousal/Resting Heart Rate

As violence and other stressful experiences typically increases arousal, one presumed effect of exposure to community violence in neurophysiology is the effect on resting heart rate (Perry, 2008). Indeed, studies have documented both increased arousal and hypoarousal of youth exposed to violence, although most of these studies have been of specific clinical populations and with a focus on trauma (Margolin & Gordis, 2000). A few studies have examined the link between exposure to community violence and arousal, and conclusions have been inconsistent. For example, high exposure to community violence has been associated with a lower resting heart rate in a sample of urban school-age children (Krenichyn, Saegert, & Evans, 2001). Similarly, Cooley-Quille, Boyd, Frantz, and Walsh (2001) reported adolescents with higher levels of community violence exposure had lower baseline heart rates than less exposed subjects in response to media violence. In contrast, Wilson et al. (2002) reported higher heart rates in exposed youth. Cardiovascular recovery was not affected by duration of poverty exposure. Notably current poverty status did not relate to these outcomes. These studies suggest the value of consideration of arousal level muting as one effect of community violence exposure. However, these studies also raise the question of confounding of effects with residence in impoverished communities, particularly those marked by more "disorder" or more limited structural resources for social organization (M. Wilson, 1988).

Implications for Understanding and Affecting Community Violence Exposure

This broad set of neurodevelopmentally focused studies has identified many promising areas of research on how community violence exposure affects youth, including some indicators of what processes might be implicated in psychopathology. The applicability of each and every area of study remains highly uncertain at this point simply due to the lack of more than a few studies of community violence effects as a specific risk factor. The complexities of differentiating such exposure, isolating effects of community violence exposure from frequently co-occurring developmental risk factors, and the size and scope of studies needed to explore neurodevelopmental effects of such exposure competently are all impediments to such efforts. However, this important prior work has suggested many promising topics for research and avenues for likely effects. Among these is how genetic variation in susceptibility to violence exposure and disordered and neglectful/non-nurturant developmental environments affect brain physiology, neurotransmitters, and important neurophysiological systems. Others are to track how variation in family management practices and/or neighborhood social processes affects violence exposure and the extent of the effects on psychopathology of those exposed. Similarly, following patterns of stress reactivity and impulsivity subsequent to incidents of violence exposure or over time due to chronic community violence exposure would help illuminate how this form of violence exposure compares to other forms.

INTERVENTIONS FOR COMMUNITY VIOLENCE EXPOSURE

As with understanding other aspects of the relation of community violence exposure, there are few direct tests of interventions meant either to lessen community violence exposure or to mitigate impact. Most efforts have focused on reducing violence exhibition by youth or by those directly involved in their supervision (e.g., reduce use of violence by parents). Although victimization was also considered in some cases, most efforts to affect community violence levels only measure impact on perpetration of crimes. Moreover, most reports are descriptive only or use empirical comparisons of limited methodological quality, which limits confidence in the validity and/or robustness of the findings. Thus, efforts to reduce youth crime and neighborhood-level violence can be considered potentially valuable in reducing community violence exposure.

Similarly, few studies have focused on mitigating exposure to community violence specifically. Often violence exposure measurement does not differentiate source of violence exposure (e.g., community versus familial) or type of exposure (e.g., direct victimization from witnessing). A set

of studies has approached mitigation of violence effects, including community violence as a traumatic experience (Lieberman & DeMartino, 2006). These studies treat the exposed youth as traumatized and typically apply individual or family interventions to help reduce the trauma symptoms and the resulting behavioral effects. Also, some studies focus on aggression or conduct problems as the targeted effect of community violence exposure, although in most cases it is not clear how exposure and involvement in violence as a perpetrator comingle in the effects (Tolan, 2001b).

Efforts to Reduce Community Violence

Community Organization for Violence Deterrence

One strategy for reducing community violence that has gained much attention is helping communities to organize, be vigilant, and act to make safe areas for children. The intent is to engage residents to help monitor their own communities, notifying police if violence seems imminent and thereby decreasing opportunities for violence. Often these efforts enlist joint efforts by police, child welfare, churches, other civic organizations, and youth services. One variant on this approach is to organize for communication and intercession to block youth violence, particularly gang-related violence that may be brewing over time (Braga & Weisburd, 2012). Often in this variant, an agency has staff that engages with gang-related youth who are informed about when disputes might be leading to violence and can stave off conflict escalation. In addition, there is a concentration of legal prosecution efforts on violence, particularly shooting, such that resorting to such violence is more likely to lead to prosecution and incarceration. A third element is to positively affect police—neighborhood relations, educating youth and minimizing any broad harassment or intimidation efforts (Graczyk & Tolan, 2005). Not infrequently, these efforts incorporate block meetings by police with residents and other aspects of community policing that can affect crime rates (Braga & Weisburd, 2012). Although there are no reports of effects on reducing exposure to community violence, there is evidence of effects on community violence overall from a meta-analysis (Braga & Weisburd, 2012) and specific tests of programs within this general approach (Braga, Kennedy, Waring, & Piehl, 2001). These effects are small. Within multisite studies, it is common to find effects in some but not all of the included sites. Overall, it appears that neighborhood organization could be useful in reducing youth exposure to community violence.

Neighborhood Watch Programs

Neighborhood watch programs fall within the category of neighborhood organization, but they limit citizen organization to monitoring neighborhood settings. Public notification of such monitoring in an effort to discourage violence and crime has been tested most frequently. In addition, these programs often emphasize norms of pride about the community upkeep and safety and are thought to improve neighborhood engagement of citizens. Often these efforts include "target hardening," meaning making citizens aware of how to be less easily victimized. Bennett, Holloway, and Farrington (2008) conducted a meta-analysis of 15 samples across 10 studies of neighborhood watch programs, reporting an average effect of a 16% drop in crime rates. However, the primary contributor to crime rates studied was burglary, not violence. This review noted an average decrease in victimization of 9% from such programs but noted that this was not statistically significant and that only three such tests with adequate evaluation design could be found. Of those, two out of three favored the control condition. These findings suggest that neighborhood watch may deter certain types of crime but may have little impact on exposure to violence. However, any conclusion is quite preliminary without an adequately conducted test of impact on community violence exposure.

Community Policing

A related effort to the previous two community organization approaches is to alter policing practices from specialists investigating and solving specific crimes to a community presence in order to discourage crime and identify methods for prevention. Police are assigned to the overall responsibility for a neighborhood's crime and the residents' safety and security. This method has been characterized as a shift of policing from crime solving to crime prevention. The best efforts focus on working with community members to learn about the community, create communication channels with the police that build trust and increase security, and work to promote safety and crime-reducing norms and activities at the neighborhood level. Often a local office is set up for police contact. It is thought that a greater connection between community members and police increases understanding and communication, which can lead to diffusing emerging violence and should lead to more effective police strategies for addressing crime causes and effects, which in turn should prevent crimes, including violence (Graczyk & Tolan, 2005). Careful studies of community policing have shown effects on perceived order and safety in the community,

and one has documented reduced victimization (Wycoff & Skogan, 1993). However, a recent meta-analysis of 65 programs across multiple countries reported a positive but not statistically significant effect on crime (5%–10%) (Gill, Weisburd, Telep, Vitter, & Bennet, 2014). Similarly, there was a small but not statistically significant effect for felt safety. It should be noted that there was considerable variation in effect sizes across the included studies and there was considerable variation in what comprised the different programs. The implication may be that the way community policing is done and, in particular, its level of implementation can relate to effects. When the primary principles are followed and multiple components are included, effects can be found for violence levels in communities and probably also for victimization. However, the way in which community policing affects children's exposure to community violence is still unsubstantiated.

Gun Control and Management Efforts

There has been considerable interest in the role of access and use of firearms as a contributor to youth exposure to community violence. In part this is because of the prominence of firearms, often illegally obtained, in community violence among youth (National Research Council of the National Academies, 2004, 2013). It is also due to the corresponding high rates of youth violence, particularly gang-related violence, in these communities. Although the value of gun control remains one of the most contentious issues in our society and within academic communities, research has suggested some findings relevant to reducing community violence that may be important in efforts to reduce exposure to such violence. These efforts can be categorized into four groups. The first is community-focused efforts to educate about the relation between gun access and lethality of violence, safe storage and proper use of weapons, and efforts to lessen youth access to guns legally or illegally. These efforts also can include community organization to affect norms about gun use, gun violence, and community responsibility for monitoring crime in the community à la community policing strategies. A second community approach is to try to obtain guns owned by youth and others through amnesty for turning in illegal firearms or buy-back programs. A third strategy is for legislation to increase penalties for use of guns in crimes, for illegal sale or buying of guns, to limit the number and type of guns that can be purchased during a given time period, and to require background checks. Fourth, law enforcement campaigns can aim to reduce gun violence. These campaigns can include concentrating on the policing of hot spots (areas of particular interest to law enforcement because of a concentration of criminal activity) to reduce opportunity for gun violence to occur, community-police engagement, gun courts that speed up the court processing and trial of crimes committed with firearms, stricter supervision of probation and paroled offenders who utilize guns in committing a crime, and required educational programs for first offenders. A recent meta-analysis was published by Makarios and Pratt (2012) of 29 studies categorized into these four types of interventions to determine the effects of policy and community interventions to reduce gun violence. Overall, they found a small but statistically significant decrease in violent gun crime ($r = –0.14$). When examining more specific interventions, small reductions on average were reported for gun laws ($r = –0.09$) and a significant moderate effect for law enforcement campaigns ($r = –0.23$). More specific analysis of gun laws found that weapons bans had significant, moderate effects on reducing gun crime ($r = –0.19$). Policing strategies in general had an effect size equivalent to law enforcement campaigns ($r = –0.23$). A similar effect was found for community education and engagement programs ($r = –0.27$). The latter finding may be particularly relevant in reducing violence exposure of youth. This finding suggests that consideration of efforts to reduce gun violence should include such community engagement strategies and that they are most useful also in affecting exposure because they include elements with some evidence of reducing exposure.

Efforts to Reduce Effects of Exposure

The scholarly literature contains many descriptions of efforts designed to reduce exposure or mitigate its impact on youth but few reports of outcomes (e.g., Bowen, Gwiasda, & Brown, 2004; Horowitz et al., 2005). Recently, two large initiatives were launched as federally funded and coordinated demonstration efforts, intended to permit testing of effects. The Office of Juvenile Justice and Delinquency Prevention launched Safe Start Promising Approaches, which funded efforts in 15 sites to develop and/or implement programs meant to mitigate effects on trauma and other problems, although decreasing exposure was also part of the charge (Jaycox et al., 2011). The consistent goal was to ameliorate the negative impacts of violence on children ages zero to 12. Programs provided differed by sites. Also, some community efforts focused on the development of specific services while others attempted to organize or support existing services. Some provided services to children only while others served both children and their families or primary caregivers. The programs also varied within site and in how recipients of services

were identified. Most targeted various exposure levels of domestic violence, with some targeting families with child abuse, but others included exposure to community violence. Launched in 1999, an evaluation report was recently released (Jaycox et al., 2011). Most notably, the report noted that outcome effects were often difficult to ascertain with any certainty, which precluded conclusions of effects across the initiative. Nor were specific effects for any given site presented. Underenrollment and attrition issues, evaluation design limitations, inadequate evaluation resources, and a premature end of the evaluation marked the projects. The retained sample in programs at most sites was too small to permit adequate power to detect expectable effects. For example, some sites had enrollment rates as low as 2% of targeted participants.

Similarly, the Attorney General's National Task Force on Children Exposed to Violence report led to a national initiative called Defending Childhood. In this case, eight cities were provided funding and technical support for community organizing to provide services to reduce children's exposure to violence (not just community violence) and to make services available that were thought to lessen the impact of such exposure. Most of the funded cities and Native American groups (included in the funding) focused on getting family-focused services to children exposed to domestic violence or abuse. However, the intent was to also address those exposed to community violence. This initiative, like Safe Start, included a variety of efforts. Therefore, surmising what might be effective was difficult since each individual effort had substantial methodological limitations (Swaner & Kohn, 2011). The Defending Childhood initiative is still in progress. However, interim reports suggest major impediments to implementation of programs as intended and engagement of families that are consistent with those in the evaluation report about Safe Start Promising Approaches (Jaycox et al., 2011). Thus, this experience in implementing needed programs provides an unfortunate but instructive example of how difficult it can be to carry out community-based violence-mitigating efforts.

Conceptual organization (what is thought to be needed), implementation challenges (getting needed efforts in place and utilized), and adequate methodological quality to permit inference are all necessary to complete adequate evaluation to determine what efforts might mitigate exposure or its impact. Each of these factors can be a major challenge. Together, they can overwhelm good intentions. It should be noted that these elements often involve large-scale community engagement efforts, shifting of some long-held approaches to services violence prevention. At the same time, identifying viable comparison conditions or communities can be difficult; and implementation in a sufficient number of neighborhoods for valid statistical inference can overwhelm budgets and the operational capabilities of evaluators. The lesson may be to consider some smaller-scale, more controlled demonstrations to establish efficacy. Furthermore, basing work on collaboration models that have shown benefits for other youth problems could then be implemented, marrying promising programming with promising organization (Hawkins, Oesterle, Brown, Abbott, & Catalano, 2014). Also, it is important to focus on community violence exposure apart from family violence as integral to the evaluation. This could be via a focus on community violence exposure specifically or as an attempt to parse the relative level of each among participants and how those levels relate to effects.

Police and Social Worker Collaboration

Marans and Berkman (2006) developed a variant on the community policing approach as a way to get services to youth exposed to violence that differs from community organization. They formed a collaboration between community police and mental health professionals to address effects of witnessing violence on children. The approach combined extensive training of the police in child development theory and violence effects on children and direct intervention by mental health caseworkers as soon as children had witnessed a violent crime. Marans and Berkman noted several promising effects on police approach and on the handling of domestic violence, but empirical evidence of specific impact on youth exposed to community violence has not been reported to date. As with most other approaches discussed here, there is some suggestion of utility in regard to violence exposure impact. However, that utility awaits empirical testing.

Trauma-Focused Efforts to Mitigate Violence Exposure Effects

As with several other approaches to community violence exposure, the literature describes multiple efforts but few target youth exposed to community violence. Or the efforts do not provide results of evaluation to judge effects. There have been multiple trials of psychological interventions for children thought to be traumatized due to maltreatment (Leenarts, Diehle, Doreleijers, Jansma, & Lindauer, 2013). This systematic review and other conceptual reviews suggest that cognitive-behavioral approaches that systematically include a mix of emotional support, opportunity to talk about the trauma in a safe place, anxiety-reducing

and thought-redirecting practices can reduce PTSD symptomology. One example, which included violence exposure not specific to maltreatment, was reported by Stein et al. (2003). They reported on a program entitled Cognitive Behavioral Intervention for Trauma in Schools. The program was designed to reduce PTSD, depression, and anxiety among children with symptoms of PTSD and who were exposed to violence. The 10-session school-based intervention taught cognitive-behavioral skills in a group format, led by mental health professionals, with six to eight students per group, using a mixture of didactic presentation, examples, and games to solidify concepts. Techniques used include relaxation training, combating negative thoughts, reducing avoidance, developing a trauma narrative, and building social problem-solving skills. In addition to the group program, students were provided one to three individual sessions and optional sessions that included parents. Teachers in the school were provided an in-service on trauma, violence, and the intervention. Youth in the program showed significant decreases in trauma symptomology compared to randomized waitlist controls. No effects on problem behavior were found, however. This trial produced results consistent with other tests of this intervention as a clinical treatment for maltreated youth and other similar approaches (Leenart et al., 2013). This single example is a weak basis to infer how community violence exposure might be mitigated through cognitive-behavioral intervention. However, this is among the few efforts meant to mitigate violence exposure in general, not just community violence exposure specifically. This type of approach deserves priority for testing.

Lessons from School-Based Programs

School-based prevention has been a popular approach to reduce aggression perpetration. Further, because these efforts are focused on youth violence in a setting where youth spend a large portion of their time, these findings can have two types of implications to affect exposure to community violence. First, these settings provide some attention to the ecology and social basis of violence exposure, with a few considering victimization and other exposure to violence in addition to the main focus on perpetration. Second, while not out in the community, school-based violence is sometimes considered a part of community violence exposure for youth. Therefore, these interventions may provide direction for direct impact on community violence exposure that occurs at school.

There is some evidence that some school-based violence prevention programs reduce victimization (Hahn et al., 2007). Similarly, there is some evidence that bullying prevention efforts also can reduce victimization. In both cases the effects can be from reducing perpetration so fewer students are victims or by making aggression/bullying less acceptable and providing potential victims coping and assertion skills, The best evidence for bullying programs is those that include family-focused components are helpful (Ttofti & Farrington, 2010). For example, Ttofti and Farrington (2010) examined 89 reports and noted an average reduction of victimization of 17% to 20%. The effect sizes varied substantially (from about 1.00 standard deviation to negative effects), with some characteristics relating to effect sizes. They noted that programs that were delivered by or focused on peer groups seem to have lower and sometimes negative effects. Among the effective programs were elements such as clear and explicit display and enforcement of norms in school against violence, engagement of families as part of this norming effort, problem-solving opportunities when conflicts arose, and opportunities for students and staff to increase social and emotional skills. Also, some programs utilized engaging games to help students learn methods to avoid bullying or to help stop victimization. Thus, a variety of approaches had some effects on victimization, at least as measured as bullying, within schools. Notably, the effect sizes tended to be larger for demonstrations in countries other than the United States. Thus, it is not clear how these efforts might translate to reducing community violence or affecting exposure impact and how these might be useful in the United States.

Two recent large-scale tests of school-based violence prevention suggested that what might affect victimization differs from what might affect perpetration. The Multisite Violence Prevention Project (2009) tested two programs for middle schools meant to affect violence rates (perpetration and victimization). One program utilized cognitive skills training and norms promotion, similar to what characterizes many programs designed to reduce violence use and acceptance and was applied as a universal classroom-delivered program. The other focused on youth whom teachers identified as among the more aggressive.

It utilized small family groups to help with parenting skills, parent-child communication, and group support for nonaggressive problem solving. Testing of effects showed no overall differences for either intervention or a combination of the two for victimization, although some effects of the selective family intervention were found (Multisite Violence Prevention Project, 2009, 2014). There was some suggestion of lower victimization of the combined program for those students with very elevated aggression.

Similarly, Espelage, Low, Polanin, and Brown (2013) reported that test of a curriculum, Second Step, that focused on many of the same cognitive features as the Multisite Violence Prevention Project (and many other such programs) showed no effects on victimization even though there were positive effects for perpetration of bullying. As with other tests of in-school programs, both of these efforts focused on within-school victimization, so results may not transfer to tests that measure effects of community violence.

ADVANCING KNOWLEDGE, PRACTICE, AND POLICIES RELATED TO COMMUNITY VIOLENCE EXPOSURE

Violence exposure has harmful effects on development. Numerous studies have implicated exposure to violence as contributing to risk for psychopathology symptoms and disorders and in exacerbating psychopathology. Community violence, one form of violence exposure, has been studied less than other forms, but research suggests its impact is similarly deleterious. In addition, it probably affects psychopathology through comparable psychological and biological processes.

Community violence differs from other forms of violence in that it occurs outside the home and is not due to violence between family and friends. It also differs from these latter forms of violence in that it may affect youth by virtue of residing within a geographic region. Thus, its forms can vary from isolated horrible events to an atmosphere where violence is endemic and frequent. Most specifically, it can range from direct victimization to witnessing victimization of others to being aware of violence nearby or occurring to neighbors. Also, unlike family violence (including partner violence, child abuse, and sibling violence), community violence tends to be concentrated in particular neighborhoods, particularly urban impoverished communities. Thus, it is substantially related to economic class and location, which is not the case for other forms of violence. This makes community violence a political and social policy issue as much as psychological and psychopathological issues.

Over the past 20 years, considerable theory, policy analyses and suggestions, and empirical study have been applied to community violence. In addition, considerable effort and advances have occurred in understanding the importance of the definition of violence applied, how distinct measurement of exposure types and sources are, and how these are interwoven into developmental tracking and intervention studies. This collective work has revealed important understanding of the issues, including alarming prevalence among some children in particular communities. The starkness of these findings and the concentration of violence within poorer communities in larger urban centers suggest the importance of contextualized understanding of impact. This can include better understanding of what community-level actions can reduce violence and exposure but also what might be needed to mitigate harm from exposure in communities marked by limited social and economic resources and limited political importance. There is sufficient evidence that community organization, community policing, and community awareness can reduce crime rates and probably reduce community violence rates. Therefore, such actions deserve to be central in efforts to reduce community violence exposure and to the study of what makes a difference.

It has also shown that while effects of violence exposure can be traumatic to some individuals, this is not universally so. In fact, there is mixed evidence for any form of violence exposure affecting symptoms of PTSD, with thin evidence of effects extending to disorder incidence. Evidence is similarly strong for violence exacerbating rather than affecting conduct disorder symptoms and other externalizing disorders and depression. Evidence is less robust for violence affecting anxiety symptoms apart from PTSD, but is the available evidence shows effects consistent with those shown for other symptoms and other disorders, suggesting potential effects for some exposed. As expected, the few studies that have examined the relation between psychopathology and impact of subsequent exposure to violence have demonstrated the transactional quality of the interdependence. Those with mental health problems seem most susceptible to exposure harm. In some cases, particularly for those with aggressive tendencies, the exposure may be due to those tendencies with additional increased impact in the presence of such psychopathology. Similarly, when related to different forms of violence, those with prior abuse or exposure to domestic violence are most affected by community violence. Impact is also dependent on multiple personal and familial characteristics, suggesting that those growing up with fewer resources or poorer functioning are also most susceptible to violence risk in comparison to others residing in similar communities. The accumulated research on community violence effects on psychopathology underscores the transactional nature of its development with attention to group level as well as individual differences in exposure risk and impact processes. Although the components of models that can explain and provide guidance for additional studies can be found significant gaps still exits in the empirical basis for

the link between community violence and psychopathology occurrence, course, and mitigation.

When theories of processes are applied, whether framed within a neurodevelopmental approach or as psychological processes of emotion and cognition, a common element is strong dependence on theories and studies from maltreatment exposure and explanations of violence or aggression perpetration. This is due to limited research on community violence, limited differentiation of community violence from other forms of violence when it is studied, the larger and more extensive set of studies on maltreatment and violent behavior, and the likelihood that there are similar if not shared processes of impact. A more carefully drawn definition of violence is critical to permit confident understanding of the meaning of various studies. But violence also must be differentiated into levels of seriousness, sources, and forms. Doing this will allow us to determine whether effects and processes are similar across community and family violence and are related to differences in level of exposure to and directness of involvement in the violence. In addition, more studies are needed that test for community violence exposure in particular as a source of stress and as impeding self-control. Also, it is necessary to trace neurobiological processes, test for differences in physiology, and document the stability/transience of effects on those processes thought to underlie/characterize psychopathology. In reviewing areas related to community violence, much of what we know is based on inference from studies of exposure to violence in general or due to other forms. There are still basic questions of how community violence exposure specifically relates to likely symptoms and behavior change. While there is great value in testing the application of lessons from these findings about violence in general to exposure to community violence in particular, this application needs to take into account differences in how this type of exposure occurs and in likely co-occurring risk factors.

Interventions for community violence exposure that are designed to test theories of psychopathology as well as those intended to demonstrate the potential for public health benefits if taken to scale are both needed, and should be priorities for future research. There have been a notable number of failures to implement adequately or to complete study of community violence interventions. Therefore, there is very limited scientific information about impact of any approach and even scarcer basis for judging one approach as advantageous over others. In part, this state of knowledge can be attributed to the scope and complexity of implementing interventions that attempt to address structural issues such as gang and criminal activity in a community, or operate with limited police availability and engagement with the community, and/or attempt to address only violence when it is part of a collective concentration of social problems (Tolan & Guerra, 1998; M. Wilson, 1988). It may be important to focus on how communities can become more engaged to form and express collective efficacy (Sampson et al., 1997). Similarly, it may be advantageous to explore how families and youth can be reached through greater school-community engagement or encouraging neighborhood supports (Tolan et al., 2003). If affecting the social forces that seem to undergird rates of violence and therefore likely violence exposure in communities is beyond the reach of most policy or service efforts, perhaps some of the promising family support, safe space, youth engagement, and youth monitoring efforts that show promise from prior trials could be utilized to explicitly limit exposure and mitigate harm from exposure.

CONCLUSION

Community violence exposure remains a compelling social and psychological problem that deserves more of the careful and informative scientific work extending what has been done in the past 25 years. In particular, what is needed are: (a) more carefully defined samples; (b) measures of community violence exposure that delve into extent of exposure (e.g., direct victimization versus witness versus being aware of) and of exposure with considerations of other bases for violence (exposure, chronicity of exposure); and (c) specific theoretically driven formulations of the relation of community violence exposure to context, family, individual behavioral, affective, and cognitive features, and neurodevelopmental underpinnings; and (d) analytic approaches that can trace causal influence of community violence exposure to changes in psychopathology symptoms and conditions. With such design features, it is plausible that knowledge could be accumulated to move us from the basic understanding available at this point toward delineation of the basis, effects, processes of impact, and needed interventions and policies for community violence exposure. The field seems poised to build on prior work to incorporate more careful definitions of key constructs and to apply methods and findings from adjacent studies of violence, aggression, crime prevention, and neighborhood organization, and on processes of developmental psychopathology. With such careful and substantial attention, understanding of community violence could be greatly improved in a relatively brief time and could be used to help lessen this harmful part of the lives of too many children.

REFERENCES 127

We live in an environment of relationships. Those relationships are important for many reasons, and one of the most important is the psychological support they provide. Family members can be counted on for understanding and advice, help with child care, and financial assistance. Friends are sources of encouragement and counseling, for sharing information and experience, and as referral sources. Coworkers can provide professional advice and guidance about workplace concerns. Neighbors are valuable sources of information and tangible aid, sometimes in the exchange of favors or resources. Marital and romantic partners support self-esteem and emotional well-being. Although not all relationships function optimally, and thus these forms of assistance may be provisional, the value of these relationships rests on their offering support in the context of the emotional ties that define them. This is especially true when individuals need help because they are under stress.

Formal helping relationships are often intended to emulate these forms of informal support. Counselors, religious advisors, social workers, and other helping professionals attend to the psychological needs of their advisees as well as their material or spiritual condition. Teachers, professional coaches, and personal advisors likewise provide encouragement and support in the context of promoting skill development and knowledge acquisition. Social support is a critical function of many forms of psychological therapy, whether support is received from an individual mental health professional, a therapy or support group, or a special preschool, classroom, or adult education program designed for troubled individuals. Although individuals benefit from the support received in formal as well as informal helping relationships on any occasion, when they face significant stress or psychological turmoil, the psychological support that formal helping relationships afford can be critical to their coping and recovery.

Children depend even more significantly than adults on the support provided by their environment of relationships. This is because central developmental achievements—emerging sense of self, social and emotional competence, cognitive and language skills, even physical health and development—are constructed in the context of social interactions in which the supportive assistance of relational

We are grateful for very helpful comments from Kristina Gelardi on an earlier version of this chapter.

partners is critical. In addition, because children (especially when they are young) are less capable of creating alternative sources of support for themselves, they rely more significantly on support from people in the family, school, and neighborhood social networks that are created for them by their parents. This is one reason why social support to children differs from social support for adults: It is mediated to a significant extent by parents and the opportunities they provide. Parents are also significant to children's support because they are key providers of the varieties of emotional, informational, material, and other resources that children need. They are, as we subsequently describe, support generalists. Where children are concerned, therefore, it is essential to think *multigenerationally* about relationships and social support.

Understanding the value and functions of social support in everyday life provides a basis for understanding its role in developmental psychopathology. As described in this chapter, social support is relevant to developmental psychopathology in at least three ways. First, social support or its absence is important to the *origins* of clinical problems for children and their families. Children who encounter adversity without the buffering assistance of supportive relationships are at higher risk of developing psychopathology. Risk is especially heightened when family relationships become sources of adversity rather than of security because of children's reliance on the support of family members. For this reason, many preventive programs, such as home visitation, enlist social support to improve family conditions for children, using the assistance of formal helpers to strengthen informal support to children. Second, social support or its absence is important to *maintaining* clinical symptomatology for children in troubled families. In this sense, family ecologies can become enabling conditions for affective psychopathology because of the absence of the kinds of support from family members that might help remediate children's anxiety, conduct problems, or other difficulties, and these family conditions instead exacerbate these problems. Third, social support is important to the *treatment* of clinical problems of children. Indeed, it is arguable that most forms of therapeutic assistance entail some form of social support, so the important questions concern the sources of support, the avenues by which it is provided, and most important the clinical symptomatology it is expected to address. Several models of therapeutic intervention entailing different kinds of supportive assistance are profiled later in this chapter.

Taken together, the value of social support seems obvious and obviously beneficial in everyday experience, and thus of clear relevance to the prevention and treatment of clinical problems in children. Such a view led to what Shumaker and Brownell (1984) described as an "era of unrestrained enthusiasm that has dominated social support research and interventions for more than 10 years." What led, then, to the close of this enthusiastic period? Some considerations are listed next.

- Social support may address some of the emotional needs of its recipients without addressing the root problems that contribute to dysfunctional behavior. This problem is evocatively illustrated by Jill Korbin's (1989, 1991, 1995) interviews with mothers convicted of fatal child abuse. These mothers were surrounded by family, friends, and neighbors who were often painfully aware of the bruises, neglect, and other harms the mothers inflicted on their offspring. But in their efforts to be emotionally supportive, they failed to challenge abusive practices and instead overlooked other signs of parental dysfunction, minimized the seriousness of abuse, and offered reassurance about the mothers' good intentions while providing noncritical emotional affirmation. In doing so, of course, they contributed little to curbing abusive practices or protecting the children. As Korbin (1991, p. 23) noted, "A high level of perceived support sustained, probably unintentionally, these women in their pattern of abusive behavior." It is not difficult to see similar patterns of emotional support enabling other forms of family pathology that victimize children, such as family practices that excuse rather than challenge parental substance abuse or domestic violence by offering reassurance without addressing the causes of clinical symptomatology.
- Social support may have attendant negative consequences that ultimately undermine sustaining support to needy recipients. Home visitors who seek to provide emotional support, material assistance, and information to at-risk parents are often surprised, for example, to discover that parents are absent during scheduled visits and resistant to the assistance they receive, and that they respond to the home visitor not with gratitude but instead with resentment and ill will. The home visitors do not understand that receiving one-way assistance, even (perhaps especially) from someone motivated by beneficent motives, often generates feelings of humiliation, failure, stigmatization, and vulnerability in recipients (J. D. Fisher, Nadler, & Witcher-Alagna, 1982; Schumaker & Brownell, 1984). One implication is that *how* social support is provided and the nature of the relationship in which it is offered are crucial to recipient

reactions to assistance and the maintenance of a helping association. Without considering recipient reactions to assistance, helping relationships often break down.

- Social support may exhaust the resources of informal and formal helpers, and the characteristics of those most in need of social support are especially likely to drain helping relationships. Friendships become stretched by the emotional neediness of someone who is in chronic distress, and individuals may begin to distance themselves from those who are depressed because of the negative affect, demandingness, and even hostility that can become part of their relationship. Troubled families with neglected children may evoke compassion in neighbors but also aversion because of parents' disorganization, social incompetence, and withdrawal (Gaudin & Polansky, 1986; Polansky & Gaudin, 1983). Professional clinicians also experience the drain of providing emotional assistance to their clients. The maintenance of supportive relationships, whether informal or formal in nature, requires attention to the needs of helpers as well as recipients.

The current era of social support research and interventions has learned these lessons, and as a consequence, there is greater attention to tailoring supportive interventions to the needs of specific recipient populations, devoting attention to the contexts in which assistance is offered, considering the characteristics of helpers and those they aid, and creating networks in which social support is most likely to be maintained (Thompson, 2015a). In addition, social support in the context of developmental psychopathology increasingly relies on understanding children's social networks and the role of parents as organizers, gatekeepers, and mediators of children's access to helpers. Research in developmental relational science provides insight into the influence of relationships to promote or undermine children's well-being. Recognizing that social support is easy to conceptualize but difficult to implement in the lives of troubled children and their families, the field of social support research and intervention is less enthusiastic, more cautious, but potentially more helpful in addressing the clinical needs of children and families than it was several decades earlier (Thompson, 2015a).

The purpose of this chapter is to consider the complex and multifaceted association between social support and developmental psychopathology. Our goal is to draw on diverse research literatures to illustrate how social support is relevant to the etiology, maintenance, and treatment of clinical disorders in children and families in the context of a developmental appraisal of children's social support networks. Our goal is also to use the lessons of treatment interventions and basic research to outline suggestions for how social support interventions can have the most positive effects for children and families as well as to outline directions for future research.

The chapter opens with a discussion of how to define and conceptualize social support, considering both what it is and what it is not. In doing so, the multiple functions of social support for adults and children are discussed, with attention to similarities and differences in the experience of social support for children and adults. Regardless of age, however, social support is believed to contribute to psychological well-being in two ways: by preventing stresses from occurring, and by buffering the effects of stress when it occurs. The next section of the chapter discusses multiple ways by which support has these consequences, including studies of the social buffering of stress neurobiology (Thompson, 2014a). Not surprisingly, the association between social support and stress is complex and bidirectional, and these bidirectional associations also are considered.

Recognizing that social support is provided most often in the context of relationships and that relationships are multifaceted, the next section considers the characteristics of relationships that afford support, as well as how relationships sometimes can undermine support between relational partners. Also discussed is how obtaining support in a relational context compares for children and adults and how children's access to support is mediated by parents and family conditions. Developmental changes in children as relational partners are also discussed, especially how these changes increasingly enable children to construct and maintain their own social networks. The nature of social support in the context of online relationships through social media and other technological avenues is considered as well. Then this relational perspective is extended to consider cultural processes related to giving and receiving social support. A series of interim conclusions about social support then follow.

In the next section, we discuss most directly the relevance of social support to risk for affective psychopathology in children in relation to the origins, maintenance, and treatment of clinical disorders. We use examples from well-studied areas of clinical psychopathology or at-risk family conditions, rather than focusing directly on a few diagnostic categories, in the hope that this will yield more general lessons for those who seek to enlist social support interventions to aid at-risk children and families. We also offer examples of promising intervention efforts as exemplary models. These lessons learned provide the

transition to the final section, which offers directions for future research and intervention.

DEFINING SOCIAL SUPPORT

To most adults, "social support" consists of the emotional affirmation received from close relational partners, particularly during periods of distress or turmoil. Most researchers believe that although emotional affirmation is important, social support is actually a more multifaceted phenomenon (Gottlieb & Bergen, 2010). The next definition reflects this fact:

> Social support consists of social relationships that provide (or can potentially provide) material and interpersonal resources that are of value to the recipient, such as counseling, access to information and services, sharing of tasks and responsibilities, and skill acquisition. (Thompson, 1995, p. 43)

Unpacking this definition provides a more complex portrayal of the functions of social support and better understanding of how social support to children compares with support to adults.

Functions of Social Support for Adults and Children

First, social support offers *emotional encouragement,* including affirmation, understanding, and empathy, the sense that others share one's troubles and are reliably "on your side" (what Gottlieb, 1985, calls "milieu reliability"). For adults, this emotional function contributes to a sense of perceived support from social network members, especially those in close relationships, that is an important component of how support buffers stress (Barrera, 1986; Cohen & Wills, 1985). The emotional understanding and companionship entailed in this support function is important also to children. From infancy, children rely on the solicitude and emotional support of their caregivers and develop secure attachments to those adults based on the sensitivity and reliability of the adult's assistance (Cassidy, 2008; Thompson, 2006). The security in a caregiver's support and responsiveness is important whether children's relationships are with adults within or outside the family, and it contributes to children's social and emotional competence and self-confidence (Thompson, 2008). Likewise, children's friendships incorporate emotional understanding and acceptance, especially as children mature and as intimate self-disclosure and emotional support become increasingly important to friendship quality (Gottman & Parker, 1987).

Second, social support provides *counseling, advice, and guidance.* For adults, counseling may be sought concerning marital or child care concerns, workplace issues, personal problems, or other issues. Children require advice and guidance for a much broader range of individual and developmental issues because caregivers have much greater knowledge and experience about major life issues, and peers are sources of relevant social understanding and perspective. This function of social support is thus, like emotional support, essential to healthy child development (Thompson, 2014b).

The counseling and guidance function of social support may be combined with emotional encouragement, but whether this occurs or not depends on the nature of the relationship between the recipient and the support agent. Adults may seek guidance from a workplace colleague or neighbor about a problem without expecting emotional support, for example, but they may obtain advice with the expectation of encouragement from a spouse. Likewise, children may obtain helpful advice from a teacher, peer, or parent in the context of different expectations for emotional support. Indeed, social discriminations concerning expectations for the kind of support that might be solicited from different members of one's social network become part of social-cognitive growth in middle childhood and adolescence. During this period, for example, peers become significant sources of advice on matters of style (hair, dress, music) and activities, whereas parents remain important for guidance on questions of moral values and future goals (Coleman, 2011). In this respect, different network associates are preferred for different kinds of advice, which may or may not be accompanied by emotional affirmation.

Third, social support enables *access to information, services, and material resources and assistance.* In this way, support agents provide tangible aid or act as brokers with others who can do so. For adults, this may occur when neighbors and friends are consulted for information about schools, community agencies, or child care settings or when extended family lend money or provide needed transportation. These activities often overlap with another function of social support, *sharing of tasks and responsibilities*, in which people assist the recipient in these ways or provide access to others who can do so. For children, these functions of social support are more extensive because children depend on adults within and outside the home for information, services, and the necessities of life. This assistance can occur in the informal settings of family or peer group, or through the formal services of school or community agencies. Importantly, however, access to these

formal services depends, at least until children are older, on the permission and assistance of parents.

Fourth, social support can contribute to *skill acquisition.* Skill acquisition occurs for adults when coworkers assist with job-related skills, neighbors assist in learning about gardening or car repair, and friends or extended family aid in personal skills related to household management, parenting, or financial planning. Skill acquisition is a central feature of social support for children, whether considering parents, peers, or people outside the family (such as teachers or members of a faith community) as support agents. As in other support functions, the contributions of others to children's skill acquisition is more extensive than for adults because many of the abilities to which parents and peers contribute are developmentally foundational. Social skills, literacy, navigating familiar routes, and consumer practices are among the multitude of skills that are acquired in the company of social partners. As with sources of advice and guidance, children acquire different skills from different people in their support networks. Peer relationships are, for example, rich contexts for the acquisition of unique social skills that are relevant to interactions between equals (Rubin, Coplan, Chen, Bowker, & McDonald, 2011).

Social Monitoring as Social Support

These four generic forms of social support are intuitively recognized and appreciated in everyday social relationships and constitute the foundation of most research portrayals of social support (e.g., House & Kahn, 1985; Thoits, 2011). But when research on social support is considered in relation to developmental psychopathology, at least one other function becomes important: *social monitoring.* Social monitoring emphasizes the protective influence of social network members, such as when friends notice signs of depression in an adult and seek assistance for this reason or extended family members detect and respond to disturbing bruises on a child. In contrast with the provisioning forms of social support earlier described, this is a protective function (House, Umberson, & Landis, 1988). It is an important, and sometimes overlooked, influence of social support and recognizes that support is important for preventing harm as well as for promoting good, and that both aspects are important to supporting individual well-being. Indeed, social monitoring may be most important, especially for some of the preventive and remedial influences that social support is believed to have in the lives of at-risk children and families, such as a home visitor's monitoring of an infant's development and of parental functioning. Furthermore, individuals and families in social isolation are commonly perceived as being at greater risk of psychosocial problems (such as child maltreatment) compared to those who are embedded in extensive social networks because the social monitoring of isolated families does not occur (Thompson, 1995). Although extensive networks do not necessarily safeguard against child maltreatment, as Korbin's (1991) research described earlier indicates, it improves the chances that child harm will be detected and that interventions on the child's behalf will be mobilized.

Distinguishing the provisioning functions of social support—emotional encouragement, counseling and guidance, access to information and resources, and skill acquisition—from the protective function of social monitoring is important for understanding why these do not necessarily operate well together. Stated simply, people are much more comfortable offering encouragement and help than with monitoring and drawing concerned attention to another's behavior, especially in informal social networks, and recipients are much more likely to respond positively to the former than to the latter (Thompson, 1995). In the families that Korbin (1991) studied, mothers were surrounded by affirmative and supportive kin who failed to intervene despite indications that a child was at risk. A similar conclusion derives from a recent study by Freisthler, Holmes, and Wolf (2014), who indicated that parents who experienced a high sense of belonging with others, especially when companionship involved drinking outside of the home, were more likely have physical abused their children. They described this phenomenon as "the dark side of social support" because the contexts of companionship may have fostered abusive conduct and friends did not help to curb this conduct. In a culture in which privacy boundaries, even within families, can cause adults to resent perceived intrusions into personal issues, these privacy norms can make neighbors, friends, coworkers, and even extended family members hesitate before bringing up uncomfortable concerns about personal conduct or parental behavior. Raising these issues can cause these individuals to be perceived as meddlesome, intrusive—and unsupportive. For most adults, formal helping professionals may be more successful than informal helpers in social monitoring and correction because of the nature of their role responsibilities. But even in formal contexts, these behaviors may be resented and resisted.

This is, however, another manner in which social support to adults and children differs. There is much less perceived dissonance between the provisioning and protective functions of social support to children, in part because

children's need for guidance is self-evident and privacy concerns do not apply as strongly to children's conduct (Smetana, 2006). In addition, both children and parents recognize that parental monitoring and correction are compatible with parental support and affirmation as long as parents are perceived as acting fairly and consistently with their parenting responsibilities (Grusec & Goodnow, 1994; Lansford et al., 2005). As Lansford and colleagues (2005) have noted, for example, even physical punishment by parents is accepted by children if this practice is perceived as normative. Thus although neither children nor adults like the attention drawn to their inappropriate or dysfunctional conduct, for children the correction of their conduct is a more normative feature of their relations with adults within and outside the family.

Distinguishing different functions of social support in this manner draws attention to the different supportive functions that can exist in relationships between a support agent and a recipient. In some relationships, individuals are support specialists who are valuable primarily because they have one or two specific forms of social support to offer, and this can also be true of formal helpers, such as physicians, counselors, and religious leaders (Bogat, Caldwell, Rogosch, & Kriegler, 1985). Other individuals are support generalists who provide many different social support functions, and these individuals can often be found in neighborhood and kinship social networks. As noted earlier, parents are support generalists to children, a fact that helps to account for their unique and significant influence on children's development (Cauce, Reid, Landesman, & Gonzales, 1990). But peers can also be support generalists of a different kind. Parker and Asher (1993) found, for example, that the friendships of children who were highly accepted among their peers provided greater validating and caring, more help and guidance, greater conflict resolution, and more intimate exchange than the friendships of children with lower peer acceptance. The extent to which children's developing social networks provide multifaceted support to them depends, in part, on the number of support generalists these networks include.

What Social Support Is and Is Not

This multidimensional portrayal of social support includes the various ways that individuals derive interpersonal and material resources from others. It recognizes that social support extends beyond the emotional affirmation and understanding that is prominent in everyday conceptions of support and includes other contributions that are ultimately valuable to the recipient (although they may not always be immediately recognized as such). Viewed in the context of developmental psychopathology, this conceptualization recognizes that support can include skills training, community referrals, economic assistance, and social monitoring for purposes of preventing or remediating clinical problems. Indeed, these functions of social support may be influential whether they are accompanied by emotional affirmation or not.

It is arguable, however, that this portrayal of social support is *too* inclusive. As earlier noted, for example, it is possible to view most forms of therapy as entailing one or more forms of social support. Any relationship that is worth maintaining likewise functions in a socially supportive manner in some form. In this light, it is perhaps less important to regard relationships as "supportive" than to delinate more specifically *how* they offer support and the particular support functions they provide. If the term *social support* is here conceived broadly, it nevertheless permits portrayals of helping relationships as functioning supportively in distinct ways.

Moreover, it is important to clarify what social support is *not.* Social support is not the same as having a large social network. Individuals who know many people may not derive support from them—indeed, large social networks may be "conflicted networks" that impose stress more than support, and this may be especially true for troubled individuals (Barrera, 1981). Moreover, some people enjoy close, supportive relationships with a very small handful of network associates. Although these conclusions may seem obvious, they challenge the view that it is important to try to integrate socially isolated children or families with larger numbers of people with the expectation that doing so will enhance their social support. Without efforts to ensure that new relationships function helpfully in the lives of socially isolated individuals, simply enhancing network size may not accomplish much.

For similar reasons, social support also is not social embeddedness (the frequency of contact with network members), dispersion (the ease with which individuals can get in contact with network members), or stability (the consistency of network members over time). Each of these structural features of social networks can be important in certain circumstances, and often these features are used as measures of social support. But research studies indicate that social network measures like these are only modestly associated with the extent to which individuals report expecting, or actually receiving, social support from others (e.g., Barrera, 1986). One reason is that relationships with social network members can be troubled, coercive, or critical in ways that undermine the benefits these relationships

potentially can provide. This is especially likely to be true for children at risk of psychological difficulty.

These considerations thus focus the conceptualization of social support on the qualities of social transactions that matter to the recipient and are influential in promoting health. Subjective perceptions of perceived or enacted support from network associates are more strongly associated with individual coping and resilience than are structural features of social networks, such as network size (Barrera, 1986; Cohen & Wills, 1985). The association between individual coping and a subjective perception of support may be based on the sense that people are benefiting from their transactions with social network members in emotional, informational, material, protective, and/or other ways that are important to them. When this occurs, those social network members function in a socially supportive manner and usually are perceived to be doing so by the recipients. It also means, however, that individuals who act protectively in the lives of troubled families or children must carefully consider how their actions are perceived by recipients or risk that their assistance will be regarded as unsupportive, even if they are striving to act in the recipient's best interests.

SOCIAL SUPPORT AND STRESS

This portrayal of the functions of social support embeds helping relationships within the everyday positive social transactions of children and adults. Social support benefits its recipients: It is part of what makes life manageable and cements close relationships. Supportive relationships are nice to have.

With respect to children, however, Thompson (2014b) goes further to argue that social support is developmentally constitutive. In other words, beyond being desirable, the ways that supportive relationships (especially with parents) provide emotional security, foster the growth of age-appropriate skills and understanding, offer essential information and guidance on matters that are important to children, and offer protection through social monitoring address essential needs of developing children, particularly when they are young. They are not optional for healthy development. The view that social support is developmentally constitutive grows out of children's dependence on those who care for them, their limited capacity (until much older) to create and maintain their own supportive social networks outside the family, the centrality of caregivers in children's environment of relationships, and the importance of supportive relationships to critical developmental achievements in self-confidence, social and emotional competence, cognitive functioning, and even physical health (Thompson, 2014b). One implication of this view is that children's experience of social support is closely tied to the quality of the relationships they experience with family members, peers, and other important network associates. This concept is explored further in the next section. Another implication is that when these relationships are troubled, particularly with parents, children are especially vulnerable because alternative sources of support are not readily available to them. This idea is explored further in the examination of social support in relation to developmental psychopathology.

Social support is important, and it is especially so when individuals are under stress. Extensive research highlights that social support mediates the impact of stress on individuals in at least two major ways (Barrera, 1986; Cohen & Wills, 1985; House et al., 1988; Taylor, 2011; Vaux, 1988).

First, social support can be *stress-preventive.* Social support provides its recipients with psychological and material resources that contribute to healthy functioning and positive development and in so doing prevents many stresses from occurring. This influence of social support has been studied most extensively in the field of health psychology, where social support is believed to encourage healthy practices through the encouragement and example of network members; the monitoring of healthy practices by others; the investment of the individual in roles and relationships that support healthy functioning; and encouragement of the individual's self-esteem, sense of belonging, and companionship (Thoits, 2011; Uchino, 2004; Umberson, Crosnoe, & Reczek, 2010). Viewed more broadly, social support can also promote mental and physical well-being by fostering needed competencies and skills, promoting effective coping strategies, and enabling access to assistance and material aid. These resources support the growth and maintenance of constructive practices and equip individuals with the capacities to manage ordinary challenges and prevent their escalation. In these ways, social support contributes to the prevention of stress.

This influence of social support is also true of children in their social networks. Parents who are warm and nurturant, support children's self-confidence and self-esteem, encourage constructive social competencies, and foster personal and academic accomplishments help to prevent sources of stress for their children that can arise from difficulties in school or with peers or from problems of adjustment. Moreover, parents often enable access to other sources of social support (e.g., health care providers, teachers, extended family, coaches, mentors, and peers) that can

have similarly constructive benefits. If social support is a protective factor, then it potentially can mitigate some of the risks that many children face in difficult or disadvantaged circumstances, but only if children experience support in their families and other relationships.

Second, when stress occurs, social support can be *stress-buffering*. The psychological and material resources available through supportive relationships can diminish the impact of stressful events by enhancing constructive coping. In health psychology, clinical studies have shown that social support is associated with a reduction of the effects of disease pathology and psychological distress, contributing to less severe symptomatology, quicker recovery, enhanced coping, and diminished long-term sequelae (Cohen, 2004; Cohen & Janicki-Deverts, 2009; Umberson & Montez, 2010). This buffering can occur by altering recipients' appraisals of stressful events, enhancing their knowledge or utilization of effective coping strategies, providing useful information or instrumental aid, and supporting self-esteem, optimism, and perceptions of self-efficacy. These benefits are even more significant for children in light of their more limited capacities for coping with stress and their reliance on the assistance of parents and other caregivers.

More than 30 years of research have provided a fairly reliable account of the association of social support with stress, although there has been much less research confirming the hypothesized behavioral and psychosocial mediators of this association (Taylor, 2011; Umberson & Montez, 2010). This lacuna constitutes an important research agenda, especially with children in at-risk circumstances, because the hypothesized mediators of the preventive and buffering effects of social support may not regularly characterize the relationships on which children rely. Relationships may for them be sources of support but also of adversity, a topic that is discussed further in a later section.

Social Buffering of Biological Stress Reactions

An important contribution to understanding the association of stress and social support comes from research on the neurobiology of stress reactivity and its social buffering. Taken together, this research contributes further evidence to the importance of social relationships in coping with stress, especially for children, for whom nurturant, supportive care shapes the functioning of biological systems relevant to stress responding.

When acute stressors occur, a network of biological systems are activated in response to cortical appraisals of threat or danger (Lupien, McEwen, Gunnar, & Heim, 2009). One of the most important (and best studied) of these is the hypothalamic-pituitary-adrenocortical (HPA) axis, which, in concert with the sympathetic nervous system, releases the catecholamines epinephrine and norepinephrine and corticosteroids, such as cortisol, into the bloodstream. This activity contributes to the mobilization of energy, enhanced cardiovascular tone, and other critical components of the stress response that have psychological as well as physiological consequences. These responses are designed to provide short-term resources for coping with threat. When stress is chronic or recurrent, however, repeated HPA activation is costly. Chronic activation of the HPA system can change its neurocircuitry over time, contributing either to hyperreactivity to threat or hyporesponsiveness of HPA function, in each case reflecting dysregulated biological functioning (see reviews by Thompson, 2014a, 2015b). In addition, chronic release of cortisol affects the functioning of limbic systems (such as the amygdala, hypothalamus, and hippocampus) and cortical systems (including prefrontal functioning) that can alter emotional reactivity, cognitive functioning, and self-regulation (Ulrich-Lai & Herman, 2009). Chronic stress also alters autonomic functioning, suppresses immune response to infectious challenges, and generally embeds proinflammatory tendencies into biological functioning (El-Sheikh & Erath, 2011; G. E. Miller, Chen, & Parker, 2011). The biological consequences of chronic stress are consistent with the concept of allostatic load: the progressive wear and tear on biological systems attributable to the long-term effects of chronic stress, which elevates risk for later health and mental health problems (Danese & McEwen, 2012). The behavioral consequences can include poorer emotion self-regulation, cognitive and attentional problems, and difficulties in social functioning (Blair & Raver, 2012; Evans & Kim, 2013).

These considerations are particularly serious when children are stressed because of the plasticity of developing neurobiological systems and their sensitivity to experiences of stress. Fetal exposure to maternal stress hormones is associated with altered stress reactivity after birth. In one prospective longitudinal study, for example, maternal depression during pregnancy was associated with heightened cortisol levels when infants were observed at 3 months in a moderately challenging procedure (Oberlander et al., 2008). In another longitudinal study of children in poverty, environmental characteristics such as poor housing quality, family economic strain, and poor parenting were associated with disrupted HPA activity from

age 7 months to age 4 (Blair et al., 2011). Yet in the same sample, observed maternal sensitivity from birth to age 2 buffered some of the effects of family stress on children's cortisol reactivity (Hibel, Granger, Blair, Cox, and the Family Life Project Key Investigators, 2011).

The latter finding is consistent with the view that social support can buffer biological stress reactivity in children and adults (Hostinar, Sullivan, & Gunnar, 2014). Studies with adults show, for example, that social contact with a supportive person can reduce cardiovascular and HPA reactivity and reduce threat-related neural activation to a stressful task (Taylor, 2011; see, e.g., Coan, Schaefer, & Davidson, 2006). In research with children, a growing literature finds that a secure attachment has comparable physiological stress-buffering consequences, especially for children who are prone to fear or inhibition (Gunnar & Donzella, 2002). Nachmias, Gunnar, Mangelsdorf, Parritz, and Buss (1996) found, for example, that behaviorally inhibited toddlers exhibited significant cortisol escalation when faced with a variety of novel and challenging events in the company of their mothers, but only when they were insecurely attached to her. For inhibited toddlers in secure mother-child relationships, cortisol response to the same events was more moderate, comparable to that of uninhibited children.

These studies underscore the importance of relationship quality to the social buffering of stress. Warm and supportive relationships are more likely to moderate stress reactivity than are those that are less affirmative or aversive, and this is true for adults as well as children (Taylor, 2011). However, owing to the plasticity of developing neurobiological stress systems, this relational buffering may have both immediate effects and long-term consequences for children's stress reactivity. This conclusion is suggested by the programmatic studies of Meaney and his colleagues on biological stress responding in rat pups (see Meaney, 2010, for a review). They have shown that differences in maternal licking and grooming (LG), an important component of maternal nurturance, are associated with differences in stress reactivity in pups, with the offspring of high-LG mothers showing lower behavioral and neuroendocrine responses to stress compared to the offspring of low-LG mothers. In the short term, maternal LG is a source of tactile stimulation that modulates endocrine and cardiovascular functioning in the pup and regulates immediate stress reactivity. Over the long term, however, the pups of high-LG mothers also show more modest behavioral and endocrine responses to stress as well as stronger performance in learning and memory tasks and greater synaptic density in the hippocampus. By contrast, the offspring of low-LG mothers show greater efficiency of fear conditioning in high-stress contexts. Cross-fostering studies indicate that these influences arise from early experience, and Meaney's research group has documented the biochemical processes by which maternal LG stimulates epigenetic changes in glucocorticoid receptor gene expression that relates to these behavioral outcomes associated with stress reactivity and early cognitive functioning (Meaney, 2010; see also Suomi, 2011, for comparable findings on the social buffering of stress in rhesus monkeys).

Social support also moderates the behavioral manifestation of genetic characteristics that, in the context of stress or danger, are likely to be risk factors for developing psychopathology. Bakermans-Kranenburg and van IJzendoorn (2006) studied this gene–environment (G×E) interaction in a sample of very young children and their mothers. They observed maternal sensitivity when infants were 10 months old, measured children's externalizing problems at 39 months, and genotyped children to identify those with the DRD4 7-repeat polymorphism, which has been associated with novelty seeking and conduct problems. Children with the DRD4 7-repeat whose mothers were insensitive were high in later externalizing, but children with same genetic profile with sensitive mothers showed much less externalizing behavior, comparable to children without the DRD4 7-repeat. In this case, the support afforded by a secure attachment buffered the behavioral risk associated with this gene polymorphism and, in fact, contributed to more optimal later behavior, consistent with the formulations of differential susceptibility theory (Belsky & Pluess, 2009).

An intervention study subsequently enlisted this G×E interaction in an effort to improve developmental outcomes (Bakermans-Kranenburg, van IJzendoorn, Pijlman, Mesman, & Juffer, 2008). A video-feedback parenting program was provided to a sample of mothers who had rated their toddlers high on externalizing behavior. A posttest after 1 year revealed that the program succeeded in improving mothers' positive disciplinary practices. In a follow-up assessment 1 year later, the children of the intervention group showed less externalizing behavior, but this finding was significant only for children with the DRD4 7-repeat polymorphism. There were no intervention program–related changes for children without the 7-repeat allele. The benefits of improved social support, through more sensitive parenting, were apparent for children who were at greatest risk of adverse developmental outcomes and who showed the greatest improvement as the result of the parenting program.

Illustrations of G×E interaction involving social support interventions for children under stress are evident in other research. Kaufman and her colleagues (2004) showed that for children with a history of maltreatment and a genetic vulnerability to depression, those without social support showed elevated depressive symptomatology, more than twice the rate of nonmaltreated comparison children with the same genotype. By contrast, those reporting access to social support exhibited only minimal increases in depressive symptomatology compared to nonmaltreated children. In other research, Luby and her colleagues (2012) studied school-age children with or without a history of preschool depression, and focused on hippocampal volume, which is smaller in adults with severe depression. Maternal support observed when children were preschoolers was positively associated with hippocampal volume at school age for nondepressed children.

What neurobiological influences can account for the immediate and long-term benefits of social support as a stress buffer? The biological mediators identified in this research complement, to some extent, the behavioral explanations discussed earlier, which focus on changing appraisals, strengthening coping, and supporting self-esteem. Hostinar et al. (2014) argue that social support (especially from caregivers) strengthens the regulatory influences on HPA activity arising from (a) the oxytocin system and (b) prefrontal activation, based on research concerning the neural regulators of HPA activity and oxytocin as a socially elicited stress buffer (Ulrich-Lai & Herman, 2009). This formulation argues that stress buffering consists not only of the downregulation of HPA activity and its associated sequelae but also the upregulation of oxytocinergic hormonal influences and cortical controls that become primed by supportive social contact. Social support also contributes to downregulation of many of the proinflammatory tendencies associated with chronic stress, although it is unclear whether support builds protective factors into the immune system (Kiecolt-Glaser, Gouin, & Hantsoo, 2010). These biological formulations certainly merit further exploration.

Unfortunately, it must be remembered that just as social support can biologically remodel stress reactivity over time, chronic stress can have comparable consequences. As earlier noted, these consequences include effects on the neurocircuitry of stress reactivity, downstream consequences for the neurobiology of learning and memory, and immune suppression. In addition, chronically stressful experiences are associated with epigenetic changes in gene expression that dysregulate stress reactivity, immune function, and neurological development (Naumova et al., 2012; see Thompson, 2015b, for a review). In these studies, parental care is the major determinant or mediator of early life stress. Children growing up in conditions of family adversity, which can range from harsh or insensitive care to maltreatment, are likely to suffer the biological dysregulation arising from these experiences in ways that are behaviorally manifested in heightened vigilance and threat detection, emotion dysregulation, chronic health problems, and risk for affective and conduct disorders (Repetti, Robles, & Reynolds, 2011). These biological programming effects can make behavioral remediation much more difficult, and they underscore the developmentally constitutive influences of supportive care.

The research on the social buffering of stress, especially newer work on its biological underpinnings, highlights the significance of the quality of parental care to children's biological and behavioral development by shaping capacities for stress regulation and coping (Thompson, 2015b). It indicates that the quality of care can have significant consequences—positive or negative—that can have a snowball effect in children's developing abilities to cope with stress and challenge, function in a self-regulated manner, and mobilize cognitive skills for learning and achievement.

Stress and Access to Social Support

In the paradigmatic portrayal of social support that guides thinking about support as a stress buffer, assistance begins when one or more individuals discern that a person or a family is in crisis. They offer to help and also mobilize others in the recipient's social network to contribute. In a short time, that person or family is surrounded by solicitous acquaintances offering emotional support, material resources, guidance and access to information sources, assistance with life tasks, or anything else they think might be of value and benefit to the recipient. Although it is often impossible to ameliorate the circumstances that led to crisis, this kind of assistance can give recipients a sense that they are not alone, provide tangible help where it is needed, and temporarily lift the burden of other responsibilities, and it is welcomed for these reasons. In some circumstances, furthermore, formal helping agents—such as religious advisors, social workers, counselors, physicians, or psychological therapists—also may be enlisted to provide professional and targeted kinds of support.

The association among social support, stress, and psychological well-being is complicated, however, because stress often is associated with the deterioration, rather than enhancement, of social support for recipients (Shinn,

Lehmann, & Wong, 1984; Vaux, 1988). Stress can undermine social support in at least two ways. First, stress can cause potential recipients to withdraw rather than engage with other people who might provide assistance. Withdrawal can occur because of the circumstances contributing to difficulty, such as how the loss of a job, divorce, residential relocation, and other events can separate individuals from familiar social networks. It can also occur because of the recipient's humiliation or feelings of vulnerability, which can accompany stressors such as mental health problems, unexpected financial difficulty, or other serious family problems. This perceived vulnerability can motivate individuals not only to avoid contact with social network members but also to avoid seeking the assistance of formal help providers who might offer tangible assistance. Withdrawal can also result from the recipient's deliberate efforts to conceal the reasons for current difficulties deriving from, for example, psychological distress, domestic violence, or child maltreatment. This withdrawal can be one of the reasons for the social isolation of families in which children are being abused or neglected (Polansky, Chalmers, Buttenwieser, & Williams, 1981; Powell, 1979; Young, 1964). Finally, individuals in crisis may simply experience too much emotional turmoil to seek or accept much assistance from others.

A second reason that stress can contribute to diminishing social support is because of the effects of stressful circumstances on potential providers of support. Individuals in natural social networks may withdraw from potential recipients because the behavior of the recipient is disturbing or repelling. Sometimes this is the response to neglectful or abusive parents, for example, or individuals with serious mental health problems. Withdrawal may also occur over time because the recipient's problems are emotionally challenging or overwhelming, such as when helpers try to support friends who are coping with the loss of a child or suffer from terminal illness. Sometimes potential support providers withdraw because they are undermined by circumstances that are similar to those of potential recipients, such as when neighbors live in poverty or face the challenges of single parenting (e.g., Belle, 1982; C. S. Fisher, 1982; Wortman & Lehman, 1985). More generally, potential support providers may withdraw from troubled individuals because of the emotional drain of providing one-way assistance to very needy individuals (J. D. Fisher et al., 1982; Shumaker & Brownell, 1984). The self-protective withdrawal of potential helpers derives from the difficulty of providing meaningful assistance to individuals who need so much. When formal helping agents are concerned, professional training and experience buffer these provider reactions to assistance for stressed individuals. Nevertheless, effective supervisory and supportive professional associations are necessary to prevent burnout of these providers also.

In everyday circumstances, these causes of diminishing access to social support can be overlapping and interactive. Young children who are physically maltreated may be prevented from gaining access to needed support because of the impact of their abuse on social skills, affect regulation, and expectations for how others will respond to them, which undermine how they function in the adult and peer relationships that might provide support (Cicchetti & Valentino, 2006). Abusive parents may, in turn, actively isolate the child from others in the community to prevent the detection of abuse, and other adults may distance themselves from a family that seems troubled or disturbed. Childhood and adult depression also shows these cumulative isolating processes (Cicchetti & Toth, 2006). In adults, the anhedonia of depressive symptomatology is typically accompanied by social withdrawal together with irritability and hostility, passivity, self-denigration, dependency, and a sense of helplessness and hopelessness. The emotional demands of this symptom profile on close relationships can cause others to withdraw and avoid contact, which, in turn, confirms the depressed person's perceptions of being rejected by others and of the unreliability of those relationships (Coyne, Burchill, & Stiles, 1991; Coyne & Downey, 1991). Adult depression is thus associated with smaller social networks, fewer close relationships, and diminished perceptions of others' support by the depressed adult, and the same associations have been found for children and youth. Dubois, Felner, Brand, Adan, and Evans (1992) found, for example, an expected negative association between social support and psychological distress 2 years later in young adolescents, with initial levels of distress and other sources of stress controlled. They also found, however, evidence that distressed youth acted in ways that inadvertently reduced their access to social support and increased the stressfulness of daily experiences.

In short, the association between social support and stress is complex. Although support can contribute to preventing stressful events and there are psychological and biological reasons to regard support as a stress buffer, there is also a reciprocal association between social support and stress. Because of the consequences of stressful circumstances for potential recipients and on potential helpers, increased stress can diminish access to social support and leave individuals more isolated than they were before. These considerations caution against simple, paradigmatic portrayals of how support affects stress and contribute

to the recognition that the effective mobilization of social support for individuals in need, from both informal and formal sources, must consider the nature of the stress, its impact on both recipients and support providers, and the context of their interaction.

SOCIAL SUPPORT IN RELATIONSHIPS AND SOCIAL NETWORKS

An important context of social support consists of the relationship between recipient and support provider and the social networks that encompass them both. To be sure, the growth of social media, online social networks, the Twitterverse, blog posts, even virtual gaming (some with avatars in simulated societies) and a growing range of technological advances enable children and adults to contact and develop associations with potentially hundreds of other people without direct face-to-face contact with them. Moreover, these associations can provide some forms of social support, especially sympathetic responses to an individual's posts, and we shall return to these considerations later in this section. But there are many reasons to argue that the most beneficial and comprehensive forms of social support, especially for stressed individuals, arise from relationships that involve mutual understanding, direct give-and-take, and emotional connectedness emerging from a history of reciprocated assistance. Most often these interactions occur in the context of social networks with distinct characteristics and affiliative connections. Individuals who are capable of providing diverse and complex forms of social support, mobilized by intimate understanding of the recipient and the recipient's problems, are most likely to be in real, not virtual, social relationships and social networks. Yet it is also true that the characteristics of those relationships and the networks in which they are embedded may pose obstacles as well as benefits to the provision of social support. This section explores these considerations with respect to both informal and formal sources of support. After considering the characteristics of relationships that contribute to perceptions of social support, the discussion turns to characteristics of the social networks that influence how relationships function and the similarities and differences between the social networks of parents and children. We then return to the question of online social support.

The "Active Ingredients" of Supportive Relationships

A relationship can be defined as an integrated network of enduring emotional ties, mental representations, and behaviors that connect one person to another over time and across space (Laible & Thompson, 2007). Why are relationships important to social support and promoting individual well-being? When relationships function well for adults and children, they uniquely offer psychological resources that are essential to perceptions of support that contribute to reducing stress and enhancing well-being. With respect to children, Thompson (2014b) has identified four characteristics of relationships in children's central social networks—family and peers—that are important to perceived support from people within them.

- *Mutual responsiveness/reciprocity* is based on the reciprocated affinity by which relationships are formed and consolidated and which contributes to a partner's perceived support. In infancy, the parent's sensitive responsiveness contributes to the development of a secure attachment as well as cognitive and linguistic achievements that are based on the reciprocated give-and-take of social interaction (Laible & Thompson, 2007). The parent's responsiveness also provides the basis for developing mutual responsiveness at somewhat older ages that supports early socialization (Maccoby, 1984; Waters, Kondo-Ikemura, Posada, & Richters, 1991). In peer relationships, reciprocity is what distinguishes friends from nonfriends: In friendship, there is mutuality of affection, intimacy, interests, initiative, and other aspects of relational interaction (Newcomb & Bagwell, 1995). When asked "What is a friend?" children of a variety of ages talk about the reciprocity or mutual give-and-take of interaction with friends (Hartup & Stevens, 1999).
- *Warmth/affection* define the affective quality of relationships. In parent-child relationships, warmth conveys love and respect for the child and, as it elicits a complementary response in children, mediates the efficacy of other parenting practices that promote cooperation and competence (Kochanska, 2002). In peer relationships, mutual affection is an important characteristic of friendship even though friends also exhibit greater conflict than nonfriends do (Simkins & Parke, 2002). Their greater mutual liking is part of what motivates friends to resolve conflict in order to remain in the relationship rather than walking away.
- *Approval/acceptance* constitutes the positive regard that supports the recipient's self-confidence and perceptions of a partner's liking and support. From parents, approval contributes to a sense of competence in children and adolescents and contributes to achievement motivation in this way (see, e.g., Pomerantz & Dong,

2006). Peer acceptance (versus rejection) is a major contributor to developing self-esteem, social skills, and social understanding as it strengthens children's constructive peer interactions (Bukowski, Brendgen, & Vitaro, 2007).

- *Security*, in relationships with family members and peers, is a contributor to and a derivative of perceived support. A large research literature in parent-child attachment documents the significance of early relational security for social and emotional well-being (Thompson, 2008), while security in friendship networks contributes to many positive outcomes, including school adjustment and academic achievement (e.g., Berndt, Hawkins, & Jiao, 1999).

These four characteristics of children's relationships with parents and peers contribute to children's perceptions of support from these social partners, and these characteristics are also important to adult relationships. Even though social support is multifaceted, as earlier argued, these relationship characteristics are significant because perceived support is the dimension of social support that is most strongly related to psychological well-being in adults and children (Barrera, 1986; Cohen & Wills, 1985; Jackson & Warren, 2000; Sarason, Shearin, Pierce, & Sarason, 1987). Perceived support is more predictive of coping and well-being than even enacted support. This finding is important because, surprisingly, there is not a strong association between perceived and enacted social support (Barrera, 1986; Haber, Cohen, Lucas, & Baltes, 2007). To be sure, the relation among enacted support, perceived support, and coping is empirically complicated, as the preceding discussion of the association between social support and stress illustrates (interpreting the correlations between these constructs is complicated by (a) the recognition that individuals under stress may be less capable of viewing others as sources of available support because of their emotional turmoil, (b) individuals in difficulty may be less capable of mobilizing supportive social networks when they are needed, (c) individuals can enact support without being perceived by recipients as doing so, and (d) individuals who experience psychosocial well-being are more likely to be high in perceived support even though there is no causal connection between them (see, e.g., Kaul & Lackey, 2003; Seagull, 1987)). Nevertheless, qualitative and quantitative reviews consistently find that perceived support has a stronger predictive association with psychological well-being than does enacted support.

The significance of perceived support underscores the importance of confidence in the availability and helpfulness of social partners, whether or not that support is actually realized, to an awareness that assistance is available if needed. This is, in a sense, what is meant by a secure (attachment) relationship at any stage of life. More broadly, Lakey and his colleagues (e.g., Lakey & Lutz, 1996; Rhodes & Lakey, 1999) have argued that perceptions of social support derive from (a) personality characteristics of the recipient (e.g., a secure or insecure attachment history; interpretive biases, extraversion), (b) characteristics of the helper (e.g., personality factors like empathy; enacted support), and, most important, (c) the interaction between helper and recipient (e.g., their similarity in background and outlook). This heuristically powerful analysis invites broader inquiry.

The significance of perceived support also underscores the importance of mental representations of relationships to developing and maintaining psychological well-being (Thompson, 2014b). Mental representations of network associates as being supportive, accessible, reliable, and helpful are based on direct experience with them, and these representations may be more important than specific acts of support to promoting coping and well-being. With respect to social support and developmental psychopathology, this conclusion has important implications. It suggests that attention to these relational representations, in children as well as adults, may be an important element of preventive and therapeutic intervention. It may not be enough, for example, to change the behavior of a parent who has been an inadequate caregiver without also altering the child's expectations for the behavior of that adult in the future (see, e.g., Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002; Toth, Rogosch, Sturge-Apple, & Cicchetti, 2009). Similarly, altering parental expectations for child conduct may be essential, along with changing damaging behavior patterns, to effecting long-standing improvement in a dysfunctional family system (see, e.g., Snyder, Cramer, Afrank, & Patterson, 2005).

Relationships and the Social Networks of Parents and Children

Relationships do not always function well for children and adults. Indeed, the psychological complexity of relationships and their multifaceted influences often cause them to be simultaneous sources of support and stress (Badr, Acitelli, Duck, & Carl, 2001). Equally importantly, the nature of the relationship helps to determine what kinds of support are possible and the limitations that may exist in giving and receiving social support. This is true of relationships with informal social network members and with formal helpers.

The informal social networks that family members depend on are both local and geographically disparate (Cochran, Larner, Riley, Gunnarsson, & Henderson, 1990; C. S. Fischer, 1982; Litwak & Szelenyi, 1969). They can include extended family members, friends who live nearby or far away, current and former neighbors, associates in the religious community, and networks based on children's peer relationships and school activities. For parents, their social networks are also likely to include colleagues at their workplace or school and perhaps individuals in local businesses and community leaders. For children, their social networks include peers and teachers at school and the variety of other adults involved in after-school programs, recreational and sports programs, and other activities; when adolescents are concerned, they may also include workplace associations. For both parents and children, the breadth of their natural or informal social networks is influenced by access to transportation and technology—each of which can significantly extend their networks of relational ties—and the availability of time to cultivate relationships with others. Informal social networks have changed historically in their breadth and diversity, and also vary according to socioeconomic status and other circumstances (Cochran et al., 1990).

There is high turnover in natural social networks, but turnover is selective. In a 3-year follow-up study of the personal and familial social networks of a sample of 240 parents living in Syracuse, New York, nearly one-fourth (22%) of the network members on average were dropped from adults' social networks over 3 years between the first and follow-up interviews (Larner, 1990a). When researchers examined the nature of the social relationships that were dropped or retained, they found the highest turnover among neighbors (32% turnover); friends, acquaintances, and former workmates (31% turnover); and other nonkin ties (34% turnover). The lowest turnover rate was among kin: only 9% turnover. This finding is not surprising, given the extent to which high rates of mobility, job change, educational completion, and other factors can alter neighborhood and workplace social networks in contrast with the stability and commitment to kinship ties that motivate efforts to remain in contact, even across a distance. These findings suggest, however, that the relative reliability of network contacts over time can influence those from whom one seeks and receives social support.

Consistent with this view, researchers have found that individuals rely primarily on support from extended kin within their natural social networks (Cochran, Gunnarsson, Grave, & Lewis, 1990; Gunnarsson & Cochran, 1990; Litwak & Szelenyi, 1969). By contrast, neighbors do not figure prominently in perceptions of social support and were readily dropped or added to personal social networks with little influence on individual or familial social support (Larner, 1990b). The turnover in neighborhood and other local associates makes depending on them as reliable sources of assistance more difficult, while the enduring, obligatory relationships that develop with extended family members provide a more consistent basis for expectations of support. Indeed, when a person is reliant primarily on neighborhood contacts for support, it may be an indicator of social insularity in other spheres of life. In a study of socioeconomically stressed single mothers, for example, Belle (1982) found that the reason these women interacted more frequently with people in the neighborhood was that they felt they had nobody else to whom they could go. However, these contacts did not help them much. The mothers who were in frequent contact with neighborhood network associates did not experience greater emotional well-being, receive more tangible assistance, or report more support than did other women who saw their neighbors infrequently, perhaps because these neighborhood associates provided social contact but not social support (see also Belle & Benenson, 2013).

The turnover in informal social networks and the distinction between kin and nonkin ties is important to the preventive and therapeutic mobilization of social support. It suggests that a focus on strengthening neighborhood-based forms of social support—"neighbors helping neighbors"—must balance the potential benefits of such a strategy against families' limited reliance on neighbors owing to residential mobility. The recommendations to Congress of the U.S. Advisory Board on Child Abuse and Neglect (1991, 1993) to encourage the development of "caring communities" by strengthening supportive connections among neighbors builds on their proximity and the commonality of neighbors' interests with those of recipients, as well as the potential utility of such a strategy in communities across the socioeconomic spectrum. Neighbors can also provide referrals to local help givers, material aid, emergency assistance, and respite child care—in short, they can be multifaceted support generalists. But if residential mobility undermines the ability of family members to even become well acquainted with their neighbors, it is also likely to undermine perceptions that social support might be obtained from them. Furthermore, in communities at risk, neighbors may experience the same economic and personal problems as do the families who need their assistance, and neighbors may have little to offer because of their own needs. Neighbors may be more concerned about finding a quick exit from a dangerous or

impoverished community than with providing support to a troubled family who lives nearby.

Kinship ties, however, also have advantages and disadvantages in the provision of social support. An extended history of shared experiences contributes to common values and mutual understanding. Family relationships are densely interconnected, with family members often knowing many other family members well, which contributes to the mutuality and intercoordination of support. Cultural expectations and practices concerning kinship also better enable family members to maintain connections through formal practices (such as celebrating holidays together and recognizing birthdays and anniversaries) and informal occasions, even though extended kin may be geographically distant. But family relationships can also be characterized by animosity, criticism, privacy intrusions, or distrust that also endures. Moreover, the shared history and values that characterize family relationships can be an impediment to healthy behavior if those values condone or rationalize abusive conduct toward children or partners, substance abuse, poor health or relational practices, or other dysfunctional individual or family behaviors. Family members may be more motivated to deny or conceal these practices if exposing them risks bringing these and other family practices to the attention of others, including clinical or criminal justice professionals. Thus, families can become enabling environments for developmental psychopathology rather than settings of health and healing.

The different constellations of strengths and weaknesses of relationships with neighbors and extended family are important because each kind of network connection is important to informal social support. Just as parents are support generalists to their children—providing many different kinds of social support—so also are family members generalists in support to each other (see, e.g., Bogat et al., 1985). To a lesser extent, neighbors can also be support generalists in the various kinds of assistance they can potentially provide to those who live nearby. This is one of the reasons why kinship networks and neighbors have often been identified as primary sources of social support that can be mobilized for preventive or therapeutic intervention. But as this analysis suggests, there should be careful consideration of the advantages and disadvantages of mobilizing social support from each source.

The same balancing of supportive benefits and risks characterizes other relationships within informal social networks. Family friends and workplace associates can offer counseling and advice, but their help may be limited to the domain of common association (e.g., workplace concerns, shared recreational interests, connections through children's peers at school), and they may otherwise have less in common with the recipient. The same may be true of associates in religious institutions or community groups, and in these cases the organization's values or mission may additionally constrain disclosure or the kinds of assistance that can be offered. In general, people in these relationships can be characterized as support specialists who can be helpful with specific kinds of supportive assistance, but not more broadly.

The same situation specificity of relationships is also true of formal support agents (Unger & Powell, 1980). A social worker may offer valuable assistance by connecting individuals or families to community resources and providing informal counseling. But an overwhelming caseload may diminish the caseworker's reliability and limit the extent of the assistance that can be offered. Similar limitations may also be true of physicians, counselors, or religious leaders, who may also view problems through the prism of their specialized background, which might compel them to offer forms of assistance that may or may not really be needed. Their support may be limited by other considerations as well. It is well known, for example, that professionals who are legally mandated reporters of suspected child maltreatment are often aware of many more cases of suspected abuse than they formally report. This fact owes, in part, to the complications introduced into their professional relationships with families once a child abuse investigation has been initiated, and the preference of many helping professionals to address family problems on their own (Zellman, 1990; Zellman & Anter, 1990). In this case, and in others, their professional role may complicate their assistance. In general, professional helpers have expertise, the benefits of a clear role definition in relation to recipients, and professional training and accountability that can enhance the support they offer. But their influence can be limited by the specific forms of assistance they are capable of offering, the fact that their assistance is not well integrated into the everyday experience of the recipient, and sometimes because their values and perspectives are different from those of the recipients of their assistance.

Although the nature and functioning of informal and formal social networks share many commonalities across subcultural and cultural groups, there are also important variations that are relevant to social support (Cochran, Larner et al., 1990; Vaux, 1985). In general, for example, the individual and familial social networks of lower-income families tend to be smaller and more kinship-based than for middle- and upper-income families (Cochran, Gunnarsson

et al., 1990; Fischer, 1982; Vaux, 1988). In one large study, these differences by size were apparent for each category of social network membership: Higher-income families had a larger number of social ties with kin, neighbors, and "others" than did lower-income families (Cochran, Gunnarsson et al., 1990). Single mothers also have smaller social networks with higher rates of turnover compared to married mothers, and these networks afford less social support (Larner, 1990a; Weinraub & Wolf, 1983). Taken together, these findings point to the importance of differences in the resources, energy, and opportunities to construct and maintain the social networks that afford social support. Unfortunately, for parents and families who are most likely to need support, their networks often may be quantitatively and qualitatively less capable of providing it.

Development and Functioning of Children's Social Networks

Children's social networks are, not surprisingly, similar to those of their parents because they are built on them. But they are also very different in several important ways (Belle, 1989; Cochran & Brassard, 1979; Salzinger, Antrobus, & Hammer, 1988).

Children's social networks evolve developmentally as a result of children's growing social competencies and their expanding social ecology. Parents are uniquely central to children's initial social networks and mediate children's relationships with other social partners. This is, of course, true from birth. The security of an infant's attachment to each parent derives from representations of support from that adult based on the parent's history of sensitive responsiveness. One reason why the development of secure or insecure attachment early in life is developmentally formative is that it influences the growth of other central socioemotional capacities, including the development of social skills, self-regulation, self-concept, and representations of other people and how to get along with them (Thompson, 2008). One implication of this conclusion is that in this earliest experience of reliable parental support (or its absence), children's capacities to elicit social support from other partners are shaped. In a sample of lower-income African American 6.5-year-olds, for example, Anan and Barnett (1999) found that secure mother-child attachment (assessed 2 years earlier) was associated with children's perceptions of greater social support from various sources (including family, peers, and teachers), and social support mediated the association between secure attachment and lower scores on measures of externalizing and internalizing problems. Bost, Vaughn, Washington, Cielinski, and Bradbard (1998) likewise found that secure preschoolers had more extensive and supportive social networks and were also higher on sociometric assessments of peer competence. These and other findings can be understood as reflecting the more constructive social skills and more positive social expectations that are associated with an early secure parent-child relationship. But they also reflect the snowball effect that can derive from the supportiveness of early parental care, which fosters a range of social and emotional competencies, which then contributes to children's developing capacities to elicit support from others. In this respect, children's experiences in early relationships affect other relationships.

Throughout the world, it is rare that the social networks of very young children are exclusively parent-focused. In many cultures, for example, caregiving is shared with other adults, including but not limited to extended family members, to whom infants and toddlers also form attachments (Hrdy, 2009). In the United States and other Western industrialized countries, child care practices also include family-based and center-based out-of-home care settings and early childhood education programs. These and other normative child care practices provide early avenues for broader sources of social support to children as well as their parents. Extrafamilial caregivers can offer parents guidance and knowledge, respite care assistance, and referrals to others who can offer help and can monitor the child's well-being. These resources depend on the nature and the quality of the care, of course, and these caregivers can also offer intervention avenues for preventive or therapeutic assistance (Thompson, Laible, & Robbennolt, 1997). Many child care and preschool programs, for example, have created avenues of mental health consultation that provide teachers access to an early childhood mental health practitioner for advice concerning the behavior of children in the classroom or general guidance concerning the needs of children encountering stressful circumstances (Johnston & Brinamen, 2006). In the context of consultation, parents are often engaged to better understand children's needs and to collaborate in the design and implementation of an intervention strategy. Early childhood mental health consultation illustrates one way of enlisting extrafamilial care settings as avenues of support to children and their parents. It also exemplifies the coordination of formal and informal sources of social support to families, as well as the value of two-generation interventions on behalf of young children.

School entry in middle childhood further expands children's extrafamilial social networks by providing access to

a more extensive range of peers as well as with adults who, as teachers or school counselors, can potentially provide advice, counseling, emotional support, and other forms of needed assistance. Teachers can potentially become important sources of social support because they, like early childhood care providers, may be the first to identify the seriousness of a child's problems and create a bridge between the family and formal helpers (Meehan, Hughes, & Cavell, 2003). In adolescence, workplace and community associations further broaden access to potential sources of social support as youth become more independent of family networks.

Throughout childhood and adolescence, peers become more important sources of social support as peer relationships increasingly draw on and advance children's developing psychological and emotional sensitivity to other people. Viewed in this light, positive peer relationships can be stress buffers for children, while peer rejection and relationships with deviant peers may contribute risk for behavioral and emotional problems. One large, prospective longitudinal study that followed over 500 randomly selected children from preschool through early adulthood found that, as early as preschool, exposure to aggressive peers predicted later aggressive behavior (Sinclair, Pettit, Harris, Dodge, & Bates, 1994). In another longitudinal study, Gazelle and Ladd (2003) found that the combination of anxious solitude (an index of individual vulnerability) and peer exclusion predicted levels of depressive symptoms in a sample of 388 children studied from kindergarten to fourth grade. But there is evidence for the stress-buffering effects of positive peer relationships as well. In the prospective longitudinal study by Dodge and colleagues just described, peer acceptance moderated the effects of low socioeconomic status, high family stress, single-parent status, and violent marital conflict on the development of externalizing behavior in early grade school (Criss, Pettit, Bates, Dodge, & Lapp, 2002). In the same study, peer acceptance and friendship moderated the effects of harsh discipline on the same outcomes. These positive effects of peer relationships remained even when the researchers controlled for child temperament and social information processing skills.

Friendship is an especially important avenue of social support, although children and adolescents also derive significant benefits from more general peer acceptance. Friendship can contribute to enhancing self-esteem and positive self-evaluation, promote emotional security, offer a nonfamilial context for intimacy and affection, provide informational and instrumental assistance, and offer companionship (Parker, Rubin, Erath, Wojslawowicz, & Buskirk, 2006). In this respect, friends also constitute support generalists. These peer influences are potentially enduring. A longitudinal study found that peer group acceptance and friendships in the fifth and sixth grades significantly predicted adult life status, perceived competence, and psychopathology 12 years later (Bagwell, Newcomb, & Bukowski, 1998). In this study, early peer group acceptance and friendship made unique contributions to adult well-being: Having a reciprocal friendship in childhood was associated with adult self-worth, for example, even when preadolescent levels of self-competence were controlled. With increasing age, adolescent and early adult peer associations become more extensive (encompassing workplace and recreational connections as well as school relationships), more intimate (incorporating self-disclosure and loyalty concerns), and more multidimensional (including romantic as well as companionate relationships).

Although increasing autonomy from the family system is a developmentally appropriate transition of adolescence, parents' continuing importance as potential social support agents should not be underestimated. Even as peer relationships become more important forums for self-disclosure and mutual understanding, parents remain preferred advisors on core moral values, political and religious beliefs, and planning and achieving life goals (Coleman, 2011). With increasing age, however, there may be important changes in children's attitudes toward seeking parental support. While seeking emotional reassurance or instrumental aid is natural and encouraged in younger children, adolescents may resist help-seeking if doing so is regarded as a threat to self-efficacy or perceived competence (Robinson & Garber, 1995). The simultaneous reliance on parental help combined with the increasing need for perceived self-reliance contributes to the mixed signals of adolescents and the mixed perceptions of their parents concerning their support needs.

There are developmental changes in how children perceive support from different people in their social networks (Furman & Buhrmester, 1985, 1992; Reid, Landesman, Treder, & Jaccard, 1989). In self-report studies, adolescents report expecting less support from their parents, for example, than do younger children, and there are similar developmental decreases in perceived support from other family members, such as siblings and grandparents. Expectations of support from peers increase from childhood to early adolescence but then stabilize or decline in later years. Teachers, by contrast, are rarely regarded as sources of social support.

Children's social networks are therefore initially based on parents and their associations but progressively expand

to encompass partners and contexts that are unique to them. But parents also mediate children's access to sources of social support, both formal and informal, in other ways (Cochran & Brassard, 1979; Parke & Bhavnagri, 1989). Parents' decisions concerning housing, neighborhoods, and schools directly affect the range of children's options for developing social connections outside the family. Ladd, Hart, Wadsworth, and Golter (1988) found that the breadth of preschoolers' social networks was inversely associated with the number of moves the family had made to a new home. Neighborhoods vary significantly in their safety, traffic congestion, availability of safe play areas, quality of schools, and access to other families with children, each of which can affect opportunities for children to create new relationships (Medrich, Roizen, Rubin, & Buckley, 1982).

Parents are also gatekeepers who typically arrange, facilitate, and monitor their children's contact with others (O'Donnell & Steuve, 1983; Parke & Bhavnagri, 1989). Parents permit children to socialize with certain children and adults but not others. Parents schedule activities, provide transportation, and supervise offspring during social or recreational activities, especially when children are young (Ladd & Le Sieur, 1994). O'Donnell and Steuve (1983) found that lower-income and middle-income mothers differed significantly in the access they provided their school-age children to community activities, with middle-income mothers participating extensively with their offspring in these programs (sometimes as volunteers and aides) in contrast with lower-income mothers, who instead permitted their children greater unscheduled freedom for "just being with friends." Mothers in economic difficulty are less likely to have time off from work, access to transportation, or the resources necessary to invest themselves in their children's activities. Children's access to extended family members is similarly mediated by parental assistance, especially when kin are not local (Thompson, Scalora, Castrianno, & Limber, 1992). To be sure, children become increasingly competent at creating and maintaining their own social networks by choosing peers and activities, arranging their own transportation, and maintaining access through indirect means (such as technology) with increasing age. Parents remain important, however, as monitors and gatekeepers, and this role may be especially important for children and families at risk (Dishion & McMahon, 1998). With respect to developmental psychopathology, of course, the parental gatekeeping role means that access to extrafamilial sources of social or therapeutic support may be contingent on the parent's support for this access.

The social networks of children and their parents overlap in other important ways. Parental social networks have significant consequences for children because they influence parents' well-being, provide opportunities for new experiences and relationships, and sometimes directly socialize and support parenting competence through modeling and mentoring (Cochran, 1990; Cochran & Niegro, 1995). Thus, when mothers receive social support from people in their social networks, it is associated with many positive outcomes for children, potentially including more secure attachment, more positive parent-child relationships, and improved peer relationships (e.g., Jacobson & Frye, 1991; Jennings, Stagg, & Connors, 1991; Melson, Ladd, & Hsu, 1993; see Parke & Buriel, 2006, for a review). These child outcomes arise, in part, from the benefits of social support for the quality of parenting, including mentoring and practical assistance (e.g., respite care). At times, moreover, parents' network associates can also be role models and natural mentors for children. Of course, parents' social networks can undermine rather than improve parenting practices, especially when extended family members, coworkers, neighbors, or others create stress rather than enhance well-being or provide reinforcement for poor parenting practices (Ceballo & McLoyd, 2002). As another illustration, then, of how relationships affect the functioning of other relationships, the social support or conflict that parents experience in their own social networks has important implications for the quality of their parent-child relationships and, in turn, children's development.

Children's and parents' social networks overlap also because they are constructed in the same neighborhood and community context and are thus affected by comparable resources, risks, and stresses. As noted earlier, neighborhoods vary in the resources they provide for families with children (e.g., safe play spaces, recreational activities); equally importantly, they also vary in the human capital on which families can rely. When neighborhoods in economically disadvantaged communities are high in these human resources, children benefit significantly (Odgers et al., 2009). In most such neighborhoods, however, limited economic resources are combined with social impoverishment to undermine support resources for family members (Garbarino & Kostelny, 1992). In a classic study, Garbarino and Sherman (1980a, 1980b) compared neighborhoods with higher-than-expected child maltreatment rates (based on sociodemographic predictors) with neighborhoods that had lower-than-expected maltreatment rates. Sampling informants in each neighborhood, they found that mothers in higher-risk neighborhoods

reported receiving less assistance from neighbors, finding fewer options for child care, and generally perceiving the neighborhood as a poorer place for raising children. Risk to children was greater in neighborhoods perceived as providing fewer human resources for the families living in them. Children can also be affected in other ways by troubled neighborhoods. Lynch and Cicchetti (2002) reported, for example, that children who reported that they had been exposed to high levels of community violence also reported feeling less secure with their mothers.

Understanding the functioning and developmental influence of children's social networks requires, therefore, perceiving them within the broader social ecology and the social networks of other family members. A study of Australian families by Homel, Burns, and Goodnow (1987) illustrates this. These researchers reported that the socioemotional adjustment of school-age offspring was predicted by the breadth and reliability of parental support networks, as indexed by the number of "dependable friends" that parents could list, and the parents' affiliation with voluntary organizations. However, the family's "neighborhood risk level" (indexed by the neighborhood's socioeconomic status, delinquency and school truancy rates, and related variables) also predicted child adjustment in the opposite direction, indicating that community-level as well as proximate features of the family's social ecology were important. Child well-being was affected both by the availability of immediately supportive partners to parents and by the broader human resources of the neighborhood.

This conclusion is affirmed by the findings of another Australian study by Cotterell (1986), who found that the child-rearing attitudes and behavior of parents were strongly predicted by an interaction between (a) the father's absence from the home (owing to job demands), (b) the mother's "informational support" from neighbors about raising children, and (c) characteristics of the community (such as the stability of the population). Support to the mother was the most significant of these predictors, but all were important to parental conduct.

It is important to remember, however, that children have their own neighborhood networks that may be relatively independent of the family. This network independence is especially likely when they reach adolescence, and those networks can buffer other characteristics of the neighborhood ecology if they function supportively. In one illustration, the internalizing symptomatology of a sample of urban African American adolescents was studied in relation to characteristics of their neighborhoods. In general, higher neighborhood poverty and unemployment rates predicted greater internalizing symptoms, and these associations were mediated by lower perceptions of neighborhood cohesion and perceived social support. However, when neighborhoods were residentially stable and had higher concentrations of African Americans, adolescents reported greater social support and higher perceptions of neighborhood cohesion, and these network characteristics were associated with fewer internalizing symptoms (Hurd, Stoddard, & Zimmerman, 2013).

Online Social Support

We close this section with the question with which it opened: Can the availability of social media, online social networks, the Twitterverse, blog posts, even virtual gaming and a growing range of other technological advances offer avenues of social support to youth and adults? In light of the foregoing discussion, it is now possible to identify more clearly some of the unique characteristics of social support through social media. Social media offers people opportunities for social contact that are convenient, self-determined, and easy to initiate. Requiring only a computer with an Internet connection, people can interact with individuals throughout the world with diverse backgrounds, perspectives, and experiences who would be inaccessible through other means, and they can also interact online with individuals whom they see on a regular basis. People can be selective in choosing these online contacts based on the websites, media, or privacy settings they use. Moreover, people can also be selective in the information they divulge about themselves, providing representations of themselves and their experiences that may be genuine, partial, or even fabricated, depending on their purposes in doing so.

Perhaps for these reasons, social media appears to be a desirable avenue for obtaining emotional support from others, such as through text messaging, Facebook posts, or tweets. The individuals selected for contact can respond with concern and support to one's descriptions of their personal experiences. Although other forms of material or protective social support may be less possible, emotional support may be an important benefit derived from online media. Emotional affirmation is especially possible because some of the obstacles to social support posed by relationships discussed earlier, such as the stresses imposed by privacy intrusions or personal demands, are less likely when one can choose one's online contacts. Furthermore, it is possible that online communication could have other benefits for psychological well-being, such as obtaining information and guidance that socializes conduct in healthy ways.

The explosive recent growth of social media and its use by older children, youth, and adults has provoked research attention by social and developmental psychologists. Research in this field is still in its infancy, but there are several lessons relevant to social support and developmental psychopathology, with a considerable research agenda remaining.

There are at least two uses of online communication for social interaction. The first consists of online contact with individuals with whom one is in direct contact. In such cases, online media—such as instant messaging and texting, e-mail, Facebook, Twitter, and other kinds of social networking media (e.g., Spotify, Pinterest)—provide a means of ongoing digital communication or, in some cases, enables continuing communication with those who were previously in one's social network, such as friends who moved from the area. Despite early concerns that participation in online social networking would be problematic for youth, precipitating a decline in healthy personal relationships and increasing risk for loneliness and depression, the most recent research indicates that adolescents who are more engaged in online communication experience *higher* relationship satisfaction with people they are in direct contact with and enhanced psychological well-being (see Valkenburg & Peter, 2009b, for a review). The same may also be true of adults (Bessiére, Kiesler, Kraut, & Boneva, 2008). One explanation for these findings is that online communication fosters enhanced intimacy and reciprocity in self-disclosure, as people are more comfortable sharing sensitive personal information with their friends in an online context, and this enhanced intimacy improves relationship quality with these friends (e.g., Valkenburg & Peter, 2009a; see also Jiang, Bazarova, & Hancock, 2011). Thus, online contact with friends strengthens relationship support. This process appears to particularly benefit socially anxious adolescents who use online communication to enhance relationships with friends, in part because of reduced social cues triggering anxiety and the opportunity to carefully craft communications (Valkenburg & Peter, 2007a, b). For these youth especially, the ability to deepen existing friendships online may provide an important buffer against psychological difficulties exacerbated by challenges in direct peer relationships. Perhaps unfortunately, socially anxious youth are also somewhat less likely than their peers to engage in online communication with friends (Valkenburg & Peter, 2007b).

A second use of online communication for social interaction is to initiate and maintain interaction with individuals who are known only online – such as through chat rooms, virtual gaming, blog posts, and other social media—although most adolescents and adults primarily use online tools to maintain and enhance existing personal (offline) friendships. Research findings are more mixed regarding the consequences of the Internet for relationship initiation and communication with unfamiliar peers. Some studies suggest that young people and adults who use the Internet primarily to communicate with contacts who are known only online may have reduced psychological well-being (Bessière et al., 2008; Valkenburg & Peter, 2007b). But there is also evidence that communication with online-only contacts can alleviate psychological distress. In one study, for example, online communication with an unfamiliar peer had a positive effect on restoring adolescents' self-esteem and perceived relational value, and reducing negative affect, following an episode of social exclusion (Gross, 2009). Additionally, unique processes may operate for individuals who are members of marginalized or stigmatized groups. For these people who have limited access to social support in their communities—and who have higher rates of depression and suicidal ideation—access to a larger virtual community can serve important support functions, reduce isolation, and aid in identity development (e.g., Gray, 2009; McKenna & Bargh, 1998). More broadly, the correlates of Internet use to form new relationships and connect with unfamiliar people may depend on the level of existing social support: People who have smaller social networks and limited social support available to them may benefit especially from social connections online (Bessière et al., 2008).

There are also important developmental considerations in the function of online social networks as relevant to psychological well-being. Very little is known, for example, about the use of online resources for social support in preadolescence. In later adolescence and adulthood, however, social network sites become an aid in maintaining supportive connections to physically distant close friends, with positive implications for emotional adjustment (Ranney & Troop-Gordon, 2012). At the same time, social networking allows individuals to expand their network of new contacts easily. Greater use of social networking for this purpose appears to promote bridging social capital: the sense of being connected with and able to effectively elicit resources from a broad community (Ellison, Steinfield, & Lampe, 2007). Although this function of social networking diverges from the more intimate functions of enhancing and deepening relationships, a sense of connectedness and access to support within a new community (e.g., during the transition to college) may still serve an important protective function, particularly during transitional developmental periods.

Still, many questions remain regarding the nature of social support in online relationships and the connections between online support and developmental psychopathology. For example, although most people use online communication as an extension of offline friendships, it is important to better understand whether unique relationship processes relevant to social support occur in online communications between friends. It is known that disclosure is often more intimate in direct and online communication to support relationship closeness, but it is not known whether the negative effects of co-rumination could be exacerbated in an online context or whether friends are willing to address dysfunctional or inappropriate conduct online (e.g., Rose, Carlson, & Waller, 2007). Further, when youth exhibit signs of psychological distress in an online context, do those signals elicit support from others, and if so, what form does support take, and how effective is it? An intriguing recent study with young college students suggests that individuals signaling depressive symptoms online would still prefer that friends and acquaintances express their concerns in person, perhaps underscoring that when concerns are deeply personal and disclosure is risky, such communications should *not* take place online (Whitehill, Brockman, & Moreno, 2013). However, this study asked only how individuals might *prefer* someone to contact them rather than how friends and acquaintances actually respond.

Finally, research on online relationships has primarily addressed informal connections rather than formal social support programs that might be created for people facing mental health challenges. This avenue merits further exploration, as some formal online support programs for individuals dealing with specific adjustment issues demonstrate benefits for participants. For example, Dunham and colleagues (1998) reported that adolescent mothers of infants who were given access to a computer-mediated social support network provided each other with positive emotional, informational, and tangible support. Mothers developed close personal relationships with each other, and active participation was related to a decrease in parenting stress over the 6-month study period. Given adolescents' comfort with online forums, the relative ease of establishing an online environment in which adolescents feel comfortable discussing personal vulnerabilities, and the decreased personal and social risk in such an environment, online social support networks or programs may hold promise for adolescents (see Caplan & Turner, 2007). However, much work remains to determine the utility of online connections—either informally or as part of formal social support systems—to buffer or alleviate distress for people at risk or experiencing psychological difficulty (see Hazzard, Celanno, Collins, & Markov, 2002, for one example for seriously ill children).

Taken together, a considerable research agenda remains for better understanding the potential benefits and risks of social media and other online resources to youth and adults. But research evidence thus far suggests that initial concerns about its problematic consequences have not been confirmed, while some of the benefits of more intimate disclosure online may be meaningful and significant. Despite widely publicized accounts of the devastating consequences of online bullying by young adolescents, for example, the supportive and potentially therapeutic uses of online resources merit further examination.

GIVING AND RECEIVING SOCIAL SUPPORT IN A CULTURAL CONTEXT

Social support is deeply integrated into cultural values and practices concerning individuals and their social connections. It is associated with cultural beliefs about the nature of the person and his or her social obligations, equity and reciprocity in social relationships, and family and parental responsibilities. This discussion of social support in cultural context extends the relational focus of the preceding section by first considering the challenges of giving and receiving support as it is experienced in mainstream Western culture. The focus is then widened to consider these issues from an expanded cultural lens, and the implications of this analysis for social support and developmental psychopathology are then evaluated.

Recipient and Helper Reactions to Assistance

Receiving assistance from another evokes surprisingly mixed reactions from recipients in the United States, which is where most research on social support is conducted. In addition to the feelings of pleasure and gratitude that helping naturally inspires, recipients may also experience various negative feelings (J. D. Fisher et al., 1982; Shumaker & Brownell, 1984). Receiving assistance can be humiliating and stigmatizing, especially when the need for assistance derives from inadequacies in the recipient (such as poor parenting, substance abuse, or inadequate personal or financial management) rather than from broader, impersonal circumstances (such as an economic recession or a natural disaster) (Heller & Rook, 2001). Receiving help can also create feelings of failure, indebtedness, and inferiority, especially when assistance cannot be repaid, because of

cultural norms of equity and reciprocity (Greenberg & Westcott, 1983). If assistance cannot be reciprocated or compensated, the recipient may also experience feelings of vulnerability or dependency because obtaining assistance from another violates Western norms of self-reliance and autonomy. There can also be sensitivity to privacy violations if helpers become intimately acquainted with aspects of the recipient's life that are not normally disclosed to others.

As a consequence of these reactions, recipients may rather paradoxically begin to resent the assistance they receive and the person providing it. This resentment is especially likely when assistance is received from voluntary benefactors (whom one cannot give back to or otherwise compensate, enhancing the violation of equity and reciprocity norms) or strangers (with whom one does not share an ongoing relationship of mutual aid) and when the helper and the recipient are from similar backgrounds and circumstances (enhancing the inequity of the helping relationship). When recipients experience assistance as humiliating, demeaning, or intrusive for these reasons, they are less likely to seek help in the future and are more likely to abridge or terminate a helping relationship if they are capable of doing so. These reactions can explain why recipients of assistance, to the surprise of their benefactors, may be ungrateful, may fail to become engaged in the helping relationship, are often inexplicably absent from scheduled meetings, do not return phone calls, and progressively make the relationship unworkable or unsatisfactory.

This analysis has surprising implications for providing social support to at-risk individuals or families. It suggests that assistance is more easily accepted when recipients have opportunities to reciprocate or repay the aid they receive, perhaps in service to other individuals. It suggests that support is more readily received in circumstances that minimize the potential for humiliation or stigmatization, such as when support services are broadly available or universal (rather than specifically targeted to those in greatest need) and accessed in everyday settings (e.g., at home rather than at an agency office). This analysis suggests also that social support is more easily received when the recipient and the helper agree about the need for assistance and the reasons for the need. By contrast, assistance from another may be resented when the recipient perceives that it derives from unshared judgments of the recipient's inadequacy or incompetence. Provider efforts to preserve the dignity and the privacy of recipients are thus important.

Interestingly, although negative recipient reactions to assistance are a risk when adults are concerned, they are much more rarely observed in children because of the universal acceptance of children's dependent status and their need for care. Children expect and readily accept the social support they receive from adults most of this time, and this is one reason why feelings of gratitude, as well as resentment, are not as characteristic of children's responses to the solicitude of their parents, teachers, or other adults. Children recognize that they need assistance and that adults are expected to provide it. To be sure, as children become more competent with increasing age, adult help that they regard as unwarranted can be threatening to self-esteem and perceptions of personal competence. Mothers often help their children with homework, for example, but with increasing age, children may begin to perceive that their mothers' helping, monitoring, and praising reflect mothers' beliefs about their children's lack of competence to do the work on their own (see Pomerantz, Moorman, & Litwack, 2007). Because children depend on adults for assistance of many kinds, especially when they are young, however, these resistant responses to help are fairly rare.

The negative responses of adults to social support often interact with other recipient characteristics that can make it difficult for them to accept assistance, such as problems with substance abuse or affective psychopathology, personal disorganization, or the emotional effects of stressful circumstances (Heller & Swindle, 1983; Shinn et al., 1984). Taken together, these characteristics not only make it difficult for adults to maintain supportive helping relationships with other adults but also place considerable strain on help providers, especially in informal social networks. Offering assistance to troubled individuals can be draining and demoralizing (Collins & Pancoast, 1976; Shumaker & Brownell, 1984). Recipients have needs, but they may also be demanding and critical, and providing help in relationships of one-way assistance can be unrewarding and exhausting because support is not reciprocated. Moreover, the relationship between support providers and recipients can be difficult because each may have different goals, with recipients seeking noncritical emotional affirmation and providers striving for changes in recipient behavior and attitudes. They may differ in their views of the recipient's problems and the best solutions to them. Crises may force support providers to focus on immediate needs (urged to do so by recipients) and neglect attention to long-term strategies for building healthy practices. For these reasons, it is common for providers and recipients each to feel frustrated by their relationship and sometimes to experience conflict. Informal social support can break down, and social support interventions enlisting natural helpers must address the frequent turnover and burnout of their staff.

These vulnerabilities derive from the challenges presented by recipient responses to the help they are offered and the challenges of providing assistance to them in relationships of one-way aid.

Cultural Considerations in Giving and Receiving Social Support

Although these challenges are, to some extent, intrinsic to providing and accepting social support, especially in informal social networks, cultural processes moderate them considerably (Dilworth-Anderson & Marshal, 1996; Jacobson, 1987). Understanding these processes is important for better conceptualizing the associations of social support with psychological well-being and developmental psychopathology, as well as for the design of effective interventions to enlist social support for children and families at risk.

A well-known dimension by which concepts of the self in relation to others vary interculturally is that of individualism and collectivism (Triandis, 1989) or independence and interdependence (Markus & Kitayama, 1991). In cultures with an interdependent view of self, there is greater emphasis on connectedness with others and on deriving important features of identity and esteem from those associations. In cultures with a more independent view of self, there is a greater emphasis on the autonomy of personal thoughts and feelings, self-reliance, and privacy. Critics of this dual-cultures approach point out the heterogeneity of cultural views of the self within each orientation, as well as the fact that some societies making the transition to increased urbanization and industrialization integrate elements of each orientation (Kagitcibasi, 2005). In any case, cultural views of the self are developed quite early and influence how children perceive themselves and their relationships from early childhood (e.g., Greenfield, Keller, Fuligni, & Maynard, 2003; Keller, 2007; Rogoff, 2003). By later childhood and adolescence, youth with backgrounds from interdependent cultures (such as Hispanic and Asian societies) acknowledge the expectation that they will assist and support family members more than do adolescents from European backgrounds (Fuligni & Pedersen, 2002; Fuligni, Tseng, & Lam, 1999), and one study of Chinese American teenagers reported that such intergenerational expectations had neither positive nor negative consequences for psychological well-being (Fuligni, Yip, & Tseng, 2002).

But the association between cultural values and family support is complex. A cultural emphasis on interdependence may facilitate help-giving and help-receiving through normative practices, but cultural values may also make receiving help more difficult in many circumstances. One illustration is a study of older Japanese American adults living in New York City for whom norms of reciprocating support made receiving assistance difficult. Adults who held strong reciprocity norms and who received material support from their families were more depressed and were less satisfied with their lives than those who did not embrace strong reciprocity norms (Nemoto, 1998). Thus, in a cultural context that emphasizes interdependence, negative recipient reactions to receiving assistance nevertheless emerged owing to the reciprocity norms of that culture.

Cultural values and practices are related to a number of features of social networks and social support. Specifically, there is significant intercultural variability within the United States in (a) the nature and functioning of informal social networks, (b) the association between social support and psychological well-being, and (c) attitudes toward receiving assistance from formal helpers. Each of these sources of variability is relevant to designing culturally competent interventions involving social support and linking formal and informal sources of support to troubled children and their families, as described below.

Although the components of social networks are similar for families in different ethnic and cultural groups (such as including immediate and extended family, friends, neighbors), the relative importance of each of these network members for social support can vary. MacPhee, Fritz, and Miller-Heyl (1996) compared lower-income Native American, Hispanic, and European American parents living in the United States on their self-reported sources of support. They found that Native Americans reported more interconnected social systems, more frequent contact with extended kin (but not friends), more members who knew one another, and greater closeness with members of their support networks. Hispanic parents reported having the largest social networks and, although these networks were close-knit, Hispanics were in general most likely to rely primarily on kinship networks for emotional support. While they reported the lowest proportion of network members who could offer emotional support, they also reported the highest proportion of network members who could provide instrumental support (e.g., material assistance). European American parents had more diffuse social networks but also reported having a higher proportion of members available for instrumental support. Unlike parents in the other two groups, they reported that friends were the primary providers of emotional support, not family members.

Children also exhibit intercultural variability in the network members on whom they rely for support. For Latino

and African American children, for example, support may derive from extended family or in broader fictive kin networks (e.g., Rhodes, Ebert, & Fischer, 1992; Sanchez & Reyes, 1999;). In African American families, children and youth report receiving greater support from their extended families than do children from European families (Cauce, Felner, & Primavera, 1982; Taylor, Casten, & Flickinger, 1993). Likewise, Hispanic values of familialism, involving strong feelings of support and reciprocity with family members, expand the social support networks of children to include adults beyond the immediate family unit (Sagobal, Marin, Otero-Sabogal, Van Oss Marin, & Perez Stable, 1987). These intercultural differences are important for understanding the network members who are likely to provide the most helpful forms of informal social support to children and families in need, as well as the avenues by which such support can be offered.

Although social support comes from potentially diverse sources and is experienced within the context of cultural values, there is good evidence that despite this, social support contributes to psychological well-being for different cultural groups within the United States. Coatsworth and colleagues (2002) examined family, school, and friend support in relation to externalizing and internalizing behavior in Hispanic girls in middle school, for example, and found that controlling for age, socioeconomic status, and years in the United States, youth reports of greater perceived family support and teacher support (but not friend support) predicted fewer externalizing problems, while greater perceived family support and friend support (but not teacher support) predicted fewer internalizing problems. Support within the family was the strongest buffer of externalizing and internalizing symptomatology. Likewise, in a short-term longitudinal study of African American male adolescents, Zimmerman Ramirez-Valles, Zapert, and Maton (2000) found that although support from friends did not predict later outcomes, support from parents predicted diminished depression and anxiety. Rodriguez, Bingham Mira, Myers, Morris, and Cardoza (2003) examined perceptions of family and friend support in relation to stress and psychological adjustment in Latino college students. They found that higher support from family and friends predicted increased psychological well-being, although only friend support was a unique predictor of lower psychological distress.

However, cultural values may significantly mediate whether members of different ethnic and cultural minorities access formal—rather than informal—supports when facing psychological distress. This difference between informal and formal supports can occur for various reasons, including lack of awareness of formal services, distrust of providers (or providers who cannot speak their language), cultural beliefs that assistance from nonfamilial helpers is unnecessary or inappropriate, resistance to formal helpers from within the family or cultural group, service delivery practices that are culturally uninformed, or for other reasons. In the study of lower-income families earlier described, MacPhee and colleagues (1996) found that European American parents were significantly more likely to have sought professional therapy than were Native American or Hispanic parents, and they also tended more to seek professional help with parenting issues.

Findings such as these underscore the need for cultural awareness in designing interventions to enhance social support to children and families of culturally diverse groups. A culturally competent service delivery system will (a) identify groups that are underserved and seek to reduce cultural barriers that may interfere with service delivery by understanding their characteristics, resources, and needs; (b) orient program planning, staff training, and community involvement to ensure that the development, implementation, and evaluation of services are respectful of the values and practices of recipient families; (c) evaluate assessment and outcome procedures and instruments to ensure their appropriateness and validity for the children and families who are served; (d) build cross-cultural communication skills within program staff, including the appropriate use of interpreters and an ethnographic understanding of communication approaches within cultural groups; and (e) seek to develop an appreciation of cultural diversity as a facilitator rather than impediment to service delivery. These practices are especially important in services that seek to strengthen the benefits of social support interventions by linking formal support to informal support networks, especially in light of how "outside" helpers can be regarded with distrust or resentment by members of closely knit families or communities. In the end, cultural beliefs and practices are among the most significant personal characteristics mediating the needs of potential recipients and the providers of social support.

INTERIM CONCLUSIONS

Before turning to research focused on social support and developmental psychopathology, there is value in summarizing the implications of the foregoing analysis of social support in the lives of children, parents, and families. Doing so provides a set of conclusions that suggest the kinds of socially supportive interventions that are likely to

prove most effective in helping children and their families. Several conclusions and their implications seem warranted:

- *Relationships influence other relationships.* Parents mediate children's access to other people outside the family and the support they can provide. The quality of parent-child relationships is affected by the support or conflict that parents experience within their own social networks. The ability of a formal helper, such as a home visitor, to engage parents and children may be affected by attitudes of extended kin. These conclusions underscore the interconnected nature of the social networks of family members and how relational influences on one person have broader scope for how that person engages others. Insofar as social support is given and received in the context of relationships, these observations suggest that supportive relationships beget other supportive relationships—with the opposite result when relationships are stressful and taxing. With respect to intervention, this conclusion suggests that multigenerational interventions are important to strengthening social support to children, as well as efforts to improve parental social networks. Improving parental well-being, such as through the assistance of a grandparent, a friendship network, or a professional helper, can contribute to improving the quality of parenting and, through this, children's well-being. Because child psychopathology is typically associated with broader family processes, intervening to improve the quality of multigenerational relationships within the family, and the quality of the social networks that each family member draws on outside the family, improves the chances for healthy development for children within that family.
- *Coordinating informal and formal sources of social support is important.* Formal and informal helpers have, as we have seen, unique strengths and weaknesses in the provision of social support (Gottlieb, 1983, 2000). Members of informal social networks share the values of recipients, and their accessibility, mutuality of assistance, trust, and multifaceted avenues of potential assistance make them influential agents in everyday life. But because natural helpers may share the circumstances of their recipients and lack extensive training, they may be ineffective and are subject to exhaustion and withdrawal as helpers. Formal sources of support, by contrast, have professional training and a formal role definition that contributes to their impact and the reliability of their assistance. But because they are less well integrated into the lives of recipients and do not share their values, experiences, and background, support can be stigmatizing, and formal helpers may have difficulty engaging the cooperation of family members.

  Because of these distinct characteristics, integrating the efforts of formal helpers with those of informal helpers in recipients' natural social networks may offer the best opportunities for creating enduring preventive or therapeutic benefits (Froland, Pancoast, Chapman, & Kimboko, 1981; J. L. Miller & Whittaker, 1988). Formal helpers working with members of informal social networks can support natural helpers in their efforts while ensuring the skill and expertise that formal helpers can provide. The integrated efforts begin with the mutual recognition that formal and informal helpers have unique contributions to offer needy recipients, and this mutual recognition can occur in many ways. Formal and informal assistance is harmonized, for example, when an early childhood mental health consultant works with parents or teachers at a local school or child care program, a perinatal home visitor encourages the involvement of extended kin during home visits, or a group therapy program for adolescents has connections to the school or to the peer group. In child welfare, children and/or family members are often encouraged to enlist someone from their natural social networks to advocate for them at social service meetings and help them follow through on the goals identified at these meetings.

  The effective coordination of formal and informal support networks is not easy, however, because of the differences in background, values, goals, and definition of the problem that may provoke mutual distrust between formal and informal helpers. All too commonly, for example, extended family members or neighbors reinforce a parent's skepticism regarding the potential helpfulness of a counselor or paraprofessional home visitor. Sometimes social workers undermine informal helpers by criticizing them to the recipient. But the integration of formal and informal helping is important to promoting the engagement of recipients in social support interventions and to providing a foundation for continuing assistance. Many well-meaning social support interventions fail because they do not sufficiently incorporate the natural helping networks of family members, or rely on them exclusively, resulting in assistance that is limited in time, scope, and impact.
- *Parents are central to children's environment of relationships, but they are not solely influential.* The first part of this conclusion affirms the importance of parent-child relationships to children's developmental competence,

emotional well-being, and capacities for receiving social support. It also underscores the vulnerability of children, especially when they are young, to parental dysfunction. Research on children in homes characterized by marital conflict shows, for example, that children become emotionally enmeshed in their parents' conflict, contributing to risk for their own emotional psychopathology. They monitor parental moods to anticipate conflict before it occurs, and they intervene in parental arguments as they are trying to manage their own emotions (Davies, Harold, Goeke-Morey, & Cummings, 2002; Davies & Woitach, 2008). The emotional dysfunction in a child created by a parent who has become a source of threat or stress is illustrated in research on the effects of parental depression, domestic violence, and, of course, child maltreatment. In the attachment literature, it is often observed in young children developing insecure disorganized attachments, manifested behaviorally in the approach-avoidance conflict of a child who needs but cannot seek assistance from the parent (Lyons-Ruth & Jacobvitz, 2008). In these and other circumstances, the social support that children need from within the family is inaccessible. Moreover, social support from outside the family also may be inaccessible because of how parents function as gatekeepers to children's extrafamilial social contacts. Parents may limit children's access to alternative support agents because of their own emotional problems or to conceal their disapproved conduct from detection. The recognition that parents are central to children's emotional well-being, therefore, underscores not only the importance of the support that parents ordinarily provide but also the vulnerability of children to parental dysfunction.

The second part of this conclusion, however, underscores that others can have important influence in assisting children even when they cannot ameliorate negative family experiences. Indeed, some research suggests that support from only one or two people outside the family can be instrumental in helping children in stressful family circumstances cope more effectively (Beeman, 2001). As this review has shown, those extrafamilial agents may be found in early child care settings, primary grade classrooms, and community and recreational activities; for older children, they may be found in the peer, after-school program, and workplace environments. When children are young, extrafamilial support agents can provide them with a safe haven of security and predictability that can support coping even when the family environment remains difficult. At best, such agents can help bridge the provision of other resources to the family (Small, 2009). When children are older, programs designed explicitly to provide support, such as youth mentoring programs, have the potential of providing considerable assistance (Hirsch, 2005). Thus, parents are central but other agents of social support can also be influential in helping children at risk.

- *Representations of support from others are important to psychological well-being.* The importance of perceived support to psychological functioning suggests that expectations that support is available are at least as important as the actual experience of receiving assistance from network associates. Indeed, perceived support seems to be more important than enacted support in many circumstances. In light of the modest association between perceived and received support, this conclusion warrants further research into the influences that cause individuals to expect that others will provide assistance when needed, even if they have not regularly obtained such aid in the recent past. How affective psychopathology influences individuals' perceptions of support, which may be independent of the actual assistance they receive from formal and informal helpers, also warrants research attention. At the very least, this conclusion means that interventions to strengthen social support to increase psychological well-being must attend as much to changes in recipients' expectations for future support as to changes in the actual support they receive because the benefits of intervention may be limited unless support expectations are altered. In this respect, it is important to recognize that expectations of support from significant people have a stress-buffering consequence.

  One reason why attention to perceived support is so important is that it requires addressing why recipients may not perceive support in contexts when it is provided. It is likely that natural helpers and formal helpers who focus attention on the recipient's dysfunctional behavior and try to help change it may be perceived as unsupportive, even if their efforts are necessary and potentially effective. The research on negative recipient reactions to assistance suggests also that *how su*pport is provided may be significant for shaping recipients' reactions to the assistance they receive and their expectations for future support. When support provision is normalized for the recipient's neighborhood or community, when it is provided in contexts that avoid stigma (e.g., at home or church rather than a clinic), when it is broadly available rather than targeted, when recipients can repay the help they are given, and when helpers and

recipients jointly agree on the need for assistance and the goals it will accomplish, it is more likely that received support will be perceived as such. Furthermore, when formal helping professionals take the time to establish relationships of trust with recipients and respect their perspectives and values, their assistance is more likely to be regarded as supportive. Understanding how to enhance perceptions of supportiveness in the context of social support interventions is an important future research task.

Little is known, furthermore, about developmental changes in expectations of social support. Research reviewed above suggests that securely attached children perceive greater support from those around them, but it is unclear whether such perceptions derive from greater amounts of actual assistance (deriving perhaps from the capacity of secure children to elicit support from others) or whether a secure attachment itself contributes to more positive expectations. Very little is known about how other child characteristics, including temperamental individuality, contribute to perceptions of social support, or about developmental changes in these expectations. It is also crucial to understand how children's actual experiences in the family, such as marital conflict, affect children's generalized expectations of social support and how they are affected by potentially stress-buffering relational influences, such as through interactions with other adults. There is potentially a very rich research agenda here with important practical applications and clinical implications.

- *Social support efforts will be more effective when there is clarity concerning the goals they are intended to achieve.* Because social support is multifaceted and recipients have different constellations of challenges, a one-size-fits-all strategy is inappropriate to social support interventions. Rather, interventions should be preceded by a careful analysis of the needs of target individuals or families, the capabilities of informal or formal helpers enlisted for them, the specific purposes or goals of supportive interventions, and the outcomes that can reasonably be expected to result (Gottlieb, 2000; Heller & Rook, 2001). Such an analysis is important is because there are inevitable trade-offs between different strategies and goals that might be envisioned. Enlisting formal helpers is typically more costly than using volunteers and/or informal network members, but it may be necessary and cost-effective when the recipient's problems are so serious that they are beyond the capabilities of nonprofessionals to address effectively. Universal or broad-scale support programs can be useful in the context of expectations that recipients need information and advice but do not have serious problems, but determining what outcomes might reasonably be anticipated from such programs can be difficult. At times, other resources may have to be enlisted in addition to supportive interventions, such as social skills training (Gaudin, Wodarski, Arkinson, & Avery, 1990–1991) or public assistance (Pelton, 1989, 1994) in order to address problems that contribute to the recipient's difficulties. Taken together, therefore, a generalized initiative to broadly provide support with the hope that it will improve the well-being of children or their parents is less likely to be successful than one that is based on a careful analysis of the child's and family's needs, who can provide assistance, and the reasons for intervening.
- *Stress and social support are complexly interwoven.* The prevailing approaches to understanding the association between social support and psychological well-being are to regard social support as either stress preventive—through the incorporation of healthy practices into the recipient's experience—or as a stress buffer, supporting more effective coping by the recipient. But this analysis has shown that the association between social support and stress is much more complex. Stress may undermine the capacity of recipients to solicit or receive support and may increase their negative reactions to receiving help. As it is shared among neighborhood or community members, stress may also impair natural helping networks from providing mutual aid as individuals must cope with the demands of poverty, dangerous neighborhoods, or other difficulties in their own lives. The experience of receiving social support may itself be stressful, especially if it is stigmatizing or humiliating or contributes to feelings of failure or vulnerability. Recipients may also perceive helpers' interventions as unsupportive if it casts light on harmful practices that must change. Moreover, the process of providing social support may be stressful to helpers, especially if it becomes draining and demoralizing.

In light of these considerations, there is value in distinguishing different sources of stress that social support interventions might address in potentially different ways. One source of stress is associated with the helper-recipient relationship, whether this is a formal professional association or an informal relationship between neighbors or friends. In each case, efforts to reduce the negative consequences of accepting aid may be necessary. Such efforts can include promoting a relational atmosphere of mutual respect and creating ways

of normalizing support within the community in which the recipient lives. Another source of stress consists of neighborhood or community stressors, such as economic impoverishment and the drain of human capital resources, which contribute to more difficult lives. These stressors can have widespread influence within natural social networks and may be difficult to ameliorate, but they must be recognized and accommodated as the context in which support is provided. Finally, there are critical events, such as immediate crises, that a social support intervention can hope to change through effective intervention. By distinguishing different sources of stress, impediments to the efficacy of social support efforts can be recognized and, where possible, reduced to increase the effectiveness of interventions.

- *Cultural awareness.* Finally, cultural beliefs, values, and practices significantly moderate how social support is received, how potential sources of support are perceived (including attitudes toward formal as well as informal support agents), and the association between social support and psychological well-being. Developing culturally informed social support interventions requires recognizing the importance of these beliefs and practices, incorporating them into program goals and design, reducing cultural barriers, developing staff training that enhances cross-cultural communication, and valuing and respecting the beliefs and values of recipient families.

Social support alone is unlikely to be an effective answer to the complex problems faced by children with serious affective psychopathology or dysfunctional families. But social support is an important component of any multifaceted effort to prevent psychological difficulties in at-risk families and children or to provide therapeutic assistance when family problems have resulted in a child with clinical disorders. The challenge is to craft well-designed interventions that improve the support afforded by natural helpers and to enlist the assistance of formal helping professionals, based on a careful assessment of the needs of the child or family at risk (Thompson & Ontai, 2000). Accomplishing this requires a thoughtful appreciation of the nature of social support, as well as the specific role of social support in developmental psychopathology, to which we now turn.

SOCIAL SUPPORT AND DEVELOPMENTAL PSYCHOPATHOLOGY

With these interim conclusions from research on social support in mind, we now turn to the research literature on developmental psychopathology. Recognizing the breadth of intervention efforts that incorporate social support, our purpose in this selective review is to focus on concepts and interventions that test and extend the conclusions described in the preceding section. To what extent, in other words, do existing preventive programs and clinical interventions draw on these conclusions, and in what ways could existing interventions be improved with greater attention to them?

In this section, we discuss the relevance of social support to three phases in the course of psychological disorders. First, we consider how the absence of social support contributes to the development of psychological disorders. This is especially important to portrayals of social support as a preventive and buffering agent in stressful circumstances, and therefore we also consider the nature of preventive interventions to at-risk families lacking social support. Second, we examine the role of social support (and its absence) in the maintenance of psychopathology over time, underscoring the importance of social factors in the persistence of affective symptomatology. Finally, we consider social support and the treatment of psychopathology and the alternative avenues that exist for enhancing support as a therapeutic aid.

Social Support, Social Isolation, and the Origins of Developmental Psychopathology

In light of the stress-preventive and stress-buffering functions of social support, it is reasonable to expect that children in families experiencing social isolation would be at greater risk of psychological difficulty than children in families experiencing considerable social support. Research on social isolation and developmental psychopathology, particularly studies of risk for child maltreatment, indicate the complexity of the concept of social isolation, however. Studies of efforts to address social isolation, particularly through home visitation, illustrate the challenges of engaging families in supportive social interventions to prevent the emergence of child and family problems.

Social Isolation and Risk for Child Maltreatment

The social isolation of families who have abused or neglected their offspring, or who are at significant risk of doing so, is the most extensively studied condition in which the absence of social support is believed to contribute to risk for the development of child psychopathology. In this case, children's risk of clinical problems is believed to be mediated by their parents' lack of social support. Many researchers have concluded that parents who abuse or neglect their offspring lack significant social connections

to others in the extended family, neighborhood, and broader community and to social agencies that can provide assistance (e.g., Daro, 1988; Garbarino & Sherman, 1980a; Polansky et al., 1981; Seagull, 1987, Gelles, & Steinmetz, 1980; see Thompson, 1995, for a review). As a consequence, their maltreatment of their offspring is likely to remain undetected, these parents have few interpersonal resources to which they can turn when they are stressed, and the ways that social connections with potential helpers can buffer the effects of stress, promote healthy behavior, and socialize positive parenting are strained.

An extensive review of this research by Thompson (1995) yields, however, a fairly complex picture of the association between social isolation and child maltreatment. Two conclusions from his review are important to this discussion of social support and developmental psychopathology. First, in most studies, the social isolation distinguishing abusive or high-risk parents consists of their smaller social networks or their more limited social contacts with network members (i.e., limited social embeddedness). Parents at risk of child abuse know fewer people, and see them less often, compared to other parents in similar circumstances. But research findings are inconsistent about whether at-risk or abusive parents experience significant deficits in enacted support or have lower perceptions of expected support from their network associates. A study by Lovell and Hawkins (1988) is typical; in it, abusive mothers reported that very few of their network associates provided practical help with child care or parenting responsibilities, but mothers reported enjoying seeing nearly 80% of these companions very much and reported that they could "share their thoughts and feelings frequently" with nearly 50% of them. Like the fatally abusive mothers studied by Korbin (1989, 1991), in other words, parents often perceived support from network associates as satisfactory even though the social support mothers received did not significantly reduce abuse potential (cf. Freisthler et al.'s, 2014, "dark side of social support"). Thus, on the most important dimension of social support for psychological well-being—perceived support—there are often negligible differences between maltreating parents and those who are nonabusive, even though the social networks of maltreating parents are smaller and less supportive in other ways.

Second, there are subgroups of maltreating parents who experience significant social isolation for specific reasons. Polansky and his colleagues (Polansky, Ammons, & Gaudin, 1985; Polansky et al., 1981; Polansky, Gaudin, Ammons, & David, 1985) have studied neglectful mothers, who report feeling greater loneliness and lack of neighborhood support compared with socioeconomically comparable nonneglectful mothers. They describe an "apathy-futility syndrome" consisting of a passive, withdrawn demeanor coupled with emotional "numbness," limited competence, distrust of others, retreat from social contact, and verbal "inaccessibility" to others that makes them hard to reach socially (Gaudin & Polansky, 1986; Polansky & Gaudin, 1983). In Polansky's view, the social isolation of these mothers derives from their general inability to develop and maintain supportive social ties owing to character disorders, deficient social skills, and difficulties in coping adaptively with life stress. In a sense, their neglect of offspring is part of a broader syndrome associated with their disorganization and lack of social and emotional competence.

Garbarino has described, by contrast, a different kind of social impoverishment of families within neighborhoods that experience heightened rates of child maltreatment (Garbarino & Kostelny, 1992). As earlier noted, by comparing neighborhoods with higher-than-expected child maltreatment rates (based on sociodemographic predictors) with neighborhoods with lower-than-expected maltreatment rates, and using informants within each community, Garbarino sought to characterize the neighborhood conditions associated with child abuse and neglect (Garbarino & Sherman, 1980a, 1980b). He found that mothers of higher-risk neighborhoods reported receiving less assistance from neighbors and regarded the neighborhood as a poorer place for raising children, but on other assessments related to social support, such as perceptions of sources of potential assistance, mothers of higher-risk and lower-risk neighborhoods did not differ. By contrast with the characterological problems of the neglectful mothers studied by Polansky and colleagues, therefore, the mothers in the high-risk neighborhoods studied by Garbarino suffered from the diminished social resources of their neighborhoods and the diminished human capital of their communities.

Studies like these indicate that social isolation is not a homogeneous phenomenon. Consequently the reasons for social isolation are diverse in families at risk for child maltreatment (Thompson, 1995). For some people, such as Polansky's neglectful mothers, isolation may derive from social marginality; for others, such as Garbarino's higher-risk neighborhood residents, it arises from the impoverishment of social capital in difficult neighborhoods. Some people may actively seek social isolation as a means of concealing abusive practices. For others, isolation may result from difficult circumstances that create feelings of humiliation and vulnerability and rob adults in the

neighborhood of the time or energy required to maintain social networks. A significant proportion of high-risk families do not feel socially isolated at all; instead, they are satisfied with their social interactions with a small network of close associates who provide emotional support that does not seem to constrain abusive or neglectful practices. Social isolation, when it is apparent, can have diverse origins.

The multifaceted causes of social isolation in families at risk for child maltreatment are important for at least two reasons. First, these studies indicate that social insularity may be a significant factor in the origins of child maltreatment for some families, especially when the causes of social isolation derive from psychological problems in parents, or difficult or dangerous neighborhood conditions, or active efforts to conceal abusive practices. In these circumstances, the absence of significant social connections increases risk for child maltreatment because there are few from outside the family who can provide assistance or monitor or socialize parental conduct, especially in the context of life stress. However, it is unwarranted to generalize this portrayal of abusive families. For many other families, social isolation does not appear to be etiologically relevant because abusive practices occur in the context of active social networks from which parents derive emotional support, but which are benign influences on abusive practices. Social isolation is not necessarily implicated in child maltreatment—and perceived support is not necessarily a buffer against abusive parenting. Second, the diverse causes of social isolation are also relevant to intervention. Strategies for enhancing social support for at-risk families who are socially isolated must also be multifaceted. They may require, for example, social skills training (Gaudin et al., 1990–1991), improving recipient reactions to receiving assistance (Tracy, Whittaker, Boylan, Neitman, & Overstreet, 1995), incorporating new support agents into natural social networks, or other approaches depending on the causes of social insularity. When enlisting social support into clinical treatment, one size does *not* fit all.

Risk for child maltreatment is not the only vulnerability for children living in socially isolated families because in these contexts, parenting quality is more likely to be poor, the family's use of community resources is more likely to be limited, and children's developmental outcomes are more likely to be problematic as the result of limited access to the mentoring and advice, information and material aid, developmental guidance and social monitoring that social networks can provide. This diversity of risks associated with family social isolation suggests that efforts to address it need to be clear about how social support is to be provided and the goals it is intended to achieve in order to be effective. This is well illustrated in the research on home visitation.

Home Visitation as a Preventive Intervention

During the past several decades, home visitation has become the most enthusiastically supported and widely recognized approach to providing social support for at-risk families. The fundamental strategy uniting diverse home visitation programs is the delivery of information, guidance, and emotional support to family members in their homes by a paraprofessional or volunteer home visitor. The purpose is to prevent the emergence of problems that may arise from parental stress, lack of knowledge or resources, or social isolation and thus to promote more healthy developmental outcomes beginning early in life. Home visits can begin prenatally, shortly after the child's birth, or later in childhood, and visits can extend in duration based on family need and engagement and program funding. Home visits are believed to provide an avenue for offering diverse forms of social support to parents and children, overcoming some of the barriers these families otherwise face to obtaining needed assistance (such as lack of transportation or health insurance), enabling monitoring of children's development, and establishing a relationship of trust with a home visitor who can provide individualized assistance and bridge connections to broader resources (Wasik & Bryant, 2000). Home visitation is the umbrella orientation of a number of programs established in communities throughout the country, most notably the Healthy Families America initiative, developed by the National Committee to Prevent Child Abuse, which has established a nationwide consortium of hundreds of home visitation programs serving families at risk (Daro, 2000; Daro & Harding, 1999). Home visitation programs are funded by direct legislative appropriation in many states, or by project grants from federal agencies, as central features of statewide efforts to strengthen child health and development, prevent child maltreatment, improve parent-child relationships, or address other issues. Most notably, as part of the Patient Protection and Affordable Care Act (ACA), Congress in 2010 established a new Maternal, Infant, and Early Childhood Home Visiting Program and appropriated $1.5 billion over 5 years to develop and improve state-administered home visitation programs.

Home visiting has considerable potential to support families with young children, especially those with limited social networks of support, but problems exist in the effective implementation of home visitation initiatives. This is one of the reasons for the mandate of the

Obama administration, through ACA, that states focus on programs offering evidence-based documentation of effectiveness. A recent review of 35 different home visiting programs commissioned from Mathematica by the U.S. Department of Health and Human Services (DHHS), however, identified only 14 programs meeting the criteria for an evidence-based early childhood home visiting service delivery model (Avellar, Paulsell, Sama-Miller, & Del Grosso, 2013). Programs were classified in this manner because they had a high- or moderately high-quality research evaluation (e.g., randomized controlled trials, quasi-experimental designs, implementation studies) and demonstrated statistically significant positive effects in at least 2 of 8 targeted areas of impact, as well as sustained positive effects for at least 1 year following program enrollment. The impact areas identified in this report reflect the diversity of developmental outcomes that home visitation programs are intended to address: child health; child development and school readiness; family economic self-sufficiency; linkages and referrals to community programs; maternal health; positive parenting practices; reductions in child maltreatment; and reductions in juvenile delinquency, family violence, and crime. Across the evidence-based programs, the most frequent positive outcomes occurred in child development and school readiness, positive parenting practices, and child and maternal health. Positive outcomes were not limited to particular subgroups of families, and many were sustained for at least 1 year following program completion. In some cases, much longer-term impacts were identified. For example, the Nurse Family Partnership, which provides support to first-time expectant mothers beginning prenatally through the child's second birthday, had initial positive impacts on parental care and maternal behavior (e.g., subsequent pregnancies, education, and work). At a follow-up at age 15, children of program participants who had been low income and unmarried during program participation had fewer arrests and convictions, less substance use, and lower levels of "promiscuous" sexual activity compared with children of control group families from similar backgrounds (Olds, 2006). The Healthy Families America initiative described earlier also had positive outcomes in all assessment areas.

Nonetheless, even the programs identified as most successful had relatively few effects relative to the range of targeted outcomes, and less frequently demonstrated positive impacts in areas such as family economic self-sufficiency, maternal and child health, linkages and referrals to community programs, and reductions in juvenile delinquency and family violence. (For many programs, these outcomes were not measured, however, because they were not part of the program's intended outcomes.) Several of these studies identified at least one unfavorable impact, although the nature of these impacts was not specified. Additionally, other programs reviewed did not meet criteria because they showed few positive effects or did not sustain positive effects over time.

The DHHS review did not identify the reasons for limited program success, but this has been the focus of other reviews of the home visitation research literature, including a 2004 meta-analysis of 60 home visitation programs by Sweet and Appelbaum (2004) and an influential assessment by Gomby, Culross, and Behrman (1999; see also Halpern, 2000). The reasons for limited program success identified in these reports include the inconsistent participation of recipients, the importance of supporting help providers, the need to develop community connections, and the problem of lack of clarity in program goals and expectations.

The failure to fully engage families in the program and the high attrition rates of participants have been identified as significant challenges for virtually all home visitation programs. According to Gomby and colleagues (1999), between 10% and 25% of families invited to participate in home visitation programs decline and between 20% and 67% of the families who enroll fail to complete the program. Moreover, even when families enroll and remain in home visitation programs, they tend to receive only about half or fewer of the planned number of contacts with the home visitor (Gomby et al., 1999). Program engagement is particularly problematic for the highest-risk families, which may explain the more limited effects seen at higher levels of family risk. For example, Early Head Start evaluators reported that families with three or more identified sociodemographic risk factors were harder to engage and remained enrolled for shorter durations compared with families facing fewer risks (Administration for Children and Families, 2002). The reasons for problems in participant engagement are diverse, often related to residential relocation, busy or disorganized family schedules, and other characteristics of recipients. But lack of engagement may also be related to the mixed recipient reactions to obtaining assistance discussed earlier, especially if family members do not perceive that home visitation addresses their needs and concerns or if they feel embarrassed, indebted, or vulnerable because of the services they receive.

A second problem in successfully implementing home visitation programs is the lack of training, supervision, and support for home visitors, which contributes to the high turnover rates that are observed in most home visitation programs and diminished program efficacy

(General Accounting Office, 1990; Gomby et al., 1999). It is common for home visitors to report shorter visits than planned, broken appointments that are not rescheduled, and preoccupation with immediate family crises rather than the delivery of intended education or guidance during home visits. Home visitors are further challenged when working with culturally or linguistically diverse families, at-risk populations, or parents who suffer from depression, domestic violence, or substance abuse (Administration for Children and Families, 2002; Margie & Phillips, 1999). Moreover, several studies have found that how the intended curriculum of a home visitation intervention is implemented varies significantly depending on the values and orientation of the home visitor (Baker, Piotrkowski, & Brooks-Gunn, 1999; Wagner & Clayton, 1999). At times, in other words, what actually occurs during home visitations may be much different than what program designers had intended. The high turnover of home visitors further undermines the relationship between participants and the program, and this factor may contribute to the lack of family engagement. Turnover can be especially difficult for adults in the highest-risk families, who may have fewer alternative sources of support on which to rely and who often have histories of abandonment and relational dysfunction (Goodvin, 2004).

These challenges to program implementation are directly related to the training, supervision, and support provided to home visitors, especially those who are volunteers or paraprofessionals. However, personnel, training, and supervision expenses account for most of the costs of a home visitation program, and thus poorly or inconsistently funded programs are likely to scrimp on these essential features of service delivery. This fact is especially unfortunate in light of findings that the professional identity of home visitors may substantively impact program results. For example, one evaluation of the Nurse Family Partnership—identified as a highly successful program for the breadth of positive impacts across target areas (Avellar et al., 2013)—included a comparison of nurses to paraprofessionals. The goal was to identify whether trained paraprofessionals could replicate the positive effects seen in earlier studies with nurse practitioners. However, results indicated that effects were not comparable: When paraprofessional home visitation produced any positive effects, they were approximately half the magnitude of those found with nurse home visitors (Olds, 2006). It is likely that in addition to their greater clinical training to support families dealing with challenges, nurses are also perceived by support recipients as having a greater degree of authority and useful information. But because of their professional training as formal helpers, nurse practitioners may not share the backgrounds, experiences, and often values of recipient families. Balancing the benefits of expertise with the value of shared orientation—which distinguishes formal from informal helpers—remains one of the challenges of designing effective home visitation programs.

Another challenge to effective program implementation is the failure of many home visitation programs to explicitly establish the development of community supports as a central goal for recipient families. Illustrating this, only 4 of the 35 programs reviewed by Avellar and colleagues (2013) assessed whether program participation increased family linkages and referrals to other resources. This finding is unfortunate because the social support approach incorporated into home visitation recognizes that a home visitor cannot provide all that recipients need. Consequently one of the significant goals of intervention must be to help families forge associations within their communities to individuals and agencies that can offer longer-term support. Moreover, community connections and visibility can enhance the positive regard for a home visitation program within the neighborhood, which can also contribute to improving family engagement and strengthening the connections between family members and community services.

Finally, the reviews by Gomby and colleagues (1999) and Sweet and Appelbaum (2004) each identified program goals as problematic because they were unclear, unduly ambitious, and/or not carefully translated into intervention strategies. Gomby and colleagues emphasized, in particular, the need for a renewed appreciation that home visitation programs must have modest expectations for what social support alone can accomplish for needy families. Thus, home visitation efforts should be combined with other services that can address other family needs. This conclusion is an additional reason for consolidating stronger connections between family members and community resources so that home visitors do not seek to do it all. Home visitation programs that focus on limited, clear, well-defined, and realistic objectives have the greatest chance of success by enabling program staff to sustain program focus and to use limited resources to achieve realistic expectations (General Accounting Office, 1990).

These concerns with the effective implementation of home visitation programs are familiar in light of the foregoing analysis of the challenges of social support interventions to address risks associated with social isolation. Together, they do not indicate that efforts to improve social support in the lives of troubled children and their families are not worthwhile. In fact, rigorous evaluation

of promising programs suggests their potential, even for long-term benefits (e.g., Olds, 2006). The concerns do, however, indicate that it is crucial to move beyond a general expectation that providing social support in itself will yield many benefits to recipients. Instead, in recognition that (a) social support is multifaceted; (b) potential recipients have diverse needs, expectations, and personal and cultural backgrounds; (c) their natural social networks have unique resources and difficulties; (d) their communities likewise have unique constellations of material and human capital; (e) support providers have needs for training and support that are central to an effective intervention; and (f) social support cannot alone address the complex needs of recipients, the importance of clear thinking concerning the purposes of social support interventions, how these objectives should be translated into program strategies, and how the outcomes of these efforts should be evaluated is warranted.

Social Support and the Maintenance of Developmental Psychopathology

Psychological problems have multifaceted origins, of course, arising from the interaction of biological, ecological, cognitive, and other influences. The absence of social support, especially in the context of conflict in close relationships, adds further risk to the development of internalizing and externalizing disorders. The availability of social support can, in turn, help to buffer the onset of clinical symptomatology. Social support and its absence are relevant also to the persistence of symptomatology over time. In other words, once clinical problems have developed, their maintenance may be associated with continuing social adversity and social isolation. Several research literatures suggest how this may be true.

Children with anxiety disorders are highly vigilant for and hyperresponsve to situations associated with fearful stimuli. They interpret everyday situations in ways that exaggerate potential threat, are acutely sensitive to their own visceral signs of fear arousal, and become preoccupied with their negative emotion (Vasey & Ollendick, 2000). They are, not surprisingly, challenging for caregivers to help, but research evidence indicates that the efforts of parents to be emotionally supportive may exacerbate rather than alleviate anxious symptomatology (Thompson, 2001; Vasey & Dadds, 2001). Many parents of anxious children respond sympathetically and protectively to the fear expressed by their offspring, assisting the child in avoiding the fear-provoking event but, as a consequence, offering few opportunities to master the anxiety (Dadds, Barrett, Rapee, & Ryan, 1996; Gerlsma, Emmelkamp, & Arrindell, 1990). In light of studies showing an intergenerational family history for anxiety disorders and their high heritability, these characteristics of parent-child interaction suggest that anxiety is learned in families as part of the shared environment and that parents may become anxious in situations in which their offspring are also fearful (Eley, 2001; Hettema, Neale, & Kendler, 2001). Thus, a child who responds to an anticipated encounter with a fear-evoking event with screaming, tantrums, hiding, and aggressive resistance offers powerful incentives for adults to accede to the child's fears. If the adults do so and the child subsequently calms down, each partner is negatively reinforced for behavior that helps to perpetuate anxious symptomatology (Vasey & Ollendick, 2000). At the same time, parents may be worried about the effects of anxious pathology on the child's capacities to act in a socially and developmentally appropriate manner, and thus parental criticism and possible rejection may accompany parental overprotectiveness (Gerlsma et al., 1990).

Thus, childhood anxiety disorders are likely to be accompanied by troubled family relationships. They are troubled by aversive encounters focused on the child's efforts to avoid fear-provoking events that are inadvertently reinforced by parents' efforts to be emotionally supportive and helpful. They are troubled also by the parents' mixed response to the child's behavior—overprotective but also critical—that contributes to parent-child relationships of insecurity and uncertainty. Parental behavior in these instances is well intentioned: Adults are striving to provide social support, even though their efforts inadvertently reinforce anxious symptomatology in children (Thompson, 2001). One reason for family difficulty is that the emotional support offered by parents does not contribute to alleviating anxious fear. The problem in these circumstances is that parental social support is conceived narrowly as emotionally supportive behaviors that, paradoxically, maintain rather than reduce child anxiety. A broader conceptualization of social support is needed that incorporates parental practices that help children to progressively cope with their fearful emotion, with parental assistance, that children may initially experience as distressing but which ultimately contribute to a reduction in child anxiety.

Another illustration of the influence of social support in the maintenance of clinical problems is the well-developed research literature linking peer relationship problems and childhood loneliness (see Asher, Parkhurst, Hymel, & Williams, 1990, for a review). Several studies have explored the associations among peer rejection, loneliness, and depressive symptoms in children (e.g., Boivin, Hymel, &

Bukowski, 1995; Boivin, Poulin, & Vitaro, 1994; Burks, Dodge, & Price, 1995; Nangle, Erdley, Newman, Mason, & Carpenter, 2003; Oldenburg & Kerns, 1997). Nangle and his colleagues (2003), for example, found that a fully mediational model of the influence of peer relationships on children's loneliness and depression was warranted in their study of 193 third- through sixth-grade boys and girls. In this study, loneliness was the gateway through which problems in peer relationships influenced the development of depression. However, friendships buffered children from depressive symptomatology. The influence of popularity, or peer acceptance, was completely accounted for by the fact that peer acceptance temporally preceded friendship, suggesting that more popular children were likely to have both larger friendship networks and better relative quality of peer relationships. The researchers concluded that before adolescence, "the mutuality that is unique to friendships appears to be critical" (p. 552). Peer rejection is important not only to the development of depressive symptomatology but also to its maintenance over time, as children without friendships are likely to continue to feel lonely, self-deprecating, and isolated in their peer networks.

Social Support and the Prevention and Treatment of Developmental Psychopathology

Social support is important to developmental psychopathology not only because of its contribution to understanding the etiology or maintenance of pathological symptomatology but also because of its promise for pioneering avenues for prevention and therapeutic assistance. The core features of social support—counseling and guidance, emotional nurturance, information, skill acquisition, and sometimes material aid—are components of successful therapeutic efforts in all theoretical approaches. Whether in the context of individual therapy sessions, peer counseling, group therapy, parent education or parent support groups, therapeutic preschool programs, crisis counseling, or other therapeutic avenues, social support is an almost inescapable element of successful clinical intervention. Understanding the nature of social support as well as obstacles to its efficacy in promoting psychological well-being and recognizing conditions that foster perceptions of support in troubled individuals are each important to successfully enlisting social support in therapeutic efforts. Moreover, just as social support is incorporated into most forms of psychological treatment, it is also a central feature of prevention efforts to avert psychological problems or to avoid their recurrence, especially for individuals at risk. Social support is a contributor to long-term adaptive functioning as well as immediate assistance to individuals and families in need.

Despite its ubiquitous contribution to therapeutic endeavors, incorporating social support in prevention and intervention strategies presents significant challenges. The forms of social support that are most helpful to individuals experiencing psychological distress are not self-evident, and, as we have seen, not all social support efforts are effective in achieving therapeutic or preventive goals. These dual observations are crucial considerations because of the many ways that well-intentioned supportive efforts can be rendered ineffective in changing maladaptive behaviors, fostering psychological well-being, or accomplishing therapeutic goals. Earlier in this chapter, we considered examples of how the emotional support of family and friends did not prevent troubled mothers from committing fatal child abuse and how parental efforts to respond sympathetically and protectively does not promote effective coping in offspring with anxiety disorders. For social support to be effective, its purposes and functions must be strategically considered within a broader array of therapeutic efforts, keeping in mind that social support should include not only emotional sustenance and counseling but also reeducation, behavioral change, and monitoring the well-being of those it is intended to assist.

In the next section, we consider five interventions that incorporate aspects of social support for purposes of prevention or therapeutic remediation. These programs were chosen to sample a broad variety of intervention strategies and goals, ranging from efforts focused on strengthening informal support through peers or mentoring relationships to more formal therapeutic strategies to alter family functioning or mental representations of relational support to changes in child welfare practices to improve the well-being of foster children. The outcomes assessed in the evaluations of these interventions are equally diverse, ranging from behavioral competence to attachment security to cortisol regulation. Together, they illustrate the opportunities and the challenges of enlisting social support for preventive or therapeutic purposes. They also illustrate how far we have to go in the evaluation of promising intervention strategies, the science underlying program design, and the extension of that science in conceptualizing the provision of social support and its anticipated benefits.

Peer Support Programs

As noted earlier, one strategy for enlisting social support to remediate clinical problems is to engage natural helpers. For children and adolescents, doing this usually means providing training and supervision to peers who are then

expected to help their classmates or friends. The goals of such strategies may be to increase the total number of peers who interact with the target child or to teach target children social skills that will help them to attract more friends. Enlisting healthy, socially skilled peers to help children or adolescents who have behavioral or emotional disorders or who are at risk for the development of such disorders has intuitive appeal because of the potential to address both of those goals. However, as we have noted, what appears simple and straightforward is often deceptively so. Lewis and Lewis (1996) identified several concerns with involving peers in helping each other. Most notably, in programs without careful role definitions and professional supervision, young people who are motivated by a desire to help others may find themselves in situations that require significantly more training, expertise, and maturity than they have. Lewis and Lewis focused their analysis on risks to peer helpers in programs enlisting peer support for children at suicidal risk, and they reported findings from a descriptive study of Washington schools indicating that suicide rates were higher at schools where peer helpers were not supervised by professional counselors. As we have noted earlier, the potential advantages of enlisting natural supporters to aid troubled children or families must be balanced by their limitations in expertise and capability.

One of the lessons of the social support literature is that designing interventions with carefully defined target behaviors and narrowly focused strategies is likely to avoid some of the ambiguity of more general supportive or mentoring approaches. Such interventions also provide more precise guidance about what works and what does not work. Consistent with this view, one group of researchers (Christopher, Hansen, & MacMillan, 1991; Guevremont, MacMillan, Shawchuck, & Hansen, 1989) trained 7- to 9-year-old children in specific social skills and rewarded them for playing with identified classmates. Same-sex peers were trained in initiating, responding to refusals, maintaining interactions, and responding constructively to negative behavior. Each was then paired with a socially isolated, dysphoric child and rewarded for playing with that child during one daily recess. The intervention resulted in a meaningful increase in positive social interactions for the target children. The improvement in peer interactions for the target children occurred with both the designated helpers and with other classmates, and the levels of positive interactions were comparable to those of social comparison children in the same setting. The treatment gains increased at a 4-month follow-up (Guevremont et al., 1989). In a similar study that also targeted socially isolated, dysphoric children, the researchers increased the training for peer helpers and achieved similarly promising results. Gains in positive interactions were maintained at the 4-month follow-up, and the positive effects generalized to situations when the intervention was not used. In addition, there was no evidence of negative impact of social support on the helpers (Christopher et al., 1991).

A similar approach has proven successful with high-risk preschool children. Fantuzzo and colleagues have demonstrated that their Resilient Peer Treatment (RPT) program improves the social competence of maltreated and nonmaltreated socially withdrawn children in Head Start programs. In RPT, highly socially competent peers help to create regular positive peer play experiences, with interactions supported by a trained family volunteer play supporter. Supporters created a space for the two children to play together and provided guidance and encouragement for interactive play. The intervention involved 15 play sessions over a 2- month period. Multiple experimental evaluations of this program indicated improvements in withdrawn children's teacher-rated social competence and decreases in withdrawn behavior within sessions (Fantuzzo et al., 1996) and with all peers during classroom free play sessions 2 weeks later (Fantuzzo, Manz, Atkins, & Meyers, 2005). Teachers also rated children as higher in self-control and lower in disconnected and disruptive play compared with control group children. Longer-term follow-up is necessary, of course, but successful intervention enlisting peers to help young high-risk children is promising, given its potential for improving later trajectories of social interactions and behavior problems.

Taken together, these programs illustrate the potential benefits that may be derived from enlisting peers as informal social support agents for children who are at risk of developmental problems or face significant adversity. They also illustrate, however, the need for clarity of goals that are suitable to the enlistment of peer helpers and the importance of guidance and support of children who are recruited to help their peers.

Youth Mentoring

Mentors outside the family may play a significant role in providing social support to youth, and this fact has given rise to a proliferation of formal mentoring programs as preventive and therapeutic interventions for at-risk youth. Over 5,000 mentoring programs were operating in the United States in 2005 (MENTOR/National Mentoring Partnership, 2006), spanning multiple program models, such as community-based programs and school- or faith-based approaches. Some programs serve children with existing emotional or behavioral problems, while

others target children with one or more risk factors for developmental difficulties (e.g., children with incarcerated parents). Mentoring programs link youth in difficulty who may not have strong natural mentors with an adult or older peer to provide support and guidance and serve as a positive role model. Rhodes and colleagues (Rhodes, 2002, 2005; Rhodes & DuBois, 2008) have proposed that when mentoring relationships develop mutuality and trust, they can potentially have a positive influence on socioemotional functioning (including developing emotion regulation), cognitive capacities (such as perspective-taking skill), and identity development.

Although formal youth mentoring programs garnered enthusiasm and funding from public and private sources with little evidence of their effectiveness for many years, recent well-designed evaluations and meta-analyses provide some indication of their potential benefits for children and the mediators of these benefits. One example is the Big Brothers/Big Sisters (BBBS) impact study (Grossman & Tierney, 1998; Rhodes, 2002). The BBBS community-based program individually matches adult mentors to children from single-parent homes. Mentors commit to at least one contact per week for a minimum of 1 year, with the expressed goal of developing a friendship with the child. The program provides high levels of supervision and ongoing support of matches. In the experimental evaluation study, diverse youth ages 10 to 16 were randomly assigned either to a treatment group and matched as quickly as possible with a mentor (n = 571) or to a waitlist control group (n = 567). Many of the children in the study had experienced relationship disturbances associated with single parenting, including parental divorce or death, domestic violence, and abuse. At the 18-month follow-up, 378 treatment group youth had been matched with a mentor for 11 months on average. At follow-up, youth who had a mentor were significantly less likely to have initiated drug or alcohol use and reported fewer instances of physically aggressive behavior. Mentored youth also reported greater trust and communication with parents and more emotional support from peers than did control group youth. The latter findings appear to support program claims that the presence of one supportive, healthy relationship may carry over into other relationships by increasing social skills, constructive forms of emotion regulation and the ability to trust others. If this is the case, an effective mentoring relationship may enhance social support both directly and indirectly, with positive implications for overall perceptions of social support and mental health (see also Rhodes, Reddy, & Grossman, 2005).

Recent meta-analyses conclude that effects of youth mentoring programs are relatively consistent but quite modest. In a 2011 meta-analysis covering 73 evaluation studies published after 1998, DuBois and colleagues reported effect sizes of .17 for positive social/relational outcomes, .15 for positive psychological/emotional outcomes, and .21 for lower conduct problems (DuBois, Portillo, Rhodes, Silverthorn, & Valentine, 2011). These results were consistent with those of an earlier analysis (DuBois, Holloway, Valentine, & Cooper, 2002). Although very few studies reported on longer-term effects, when follow-up data were available (7 studies), the effects of program participation showed little to no deterioration over periods lasting up to 4 years.

DuBois and colleagues also reported a number of moderators of mentoring program effectiveness. Prominent among these were characteristics of the mentor-child relationship. Several characteristics were important to program efficacy. First, the positive effects of mentoring relationships were more likely to exist in longer, more established relationships that provided extended opportunities for the development of trust. For example, in a reanalysis of the BBBS evaluation data, Rhodes and colleagues (2005) found that the positive effects of mentors on parent-child relationships and on lowering levels of substance use were present only in relationships established for at least 1 year. Second, the style of mentoring also plays a role in the efficacy of this helping relationship. Reanalyzing the BBBS data, Langhout, Rhodes, and Osborne (2004) found that there were different mentoring relationship styles characterized by varying levels of support, structure, and activity, and these were differentially related to youth outcomes at follow-up. An "unconditionally supportive" mentoring style, for example, was high in levels of positive support but lower in structure of conversations concerning goals and the number of shared activities. By contrast, a "moderate" mentoring style was comparable in shared activities and structured conversations but lower in positive support, while an "active" style was characterized by the highest number of shared activities. Interestingly, youth experiencing "moderate" mentoring showed the best outcomes on follow-up, with decreased feelings of alienation from parents, lower levels of peer conflict, and improved academic competence compared to controls. By contrast, an "unconditionally supportive" mentoring style was associated with an increase in both alienation and peer conflict over the study period. The authors suggested that children in this program may have benefited most from mentors who provided a sense of structure and goal orientation within the context of an emotionally positive

adult-child relationship rather than unconditional positive regard with little structure.

Are there groups of children who are more likely to benefit from the social support provided by a mentor? Although effects held across a range of ages, from early childhood through late adolescence (DuBois et al., 2011), other child characteristics moderated effects. For example, children with prior behavior problems and children who brought *either* high individual or environmental risk appeared to benefit more from mentoring. It is important to note that mentoring programs appear most effective for those children who face an intermediate but not an overwhelming degree of challenges; as earlier noted, the potential impact of nonprofessional mentors may be blunted by the complex problems of children facing both high individual and environmental challenges. The nature of individual mentoring programs may also bear on their effects. DuBois et al. (2002, 2011) reported that mentoring effects were considerably stronger when programs were structured using research-based best practices, such as matching mentors and children based on individual interests, family involvement, and high levels of program supervision and mentor support.

Taken together, studies of the efficacy of formal and informal mentoring relationships for enhancing the well-being of at-risk children and youth suggest that these programs can be helpful for improving social functioning, reducing behavioral problems, and even strengthening academic success. They suggest that in many circumstances, the positive relationship established with an older mentor may provide a foundation for improved relationships with family members, peers, and others in the child's social ecology and may contribute to enhancing perceptions of social support that are important to psychological well-being. The findings also indicate, however, that understanding the characteristics of effective mentoring relationships is important, especially as they concern the match between youth and mentors in background, interests, and other characteristics; the nature and longevity of their relationship; and the severity of youth difficulties that a mentoring relationship is expected to address.

Family Support Intervention

Interventions designed particularly for family members, especially parents, are often part of the therapeutic effort for children and adolescents. Families are the primary source of support for children, and family dysfunction—whether it is manifested in child maltreatment, domestic violence, serious marital conflict, parental depression, or other conditions—poses significant risk to children's emotional health. Consequently, the quality and effectiveness of the support that family members provide to children with clinical problems is crucial to children's healthy adjustment.

As we have seen, however, not all efforts to enhance social support are helpful, and, indeed, emotional support alone may not be effective in remediating children's problems in many situations. In fact, a parent's emotional engagement may have negative effects in certain circumstances. For example, children's emotional or behavioral difficulties may lead to heightened criticism and hostility toward the child (Hooley & Richters, 1995). Expressed emotion (EE) (Hirshfield, Biederman, Brody, Faraone, & Rosenbaum, 1997a) is an index of parental attitudes of criticism or emotional overinvolvement in a child's problems that has been studied as a contributor to the onset, maintenance, or relapse of a number of clinical problems, including schizophrenia (Brown, Birley, & Wing, 1972), depression (Hooley, Orley, & Teasdale, 1986), bipolar disorder (Pavuluri, 2008), behavioral inhibition (Hirshfield et al., 1997a, 1997b), and conduct disorder (Caspi et al., 2004; Rogosch, Cicchetti, & Toth, 2004). EE is associated with these clinical outcomes because it constitutes a major relational stressor in family experience that undermines psychological functioning in an environment that should ordinarily provide social support.

Family support or treatment components have been designed to include a specific focus on EE as a way of improving the quality of social support for young people with clinical problems. The RAINBOW treatment protocol, for example, is a child- and family-focused cognitive behavioral therapy for children with bipolar disorder that addresses the intense personal demands of raising a child with bipolar disorder in an effort to decrease the potentially harmful effects of EE (Pavuluri, 2008; Pavuluri et al., 2004). Elements of this program include encouraging family members to distinguish helpful from unhelpful reactions in their efforts to cope with a child who can be difficult to live with, helping parents model appropriate strategies for affect regulation, fostering shared effective problem-solving strategies in which parents and target children jointly participate, assisting children in their efforts to develop successful peer relationships, and identifying other sources of social support. The program, designed for families with children in the middle childhood or adolescent years, consists of twelve 60-minute sessions that occur weekly over a 3-month period. Conclusions from a study of 34 families participating in this program indicated that symptom severity for children decreased significantly following therapy and parents reported strong satisfaction

with the treatment, although there were no family-based measures of the emotional environment (Pavuluri et al., 2004; see also West et al., 2009). A maintenance model of this intervention showed that these benefits persisted 3 years after initial participation in the program (West, Henry, & Pavuluri, 2007).

Family support interventions like this illustrate how informal social support in the family can be strengthened with the therapeutic assistance of formal helpers from the psychological and psychiatric community. This collaboration can occur even in circumstances when the child's symptom severity has contributed to elevated family stress and hostility toward the child. The duration of the program, however, and the need for a maintenance regimen together illustrate that these benefits are not easily achieved in troubled families.

Child-Parent Psychotherapy

Because social support is based on the quality of helping relationships, efforts like family support interventions are designed to strengthen these relationships by altering the behavior of each partner. But often behavioral change is insufficient because relational interactions are affected not only by the behavior of the immediate partner but also by the individual's prior history of the relationship and its psychological impact. This idea is captured in attachment theory in the concept of internal working models, or mental representations that emerge from early caregiving experience and subsequently color the child's expectations and interactions for subsequent relational partners (Thompson, 2006, 2008). For adults, the quality of their earlier close relationships can color their capacity to respond to a child's needs and emotions. The importance of these mental representations of relationships is reflected also in the social support literature reviewed earlier, particularly in the realization that *perceived* support is more important to psychological well-being than are the actual experiences of receiving support from social network associates. The expectation that others are available to provide assistance, which is important to a sense of social support, may be undermined by earlier experiences of trauma, neglect or abuse, relational violence, and other experiences that impair how individuals are capable of functioning in other relationships.

One approach to therapeutic assistance is thus to address the relational representations that may be obstacles to functioning effectively in potentially supportive relationships. One example is Child-Parent Psychotherapy, an attachment-based approach designed for young children who have experienced a traumatic event, such as maltreatment or exposure to domestic violence, that can be manifested in posttraumatic symptomatology and attachment disorganization (Lieberman, Ghosh Ippen, & Van Horn, 2006; Lieberman & Van Horn, 2008; Lieberman, Van Horn, & Ghosh Ippen, 2005). This is a two-generation intervention because of the recognition that parents of children in these circumstances often have their own history of traumatic experiences that significantly affect their interactions with the child. Thus, trauma-focused therapy for the parent is also a focus of intervention, which may include recollections of difficult childhood experiences as well as explicit attention to the impact of these experiences on the mother's representations of herself and her child. In addition, therapy focuses on parent-child interaction, including guidance for the mother concerning the child's developmental needs and fostering healthier patterns of maternal behavior to alter the young child's expectations for maternal responsiveness and encourage the development of a more secure attachment to her. Age-appropriate therapeutic assistance to the child is also a component of the intervention. Evaluation studies of Child-Parent Psychotherapy have found a reduction in behavior problems and posttraumatic stress symptomatology in preschoolers in a therapeutic group compared to a control group (Lieberman et al., 2006).

In an adaptation of this approach, Toth and her colleagues (2002) used Preschooler-Parent Psychotherapy with a sample of young children who had been maltreated by their mothers and focused on changes in children's representations of the mother and their relationship (assessed through semiprojective narrative story stem completions with dolls) in the assessment of therapeutic outcome. Children and their mothers were seen in weekly 60-minute sessions with a clinician over the course of 12 months. Toth and colleagues found that children in the intervention group exhibited a greater decline in negative maternal representations, a greater decrease in negative self-representations, and more positive expectations of the mother-child relationship by postintervention compared to children treated in alternative approaches. In another study, Toddler-Parent Psychotherapy was used with a sample of mothers with major depressive disorder and their children. After a year of weekly therapeutic sessions, the rate of secure attachment for children in the intervention group had increased significantly and was higher than for a nontreated control group and a nondepressed community group (Toth, Rogosch, Manly, & Cicchetti, 2006; see also Cicchetti, Toth, & Rogosch, 1999). Similar findings have been reported in other applications of this psychotherapeutic approach. Cicchetti, Rogosch, and Toth

(2006), for example, reported significant increases in secure attachment in 2-year-olds after participating with their mothers in a year of Infant-Parent Psychotherapy. In a follow-up study, Stronach, Toth, Rogosc, and Cicchetti (2013) reported that these benefits were sustained for a year following the intervention.

Taken together, these studies underscore the importance of attention to the representational dimensions of receiving support in the design of social support interventions. Indeed, they suggest that without consideration of how prior experience has affected a potential recipient's expectations for assistance from others, efforts to enhance social connections or aid may be blunted because greater received support may not yield increased perceptions of support or expectations that others will be helpful in the future. Conversely, support interventions that focus explicitly on improving expectations of support from others, especially in the context of efforts to strengthen supportive social network ties, may provide greater benefits. But much more remains to be understood about how mental representations of relationships change and grow over time and, in particular, how enduring are therapeutic interventions that address these representations related to social support.

Supportive Interventions in Foster Care: Behavioral and Biological Outcomes

A theme of the research surveyed in this chapter is that stress has psychological and physiological consequences, and the social buffering of stress is likewise psychological and biological in nature. Social support is believed to foster more effective coping and promote psychological well-being through its effects on an individual's psychological stress and its physiological substrates. Although research confirms this multilevel orientation, supportive programs rarely examine the effects of interventions on biological processes, such as stress neurobiology, that are believed to be associated with stress and coping. Even more rarely do they consider concurrent behavioral and biological outcomes of social support. A final illustration of a social support intervention that does so shows how these biological and behavioral outome can be studied together and provides a model for similar kinds of evaluation research in the future.

Children in foster care commonly experience chronic adversity owing to the conditions associated with their initial removal from the family, their experience in foster care, and transitions between care settings. Considerable research has shown that these experiences create stress that is manifested in behavioral problems, distrustful relationships, and dysregulated patterns of biological stress reactivity. Concerning the latter, children in foster care have been shown to exhibit either elevated diurnal cortisol levels or flattened diurnal cortisol, depending, it appears, on the quality of care they have received (e.g., abusive or neglectful treatment) (Bruce, Gunnar, Pears, & Fisher, 2013). In either case, their biological stress systems, most notably HPA activity, have become dysregulated as the result of their experiences of care. This dysregulation of biological stress reactivity is consistent with findings for other groups of children experiencing chronic stress, such as those who are maltreated or are in institutional care (see Thompson, 2014a, 2015, for reviews).

Can social support provide benefits to children in foster care that improve their behavioral functioning and normalize biological stress reactivity? The results of two intervention studies that share many common features suggest that this may be possible. In one program, Fisher and colleagues (Fisher, Stoolmiller, Gunnar, & Burraston, 2007; Fisher, Van Ryzin, & Gunnar, 2011) designed an intervention to ease young children's transition to new foster care placements and enhance continuity of care to reduce the stresses of such placement. Before the intervention began, these children showed a profile of flattened cortisol activity as a result of their earlier placements. The intervention program was designed to promote warm, responsive, and consistent relationships between children and new foster parents in which positive behavior was encouraged, problem behavior was reduced, and caregiver stress was lowered. The program included individualized sessions with child therapists, weekly playgroup sessions, and other child-focused services. Foster parents completed intensive training prior to the children's placement, and they continued to receive support and supervision in daily phone contacts, weekly group meetings, and on-call assistance. The program was thus a 2-generation intervention involving multiple adults who functioned as caregivers for the child. Compared to children assigned to regular foster care placements, who showed the pattern of cortisol hyporesponsiveness described earlier, children in the intervention group showed patterns of HPA reactivity that progressively resembled the normal patterns of a nonabused community comparison group over the course of 6 to 12 months of treatment. Reductions in foster parent stress were directly implicated in these changes in young children's HPA function recovery (Fisher & Stoolmiller, 2008).

In another intervention with very young children, Dozier and her colleagues (Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008; Dozier et al., 2006) reported

that following a home-based 10-week program, infants and toddlers in foster care showed more typical daily patterns of HPA activity and moderated cortisol reactivity to a stressor compared to a group of foster care infants in a different treatment program. This attachment-based intervention was designed to improve young children's relationships and self-regulation by assisting foster parents in better interpreting and responding to infants' signals, enhancing affectionate behavior, and providing more reliable support for infants' self-regulation.

In both intervention studies, moreover, the researchers also obtained concurrent measures of behavioral change that may be viewed as additional indicators of treatment efficacy. In the Dozier study, infants and toddlers showed greater evidence of attachment to their foster parents (Dozier et al., 2009); in the Fisher intervention, a similar gain in secure attachment behavior was noted, together with greater placement success (Fisher, Burraston, & Pears, 2005; Fisher & Kim, 2007). In light of the goal of each intervention to improve the quality of children's relational experience, and in view of research indicating disturbance of biological stress systems in young children with insecure attachments (Spangler & Grossmann, 1993), these behavioral changes should be regarded as indicators of intervention efficacy, parallel to the changes in HPA reactivity occurring over the same period.

Both of these intervention programs for foster children can be regarded as focused on improving social support. Each emphasized strengthening young children's relational security by improving caregiver responsiveness and reducing caregiver stress. The success of each program in improving the quality of children's attachments while also regularizing their HPA functioning is consistent with the research reviewed earlier concerning the social buffering of physiological stress reactivity and provides some of the earliest evidence for how social support interventions can have both psychological and biological consequences.

Even so, much more remains to be understood. Longer-term follow-up research on children in intervention and comparison groups is needed, for example, to examine how enduring are the changes in stress reactivity resulting from these interventions or, more specifically, the conditions in which these changes endure or not. Recognizing that the plasticity of HPA functioning can be limited in conditions of highly aversive care (e.g., Gunnar, Morison, Chisholm, & Schuder, 2001), it will also be important to understand how early adversity is related to the intensity and duration of intervention efforts required to normalize children's stress reactivity and its behavioral correlates. In the end, what makes this research field so exciting is the opportunity to extend research on socially supportive interventions to the biological domain and, in so doing, to better comprehend the behavior-biology associations that underlie psychological functioning and its changes over time.

Taken together, the preventive and therapeutic programs surveyed in this section certainly do not exhaust the range of interventions that have been designed to strengthen social support in the lives of troubled individuals and families. But they illustrate the significant opportunities that exist to improve informal and formal sources of support for beneficial purposes as well as the challenges of enlisting social support for these purposes that have been discussed throughout this chapter. More specifically, these programs illustrate and confirm the interim conclusions about social support identified earlier from the research literatures discussed in the opening sections of this chapter. They show, for example, the importance of recognizing how relationships influence other relationships and the value of multigenerational interventions that provide support both to children and their caregivers. They illustrate the significance of coordinating informal and formal sources of social support for providing multifaceted avenues of assistance to those who need it. These programs show both that parents are central to children's environment of relationships but that they are not alone influential, and sometimes support can be provided by enlisting other people in children's natural social networks (e.g., peers) or by enlisting others outside the family (e.g., mentors). These programs indicate how representations of support from others are important to psychological well-being and that sometimes interventions with a representational focus can be most valuable. Most important, these programs together show that social support efforts will be more effective when there is clarity concerning the goals they are intended to achieve. Taken together, these interventions illustrate both the lessons learned and to be applied in future social support interventions.

CONCLUSIONS AND FUTURE DIRECTIONS

Two of the central conclusions from the research on social support and developmental psychopathology are how complicated is the provision of social support in intervention and how beneficial everyday social support is for psychological functioning. When people are surrounded by natural networks of family, friends, neighbors, coworkers, and others who offer emotional guidance, instrumental aid, and monitor well-being, the odds in favor of psychological

health and healing are meaningfully improved. But it is difficult to create the benefits of natural forms of social support in preventive or therapeutic interventions. This conclusion owes to the challenges of instituting formal helping relationships that can offer social support and also because when natural social networks are not functioning supportively (e.g., because they are drained or stressed), it is difficult to reconstitute them in healthy and helpful ways. Added to these challenges are the characteristics of support recipients and how their personal and ecological conditions can pose obstacles to the success of social support interventions. Moreover, in order to be effective in addressing clinical psychopathology, social support must accomplish more than simply providing the emotional reassurance that recipients might want most; it must also change behavior and thinking.

In short, the benefits of social support are easy to envision but difficult to implement. This finding poses a challenge to researchers, theorists, clinicians, and practitioners who, after the initial wave of enthusiasm for the preventive and therapeutic benefits of social support interventions two decades ago, must now confront the host of practical challenges to effectively implement social support in the lives of at-risk children and their families. As the summary of preventive and therapeutic program models illustrates, however, there is cause for hope. From the varieties of programs that have documented measurable and predictable benefits for recipients—and from those that have failed to do so—there is now a wealth of good ideas for crafting more carefully conceived, thoughtfully designed social support interventions that have greater promise of success. There are also some excellent program models to draw on.

The research literatures we have discussed related to social support are broad, detailed, and expanding and will continue to provide new ideas about support and its effects in the years to come. Although basic conclusions concerning the benefits of social support seem to be settled (some perhaps prematurely) and the era of unbridled enthusiasm concerning the promise of social support interventions is over, we believe that there are three questions meriting further research that have the greatest promise of significantly expanding understanding of social support and its relevance to developmental psychopathology.

First, *why is social support a stress buffer?* A vast research literature documents the association between perceived (and sometimes received) social support and measures of coping and psychological well-being. But reviewers of this research, including us, find process explanation lacking (see also Cohen & Janicki-Deverts, 2009; Thoits, 2011). Psychological researchers typically focus on intervening processes, such as enhanced self-esteem, perceptions of self-efficacy, modeling, sense of belonging and companionship, while sociological and community researchers more commonly focus on processes like resource acquisition, networking and mentoring, and skill development. But there is no widely accepted model for why social support should enhance health and coping. As we have emphasized, the multifaceted nature of social support probably means that different constellations of intervening processes are influential with different subsets of recipients.

Research on stress neurobiology and the social buffering of stress reactivity may, however, offer new perspectives to this question. In the context of behavior-biology transactions—or, as emphasized by Thompson (2015b), behavior-*representation*-biology interactions—researchers in developmental neuroscience are beginning to identify some of the constituent mechanisms by which social support modulates neurobiological stress reactivity. The intervening processes currently hypothesized include, for example, the effects of social support on the biological regulators of HPA activity (including prefrontal influences but possibly also limbic regulators), the downregulation of the proinflammatory tendencies induced by chronic stress, and the influence of other neurohormonal processes, including oxytocin (see Hostinar et al., 2014; Kiecolt-Glaser et al., 2010; Ulrich-Lai & Herman, 2009). This research is still at an early stage, and establishing connections between neuroscience and behavioral functioning in this area poses an additional challenge. But there is the potential for the development of theoretical models of social support that describe the ongoing transactions between different levels of the neuroaxis and behavior that can help clarify the physiological mediators between social support and mental health as well as other neurobiological processes associated with clinical psychopathology that may alter these processes. This is an exciting prospect for theoretical portrayals of biology-behavioral interactions and has potentially important intervention applications.

Second, *what developmental processes guide children's changing representations of social support in their environment of relationships?* One of the conclusions of this chapter is that the experience of receiving social support is similar for children and adults in some ways but very different in others. As we have noted, for example, children's access to social support is significantly mediated by parents and their social networks. But this review has underscored how little is known about developmental changes in children's experience or representation of social support. This is an important question for future understanding

of the association of social support and developmental psychopathology.

In this discussion, for example, we have underscored that social support is developmentally constitutive for children in a way that it is not for adults: Children depend significantly on the various kinds of support they receive from others for their survival, health, and well-being. This dependency has an effect on their reactions to receiving assistance: Children do not seem vulnerable, for example, to the feelings of indebtedness, humiliation, or vulnerability that adults often experience when receiving unreciprocated assistance from another (for that matter, they are also much less likely to experience gratitude) because it is widely acknowledged that children depend on the solicitude of adults. But we know little about how these perceptions change with increasing age and children's growing autonomy. We know little about developmental changes in how children represent more broadly the support that is available to them from parents and extended family members, neighbors, peers, teachers, and others in their social ecology. How are individual differences in characteristics such as temperament influential in the growth of these mental representations? And although the attachment literature suggests that the internal working models of secure attachment cause children to perceive greater supportiveness from others and perhaps also to elicit that support, little is known of how this occurs or whether it creates a snowball effect that might contribute to some of the broader socioemotional outcomes associated with attachment security. Finally, the emergence of online forms of social support raises important new questions concerning the extent to which children and youth experience support in these transactions and the conditions in which this support can occur. In short, better understanding of developmental processes associated with children's experience and representation of social support is a crucial future research task.

Third, *what are the essential ingredients for effective preventive and therapeutic social support interventions?* As researchers have increasingly recognized the complexity of designing social support interventions for at-risk children and their families, a number of promising interventions have been developed, some of which we have discussed in this chapter. Furthermore, these efforts have provided clinicians with a short list of things to do (e.g., engage recipients; clarify goals; support help providers; respect culture) and to avoid (e.g., expect more than informal helpers can do; view social support alone as the answer to recipients' needs) in their thinking about intervention strategy. It is probably too soon to expect that a recipe for effective social support interventions will emerge, especially in light of how limited current evaluation studies are in clarifying these ingredients and the need for long-term follow-up studies. But such a recipe should be a long-range goal receiving current attention by those who are involved in studying, designing, conducting, and evaluating these interventions.

Social support is essential to psychological growth, well-being, and effective coping. It is also a core element to successful preventive and therapeutic efforts to assist at-risk children and their families. Understanding how to better engage social support into the lives of those who need it remains an essential and enlivening research and clinical endeavor.

RATIONALE AND BACKGROUND

Why a Chapter on Poverty in this Handbook?

Affecting more than 16 million (22%) U.S. children, poverty places children at elevated risk for most forms of psychopathology. Of all of the factors that threaten the health and well-being of children and adolescents, poverty has the widest reach. It is a largely nonspecific risk factor, one that lays fertile ground for various genetic and nongenetic etiologic factors to emerge, take hold, and compound or interact with one another. Physical and mental health disparities stemming from socioeconomic inequality and poverty are well documented (Evans, Wolf, & Adler, 2012). Although the most startling effects, such as premature death, occur mostly during adulthood (Gruenewald, Cohen, Matthews, Tracy, & Seeman, 2012), research has clearly shown that the roots of health disparities take hold during childhood (e.g., Chen, Hanson, et al., 2006; Evans, Chen, Miller, & Seeman, 2012). Poor children are at significantly elevated risk for developing a wide array of internalizing and externalizing symptoms and disorders (Grant et al., 2003), including higher rates of anxiety, depression, and aggressive behavior (Miech, Caspi, Moffitt, Wright, & Silva, 1999; Wadsworth & Santiago, 2008), as well as other types of pathology as wide-ranging as schizophrenia and delinquency (McBride Murry, Berkel, Gaylord-Hardin, Copeland-Linder, & Nation, 2011).

Poverty's pernicious effects are widespread for several reasons. First, poverty can have direct effects on children's health and development, stemming from problems such as hunger, exposure to toxins, and increased incidence of accidents and injuries (Evans, 2004). Poverty also increases a child's risk for exposure to a variety of known familial and parental risk factors, such as disrupted parenting, parental absence, interparental conflict, family violence, child maltreatment, and substance abuse, as well as parental psychopathology, such as depression, substance abuse, and antisocial behavior (Wadsworth et al., 2008). Additionally, poor children are often exposed to negative neighborhood characteristics, such as crime, deviant peer groups, poor-quality schools, and a variety of environmental hazards (Leventhal & Brooks-Gunn, 2000). An additional feature of poor children's lives is that these problems and exposures often co-occur, and Evans (2004; Evans & Kim, 2010) has shown that an accumulation of environmental and family risks takes the heaviest toll. Hence, poor children face numerous and varied risk factors in their homes, within their families, in their neighborhoods, and

in the schools that make them more likely to experience psychological distress and disorder. Unfortunately, children in poor families are also substantially less likely to have protective factors that can counterbalance the risks, such as high-quality childcare, enrichment activities, and access to alternative learning materials (Sameroff, 2006). Moreover, children from low socioeconomic status (SES) backgrounds on average have compromised personal resources including coping skills and more poorly developed executive functioning skills, such as inhibitory control and planning (Wolff, Wadsworth, & Santiago, 2010; see "Mediators and Moderators of Poverty's Effects on Psychopathology" section).

Despite these risks outlined (covered in more detail later in the chapter), there is much resilience within this population. Not all poor children succumb to school failure, experience depression, or become involved in criminal activity. Some even thrive despite great odds. Increases in income, or emergence out of poverty arising from natural and/or governmental experiments, have been linked to declines in children's psychological problems, such as aggression (Costello, Compton, Keeler, & Angold, 2003) that persist into adulthood (Costello, Erkanli, Copeland, & Angold, 2010), while other resilient children have personal strengths, a strong adult mentor, or family/cultural strengths and resources (e.g., Werner & Smith, 2001). Psychopathology stemming from poverty is not inevitable or irreversible, but attention to the problem of poverty and its mediators and moderators is required to help eliminate this highly damaging risk factor.

Mental Health Costs of Poverty

Merikangas and colleagues (2011) recently published lifetime prevalence data on psychological disorders using the National Comorbidity Study Replication adolescent supplement sample of over 10,000 adolescents aged 13 to 18. Prevalence rates were 14.3% for any mood disorder, 31.9% for any anxiety disorder, 8.7% for attention-deficit/hyperactivity disorder (ADHD), 12.6% for oppositional defiant disorder, 6.8% for conduct disorder, and 11.4% for any substance use disorder. This nationally representative sample constitutes one of the best samples to estimate the effects of SES on rates of psychopathology. In multivariate analyses accounting for family income, parental marital status, age, gender, ethnicity, and urbanicity, parental education level of less than a college degree increased the odds of all of the preceding classes of mental disorder by an overall average odds ratio of 1.6. This means that, even after accounting for a host of potential confounds, children from low-SES households were 1.6 times more likely to meet diagnostic criteria for a mental disorder than were children with college-educated parents. Unfortunately, with increasing rates of child poverty (child poverty in the United States rose from 17% to 22% between 2008 and 2012), the costs of these SES–mental health disparities are likely to continue to increase.

Estimates of the economic costs of mental health problems among the poor need to take into account not only the cost of mental health care but also the costs incurred in related areas, such as psychiatric emergency room visits and inpatient stays, academic failures, crime and delinquency, and lost productivity in adulthood. Greg Duncan and colleagues (Holzer, Schanzenbach, Duncan, & Ludwig, 2008) reviewed the results of scores of rigorous research studies examining a variety of poverty-related outcomes to estimate the monetary costs to society of childhood poverty in the United States. Factoring out a conservative estimate for genetic contributions, they estimated that the experience of growing up in or near poverty, which at the time took into account approximately 17% of children (a rate that since has gone up considerably) creates a yearly opportunity cost of 1.3% of the U.S. gross domestic product (GDP), which at the time was about $170 billion per year. Opportunity costs are lost earnings resulting from reduced productivity and lower wages in adulthood as a result of growing up in poverty. Duncan and colleagues also estimated the monetary costs associated with crime and delinquency stemming from poverty, again factoring out a conservative estimate for genetic contributions. This estimate of the costs of crime, including incarceration and costs to crime victims, accounted for another 1.3% of the GDP, or another $170 billion annually. Finally, they computed the likely economic impact of child poverty on the incidence of poor physical and mental health and their associated costs, which amounted to 1.2% of GDP and approximately $156 billion. The authors concluded that their "best estimates suggest that childhood poverty imposes costs on American society equal to nearly 4% of GDP, or about $500 billion per year" (p. 41).

Thus, poverty results in enormous losses of human and economic capital every day.

Ethical Issues and Social Justice

Although a thorough discussion of the causes and consequences of poverty is well beyond the scope of this chapter, it is important to place our findings within a socio-historical context. A well-documented SES–health

gradient begins during childhood and persists throughout adulthood; unsurprisingly, those in poverty and with the lowest incomes have the worst health (Adler & Stewart, 2010; Braveman, Egerter & Williams, 2011). What is more surprising is that the gradient in physical health exists at all SES levels, with health deteriorating even when moving from the wealthiest SES-income level to the second wealthiest. For mental health, the same is true for the middle and bottom portions of income, but Luthar's research has shown that risk for substance use and mental health problems also show elevations in children from the most affluent homes (Luthar, 2003). The full-spectrum health gradient exists in most modern industrialized societies today. The steepness of the gradient (or the severity of health loss occurring between SES levels) varies across countries, and what determines the steepness of the gradient is the degree of income inequality in a country (Wilkinson & Pickett, 2009). In other words, the larger the gaps between the wealthiest and poorest in a society are, the steeper is the relationship between income and health. Accordingly, the United States, which has one of the largest gaps between wealthy and poor, also has one of the steepest SES-health gradients in the world.

Children, who are not responsible for household incomes or economic recessions, bear a disproportionate health burden from inequality. For example, many children in the United States regularly experience food insecurity. The most recent report by the U.S. Department of Agriculture showed that 20% of households with children are characterized as food insecure, meaning that members of those households are unable to consistently access an adequate amount of nutritious food necessary for a healthy life (Coleman-Jenson Nord, Andrews and Carlson, 2011; McLaughlin et al., 2012). The effects of malnourishment on children's developing brains and bodies are well documented, and even "moderate nutritional vulnerability," such as that found in the United States, can interfere with cognitive development (Jyoti, Frongillo, & Jones, 2005). In addition, being hungry on a regular basis interferes with the ability to concentrate and sleep and causes psychological and physiologic stress to the developing organism. Research has documented serious psychological and emotional consequences of food insecurity (Chilton, Chyatte, & Breaux, 2007; Cook & Jeng, 2009). Behavior problems, hyperactivity, aggression, social withdrawal, peer problems, and school suspension are all elevated in children who experience food insecurity, as are depression, suicidal behaviors, and anxiety (e.g., Slopen, Fitzmaurice, Williams, & Gilman, 2010). Physical health is impaired, resulting in more days sick, more days absent from school, learning problems, and school failure, all of which can exacerbate psychological problems (Cook & Jeng, 2009). Moreover, the stress of financial strain on parents in conjunction with vigilance and anxiety about adequate food for children likely affects parental mental health in negative ways that have further repercussions for their children.

Poverty also robs children of opportunities. As highlighted by the striking economic costs of childhood poverty estimated by Duncan and colleagues and further examined in Duncan, Ziol-Guest, and Kalil (2010), adults who experienced poverty during their early childhoods had numerous negative work and health outcomes compared to adults whose early childhoods were not marked by poverty. On average, those who grew up poor completed 2 fewer years of schooling, worked 451 fewer hours per year, earned less than half as much income, had poorer health and higher psychological distress, were more likely to receive food stamps, and had elevated body mass indexes and overweight status. In addition, poor males were twice as likely to be arrested and poor females were six times as likely to bear a child out of wedlock compared to nonpoor counterparts. Hence, children who grow up poor are less likely to have financially rewarding careers, enjoy good health, and avoid involvement with criminal and/or social service institutions as adults.

U.S. Poverty Demographics

There are approximately 72 million children under the age of 18 in the United States at this writing. Of those, 45% (32.4 million) live in homes classified as low income or near poor, and 22% (16.1 million) live in homes with incomes at or below the federal poverty threshold (FPT). Poverty rates are even higher for ethnic minority children, with poverty rates of 34% for Hispanic and 39% for African American children. The official FPT is widely recognized to be inadequate to meet the daily needs of most families, and even the federal government provides supplemental food assistance to families up to 185% of the FPT. Research has shown that many families with incomes up to 200% of the federal poverty line cannot make ends meet even with federal in-kind subsidies such as WIC (Women Infants and Children supplemental food subsidy), SNAP (Supplemental Nutrition Assistance Program, formerly known as food stamps), and the school lunch program. Taking such information into account effectively doubles the number of children facing risk from inadequate financial resources, especially for younger children and children of color. Children under the age of 6 represent 33% of the U.S. population and 48% of the low-income population

(11.5 million). Rates decline slightly as children age, with rates of 45% (10.9 million) and 41% (10 million) for 6- to 11-year-olds and 12- to 17-year-olds, respectively. Rates also differ by ethnicity, with 65% of African American (6.5 million) and Hispanic (11 million), 63% of American Indian (0.4 million), 32% Asian (1 million), and 31% of white (12.1 million) children living in homes meeting low-income criteria (Addy, Engelhardt, & Skinner, 2013). Despite programs such as Medicaid and the Children's Health Insurance Program (CHIP), 11% of children in low-income families have no health insurance.

Poverty Metrics

Poverty and the related but separable constructs of economic inequality, low SES, and low income have been measured in a variety of manners (Diemer, Mistry, Wadsworth, Lopez, & Reimers, 2013). Much scholarship in this area has focused on family-level income, social class, or SES, but increasing research is capturing poverty in a broader context of a child's life, such as in the school and in the neighborhood. We briefly review all three types of metrics. In this chapter, we use the terms *poverty*, *low income*, and *low SES* somewhat interchangeably because findings are generally consistent across these different ways of indexing economic hardship and/or low social position. In our reviews of the research on internalizing and externalizing and on mediators and moderators, we have tried, however, to report findings along with the specific index used in the study.

Much psychological research has used either an index of social standing, such as the Hollingshead Index of Social Position, or an income-based indicator of poverty and/or wealth. Both measurement approaches have yielded important information about the size and direction of poverty's effects as well as mediators and moderators of these effects. The most basic measure is income. Duncan and colleagues (e.g., Duncan & Magnuson, 2002a) have written extensively about both the utility of income as a predictor of health and well-being and best practices for measuring income. They recommend, for example, using multiple years of income rather than a single year, because of the instability of incomes, especially among those in lower wage brackets and seasonal workers, for example (Magnuson & Duncan, 2002b). They have also developed interview questions and techniques designed to help respondents provide the best estimate of their wages (e.g., Duncan & Petersen, 2001).

An alternative way of indexing family poverty is using income thresholds originally developed by the U.S. government for the purposes of determining eligibility for public assistance programs and for tracking census data. Measures of absolute poverty (e.g., the FPT) identify the amount of income minimally required to support a family (Iceland, 2003; Roosa et al., 2005). The FPT, which is designed to capture the cost of maintaining a "minimally adequate diet," consists of a set of thresholds that vary by family size and members' ages compared to a family's pretax income (DeNavas-Walt, Proctor, & Smith, 2012). A newer supplemental poverty measure (SPM) has been developed, which takes into account the cost of clothing, shelter, and utilities in addition to food, and allows for geographic adjustments in housing costs, for example (U.S. Census Bureau, 2013). Alternatively, a child's Hollingshead Index is, for example, calculated by combining the parent(s)' educational attainment and the prestige level of their usual occupation. Such composite indices generally correlate with income, seem to be most useful in predicting family processes that mediate poverty's effects on psychopathology, and may be especially useful in samples with restricted income ranges (e.g., Wadsworth et al., 2005).

Another measure of family poverty is the income-to-needs ratio (INR), which is computed by dividing total family income by the FPT for a given year and family size. INR thereby adjusts for the number of family members requiring economic resources in a household and the FPT for that year. INR cutoffs have been proposed to nominally classify the SES continuum, including families who experience extreme poverty (i.e., an INR of .50 or lower; approximately $11,500 for family of four in 2012 using the FPT; Census Bureau, 2012), low income or near poor (i.e., an INR between 1 and 2; roughly between $23,100 and $46,000 for a family of four in 2012); and affluent (i.e., an INR greater than 4; income greater than $92,200 for a family of four in 2012) (Roosa et al., 2005).

Indices of family material deprivation and hardship (Gershoff, Aber, Raver, & Lennon, 2007; Iceland, 2003; Mayer & Jencks, 1989) capture the most bare-bones basic necessities of life: food, shelter, and clothing, or lack thereof. These measures therefore tend to be most useful in samples with incomes restricted to the poor and near-poor ranges because higher-income families are unlikely to be homeless or hungry. Measures of material hardship have been useful in identifying mediators within impoverished samples, such as a parent's ability to provide educationally rich experiences and intellectually stimulating environments for their children. Material deprivation can be captured via a sum of hardships, such as housing, food, and medical care, and can be added to broader indices of cumulative risk, such as those captured by Evans and

colleagues. Such cumulative risk measures expand the range of outcomes linked to material hardships to physiologic markers (Evans & English, 2002) and academic, social, and behavioral functioning (Gershoff et al., 2007).

At the school level, poverty can be indexed using the proportion of the student body that qualifies for or is enrolled in the school free or reduced-cost meal program. The Healthy, Hunger-Free Kids Act of 2010 subsidizes school meals and snacks for poor and low-income children, based on FPT. Children from families with incomes at or below 130% of the FPT are eligible for free meals; those from families with incomes between 130% and 185% of the FPT are eligible for reduced-price meals. The proportion of a school that qualifies for free and reduced-cost school meals is a useful gauge of a school's aggregated poverty status; an individual's receipt of free or reduced-priced lunches can be used as an additional indicator of a child's economic status (as in Wadsworth & Compas, 2002).

Finally, poverty can be assessed at a neighborhood level. For example, neighborhood disadvantage is a robust predictor of child academic failure, conduct problems, teen pregnancy, and symptoms of anxiety and depression, even in examinations spanning longer than a decade and when controlling for various measured risks and unmeasured confounds (e.g., Goodnight et al., 2012). A fairly straightforward approach to measuring neighborhood poverty, which is commonly employed in child development research, is to use the percentage of households in a given catchment area that are living below the poverty line. Neighborhoods with 30% to 40% of households with incomes at or below the FPT are generally considered "impoverished" (Leventhal & Brooks-Gunn, 2011). More complex indicators of neighborhood quality have also been calculated by capturing multiple risks within a catchment area, such as the percentage of people in a neighborhood with less than a high school education, percentage of female-headed households, violent crime rates, and percentage of unemployed adults (e.g., Santiago, Wadsworth, & Stump, 2011). Subjective assessments of the quality of a neighborhood from the perspective of current residents can also be used as indicators of neighborhood poverty, ranging from single items asking how "safe" a neighborhood is to multiple-item scales assessing social disorganization or low collective efficacy (e.g., Kohen, Leventhal, Dahinten, & McIntosh, 2008). While measures capturing multiple indicators of a neighborhood's quality tend to outperform single-item indicators, measures capturing duration of residence in addition to quality of residence tend to capture the clearest picture of neighborhood poverty (e.g., Wodtke, Harding, & Elwert, 2011). Although neighborhood deprivation relates to children's mental health, its effects tend to be much smaller in comparison to family indices of deprivations, such as income or SES (Leventhal & Brooks-Gunn, 2000).

Interrelations of Poverty and Psychopathology with Other Important Life Areas

In addition to psychopathology, poverty and low SES are strongly associated with adverse outcomes in other spheres, such as school readiness (Galindo & Fuller, 2010; Isaacs & Magnuson, 2011; Kingston, Huang, Calzada, Dawson-McClure, & Brotman, 2013). In their own right, academic failure, health problems, and social problems can lead to and exacerbate mental health problems, and vice versa. For example, poverty status was associated with lower cognitive skills and material hardship was associated with more social problems for children in a representative sample of 1,292 children in six rural counties in the United States (Kainz, Willoughby, Vernon-Feagans, & Burchinal, 2012). Not only does family poverty and income predict children's school readiness, but neighborhood poverty also predicted decrements in a composite measure of school readiness over time in three samples of Canadian kindergarteners (Cushon, Vu, Janzen, & Muhajarine, 2011). Similarly, neighborhood economic hardship was a significant predictor of children's lower mathematics and letter knowledge, academic outcomes, and social skills in a sample of 1,004 ethnically and geographically diverse 4-year olds, even after accounting for maternal education (an indicator of family SES) (Hanson et al., 2011). Finally, concentrated neighborhood poverty during the kindergarten years had a persistent negative effect on the reading comprehension outcomes of a sample of 2,648 urban Canadian children (Lloyd, Li, & Hertzman, 2010).

Indicators of physical health, illness, and disease are also patterned by SES in children. In a sample of 8,800 children followed to 48 months of age (the Early Childhood Longitudinal Study, birth cohort), poverty increased children's odds for chronic health problems, low cognitive achievement, poor social skills, and elevated behavior problems. (Hillmeier, Lanza, Lansdale, & Oropesa, 2012). Mental health relevant biomarkers such as cortisol also show patterning by SES, as highlighted by Blair, Raver, Granger, Mills-Koonce, and Hibel (2011). They found that poor housing quality and perceived economic insufficiency were both related to children's cortisol levels in the first 4 years of life, including accumulating physiologic indicators of allostatic load. Similarly, cumulative hardship based on

adequacy of food, housing, and energy predicted significantly reduced odds of health and wellness in terms of hospital visits; developmental risk; and body size, weight, and proportions in a sample of 7,141 children 4 to 36 months of age (Frank et al., 2010).

Direction of Causality

Considerable debate has waged regarding the direction of the relationship between poverty and psychopathology. Social causation, or what are sometimes referred to as the social determinants of health, clearly proposes that poverty leads to psychopathology. Social selection, however, acknowledges that individuals' own characteristics, such as their psychopathology, contributes to poverty, as a result of interference with educational and occupational attainment, for example. Consistent with selection theories, is the possibility that a third variable, such as genetics, leads to both pathology and poverty—perhaps IQ, temperament/personality, or disease-specific genes. Social selection arguments are less compelling when considering children, because children by and large do not determine their family's SES level. Here we briefly review alternative causative models.

The first model, referred to as the social selection or downward drift hypothesis, posits that adults with psychological or physical health problems drift down the SES ladder due to their problems and their resulting inability to fulfill expected role obligations. The initial causes of psychopathology or poor health are assumed to be factors unrelated to SES, such as genetic liabilities (e.g., Kendler & Eaves, 1986) or unfortunate circumstances, such as an accident. Findings from several studies suggest that SES differences in the rates of a few psychological disorders, including schizophrenia (Dohrenwend et al., 1992), and possibly ADHD (Miech et al., 1999), are consistent with this hypothesis. Thus, schizophrenia, for example, may impair people's ability to secure employment and financial status commensurate with that of their parents. Little research has addressed the possibility of downward drift with regard to physical illnesses, although the few that have looked have not found evidence in support of such selection effects (e.g., Lynch, Kaplan, & Shema, 1997).

The second model arises from observations that people living in poverty are more likely than those not living in poverty to engage in a variety of unhealthy behaviors—behaviors linked to various physical illnesses and diseases (e.g., Wray, Alwin, & McCammon, 2005). Rates of cigarette smoking, for example, are higher among the poor than the nonpoor, and the linkages between smoking and diseases such as cancer and heart disease are very strong (Ekberg-Aronsson, Nilsson, Nilsson, Löfdahl, & Löfdahl, 2007). Similarly, higher rates of overweight and obesity are found among the poor, and once again obesity is linked with a variety of poor health outcomes. This is apparently an appealing explanation—poor people smoke, drink, and overeat, and that is why they are unhealthy. Unfortunately, the data do not bear out this as a complete explanation of the link between low SES and poor health by any means. In fact, studies have generally found that health risk behaviors such as these at best explain only a quarter of the association between SES and physical health and often explain significantly less than that (e.g., Lantz et al., 2001; Månsson, Råstam, Eriksson, & Israelson, 1998). In addition, as mentioned, the robust SES-health gradient also exists for mental health problems. Yet there are no compelling reasons to suspect that smoking or overeating leads to ADHD, schizophrenia, or anxiety disorders. Thus, while health risk behaviors may add something to the picture of explaining the SES-health gradient, there is much left to be explained by some other mechanism.

The third model explores a related factor that could contribute to the SES-health gradient. In the United States, millions of poor people have historically not had adequate access to health insurance. Thus, many poor individuals and families have been forced to seek medical care only in emergencies, at which point many health problems are too far advanced to treat easily. While it is intuitively appealing to attribute the gradient to inadequate health insurance, once again, this idea is not borne out in the research that has been conducted. Studies that account for access to health care have found only small percentages of the gradient explained by health care access and usage (e.g., Sapolsky, 2004). In addition, the SES-health gradient exists in virtually every country in the world, even those with universal health care programs, such as England and Sweden. Interestingly, the gradient is steepest in countries with the greatest degree of income inequality between the rich and poor, such as the United States. Finally, the SES-health gradient exists even for diseases whose incidence is not related to access to preventive health care, such as rheumatoid arthritis and juvenile diabetes (Sapolsky, 2004). Thus, while poor access to health care is a problem and certainly does not help the situation created by the gradient, it does not appear to be the primary mechanism of the gradient.

The fourth model, called social causation, posits that poor people develop psychological and physical health problems as a result of living with poverty-related

adversity. Studies comparing social causation of psychological disorders with alternative models, such as social selection, generally find strong support for the social causation of multiple disorders, including depression and anxiety (e.g., Wadsworth & Achenbach, 2005). Because of the pervasiveness and chronicity of poverty, living with poverty is grueling and demoralizing—it literally wears one down mentally and physically, as evidenced by significantly higher mortality rates for those in poverty (e.g., Rehkopf & Buka, 2006). Research suggests that this wear and tear is not just metaphorical; chronic adversity and stress due to poverty simultaneously dysregulate the body's physiological stress response system and reduce psychological resources for coping with stress. This allostatic load eventually weakens resistance to disease-causing agents of both the physical and the psychological variety (Kahn & Pearlin, 2006; McEwen, 1998). There is considerable support for this fourth model and especially the importance of stress to the SES-health gradient (e.g., Almeida, Neupert, Banks, & Serido, 2005). Yoshikawa, Aber, and Beardslee (2012), for example, recently concluded that the evidence in support of the social causation of psychopathology supports the causal role for poverty. This evidence stands up against a variety of potential threats to validity. These authors emphasized the importance of a wide variety of mechanisms that transmit poverty's negative effects, which is consistent with the fact of poverty's long reach to almost every form of psychopathology in existence.

Using a multigenerational approach to understanding causation and selection perspectives, Conger, Conger, and Martin (2010) essentially found evidence that both are in operation, but at different points in development. Research guided by their interactionist perspective, for example, has demonstrated that characteristics of the individual prior to adulthood predict adult SES and family processes, consistent with the selection proposition, and that those social and economic family characteristics predict the functioning of the next generation, consistent with social causation. Adler, Bush, and Pantell (2012) similarly reviewed the evidence relevant to social causation and selection, concluding that "there is little doubt that low SES and its accompanying social disadvantages affect health" (p. 5). They also noted that health can affect SES, and therefore the relationship between the two is dynamic, and that efforts to improve SES, for example, will likely result in health improvements, and vice versa. Thus, current thinking on the causality issue presents a more nuanced view and draws on modern genetically informative designs and advances in neuroscience to showcase the power of the socioeconomic environment in shaping brain structures and physiologic and psychological processes related to a wide array of mental and physical health problems. We review some of the neuroscience work on SES and the brain in the section titled "Mediators and Moderators of Poverty's Effects on Psychopathology."

Current theory and research on dynamic systems models and concepts such as experiential canalization have the potential to further clarify the directionality of effects issue. For example, the experiential canalization model (Blair & Raver, 2012) proposes that as a child develops, he or she encounters a multitude of forks in the road. The pathways available to a particular child at a certain point in time are determined by both past development and current circumstances. Some circumstances promote or create a variety of pathways that lead to further growth and positive development, whereas other circumstances constrain the number of positive pathways and present more pathways with nonoptimal outcomes. This type of interactive model is not new. What is new is the idea that once a pathway is taken, the other options can become closed off, for better or worse, and subsequent forks are dependent on the previous "selected" pathway. Such models were developed in part to explain neural plasticity and the fact that some neural development will not occur for children who do not encounter the full range of pathways at a given juncture. Taking seriously the need to consider behavior at multiple levels of analysis, these models are also useful for considering how poverty may constrain positive development in some areas or amplify negative development in others. It is in this way that the expression of genes can be environmentally determined—some circumstances prevent the protein synthesis necessary to express a particular gene or the reverse (see "Future Directions" section for further discussion on genetic aspects of poverty and child psychopathology). We believe that it is in this way that poverty lays the groundwork for maladaptive pathways from developmental forks in the road, which shape a child's life pathway, neural and otherwise.

POVERTY AND PSYCHOPATHOLOGY

That poverty places children at risk for negative life outcomes is not a new idea. The first wave of psychological scholarship on the topic began in the 1960s, coinciding with the War on Poverty. This research mostly focused on IQ and how to improve poor children's IQs and life chances. Research expanded to include socio-emotional outcomes in the 1980s and 1990s (Luthar, 1999). A special

issue of *Child Development* on children and poverty was published in 1994, creating the first compilation of psychological scholarship covering studies of poverty's effects on child health, contextual moderators, family mediators, and interventions. In that volume, Duncan, Brooks-Gunn, and Klebanov (1994) presented results of rigorous analyses demonstrating substantial effects of family income, neighborhood composition, and family structure in the first 5 years of life on internalizing and externalizing problems at age 5. Since that special issue publication, research on the topic of child poverty has flourished, leading to several review articles in the last few decades (e.g., Aber, Bennett, Conley, & Li, 1997; Bradley & Corwyn, 2002; Brooks-Gunn & Duncan, 1997; Evans, 2004; McLoyd, 1998). Each of these reviews focuses on slightly different sets of outcomes, but the conclusions are generally the same—poverty and income status have large effects on IQ and achievement and substantial effects on psychopathology beginning in early childhood (Bradley & Corwyn, 2002). Although genetic contributions to internalizing and externalizing pathology have gained prominence in etiologic theories in the last several decades, most research still supports that low SES, low income, and/or poverty play an important causal role (e.g., Costello et al., 2010; Odgers et al., 2012). The effects of poverty and low SES appear as both solid main effects and in interaction with inherited characteristics, such as temperament.

Internalizing

Early Childhood

Few studies have examined the relation between poverty and internalizing symptoms exclusively in early childhood. Rather, several studies have demonstrated a relationship between poverty and internalizing symptoms across a wide age range albeit without isolating rates of internalizing symptoms in early childhood. For example, Beidas et al. (2012) investigated whether youth living in disadvantaged neighborhoods reported higher levels of anxiety and comorbid depression as compared to youth ages 2 to 19 not living in distressed neighborhoods. They found that those living in disadvantaged neighborhoods reported higher levels of overall anxiety, social anxiety, and somatic anxiety symptoms and comorbid depressive symptoms. However, these findings are not specific to early childhood and thus do not provide a clear demonstration of the linkage between poverty and internalizing symptoms in early childhood.

Of the few studies that did investigate the impact of poverty on the expression of internalizing symptoms in children in early childhood, results overwhelming indicate a positive relationship between poverty and internalizing symptoms. These findings are consistent across various poverty measures. Using measures of family level poverty (i.e., individual income) and neighborhood level poverty (i.e., percentage of households with income levels within poverty range), Duncan et al. (1994) found that youth living in persistent poverty from zero to 5 years of age had higher levels of internalizing symptoms via parent report than those who never lived in poverty. Similarly, using housing status (i.e., housed versus homeless) of families with children in early childhood, Park, Fertig, and Allison (2011) found that children who have experienced homeless episode(s) had a significantly higher percentage of internalizing problem scale scores in the clinical range than youth who were low income but housed. Strohschein (2005) found that children whose family household income at time of first evaluation (approximately 4 years of age) was higher than average had, on average, lower than expected rates of depression than those whose household income was average. Strohschein argued that these results indicate that as income increases, child depression rates decrease. This conclusion coincides with previous and more recent research illustrating the negative impact of poverty on internalizing symptoms in early childhood.

Other research has indicated that experiencing persistent poverty in early childhood has short- and long-term impacts on youth, although the findings of a positive or negative impact are somewhat mixed. For example, Eamon (2000) found that both persistent and recent poverty are positively related to internalizing symptoms, such that youth whose families recently entered poverty or have been in persistent poverty report higher levels of sadness, anxiety, and dependency than their non-poor peers. Persistent poverty in early childhood has been found to have significant impact on the emergence and continuous expression of internalizing symptoms. Najman and colleagues (e.g., Najman, Clavarino, et al., 2010; Najman, Hayatbakhsh, et al., 2010) also found that multiple experiences of family poverty across early childhood (e.g., prenatal, 6 months, 5 years) significantly increased odds of anxiety and depression during later childhood. In contrast, Strohschein (2005) found that the positive relationship between poverty and depressive symptoms attenuated over time as children matured into middle childhood. These contrasting research findings indicate that while the negative impact of poverty on internalizing symptoms in childhood is firmly established, the long-term nature of this impact is less certain.

Middle Childhood

Numerous studies with school-age children have found positive relations between poverty and internalizing symptoms in both cross-sectional (e.g., Reising et al., 2013; Tracy, Zimmerman, Galea, McCauley, & Vander Stoep, 2008; Wadsworth & Santiago, 2008) and longitudinal studies (e.g., Slopen et al., 2010; Spence, Najman, Bor, O'Callaghan, & Williams, 2002; Wadsworth, Rindlaub, Hurwich-Reiss, Rienks, Bianco et al., 2013). Longitudinal studies are particularly valuable due to their ability to clarify whether poverty status and patterns of poverty predict changes in children's internalizing symptoms over time. Longitudinal studies typically examine children at two points in time (e.g., Krishnakumar & Black, 2002; & Slopen et al., 2010), but several studies assessed children at three or more time points that span developmental periods including middle childhood (Ackerman, Brown, & Izard, 2004; Spence, 2002; Wadsworth et al., 2013). For example, findings from an ethnically diverse sample of children assessed every 2 years between prekindergarten and fifth grade showed that children who were poor in third and fifth grade had higher levels of internalizing symptoms, even when controlling for initial levels of symptoms (Ackerman et al., 2004).

Studies that target school-age children vary according to their conceptualization and measurement of poverty which, in turn, influence results. Most commonly, poverty status is defined based on parent-reported family income and is calculated as an income to needs ratio (e.g., Brody, Stoneman, Flor, McCrary, Hastings et al., 1994). However, others have defined poverty status through receipt of welfare benefits (Takeuchi, Williams, & Adair, 1998), economic strain or financial pressure (Wadsworth et al., 2013), or a combination of poverty-related variables, such welfare receipt, single-parent status, education, and household overcrowding (Krishnakumar & Black, 2002). The combination of poverty-related variables measured when children were 5 years of age did not predict changes in internalizing symptoms the following year (Krishnakumar & Black), suggesting that measures of poverty that are more closely related to income are better predictors of internalizing symptoms in school-age children. Other studies have found that poverty-related stress is associated with internalizing disorder symptoms and diagnoses (Wadsworth et al., 2008) and that both welfare and the inability to meet financial obligations independently contribute to internalizing symptoms (Takeuchi et al., 1998). These findings suggest that different features of poverty make different contributions to the prediction of internalizing symptoms, and multiple features should be independently examined within the same study to further clarify these patterns.

Several studies examining the relation between poverty and internalizing children in school-age children have taken a developmental psychopathology perspective examining patterns of poverty throughout different stages in children's development (e.g., Pachter, Auinger, Palmer, & Weitzman, 2006; Slopen et al., 2010; Takeuchi et al., 1998). For example, McLeod and Shanahan (1993, 1996) found that histories of poverty in early childhood were not associated with children's internalizing symptoms at ages 4 and 5 but did predict higher trajectories of symptoms through age 10. Furthermore, these authors found that poverty history between the ages of 4 and 10 was not associated with internalizing symptoms. These findings suggest that poverty in early childhood has a latent but significant impact on the course of internalizing symptoms throughout childhood. In contrast, Spence et al., (2002) found that chronic poverty from 6 months of age through 14 years of age predicted parent- and child-reported internalizing symptoms for girls only. These two studies differed in their definitions of poverty and their age ranges, which might in part explain their discrepant findings.

The strength of the relation between poverty and internalizing symptoms also depends on how internalizing symptoms are measured. The majority of studies measuring this relation in school-age children use parent-reported questionnaires of symptoms (e.g., Pachter et al., 2006; Slopen et al., 2010). Other studies have created composite variables using parent and child reports of symptoms (e.g., Reising et al., 2013; Spence et al., 2002), teacher-reported symptoms (Ackerman et al., 2004), or mother and father reports of depressive symptoms (Brody et al., 1994). The few studies that have used diagnostic interviews have shown poverty to be related to clinical disorders and symptom severity (Costello et al., 2003; McLaughlin et al., 2012; Tracy et al., 2008). Future research in children of this developmental time frame should focus on utilizing children's self-reports, which can be reliably obtained in children as young as 8 years old (e.g., Tilghman-Osborne, Cole, & Felton, 2012; Twenge & Nolen-Hoeksema, 2002).

Adolescence

Several studies have demonstrated mixed findings for a significant relationship between neighborhood poverty and internalizing symptoms in adolescents. In their comprehensive review of the relationship of neighborhood poverty on adolescent development, McBride Murry, Berkel, Gaylord-Harden, Copeland-Linder, and Nation (2011) found some support for direct effects of neighborhood

poverty on internalizing symptoms in youth. For example, youth from low-SES families reported higher levels of depressive symptoms than youth not living within low-SES families (Wickrama & Bryant, 2003). In contrast, some research findings did not demonstrate a significant relationship between poverty and internalizing symptoms in youth. For example, in their investigation of mediating factors in the relationship between neighborhood disadvantage (as measured by indicators of neighborhood poverty) and adolescent internalizing problems, Deng and colleagues (2006) did not find that residing in a disadvantaged neighborhood was associated with reported youth internalizing symptoms. These contrasting findings suggest that the link between poverty and internalizing symptoms may be different based on level of poverty experienced by youth (neighborhood versus individual) and/or in combination with family poverty levels.

Similar to research in early childhood, length of poverty experience has a significant impact on the presentation of internalizing symptoms in youth. For example, Slopen and colleagues (2010) investigated the effects of persistent poverty on children at two time points (baseline 4 to 14 years of age and follow-up 5 to 16 years of age) and found that, at follow-up, those youth whose family reported continued food insecurity were 1.5 times more likely to experience internalizing symptoms. Other dynamic relationships between poverty and internalizing symptoms in youth have been found. Leventhal and Brooks-Gunn (2011) found that in high-poverty neighborhoods decreasing poverty was, surprisingly, associated with an increase in male internalizing problems, while in moderate-poverty neighborhoods, increasing poverty was associated with an increase in male internalizing problems. Similar effects were not found for female youth.

Externalizing

Early Childhood

Much research on psychopathology in young children has focused on behavioral and emotional dysregulation rather than psychiatric diagnoses. In numerous studies, toddler and preschooler behavior problems occur at significantly higher rates in samples of low-income children (e.g., Barker, Copeland, Maughan, Jaffee, & Uher, 2012; Dearing, McCartney, & Taylor, 2006; Yoshikawa et al., 2012). The association exists in studies using umbrella terms such as *conduct problems*, *behavior problems*, and *undercontrolled behavior* as well as studies examining more specific behaviors, such as aggression, noncompliance, hyperactivity, and oppositionality. Moilanen, Shaw, Dishion, Gardner, and Wilson (2010), for example, examined predictors of the growth of inhibitory control (protective against externalizing problems) from 2 to 4 years of age. Extreme family poverty predicted significantly slower growth in inhibitory control in this sample of 731 youngsters. Barker and colleagues (2012) found, for example, that contextual risk (e.g., poverty) during pregnancy predicted children's subsequent age 0 to 2 behavioral dysregulation (a composite of hyperactivity, conduct problems and emotional difficulties); contextual risks during the child's first 2 years of life predicted subsequent age 4 behavior dysregulation. Henninger and Luze (2013) estimated latent growth curve models of predictors of externalizing symptoms among early Head Start enrollees (ages 0–3). A primary pathway to externalizing in this population was via poverty, and the authors identified parental stress and depression as mediators of this pathway. Gershoff and colleagues (2007) examined the ability of both income and material deprivation to differentially predict social-emotional functioning in the Early Childhood Longitudinal Study sample of 21,255 kindergarteners. They found that the combination of both family income and material hardship was the strongest predictor of child competencies (a latent factor consisting of internalizing, externalizing, and social skills).

Some research has focused on the presence and stability of clinically elevated externalizing symptoms in toddlers and preschool-age children. Hill, Degnan, Calkins, and Keane (2007), for example, found low SES at age 2 to be a significant predictor of chronically elevated clinical levels of externalizing symptoms at ages 2, 4, and 5. This type of chronic course of clinically elevated externalizing symptoms, referred to as the early starter pathway, tends to occur much more frequently in low-SES families. The early starter pathway to disruptive behavior disorders is a particularly troubling pathway that portends lifelong disorder (Campbell, 1995; Hinshaw, Lahey, & Hart, 1993). Toddlers in general engage in high levels of aggressive, antisocial behaviors that tend to desist over time as they acquire better communication abilities and ways of handling conflicts and negative emotions (Coie, Dodge & Damon, 1998). There is a subgroup of children, however, that does not desist over time and rather stays elevated into middle childhood and beyond, ultimately meeting diagnostic criteria for disruptive behavior disorders such as conduct disorder. Poverty and low SES are strong predictors of membership in this early starter pathway. Keller, Spieker, and Gilchrist (2005), for example, found that an index of ecological risk, which included family economic distress and parenting stress, predicted membership in an early starter pathway of increasing conduct problems over

time at twice the rate expected by chance, specifically for children with insecure attachments.

Studies have increasingly used rigorous quasi-experimental and genetically informed designs to isolate the causal contribution of poverty and SES to the development of externalizing problems. D'Onofrio et al. (2009), for example, incorporated comparisons of target children with genetically related and unrelated children to rule out a variety of unmeasured environmental and genetic confounds in their estimates of the causal effects of income on conduct problems in children as young as age 4. These authors found strong evidence in support of the inference that family income is inversely and causally related to conduct problems, especially for boys.

Middle Childhood

Rates of diagnosed externalizing disorders rise during the school years, in part due to children's entrance to school and the increasing compliance demands. School also often creates a context in which underlying liabilities, such as ADHD, create additional problems with peers, teachers, and parents that can contribute to further behavior problems. Lansford et al. (2006) found consistent effects of low SES on the development of externalizing trajectories over time, from kindergarten to the eighth grade, in their community sample of 585 children with and without physical abuse histories. Similarly, Slopen and colleagues (2010) found robust effects of food insecurity (highly correlated with poverty) on externalizing problems of a sample of 2,810 children aged 4 to 14 followed for 1 year. Church, Jaggers, and Taylor (2012) used data from the Fragile Families Project to test a variety of predictors of child behavior problems in this at-risk sample of more than 5,000 children. Family poverty level was a robust predictor of behavior problems, even while simultaneously accounting for neighborhood SES, gender, parenting, and parental stress. Parental stress partially mediated this pathway.

Using data on 3,259 families with a total of 5,808 children from the National Longitudinal Survey of Youth, Hao and Matsueda (2006) examined the effects of concurrent poverty as well as poverty during early childhood on externalizing behavior problems in middle childhood. They found strong evidence of negative effects of early childhood poverty on subsequent externalizing symptoms, an effect that was not mediated by current parenting behaviors. Odgers and colleagues (2012) examined the differential patterning of antisocial behavior by SES level over time in a large, nationally representative British birth cohort of 2,232 children followed from age 5 to 12. They found that rates of antisocial behavior did indeed show a patterning by SES, such that children in the "deprived" SES group had significantly higher rates of antisocial behavior than did middle-SES children, who in turn had significantly higher rates than high-SES children. These disparities persisted from age 5 to age 12 and widened over time, such that the mean difference in levels of antisocial behavior between the deprived and more affluent SES groups increased from $d = 0.38$ at age 5 to 0.51 at age 12. Odgers and colleagues also found that supportive parenting mediated the relationship between both neighborhood and family-level SES and child antisocial behavior.

Finally, Cote, Vaillancourt, LeBlanc, Nagin, and Tremblay (2006) followed 10 cohorts of children for 6 years and examined trajectories of physical aggression over the period from 2 to 11 years of age. They identified three subgroups of children, two of which exemplified a typical developmental pattern of infrequent and declining physical aggression over time. The third group of children contained mostly boys from disadvantaged families and these boys exhibited an atypical developmental pattern consisting of more frequent and stable use of physical aggression.

Adolescence

The effects of adverse environmental circumstances on the development of adolescent disruptive behavior problems are undeniable (Moffitt, 2005; Paschall & Hubbard, 1998; Thornberry, Freeman-Gallant, Lizotte, Krohn, & Smith, 2003; Wiesner & Windle, 2004). Several studies have followed children from infancy or toddlerhood into adolescence. Such studies provide strong support for causal linkages between SES and externalizing pathology. Schonberg and Shaw (2007) examined early childhood predictors of trajectories of conduct problems into early adolescence, finding that children who experienced stable poverty in early childhood were at significantly elevated risk for being classified in a chronic conduct problems group as compared to children who did not experience poverty or who experienced only temporary poverty. Fanti and Heinrich (2010) found high levels of sociodemographic risk (low maternal education, low income) predicted high and continuing levels of conduct problems in the National Institute of Child Health and Human Development (NICHD) Study of Early Childcare sample of 1,364 children followed from age 2 to age 12. Dearing and colleagues used this same data set to examine within-child associations between family income and externalizing symptoms. They also found large main effects of chronic poverty and smaller effects of income on externalizing symptoms, but, importantly, chronic poverty and income interacted such that chronic poverty amplified the effects of low income

on externalizing (Dearing et al., 2006). Finally, Stroschein (2005) used the National Longitudinal Study of Youth, Child Supplement, sample of 7,143 children age 4 to 14 to examine the dynamic effects of income and income changes over time on children's antisocial behavior. Her analyses showed that low income at entry into the study was associated with both initially high levels of antisocial behavior and with increasing levels and rates of change in antisocial behavior over time. Additionally, increases in income were associated with decreasing antisocial behavior and vice versa.

Bøe, Øverland, Lundervold, and Hysing (2012) examined the effects of several different indicators of SES in predicting externalizing disorders in a large sample of 11- to 13-year-olds (N = 5,781), and found that each of their SES indicators consistently predicted externalizing disorders. Analyses of data from the Mater-University Study of Pregnancy on 3,103 children followed from birth to age 21 revealed very strong effects of poverty on persistent aggressive and delinquent behavior (Najman, Clavarino, McGee, Bor, et al., 2010). Family poverty experienced at the 14-year follow-up, for example, predicted persistent aggression, delinquent behavior, smoking, and alcohol use at the 21-year follow-up. Additionally, the largest effects were found for children with recurrent experiences of family poverty. Children who were classified at three or four of the five assessments as living in poverty were more than twice as likely to be aggressive and delinquent at both 14 and 21 years. A compelling new study by Boyce and colleagues recently examined rates of physical and mental health problems using several different types of indicators of SES (Nuru-Jeter, Sarsour, Jutte, & Boyce, 2010). By every metric examined, externalizing problems were inversely associated with SES. A unique feature and finding of this study is that associations involving categorical representations of SES were much more pervasive and stronger in magnitude than were measures capturing monotonic gradations in SES. The authors suggested that the standard use of income and maternal education in research probing the SES-health phenomenon may be underestimating the strengths of the SES-health association by using these "less impactful" measures.

The effects of low SES and poverty have also been examined among particular high-risk groups of children. In their study of children of depressed parents, for example, Reising and colleagues (2013) found that economic disadvantage predicted externalizing symptoms, even among this at-risk group. Disrupted parenting was a significant moderator of this effect. In Kjellstrand and Eddy's (2011) study, children of incarcerated parents had consistently higher levels of problem behavior between fifth and tenth grade than children without an incarcerated parent. The strength of this association increased over time.

A growing number of studies have documented that poverty or disadvantage at the neighborhood level is also strongly associated with the development of aggression, violence, and delinquency in adolescents (e.g., McBride-Murry et al., 2011). Exposure to deviant peers and lack of collective efficacy have been offered as potential mechanisms of this effect (e.g., Haynie, Silver, & Teasdale, 2006), and gender sometimes is found to moderate these effects (e.g., Kroneman, Loeber, & Hipwell, 2004). Harrington (2003) used behavioral genetic methods to estimate genetic and environmental contributors to aggression and delinquency in the Add Health project sample of 2,434 sibling pairs of children. First, they found that aggression and delinquency were significantly higher in disadvantaged neighborhoods than in advantaged neighborhoods. In addition, they found significant shared environmental effects on aggression and delinquency, but only in the disadvantaged neighborhood context, "providing general support for the idea that disadvantaged neighborhood contexts directly affect developmental influences on adolescent aggression" (p. 233). Karriker-Jaffe, Foshee, Ennett, and Suchindran (2009) found that both neighborhood disadvantage and social disorganization predicted adolescent aggression trajectories over 2.5 years for boys, whereas only neighborhood disadvantage predicted aggression for girls.

MEDIATORS AND MODERATORS OF POVERTY'S EFFECTS ON PSYCHOPATHOLOGY

In this section of the chapter, we describe other constructs, such as stress and coping, that likely play a role in the relations between childhood deprivation and mental health. Much of the work has focused on underlying pathways or mediators that help account for the robust SES–childhood pathology link. Three predominant examples of mediators of the SES–psychopathology link in children are disrupted parenting, elevated stress, and alterations in executive functioning. Other constructs factor in as moderators or variables that alter children's vulnerability to deprivation. Gender, ethnicity, and coping strategies are the three most studied moderators of the relations between SES and children's mental health. There are even a few rare instances of moderated mediation whereby the underlying pathway linking SES to child psychopathology is moderated by some other variable. For example, we show

that a major pathway linking SES to psychopathology is parenting problems created and exacerbated by chronic poverty-related stress. The dynamics of this pathway can be altered by social support. In the "Future Directions" portion of this chapter, we outline some other mediating constructs warranting attention in investigations of SES and child psychopathology.

SES and Parenting

Low-SES parents tend to be harsher and less responsive to their children—theoretical and empirical models have suggested that these parenting problems do not necessarily reflect underlying parenting deficits (though they may in some cases) but rather that the stress and chaos of life in poverty interferes with the ability to deliver warm, responsive parenting (Conger, Conger, & Martin, 2010). These features of parenting are strongly and consistently related to concurrent and future mental health problems in children (Bradley, 2003; Repetti, Taylor, & Seeman, 2002). A large number of studies support that stress, especially economic strain and family conflict, accounts for the association between SES and parenting, as illustrated in Figure 4.1. Beginning with early work examining the role of financial difficulties during the Great Depression and child development (Elder, 1974), considerable research has uncovered support for this model. Rand Conger and colleagues, including Elder (Conger & Elder, 1994), have extended this model, suggesting that financial strains related to insufficient income for families leads to emotional distress in parents as well as interparental discord, both of which lead to more negative parenting (Conger & Donnellan, 2007).

Evidence supporting the model depicted in Figure 4.1 is impressive, including both cross-sectional and longitudinal data that cut across ethnic samples within the United States and across different countries (for reviews, see Bradley, 2003; Conger & Donnellan, 2007; Grant et al., 2003; Hoff, Laursen & Tardif, 2002; Magnuson & Duncan, 2002b). There is also a small amount of experimental research showing that supplements to family income can lead to increased parental warmth and responsiveness (Costello et al., 2003; Gennetian & Miller, 2002; Morris, Duncan, & Clark-Kauffman, 2005), presumably via reductions in poverty-related stress.

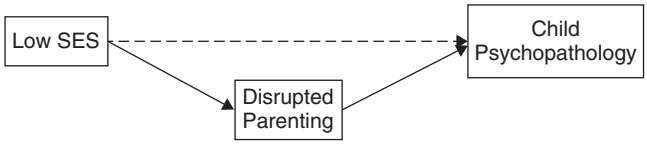

Figure 4.1 Conceptual model of SES and parenting.

In a meta-analysis of nearly 50 studies on family SES, parenting, and youth development, Grant and colleagues (2003) found an overall effect size of poverty on negative parenting of $d = .48$ (cross-sectional evidence) and $d = .55$ (longitudinal evidence). Analyses indicated that poverty had both direct and indirect effects on both internalizing and externalizing symptoms in children and youth. Grant et al.'s conclusion that a partial mediation model is the best fit to the data is in line with findings reviewed later that low-SES environments have direct effects on children. Furthermore, it is likely that the effects of a low-SES childhood are due to the accumulation of exposure to multiple risk factors. In terms of Figure 4.1, there is good evidence of additional, parallel mediating factors, which operate similarly to negative parenting, that are also capable of accounting for some of the ill effects of poverty on children's mental health.

A critical risk factor for negative mental health outcomes in children is maternal depression (Downey & Coyne, 1990; Green et al., 2010; see also Chapter on Depression/Mood Disorders. in this handbook). Low-income adults, especially women, have higher rates of depression (Belle, 1990; Green et al., 2010). Given abundant documentation that depressed maternal affect and poverty are both linked to diminished parental responsiveness, more work needs to be done on the potential critical role of parental mental health and particularly maternal depression in the relations between childhood poverty and children's development (Shonkoff & Garner, 2012). Across several studies, parents experiencing greater financial strain suffer greater emotional distress, including symptoms of depression, with a median path coefficient of .42 (Conger & Donnellan, 2007). In an interesting set of results, Harnish and colleagues (1995) showed that the inverse link between SES and externalizing symptoms in first graders was mediated by maternal responsiveness and warmth. Much of the negative covariation between SES and parenting was caused by elevated maternal depression. Among a sample of younger children (28–50 months), the adverse impacts of SES on behavioral adjustment were accentuated for those whose mothers were more depressed (Petterson & Albers, 2001).

This model of SES, parenting, and children's mental health is also robust with respect to ethnicity (Conger & Donnellan, 2007; Eccles & Gootman, 2002) and gender (Grant et al., 2007), although some research suggests enhanced benefits of warm parenting for ethnic minority children. Bradley and colleagues (2001), for example,

showed that the link between poverty and less nurturant parenting was stronger in African American families vis-à-vis white or Hispanic families in a large, nationally representative data set. Of additional interest, a Canadian national cohort study indicates that children (ages 4–11) in recent immigrant families may experience some protection, particularly for externalization symptoms, because of more positive parenting practices (Georgiades, Boyle, & Duku, 2007).

There also does not appear to be any clear pattern for ethnic variation in the direct effects of SES or income levels on psychopathology in children. In a 4-year longitudinal study of children in grades 2 through 4, Bolger, Patterson, Thompson, and Kupersmidt (1995) at the onset found that African American children manifested more internalizing symptoms as a function of persistent poverty whereas White children showed more externalizing symptoms. Costello, Keeler, and Arnold (2001) showed a stronger link between poverty and psychopathology among White relative to African American school children. An index of cumulative risk that incorporated family and neighborhood poverty along with several other risk factors that co-occur with poverty was also more strongly associated with internalizing and externalizing symptoms among White relative to African American children (Gerard & Buehler, 2004). Among young adolescents, however, Nuru-Jeter and colleagues (2010) found the opposite pattern for externalizing symptoms with stronger income effects on African American youth.

Furthermore, some studies suggest that chronic poverty may have more pronounced effects among boys than girls because of harsher parenting (Bolger et al., 1995; Grant et al., 2007). Elder, vanNguyen, and Caspi (1985) also found the impacts of economic hardship were conditioned by the gender composition of the parent-child dyad. But overall, the degree of fit for the model depicted in Figure 4.1 across gender is high. Turning to gender as a moderator of the direct effects of SES on psychopathology, again the data generally indicate weak or contradictory findings. In their longitudinal study of poverty duration and psychopathology in a sample of grade-school children, Bolger and colleagues (1995) found no effects of poverty by gender for internalizing symptoms, but boys were more vulnerable for externalizing symptoms. Henninger and Luze (2013) found the opposite effect among children with girls showing greater externalizing symptoms in relation to time spent in poverty. In a sample of Australian youth followed from birth through adolescence, girls, but not boys, with early childhood exposure to poverty manifested more internalizing symptoms (Spence et al., 2002). In a longitudinal study spanning age 9 to 17, Evans and colleagues (Evans & English, 2002; Evans, Gonnella, Marcynyszyn, Gentile, & Salpekar, 2005) found no evidence of gender differences across a wide range of physiological stress, self- and parental ratings of children's mental health, and in behavioral probes of psychological health. Roosa et al. (2005) as well as Mrug and Windle (2009) found no gender differences in children's internalizing or externalizing responses to neighborhood poverty. Similarly, Nuru-Jeter and colleagues (2010) found no gender differences in young adolescents' externalizing responses to family income.

Summarizing, the studies on SES, parenting, and psychopathology indicate clear and consistent support for the pathway depicted in Figure 4.1. This robust pathway holds across gender and ethnicity and has been replicated several times internationally. The direct effect of SES or income on psychopathology also tends to be robust with no clear pattern emerging for variable vulnerability as a function of either ethnicity or gender. This is not to argue that these factors are unimportant in thinking about poverty and children and youth's mental health. Our point is simply that the SES → Problematic Parenting → Mental Health model is strong and well documented. At present, we do not have clear-cut indications of whether this pathway varies by gender or ethnicity. The preponderance of current data suggests that the effects of poverty or low SES early in life on children and later on adolescents appear to be similar across race and gender.

A few studies suggest that high levels of social support may buffer the ill effects of poverty on parenting (Conger & Elder, 1994; Hashima & Amato, 1994; McLoyd, 1997). Greater religiosity may have similar protective effects (Brody, Stoneman & Flor, 1996; Grant et al., 2000). Although social support and religiosity may buffer some of the ill effects of poverty on parenting, chaos can have the opposite effect. Chaos is a composite index reflecting noise, crowding, interruptions, routines, and structure in the household. Chaotic household conditions accentuated the effects of negative parenting on preschool and elementary school children's problem behaviors (Coldwell, Pike, & Dunn, 2006). The negative impact of chaos on the executive functioning of preschool mothers was exacerbated by multiple risk factors associated with poverty (Deater-Deckard, Chen, Wang, & Bell, 2012). Thus, it is also worth thinking about not only the direct effects of low SES conditions on parents which, in turn, can alter critical parenting behaviors such as warmth and responsiveness, but also factors that might undermine parental resources. Some of the conditions that covary with poverty

and deprivation, such as chaotic living situations, lower levels of social support, or food insecurity, likely also erode parental coping resources, which in turn could alter important parent-child interactions as well as the overall social climate of the family.

SES and Stress

In addition to the work reviewed earlier on SES, parenting, and children's psychopathology, multiple methodological probes indicate that children themselves experience poverty as a stressful condition. Children in low-SES households report high levels of poverty-related stress, including such things as financial pressure, family conflict, family disruption and change, discrimination, and violence (Wadsworth & Berger, 2006; Wadsworth & Compas, 2002; Wadsworth &t Achenbach, 2005; Wadsworth et al., 2008; Santiago et al., 2011; Wolff, Santiago, & Wadsworth, 2009). Many studies revealed that among low-SES children, those experiencing greater poverty-related stress also had higher symptoms of internalizing and externalizing. Moreover, Santiago and colleagues (2011) found that poverty-related stress within a low-SES sample also interacted with prior mental health symptoms, aggravating their severity over time. Wolff and colleagues (2009) also showed in a prospective, longitudinal design that the impacts of poverty-related stress on adolescent mental health symptoms were more severe for those individuals with greater reactivity to stress.

The descriptive data on high levels of poverty-related stress among children and youth from low-SES households matches comparative data contrasting low-SES children relative to middle-SES children. In comparison to their middle-SES peers, low-SES children and youth are exposed to substantially more psychosocial stressors, such as family conflict and turmoil, changes in family composition, violence, parental harshness and low responsiveness (Attar, Guerra, & Tolan, 1994; Bendersky & Lewis, 1994; Brooks-Gunn, Klebanov, & Liaw, 1995; Brown, Cowen, Hightower, & Lotyczewski, 1986; DuBois, Felner, Meares, & Krier, 1994; Dubow, Tisak, Casey, Hryshko, & Reid, 1991; McLoyd, 1998; Pungello, Kupersmidt, Burchinal, & Patterson, 1996) as well as to worse physical conditions capable of producing stress, such as toxins, noise, crowding, and substandard housing (Evans, 2004). One aspect of the settings of low-SES children and youth that appears to be especially problematic is elevated exposure to multiple stressors or cumulative risk factors. A large literature documents that exposure to cumulative risk factors relative to singular ones, leads to worse developmental outcomes, including psychopathology, physiological stress, and poorer cognitive development (Evans, Li, & Whipple, 2013; Obradovic, Shaffer, & Masten, 2012; Sameroff, 2006). Children from low-income households from birth through late adolescence are much more likely to be exposed to a high number of cumulative risk factors (Burchinal, Roberts, Hooper, & Zeisel, 2000; Deater-Deckard, Dodge, Bates, & Pettit, 1998; Evans & English, 2002; Evans & Kim, 2007, 2010; Federman et al., 1996; Felner et al., 1995; Greenberg, Lengua, Coie, & Pinderhughes, 1999; Liaw & Brooks-Gunn, 1994; Rutter, 1979). They are also more likely to be exposed to chaotic living conditions indicative of a low degree of structure, stability, routine, and predictability in daily life (Evans, Eckenrode, & Marcynyszyn, 2010). Considerable work has linked high levels of family chaos with deficits in socioemotional development in children and youth (Fiese, 2006; Fiese & Winter, 2010).

An important, emerging area of research on SES and health focuses on physiological indices of chronic stress as candidate mechanisms to account for well-documented SES gradients in health in both children and adults (Adler & Stewart, 2010; Braveman et al., 2011). This research is too voluminous to describe in detail so we summarize major findings from overviews of this work. Prior to adolescence, lower SES is associated with higher blood pressure (Chen, Matthews, & Boyce, 2002; Evans et al., 2012). A number of studies also reveal that childhood SES is inversely related to stress hormones in children, including cortisol, epinephrine, and norepinephrine; metabolic impairments, such as inefficient glucose metabolism, higher levels of cholesterol and low-density lipids; as well as elevated inflammatory responses indicative of disturbed immune function (Evans et al., 2012). Allostatic load, a marker of dysregulation across multiple response systems (i.e., hypothalamic-pituitary-adrenal axis, sympathetic adrenal medullary axis, metabolic function, inflammation, and immune function) is an exciting direction because of encouraging evidence that this marker of wear and tear on the body is a better predictor of physical and psychological morbidity than singular stress markers (Ganzel, Morris & Wethington, 2010; Juster et al., 2011; McEwen, 1998). Children from lower-SES backgrounds have higher levels of allostatic load (Evans et al., 2012).

Summarizing, there is abundant evidence that household SES is inversely related to both psychosocial and physical stressor exposures. One feature of this inequality that may be particularly important for children's mental health is exposure to the accumulation of multiple stressors or risk factors. Low-SES children and youth are much

more likely to encounter a plethora of risk factors, both psychosocial (e.g., family turmoil, negative parenting) and physical (e.g., substandard housing, toxins), in comparison to their more advantaged peers. Finally, low-SES children manifest a consistent pattern of elevated, chronic physiological stress relative to middle-SES children.

Although there is emerging work showing that chronic stress accompanying a low-SES childhood may help explain the etiology of physical morbidity later on in life (Evans et al., 2012; Evans & Kim, 2010), very little research has directly examined SES → Stress → Mental Health pathways. In a large, nationally representative sample of American kindergarten children, negative associations between household income and both cognitive skills and socio-emotional competency were partially mediated by a composite index of exposure to material hardship (Gershoff et al., 2007). (Material hardship incorporated measures of food insecurity, residential instability, inadequate medical care, and duration of financial difficulties since the child's birth.) Furthermore, the pattern of findings was similar across White, African American, and Hispanic kindergartners (Raver, Gershoff, & Aber, 2007). Higher levels of cumulative risk exposure mediated much of the relation between poverty in elementary-age school children and both elevated physiological stress and psychological distress (Evans & English, 2002). Cumulative risk consisted of an index of substandard housing, residential noise, residential crowding, family turmoil, child separation from family, and exposure to violence. Chaotic living conditions among middle school children partially mediated the link between childhood poverty and elevated symptoms of internalizing and externalizing (Evans et al., 2005). Felner and colleagues (1995) showed that the inverse relation between SES and multiple measures of internalizing symptoms among middle school children was mediated by stressful events, family supportive climate, and school belonging. Similarly, eighth-grade students from lower-SES families have higher rates of substance abuse (Wills, McNamara, & Vaccaro, 1995). This finding was mediated, in part, by a composite index of multiple risk exposures (e.g., low parental support, high negative life events, deficient youth competency, and contact with peer substance abusers). In a large sample of early adolescents, Amone-P'Olak and associates (2009) noted that the inverse relations between SES and both internalizing and externalizing symptoms were mediated by exposure to negative life events outside the personal control of adolescents (e.g., housing and neighborhood problems, serious illness/injury to family members). Sameroff, Bartko, Baldwin, Baldwin, and Seifer (1998) formed a composite index of adolescent adjustment incorporating internalizing, externalizing, extracurricular/community involvement, and academic performance that was negatively correlated to family income. This significant association, however, was reduced to near zero when exposure to cumulative risk factors was included in the model. A large number of cumulative risks across the domains of maternal competence, parenting, family structure, family social networks, peer deviance exposure, and neighborhood social capital were incorporated into their model of cumulative risk exposure. African American adolescents (ninth and eleventh grade) from poorer families experienced higher levels of depression (Hammack, Robinson, et al., 2004). For girls but not boys, these relations were mediated by higher levels of family stress (e.g., unmarried family member pregnancy, close family relative died). Finally, we also know that cumulative risk exposure appears to be an important factor underlying the robust relations between childhood deprivation and many of the indicators of chronic physiological stress already outlined (e.g., elevated blood pressure, stress hormones, allostatic load) (Evans & Kim, 2010, 2012). One study that found a different pattern of results among SES, stress, and psychological health among children was conducted by DuBois and colleagues (1994). They found a synergistic interaction between the degree of disadvantage among adolescents and exposure to daily hassles on indices of both internalizing and externalizing symptoms in a prospective, longitudinal design over the academic year among seventh and eighth graders. One possible explanation for this pattern of moderation rather than mediation indicated by the majority of studies mentioned could be the index of daily hassles used by DuBois and colleagues. They summed the ratings of hassle severity to form a composite score. This method contrasts with other studies that relied on risk exposure metrics.

SES, Executive Functioning, and Coping

Given evidence that SES is associated with levels of stress in children, there are at least three reasons also to explore executive functioning and coping as mechanisms that may contribute to the relations between SES and psychopathology. First, considerable work shows that chronic stress, in both animal and human models, is capable of damaging executive functioning (EF) (Blair, 2010; Lupien, McEwen, Gunnar, & Heim, 2009; Repetti et al., 2002). EF is a complex construct that typically encompasses self-regulation, attentional control, working memory, behavioral inhibition, delay of gratification, and planning. EF is believed to lay the early foundation that undergirds subsequent

development and maintenance of coping strategies invoked when stressors are encountered, and it increasingly plays an important role in theory and research regarding the development of various types of psychopathology (Hofer, Eisenberg, & Reiser, 2010; Rinsky & Hinshaw, 2011). In the next study descriptions, we provide thumbnail sketches of EF measures in order to convey a better sense of what processes actually are involved. The second reason why EF and coping are likely related to childhood SES is because many of the risks encountered early in life among low-SES children are chaotic and largely uncontrollable, both critical conditions that can undermine the development of coping skills (Evans & Kim, 2013; Lengua, 2012; Raver, 2004; Repetti et al., 2002; Wolff et al., 2011). Third, a large body of literature in the stress field indicates that coping strategies can moderate experiences of stress in children and adolescents (Aldwin, 2007). Thus, we would expect that how children cope with poverty and some of its accompanying risk factors has implications for mental health outcomes.

A standard approach to the assessment of EF is to use neurocognitive testing batteries with well-characterized brain correlates in the prefrontal cortex. In a program of research on childhood SES and neurocognitive development, Noble, Farah, and their colleagues uncovered consistent evidence of EF deficiencies among low- compared to middle-SES children ranging from 5 to 13 years of age (Farah et al., 2006; Noble et al., 2005; 2007). EF was assessed by standard neurocognitive batteries including measures of inhibitory control such as reaction time on the number Stroop task (say the number shown ["2"] or say the quantity of numbers shown [e.g., four "2s" are shown in a square, correct answer "4"]), and the flanker task, which measures reaction time to indicate what direction a stimulus (e.g., arrow) is pointing in when surrounded by adjacent stimuli pointing in the same or in opposite directions. They also found deficits in working memory. Utilizing an EF composite consisting of (1) working memory, (2) the classical Stroop task (say the color of ink a color word is written in), and (3) an index of planning, Hughes, Ensor, Wilson, and Graham (2010) found that family income was negatively associated with EF among 3.5-year-olds, but it did not influence their rate of improvement from toddlerhood to 6 years of age. Mezzacappa (2004) also found that 4- to 7-year-olds performed worse on the flanker task if they were from lower-SES families. Three- to 5-year-olds from lower-SES backgrounds manifested worse EF on two Stroop-like measures adapted for preschool children (Li-Grining, 2007). Raver, Blair, and colleagues (2013), utilizing a composite EF battery (working memory, attention control, inhibitory control) at 48 months of age, showed that the number of times families had incomes at or below the poverty line in the 3 previous years predicted EF among 4-year-olds. They also found that a parallel index of perceived financial strain had similar prospective association with EF, but in the latter case, the association between financial strain and EF was moderated by an index of infant emotional reactivity. Only infants high in emotional reactivity showed the expected negative association of early experiences of deprivation and EF deficits.

Five- to 14-year-old children from Colombia and Mexico performed a standard index of attentional control in which they had to classify visual stimuli according to varying dimensions (e.g., shape, color, number). Children from lower-SES households had more difficulty with the task (Ardila, Rosselli, Matute, & Guajardo, 2005). Similarly, Lipina, Martelli, Vuelta, and Colombo (2005) found that 6- to 14-month-old infants from lower-SES families were less skilled in an attentional control task in which they had to search for a hidden object either where it was originally placed or after it had been placed in a new location. This task pulls for both working memory and attentional control. Five- to 6-year-olds from low-income families had greater difficulty resisting an interesting visual distractor while sustaining performance on a visual attention task (Howse, Lange, Farran, & Boyles, 2003). Recently a team of investigators examined how EF developed throughout preschool and kindergarten in relation to income (Wanless, McClelland, Tominey, & Acock, 2011). At the initial evaluation, low-income 4- and 5-year-olds had more difficulty in a response inhibition task (Simon says), but, interestingly, these same children gained more inhibitory skills throughout the second half of their prekindergarten year on through kindergarten. Low-income children whose first language was not English, however, did not manifest this more rapid gain in inhibitory skills. It is also worth noting that despite the more rapid gains overall among the low-income preschoolers and kindergartners, their EF skills did not catch up to those of their more affluent peers by the end of kindergarten. Utilizing maternal ratings of inhibitory control (e.g., "Can easily stop an activity when s/he is told no."), the EF skills of 2- to 3-year-olds were unrelated to family poverty, but the maturation of EF skills over a 2-year period was slower for poor than nonpoor toddlers (Moilanen et al., 2009).

A few studies have looked directly at the possible role of stressor exposure in the linkage between SES and EF. In a series of studies, Evans and colleagues have shown that

poverty is related both cross-sectionally and longitudinally with deficits in the ability to delay gratification in toddlers (Evans & Rosenbaum, 2008) and in 9-year-olds (Evans & English, 2002) as well as teacher ratings of elementary school children's self-regulatory abilities in the classroom (Evans et al., 2005). The latter two studies also found that the poverty–delay of gratification link was mediated in part by cumulative risk exposure and chaotic living conditions, respectively. On a different measure among a sample of low-income preschool children, Li-Grining (2007), however, found no relation between SES and of delayed gratification. Evans and Schamberg (2009) showed that the prospective relation between early childhood poverty and working memory in young adults was mediated by elevated levels of allostatic load during childhood. Employing an EF battery consisting of working memory, inhibitory control, and attentional control tasks, Blair and colleagues (2011) showed that poverty early in life (7–24 months) is related prospectively to worse EF skills at 3 years of age. Moreover, this relation was partially mediated by elevated cortisol levels during the same period of poverty. Recently, Sarsour and colleagues (2011) uncovered evidence that negative relations between family SES and 8- to 12-year-olds' performance on indices of working memory were partially mediated by cognitive enrichment in the home whereas Stroop performance was mediated by parental responsiveness and family companionship. Finally, Doan, Fuller-Rowell, and Evans (2012) examined in a prospective, longitudinal design an index of cumulative risk that included multiple factors, such as poverty, single-parent status, high school dropout, family turmoil, and violence in relation to internalizing and externalizing symptoms in late adolescents (16- to 18-year-olds). The adverse effects of cumulative risk on externalizing but not internalizing symptoms were mediated by a multimethodological index of self-regulation. Higher risk led to lower self-regulation skills, which, in turn, led to more behavioral conduct problems.

Limited data suggest that links between SES and adverse developmental outcomes, including psychological distress and behavioral conduct disorders, may be explained, in part, by EF deficits. Examining heterogeneity in self-regulation skills, which includes both EF and emotion regulation, Garner and Spears (2000) found that more positive family expression of emotion along with parental consistency of discipline predicted better emotion regulation skills among low-income preschool children in their nursery school setting. Observers evaluated use of emotion regulation strategies, such as revenge, venting, or expression of dislike toward another child in response to anger and sadness. In a program of research on low- and working-class African American families in rural Georgia, Brody and his colleagues (e.g., Brody et al., 2006; 2013) were the first group to explore the potential role of EF and coping in children's mental health in relation to early deprivation. Household income among 9- to 12-year-olds in one sample was positively related to a standard index of children's self-regulatory abilities that largely tapped their planfulness and ability to reflect ("thinks ahead of time about the consequences of his or her actions"). Parents and teachers filled out this self-regulatory rating scale. Self-regulatory abilities, in turn, mediated adverse impacts of poverty on both internalizing and externalizing symptoms. Using similar measures, Brody and Flor (1997) showed that parents' perceived financial strain among the households of 6- to 9-year-old African American children was also associated with worse self-regulatory skills. As in the previous study, deficits in self-regulatory skill mediated the link between deprivation and psychological well-being. In a second study focused on 7- to 15-year-old, low-income African American children living in single-parent families, Brody, Dorsey, Forehand, and Armistead (2002) replicated their earlier study plus found that more positive classroom processes, such as higher organization, better rule clarity, and high student involvement, along with more positive parenting processes, contributed to better self-regulatory skills, which, in turn, led to better child adjustment. Sektnan, McClelland, Acock, and Morrison (2010) found that parental ratings of self-regulatory behaviors (staying focused and on task plus ability to inhibit inappropriate responses during tasks) in their child at 54 months along with similar teacher ratings in kindergarten were significantly related to both family income and maternal educational attainment. The adverse impacts of low maternal education and low family income on math, reading, and vocabulary scores in first grade were partially mediated by self-regulatory behavior ratings at both developmental periods. More recently Crook and Evans (2014) have shown in a large heterogeneous, national sample that poverty during infancy predicts subsequent deficits in a planning task among preschool children. The Tower of Hanoi planning task requires participants to rearrange wooden rings onto a series of vertical poles from the ring that is smallest in diameter at the top to the ring that is largest diameter on the bottom of each pole. Only one ring at a time can be transferred from one pole to another. Performance on this planning task, in turn, was linked in a prospective, longitudinal analysis to fifth-grade math and reading standardized test scores. IQ was statistically controlled throughout.

A smaller number of studies show that enhanced EF can serve as a resource enabling low-SES children to have better mental health outcomes than might otherwise be expected. Lengua, Bush, Long, Kovacs, and Trancik (2008) showed that the adverse mental health sequelae of poverty among third to fifth graders were attenuated among children with better attentional control. The EF index consisted of a composite of two different behavioral assessments of EF: the Stroop task and a Simon-says task, where the rules are periodically reversed. In a similar study, Veenstra, Lindenberg, Oldehinkel, DeWinter, and Ormel (2006) found that preadolescents from low-SES backgrounds engaged in more antisocial behaviors. This well-documented relation, however, was significantly attenuated among those with high effortful control, based on a parental rating scale. Buckner and colleagues (2003) were interested in whether resilience among low-income children and youth (8–17 years) would be influenced, in part, by better EF skills. They used a Q sort rating conducted by highly trained clinicians who were quite familiar with each participant in order to quantify EF (e.g., "Is attentive and able to concentrate"). Resilience was defined in terms of good mental health, academic performance, and overall competency as assessed on a series of standard instruments. Low-income youth who were resilient had significantly higher EF scores. Furthermore, higher EF scores predicted subsequent socio-emotional and academic outcomes over a 2-year period (Buckner, Mezzacappa, & Beardslee, 2009).

Low- relative to middle-SES children tend to have compromised EF—EF is a fundamental resource that aids in the regulation and management of stress. The direct, adverse impacts of chronic stress related to impoverished environments likely account for some of the covariation between SES and EF. A few studies also suggest that EF itself can mediate some of the mental health sequelae of childhood poverty. For older children, EF may function more commonly as a moderator, providing some modicum of protection against the ill effects of deprivation on children's mental health.

Just as self-regulatory skills can help us understand some of ways in which a low-SES childhood can lead to psychopathology, there is also evidence showing that coping strategies can alter the impacts of low SES on mental health outcomes. One noticeable omission in the SES and coping research is a paucity of research comparing coping strategies between low- and higher-SES children or youth. Neuendorf, Kim, and Evans (2009) found in two different studies that low- relative to middle-income adolescents (age 16–18) were more likely to rely on disengagement coping strategies, such as denial and avoidance, rather than on engagement coping strategies, like problem solving or marshaling social support, when dealing with an important, recent stressor in their life. Most coping and SES studies have examined linkages between different coping strategies and psychological health within low-SES samples. A smaller number of researchers have also investigated whether coping strategies help explain the relation between poverty-related stress and mental health outcomes.

Low-income children in fourth and sixth grade, who are more resilient in terms of good behavioral adjustment evidenced more effective interpersonal problem-solving skills and relied more on positive coping skills, such as self-reliance and support seeking, relative to their nonresilient peers (Parker, Cowen, Work, & Wyman, 1990). Tolan, Gorman-Smith, Henry, Chung, and Hunt (1998) investigated the relations between various coping strategies and mental health outcomes in a sample of low-income, predominantly African American and Hispanic adolescents (age 12–16) living in the inner city. Cross-sectionally, youth who relied predominantly on problem solving and quiet substance users (reliant on avoidance through substance abuse but overall low levels of coping) had fewer internalizing symptoms. At the same time, cross-sectional data also revealed that emotion-focused coping as well as youth who depended heavily on avoidance through substance abuse but who also vented emotionally (emotional substance users) had higher levels of externalizing symptoms. One year later both the quiet and the emotion-focused substance abuse users showed the greatest rise in externalizing symptoms. The quiet substance users also showed a significantly greater rise in internalizing symptoms. Gonzales, Tein, Sandler, and Friedman (2001), looking at a younger adolescent sample (seventh–eighth grade) in similar circumstances (poor, inner city, predominantly non-White), found that active coping and distraction, respectively, buffered the relation between family stress and conduct problems in girls; active coping did the same for depression in boys.

These data on coping and psychological well-being within low-SES samples are consistent with Wadsworth's program of research on poverty-related stress, coping, and mental health (Wolff et al., 2011). Adolescents from low-income families who cope with poverty-related stressors using engagement coping strategies (e.g., problem solving, emotion regulation, distraction, cognitive restructuring) tend to fare better psychologically than their low-income peers who instead rely more on disengagement strategies, such as avoidance or denial (Wadsworth & Berger, 2006; Wadsworth & Compas, 2002; Wadsworth et al., 2005; Wadsworth & Santiago, 2008).

Further analyses also suggest that some of the ill effects of poverty-related stress on internalizing and externalizing symptoms among adolescents are partially mediated by coping strategies with engagement strategies, particularly secondary control techniques, such as cognitive restructuring and distraction, which are helpful in attenuating negative impacts (Wadsworth & Compas, 2002; Wadsworth et al., 2005). Interestingly, in the Wadsworth et al. (2005) study, for parents, more engagement buffered rather than mediated the negative correlates of poverty-related stress on their own mental health outcomes. For parents, disengagement strategies had the opposite effect, accentuating the negative relations between poverty-related stress and psychological distress. The findings of coping strategy mediation among adolescents and the interaction between coping strategies and poverty stress among adults suggests the possibility of a developmental sequence with coping strategies of older individuals being less malleable in comparison to those of children and adolescents. However, in a prospective, longitudinal study of low-income middle and senior high students, Wadsworth and Berger (2006) found one interaction between poverty stress and primary control strategies. Youth higher in poverty stress had greater increases in internalizing symptoms over an 8-month period, but this was largely attenuated if they relied primarily on primary control coping strategies. This interaction between poverty-related stress and primary control coping, however, was the only moderation detected among several possible interactions between coping strategies and poverty stress.

Gonzales and colleagues (2011), however, did detect an interaction between various sources of stress (family, peer, community) and coping on mental health outcomes within their low-SES middle school sample. Both active coping and distraction buffered the adverse effects of family stress on behavioral conduct for girls. For boys, the effects of peer stress and community stress, respectively, on depression were exacerbated by more active coping. The authors suggest that boys who try to actively cope with intractable, chronic stressors like peer or community violence may suffer the frustration of invoking an instrumental coping strategy when in fact accommodation might fit better with the nature of the demands. One possible reason for the discrepancy between the absence of coping moderator effects in the Wadsworth and Berger (2006) study compared to that of Gonzales et al. is that Wadsworth and Berger examined stress directly related to poverty (not enough money to buy clothes, parents worried about paying bills), whereas Gonzales et al. examined various sources of stress (peers, community, family) in conjunction with coping strategies.

Edith Chen and Greg Miller have been conducting a program of research examining how cognitive appraisals and adjustments to the stressors accompanying low-SES childhoods can affect health and well-being. In an initial series of studies, youth who saw videotapes of simulated encounters between adolescents evaluated how threatening/hostile the situations were. Low-SES youth were more likely to attribute threat or hostile intent in ambiguous social interactions compared to their middle-SES peers. These attributions, in turn, were linked to elevated physiological stress responses (Chen & Matthews, 2001; Chen, Langer, Raphaelson, & Matthews, 2004). More recently, Chen and Miller (2012) initiated a series of studies examining a coping strategy, shift and persist, as a potential protective process among low-income children. *Shifting* refers to the ability to adjust individual responses to stressors through emotion regulation strategies, such as cognitive restructuring. *Persisting* reflects enduring adversity by strategies such as finding meaning in difficult circumstances or remaining optimistic. Asthma occurs more often and with greater severity among low-income children. In a sample of children (mean age 12) with diagnosed asthma, low-SES children who were high in shift and persist had lower levels of inflammation and degrees of impairment (e.g., school absence) compared to their low-SES peers with low shift and persist skills (Chen, Strunk, et al., 2011). In fact, low-SES asthmatic children who used this coping strategy resembled their high-SES counterparts. In a different sample, childhood SES was inversely related to allostatic load in a national sample of middle-age adults (Chen, Miller, Lachman, Gruenewald, & Seeman, 2012). However, adults from more deprived backgrounds who engaged in more shift and persist did not have higher allostatic load scores than their counterparts from higher SES backgrounds.

Another coping resource that appears capable of buffering some of the ill effects of childhood poverty on mental health is social support. As noted earlier, one reason for this could be because support appears to reduce the negative effects of stress on parenting behaviors of low-income parents. A large developmental literature demonstrates the protective effects of maternal responsiveness on socio-emotional development among children (Bornstein, 1989; Bradley, Corwyn, Burchinal, McAdoo, & Garcia-Coll, 2001; Bradley, Corwyn, McAddo, & Garcia-Coll, 2001; Shonkoff & Phillips, 2000). Studies of resilient children in the context of poverty routinely find that a strong, positive bond with an adult

caregiver is among the most protective factors (Werner & Smith, 1982; Wyman, Cowen, Work, & Parker, 1991). Maternal responsiveness attenuates several adverse effects of childhood deprivation, including elevated levels of allostatic load in adolescents (Evans, Kim, Ting, Tesser, & Shanis, 2007), the metabolic syndrome in middle-age adults (a cluster of risk factors predictive of diabetes, stroke, and cardiovascular diseases) (Miller et al., 2011), and proinflammatory processes among healthy 25- to 40-year-olds (Chen, Miller, Kobor, & Cole, 2011). There could be a link between responsive parenting and the development of children's own adaptive coping responses. Children who grew up in families with multiple problems, including poverty, but who had more responsive and nurturing parents develop enhanced self-regulatory skills (Repetti et al., 2002). They may also learn that enlisting support from others is effective. Enlisting such support may be particularly important given the well-documented inverse relation between SES and social support (Evans, 2004; Matthews & Gallo, 2010). Low-SES children and their parents typically have fewer social resources they can call on.

Both EF and coping are central psychological processes involved in the relations between SES and child psychopathology. A robust finding is that children and adolescents who cope with poverty-related stress by relying primarily on disengagement strategies, such as avoidance or denial, have worse mental health outcomes. Problem solving, emotion regulation, finding meaning, and maintaining optimism, along with the recruitment of social support, appear to be adaptive strategies that help counter some of the ill effects of impoverishment in regard to mental health.

Brain and SES

An exciting, emerging area of scholarship in the neurosciences is examining the potential role of the brain in linking SES and other forms of early childhood deprivation to psychopathology as well as cognitive outcomes (Gianaros & Manuck, 2010; Hackman & Farah, 2009; Hackman, Farah, & Meaney, 2010; McEwen, 2012; McEwen & Gianaros, 2010; Raizada & Kishiyama, 2010). Although the focus of much of this work is on exploration of cortical and subcortical mechanisms responsible for the SES-achievement gap, a small amount of the research has potentially major implications for the development of psychopathology.

Much of the initial neuroscience work examined neurotransmitter processes or conducted electrophysiological protocols, but recently the field has moved more into structural and functional neuroimaging techniques. Attenuated serotonin responsivity is related to elevated symptoms of aggression as well as depression. Lower-SES adults have attenuated serotonin responsiveness (Manuck et al., 2005; Matthews, Flory, Muldoon, & Manuck, 2000). There may also be a genetic component of the serotonin neurotransmitter system and the effects of early life deprivation. The positive association between SES and serotonin responsiveness is accentuated among persons with the short allele on the 5-HTTLPR serotonin transporter gene (Manuck, Flory, Ferrell, & Muldoon, 2004). As we discuss later, this genetic polymorphism may be a salient marker for vulnerability to chronic stress.

A small number of electrophysiological brain wave recording studies suggest that children from lower SES backgrounds have delays in development of the prefrontal cortex (PFC), which is a major cortical area responsible for executive functioning, such as the self-regulation of behavior and emotional control (Heatherton, 2011). Earlier we reviewed several studies indicating that childhood SES is positively associated with better executive functioning. The PFC is believed to operate as a top-down regulator of behavior enabling individuals to inhibit strong emotional responses and to reflect on various coping strategies in contemplation of action. Examining brain wave activity at 18, 30, and 48 months, Otero (1994, 1997) found evidence of delayed maturation in the prefrontal PFC of children from low-SES families relative to children from middle-SES families. Early extrastriate attention-sensitive components and novelty-evoked related potential (ERPs) are attenuated in low-SES relative to high-SES 7- to 12-year-olds who also had more difficulties with several neurocognitive measures of executive functioning (Kishiyama, Boyce, Jimenez, Perry, & Knight, 2008). Three- to 8-year-olds and middle school children from lower-SES compared to middle-SES families appeared to require greater effort to selectively attend to auditory stimuli while gating out distracting background stimuli (D'Angiulli, Herdman, Stapells, & Hertzman, 2008; D'Angiulli, Weinberg, Grunau, Hertzman, & Grebenkov, 2010; Stevens, Lauinger, & Neville, 2009). The positive indication from electroencephalographic research that low-SES children have depleted attentional capacity fits well with several of the EF studies reviewed earlier that showed compromised attentional control abilities among low-SES children.

Evidence from SES-related brain structural and functional imaging studies also implicates childhood SES in brain development. Similar to the electrophysiological studies on SES and brain activity, Sheridan, Sarsour, Jutte,

D'Esposito, and Boyce (2012) found that 8- to 12-year-olds from lower-SES families had more difficulty learning a response discrimination task that appeared to be related to greater activation in a portion of the PFC, the right middle frontal gyrus. Increased neural recruitment in this area may have reflected greater effort or less efficiency in the learning of the rules necessary to perform optimally on the task. In a series of studies, Gianaros and colleagues (2007) have shown both structural and functional alterations in brain development among low-SES relative to middle-SES individuals with potentially profound mental health implications. Adults who perceive themselves as lower in relative social status have lower gray matter volume in the anterior cingulate cortex, a limbic brain area centrally involved in emotional regulation as well as responsivity to stressors. Similar volumetric reductions in the anterior cingulate cortex are associated with mood disorders and depression.

As indicated, self-regulatory and executive control functions appear to be damaged in adults and children from low-SES childhoods. Adults from low-SES childhoods evidenced reduced connectivity between portions of the PFC and orbitofrontal and striatial areas of the brain implicated in reward sensitivity and impulse control (Gianaros et al., 2010). In a second study, adults who grew up in families with perceived lower relative social standing had elevated amygdala activation to emotionally threatening faces but responded similarly to their peers from family backgrounds of average and above average social standing to neutral and nonthreatening faces (Gianaros et al., 2008). Similarly, adolescents from lower-SES families evidenced greater amygdala as well as dorsomedial PFC activation in response to emotionally threatening faces (Muscatell et al., 2012). Yanagisawa and colleagues (2012) asked college graduates how much financial strain their family faced when they were growing up. Higher levels of perceived financial strain were associated with greater social distress and lower levels of activity in the right ventrolateral PFC during a social exclusion task. In the cyberball task, participants play a virtual game of catch with what they believe are two other players (whose pictures are displayed during the game); in actuality, participants are interfaced with a computer that exposes participants to two different conditions: inclusion in the game of catch and exclusion in the game of catch. The former serves as a baseline contrast for the exclusion phases of the experiment. The pattern of findings from these recent neuroimaging studies on greater threat activation when confronted with emotionally charged stimuli fits nicely with the work by Chen and colleagues, reviewed earlier, showing that low-income youth more readily attribute threat and hostile intent to ambiguous interpersonal encounters (Chen & Matthews, 2001; Chen et al., 2004).

Another area of the brain, the hippocampus, helps integrate information about emotionally laden information to past experiences and context, better enabling the organism to respond more adaptively to challenging situations. Considerable animal work indicates damage to the hippocampus at the cellular level from chronic stress as well as reduction in gray matter volume (Lupien et al., 2009; McEwen & Gianaros, 2010). Recently different teams of investigators have linked lower-SES childhoods to smaller hippocampal volumes in 5- to 17-year-olds (Noble, Houston, Kan, & Sowell, 2012), in 9- 11-year-olds (Hanson, Chandra, Wolfe, & Pollak, 2011), and in both middle-age (Butterworth, Cherbuin, Sachdev, & Antsey, 2012) and older adults (Staff et al., 2012). Recently, Pilyoung Kim and her colleagues (Kim et al., 2013) integrated these brain and self-regulatory behavior findings with the findings from stress research, finding that adults who grew up in poverty had reduced activation in the PFC and less efficient regulation of the amygdala during a task in which they had to regulate negative emotions. Furthermore, chronic stressor exposure during childhood mediated the association between poverty and PFC activity.

Taken in concert, this newly emerging literature on SES and the brain appears to hold great promise for unpacking the underlying biological mechanisms that help transmit the experience of childhood poverty and deprivation into adverse mental health outcomes. In particular, the neuroscience findings suggest that persons from low-SES backgrounds may respond more strongly to aversive and threatening stimuli in areas of the brain associated with autonomic, rapid responses to threat and emotionally negative stimuli (e.g., the amygdala). At the same time, persons from lower-SES backgrounds appear to have a less well developed top-down regulatory PFC system for controlling these rapid, automated emotion responses. Thus, individuals growing up in low-SES environments may be subject to a kind of triple jeopardy when it comes to responding to adverse experiences. First, they are likely to encounter many more psychosocial and physical risk factors that are threatening. Second, low-SES children appear to be downwardly regulated, being hyperresponsive or hypersensitive to threatening events. Third, at the same time, they are less able to monitor, regulate, and modify these rapid, emotion-laden responses to threat and other negative emotionally evocative situations. One major shortcoming of all of the neuroscience work to date on SES is the absence of direct evidence for structural or functional changes in the brain operating as mediators or underlying explanatory

mechanisms directly accounting for well-established linkages between SES and psychopathology. We currently do not have evidence for the full pathway: Low SES → Brain Alteration → Psychopathology.

PRACTICE AND POLICY

Community and/or Government Interventions: Policy

Several safety net programs were designed by the federal government in an effort to meet the goals of the War on Poverty efforts of Presidents Kennedy and Johnson in the early 1960s. These programs, collectively referred to as social welfare, have parallels in most every industrialized nation, and are designed to prevent individuals and families from starvation and homelessness. As shown in national poverty rate trends, programs such as Aid to Families with Dependent Children (AFDC, formerly known as Welfare, and now referred to as Temporary Assistance to Needy Families, TANF), WIC, and SNAP contributed to significant reductions in poverty rates, from a high of 22.4% in 1959 to a low of 11.1% in 1973. Unfortunately, despite continued increases in the GDP since the 1950s, the poverty rate has not seen further reductions since the early 1970s, in part because eligibility levels for these programs have not been adjusted for inflation and cost-of-living increases over the last four decades. Such safety net programs have also been documented to produce improvements on a variety of child health and developmental outcomes, such as reduced low-weight infant births (Kowaleski-Jones & Duncan, 2000); lower risk of abuse and neglect; and fewer nutritional deficiencies, such as anemia and failure to thrive (Lee & Mackey-Bilaver, 2007).

In 1975, the Earned Income Tax Credit (EITC) was passed to benefit low- and moderate-income working families, designed to offset the burden of Social Security taxes and to provide an incentive to work. The EITC was also successful in raising the incomes of working families, and Dahl and Lochner (2012) found that each $1,000 increase in family income stemming from the EITC was accompanied by significant increases in math and reading achievement, especially for children in the most disadvantaged families. Similarly, Strully, Rehkopf, and Xuanc (2010) found that state EITCs led to increased birthweights and reduced maternal smoking in families in poverty.

The estimate of the $500 billion annual cost of childhood poverty to the United States calculated by Holzer et al. (2008) suggests that there are large potential gains to be had by poverty-reduction programs and other types of interventions targeting the environment of childhood poverty. Holzer et al. outlined the next types of programs as having the potential to reduce poverty and have high monetary returns on the investment: programs that increase wages and incomes (e.g., increases in minimum wage, EITC), programs that increase earning potential via training and education, programs that improve neighborhood conditions and housing quality, and universal high-quality preschool programs. Calculations by Dickens, Sawhill, and Tebes (2006) suggested, for example, that making high-quality preschool programs universally available to children could increase GDP by 3.7% annually, coming close to offsetting the $500 billion price tag of child poverty in the United States. Knudsen, Heckman, Cameron, and Shonkoff (2006) similarly reviewed the range of potential benefits to be gained from early intervention programs for disadvantaged children, concluding that the estimated return on each dollar invested in early childhood programs, such as the Perry Preschool Program, exceeded 17%, which these authors noted is a much higher rate of return than standard stock market returns. With positive outcomes in adulthood spanning academic achievement and attainment, cumulative wage earnings, likelihood of owning a home, likelihood of receiving public assistance, and years spent incarcerated, early childhood interventions have a very large potential to translate into high gains in human and economic capital. Heckman (2006) estimated that the total cost of implementing the Perry Preschool Program was $16,514 (in 2004 dollars) per child and that benefits saved by implementation across earnings, special education, crime, and public assistance totaled $144,345, with a benefit to cost ratio of 8.74.

The results of Nuru-Jeter et al.'s (2010) study of categorical versus continuous measures of SES and relations with mental and physical health outcomes suggest that "efforts to alter the social conditions that drive health effects will demand mobility into meaningful strata of educational and financial well-being" (p. 17). Hence, while reducing low birthweights and reducing hunger are incredibly important and worthy goals, efforts to improve poor children's life chances must do more than marginally increase family incomes; rather, they must strive to help children achieve the education and training they need to rise in social stature.

Consistent with the message of Nuru-Jeter et al. (2010), Zaslow et al. (2002) reviewed the impacts of four kinds of welfare-reform programs on child outcomes: (1) work-first or education-first programs that make assistance contingent on getting a job or job training (e.g., Job Opportunities and Basic Skills Training); (2) imposing time limits on public assistance receipt (e.g., Florida

Family Transition Program); (3) programming delivered specifically to teenage mothers (e.g., New Chance Demonstration); and (4) financial incentives tied to working (e.g., New Hope Project). Of the four program types, Zaslow et al. found that only the programs that led to sustained financial gains for families had favorable impacts on child health and well-being. Programs that failed to increase employment and income had either neutral or detrimental effects. Similarly, in analyses making use of random-assignment experimental design and instrumental variables estimation, Gennetian and Morris (2003) found evidence that increasing income via the Minnesota Family Investment program can improve children's school engagement and social-emotional functioning. Their findings further supported the conclusion that income has a causal and reversible impact on child functioning.

A new generation of antipoverty programs has expanded on this strategy of contingent safety net provision by making public assistance contingent on poor parents performing a number of stipulated tasks designed to increase their children's human capital. Such conditional cash transfer (CCT) programs reward parents with money for taking their children to medical checkups, getting them vaccinated, and improving school attendance. Some CCT programs implemented outside the United States have demonstrated decreased rates of poverty and child illness and improved school attendance (e.g., Rivera, Sotres-Alvarez, Habicht, Shamah, & Villalpando, 2004). Fernald, Gertler, and Neufeld (2008), for example, examined child outcomes associated with the Mexican CCT program Opportunidades. A doubling of income via cash transfers was associated with better infant and toddler outcomes, such as taller height for age, less stunting, lower body mass indexes as well as higher motor, cognitive, and language development scores. CCT programs have been implemented in several other lower- and middle-income countries, including Brazil, Peru, Honduras, Nicaragua, Colombia, India, and Nepal. Overall, outcomes are mixed (Wolf, Aber, & Morris, 2013), with short-term positive effects found in some countries, but not others (e.g., Fiszbein & Schady, 2009). Only one large-scale CCT program has been evaluated in the United States (Opportunity New York; Riccio et al., 2010). Results of this evaluation showed that, while the program decreased current poverty and material hardship, it did not result in improved school outcomes for elementary or middle school students. It did however, lead to improved academic outcomes for high school students who were already meeting grade-level standards at the beginning of the study.

Implications of Poverty and Psychology Research for Policy

Not surprisingly, U.S. government programs that directly increase the income of families living in poverty have reduced poverty rates. What is surprising is that Americans have allowed these programs to lose power by not indexing them for inflation. Research on the effects of poverty on children has provided more data than needed to justify increased investment in antipoverty programs; yet the public, in general, has not prioritized such expenditures—despite the fact that most, if not all, Americans believe in an ethic of justice (Hamlin, Wynn, Bloom, & Mahajan, 2011; Masters & Gruter, 1992).

The disconnect between Americans' stated values and voting patterns suggests that developmental psychopathologists who are committed to reducing the negative effects of poverty on children might consider bringing psychological research to bear on factors affecting U.S. voting priorities. Psychological constructs, such as cognitive dissonance (Cooper, 2007; Festinger, 1957/1985) and belief in a just world (Furnham, 2003), can help explain why voters may blame others for negative experiences that would otherwise simply seem unfair (Godfrey & Lowe, 1975; Janoff-Bulman, Timko, & Carli, 1985). In the case of cognitive dissonance, for example, middle- and upper-class individuals are likely to experience discomfort associated with incongruous beliefs, such as: (a) there are children in our country who are living under life-threatening conditions of violence because they reside in urban poverty; (b) we live our lives without substantially addressing this problem; and (c) we are good, kind people. The just world belief (i.e., that those who suffer have brought that suffering upon themselves in some way; Lerner, 1980; Montada & Lerner, 1998) can reduce that cognitive dissonance. If those who are disadvantaged deserve their fate, then the rest of us can bear less guilt for not intervening (Lodewijkx, de Kwaadsteniet, & Nijstad, 2005; Loseman & van den Bos, 2012). We can eliminate the discomfort of the cognitive dissonance associated with the three statements by adding a fourth: Everyone who works hard can escape poverty and violence (Murray, Spadafore, & McIntosh, 2005; van den Bos & Maas, 2009).

Two additional psychological constructs may help explain the lack of investment in addressing poverty. The first is diffusion of responsibility (Darley & Latané, 1968; Latané & Darley, 1968). If one believes that action does not rely solely on oneself, one is less likely to act (Leary & Forsyth, 1987; Mynatt & Sherman, 1975). The second is a lack of knowledge of how one can effectively intervene (Fielding & Head, 2012). When pathways to successful

intervention are unclear and the outcome is uncertain, individuals are less likely to act (Jorm, 2012).

Most developmental psychopathologists who conduct poverty research have focused on poverty's effects on children's mental health and the mechanisms of those effects. This work lays the groundwork for psychological interventions (as summarized in the next section). Given that a lack of knowledge of how to intervene effectively reduces the likelihood that individuals will intervene, developing effective interventions also is important for policy efforts.

Furthermore, despite the fact that safety net programs can protect children from some of the most dire effects of poverty (malnutrition, homelessness), they have not proven sufficient to alter the economic trajectories of children born into poverty (or poverty would have been eradicated by now). And welfare-reform programs designed to alter those trajectories by bolstering the capacity of low-income families to increase their own incomes (through education, training, or investment in the training and education of their children) have had only mixed effects, as reviewed earlier. Thus, there is a real need for the development of effective programs that can change the economic trajectory of children born into poverty.

There is strong evidence that changing children's educational trajectories can change their economic trajectories and break the cycle of poverty (Haskins & Rouse, 2013). Since the 1980s, earnings have increased only for families that include an adult with a college degree (Haskins & Rouse). As a result, policy experts like Haskins and Rouse have proposed that federal programs focus on increasing the preparedness of low-income students for college.

Early childhood programs like Head Start have demonstrated success, but they have not succeeded in eliminating achievement or income gaps for low-income children, and programs that target older children for college have had only modest effects at best (Haskins & Rouse, 2013). So there is great need for additional intervention development and evaluation efforts. To coordinate and support such efforts, Haskins and Rouse recommend that the federal government (a) consolidate existing funding efforts into a single grant program that requires funded initiatives to be backed by rigorous research and (b) give the U.S. Department of Education the authority to plan and execute a coordinated set of studies that develop and rigorously test several approaches to college preparation.

A team of scholars and practitioners in Chicago is following the recommendation to focus on college preparedness while also addressing barriers to middle and upper-class investment in anti-poverty programs. The Chicago Public School System (CPS) is 87% low income, and only 8% of its students graduate from a 4-year college (Allensworth, 2006; Chicago Public Schools, n.d.). With the goal of changing those statistics, CPS has partnered with five major universities in the city of Chicago—DePaul University, Loyola University, Northwestern University, the University of Chicago, and the University of Illinois at Chicago—to submit a proposal to the U.S. Department of Education that is focused on both (a) supporting the academic preparedness of CPS students for college and (b) increasing the sense of responsibility for ending poverty among college students through an innovative program called Cities Mentor Project.

Cities Mentor Project provides early adolescent CPS students with (a) training in research-based strategies for engaging with academic challenges and coping with severe and chronic stressors endemic to urban poverty that impede learning (e.g., community violence); (b) connection to undergraduate mentors who support youth engagement and coping efforts in real-life situations, advocate for youth academically, and connect youth to (c) high-quality after-school and summer programming that provides additional support. Cities Mentor Project makes a long-term commitment to youth, supporting them from middle school all the way through their first year in college.

University student mentors in the program take part in a service learning course focused on training and supporting their mentoring work. The class also educates the mentors about the roots and effects of poverty in Chicago and brings the powerful cognitive-behavioral tools of Socratic questioning and collaborative empiricism (which are typically used to target mental health problems; Cohen, Edmunds, Brodman, Benjamin, & Kendall, 2012; Tee & Kazantzis, 2011) to bear on psychological barriers to moral action (Hart et al., 2009; Overholser, 2011; Palmer & Williams, 2013). Sample questions used in the class include: (a) What is the cause of poverty and inequality in the city of Chicago? (b) Who is to blame? (c) What can be done about it? (d) What should I do about it as an individual? (e) What should we do about it as a group? Thus, this program moves beyond intervention strategies characteristic of traditional psychology to include community psychology principles of empowerment and advocacy, principles that may be necessary to change policy (Dalton, Hill, Thomas, & Kloos, 2013; Speer, Peterson, Armstead, & Allen, 2013).

The CPS-university partnership plans to evaluate the effects of this new approach on a broad range of outcomes, for mentors and mentees alike, including mental health and academic achievement as well as moral understanding and civic engagement. If there are expected empirical changes on these measures, this partnership could become a model not only for changing the educational and economic

trajectories of low-income children but also for increasing a sense of responsibility for ending poverty among more highly resourced individuals. Based on our review of research and policy, it appears we need both.

Individual and Family Interventions: Practice

Numerous early intervention programs have been developed with the aim of promoting educational and socioemotional success and preventing dysfunction stemming from poverty and socioeconomic disadvantage in young children. In a comprehensive review of results from 20 rigorously evaluated programs, including a mix of home visiting, parent education, early childhood education (ECE), and combination programs (e.g., Abecedarian Project, Nurse-Family Partnership), Karoly and colleagues (2005) report positive benefits, both immediately following intervention (e.g., IQ scores, prosocial outcomes) and at long-term follow-up (e.g., educational attainment, teen pregnancy, arrests) to participating children. Successful early childhood intervention programs tend to have multiple components that target parents (e.g., job-related services), children (e.g., enrollment in high-quality ECE), and/or the parent-child dyad (e.g., parenting classes). Karoly and colleagues also identified several program elements that characterized effective programs, including well-trained program leaders (e.g., home visitation services provided by trained nurses), intensive program scope and delivery, and center-based education-focused child care in settings with small child-staff ratios and well-educated lead teachers.

Several successful large-scale programs have been in operation for several decades, allowing for evaluation of the long-term outcomes possible with high-quality ECE. Head Start (e.g., Ripple & Zigler, 2003) and the Perry Preschool Program (Weikart & Schmeinhart, 1992) are successful prevention programs targeting poor families with preschool children designed to prevent the emergence of behavioral difficulties and promote positive social skills, emotional competence, and academic achievement. Both of these programs focus on providing families with access to basic human necessities, such as food, housing, education and health care, as well as high-quality child care. These programs have produced both substantial initial effects on child IQ scores and social/emotional outcomes as well as employment, criminality, and family stability outcomes that persist until well into midadulthood (e.g., Pungello et al., 2010; Ramey & Ramey, 1998). Brooks-Gunn (2003) challenged us to find any other interventions that come close to the magnitude of these kinds of effects in the learning sciences (and beyond).

The Nurse-Family Partnership program has produced strong outcomes for families who receive perinatal and infancy home visits from qualified nurses (e.g., Olds, Sadler, & Kitzman, 2007). A recent evaluation by Eckenrode and colleagues (2010), for example, examined results of the program on the life course development of 19-year-olds whose mothers had participated in the program. Girls from the home visitation group were significantly less likely to be arrested (10% versus 30%) and convicted of a crime (4% versus 20%) and had fewer lifetime arrests (.10 versus .54) than girls in the control group. Additionally, for high-risk girls in particular, significantly lower rates of teen pregnancy and public assistance usage were found for home visitation girls in comparison to controls.

The Strong African American Families program was developed by Gene Brody and colleagues (2006) to prevent substance use, conduct problems, and depression in rural, low-income African American adolescents. This program, which built on over a decade of basic research on rural African American families and their strengths, focuses on building caregiving practices, such as limit setting, monitoring, instilling racial pride, and effective problem solving. Adolescent self-regulation is also directly targeted. Participation in the 5-session intervention was associated with a 36% reduction in the frequency of conduct problems, a 32% decrease in overall substance use, and a 47% decrease in substance use problems over the course of almost 2 years (Brody et al., 2012).

The Families Coping with Economic Strain intervention (FaCES; Raviv & Wadsworth, 2010) teaches children (age 8–12) and their parents coping strategies to effectively manage poverty-related stress. Sessions introduce various ways of coping, teach emotion regulation skills, and educate parents and children about the effects of poverty on the family and the benefits of having strategies to utilize when stressors occur. An evaluation of FaCES using a multiple baseline design, found that children increased their use of effective coping, which was accompanied by substantial decreases in internalizing and externalizing symptoms (Raviv & Wadsworth, 2010).

Parenting-specific interventions have also been shown to improve dysfunctional parenting styles by addressing the parenting practices involving appropriate discipline, promotion of prosocial behaviors, and engagement with children's schools (e.g., Brotman et al., 2011). For example, a new family-strengthening intervention developed to address the key parts of family stress model targets strengthening the interparental relationship, improving coping and reducing stress, and teaching child-centered parenting. This intervention has demonstrated

improvements on parenting, parental coping, and depression that appear to translate into improved child internalizing and externalizing symptoms (Wadsworth et al., 2013).

Similarly, the family-focused SAFEChildren (Schools and Families Educating Children) intervention targets supportive parenting, teaches parental skills for managing neighborhood challenges, and promotes school involvement among low-income parents. The program includes a tutoring component to improve child academic achievement. Program evaluation results have shown significant improvements in parents' use of stable, consistent caregiving and limit setting as well as improvements in children's behavior and attention regulation (Tolan, Gorman-Smith, Henry, & Schoeny, 2009).

Finally, some school-based interventions targeted to school-age children have also shown promise. The Fast-Track program, for example, provides a wide array of basic services to families. In addition, however, Fast-Track incorporates the teaching of basic self-regulation skills into units developed for both parents and children. Children participating in Fast-Track receive a classroom program, called PATHS (Promoting Alternative Thinking Strategies). PATHS helps children work on self-control skills by teaching emotional awareness and understanding. It also helps children enhance peer-related social skills and social problem solving to increase social competence (Bierman, 2002). The program, which began with a sample of first graders and followed them through the end of elementary school, has been successful in reducing the incidence of home and community conduct problems, involvement in peer deviance, and social incompetence (Dodge & Conduct Problems Prevention Group, 2007).

Implications of Poverty and Psychology Research for Practice

Studies on mediators and moderators of the effects of poverty are especially relevant for psychological practice focused on mitigating the effects of poverty on children's mental health, as these studies highlight mechanisms that can be targeted for intervention and indicate groups and contexts that could influence efficacy. Implications of findings from each of these literatures are summarized in the next sections.

Implications of Mediator Data for Future Interventions

Individual and Family Mediators

Basic research on mediational processes linking poverty exposure to negative outcomes is especially relevant to intervention, as findings in this area highlight pathways between poverty and symptoms that can serve as intervention targets. To date, mental health interventions have built primarily on mediational findings related to parenting and stress exposure. In particular, as outlined earlier, interventions have focused on teaching parents and children to manage poverty-related stressors in ways that support healthy family functioning and disrupt pathways linking poverty to youth psychological problems. Although coping, per se, has yet to emerge consistently as a significant mediator or moderator of poverty effects on youth mental health (Grant et al., 2006), the preliminary success of interventions targeting coping provides evidence that coping is an important intervention target (Raviv & Wadsworth, 2010).

The constructs of self-regulation, executive functioning, and mastery are all interconnected with the construct of coping. In particular, coping interventions focused on helping youth identify which coping strategies to use in a given situation require use of self-regulation and executive functioning and, if effective, are likely to build mastery and reduce helplessness. As noted, a solid body of research has established various components of executive functioning as mediators of the negative effects of poverty. Nonetheless, few intervention research studies have examined changes in mental health as a function of changes in executive functioning. There also have been few studies to examine changes in self-regulation or executive functioning or mastery (beyond coping mastery) as a result of coping training or vice versa.

A larger body of research has addressed mediation effects of executive functioning than of coping. Nevertheless, a greater number of mental health interventions have been developed to target coping. This phenomenon may reflect a belief among developmental psychopathology researchers that executive functioning interventions target academic outcomes and coping interventions target psychological outcomes. There is mounting evidence, however, that executive functioning is an important prerequisite of effective coping, especially in light of findings that selecting the coping strategy that best fits a particular type of problem is essential for coping effectiveness (Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2002; Compas et al., 2010).

Additional intervention work is needed to better understand how executive functioning, self-regulation, mastery, and coping might be targeted synergistically. For example, it would be helpful to know whether there are benefits to targeting self-regulation or executive functioning in advance of coping training or whether coping training

itself is the most efficient and relevant approach to teaching self-regulation and executive functioning in the context of poverty-related stressors. In addition, it would be ideal to integrate such intervention work with basic research by testing differences in basic cognitive functioning and brain structure as a result of coping training.

Such research also is needed to help us understand how structural, physiological, cognitive, and emotional processes function together to mediate poverty. For example, the next questions remain: (1) Does poverty directly affect brain structures (e.g., through malnutrition), thereby reducing capacity to learn adaptive strategies, or do limited learning opportunities lead to reduced brain growth, or do both processes occur and affect one another reciprocally? (2) Which specific poverty-related stressors predict which mediating processes and disrupt which protective moderators? (3) In the case of multiple mediators (e.g., cortisol, cognitions, emotions, executive functioning), does one predict the other, or do they reflect different measures of the same process? Answering these questions through basic and/or intervention research will help determine intervention approaches most effective at disrupting naturally occurring pathways between poverty and negative outcomes.

Peer, Neighborhood, and Physical Environment Mediators

Far fewer poverty interventions focused on mental health outcomes have targeted neighborhood, physical environment, or peer mediators. This fact likely reflects the fact that targeting such variables requires considerably more resources than a typical mental health intervention and/or requires buy-in from large groups of individuals and/or requires shifts in social policy that fall beyond the purview of mental health providers. Nonetheless, a few housing studies have examined mental health effects of moving low-income families from low-income, low-resource neighborhoods, characterized by community violence, poor physical environments, and high proportions of aggressive peers, to middle-class, high-resource neighborhoods with fewer risk factors (Fine, 2002; Leventhal & Newman, 2010). Findings for youth mental health have been mixed (Fine, 2002; Leventhal & Newman, 2010). One reason for the lack of consistent positive findings may be that youth who move from low- to high-resourced communities experience negative effects associated with moving (e.g., disrupted social ties, being new to a school and community) and/or increased exposure to classism and racism. Much additional intervention research is needed to determine the most effective approaches for addressing neighborhood, peer, and physical environment mediators of the effects of poverty on mental health.

One potential approach would be to build on existing coping interventions as well as community psychology constructs of empowerment (Bond & Keys, 1993) to expand definitions of active coping to include activism. Current coping interventions that focus on matching particular coping strategies with particular stressors in the context of urban poverty teach youth to avoid community violence so that they do not (a) experience the internalizing distress that can result from trying to fix something beyond their capacity to fix or (b) display the externalizing behavior that may be required to stay safe under threatening circumstances (Grant et al., 2014). It might be useful, however, to teach youth that although community violence likely cannot be addressed by individually based active coping, it could be addressed by group-based active coping or activism. Such intervention would require partnerships between mental health providers and community-based organizations capable of involving youth in such work.

Such interventions would also necessitate a lengthier investment than is typical of existing coping interventions (Gaylord-Harden et al., 2013). A recent meta-analysis of coping programs with all youth provides a basis for lengthier intervention. In particular, Gaylord-Harden and colleagues (2013) found positive effects (.31/–.09) for coping interventions at the conclusion of programming but no or negative effects at follow-up (first follow-up = –.02 /–.09; second follow-up = –.08/–.17). These findings may indicate that lengthier intervention and/or booster sessions are required to help youth generalize or ingrain new coping skills. Additional intervention research is needed to test this hypothesized interpretation. If it proves valid, we may need to shift our typical approach to administering coping interventions from discrete, individually based, brief interventions provided by mental health professionals to intervention that is embedded within ongoing programming of schools or community-based organizations that includes group-based activism focused on systemic problems affecting low-income youth.

Implications of Moderator Data and Related Findings

Although results of moderator studies just reviewed provide few consistent messages relevant to intervention, related findings provide evidence that contextual variables can affect the extent to which protective factors are helpful and interventions are effective, particularly within the context of urban poverty. For example, as with the broader coping literature (Compas et al., 2002, 2010), most basic

and intervention studies of coping with poverty stressors have reported positive effects for active, problem-solving, engagement approaches and negative effects for avoidance and disengagement (Raviv & Wadsworth, 2010; Wadsworth & Berger, 2006; Wadsworth & Santiago, 2008). Nonetheless, this general pattern is tempered by findings, particularly with youth residing in urban poverty, of positive effects for avoidant, disengagement strategies, at least in the short run (Gaylord-Harden, Taylor, Campbell, Kesselring, & Grant, 2009; Gonzalez et al., 2001). For example, Gaylord-Harden and colleagues (2009) found that youth who behaviorally avoided stressors associated with urban poverty (e.g., exposure to community violence) were better off than those who actively engaged. These findings highlight the importance of matching coping strategy with stressor (Compas et al., 2002, 2010). Future intervention work would benefit from greater integration with basic moderator studies to iteratively determine which methods of coping are most effective for specific poverty-related stressors.

This body of studies also suggests not only that strategies deemed ineffective in other settings may be protective in the context of urban poverty but that generally effective strategies may prove ineffective or even problematic for low-income urban youth (Ceballo, Ramirez, Hearn, & Maltese, 2003; Hammack, Richards, Luo, Edlynn, & Roy, 2004; Li, Nussbaum, & Richards, 2007; Youngstrom, Weist, & Albus, 2003). For example, D'Imperio, Dubow, and Ippolito (2000) reported no protective effects for individual, family, or extrafamilial resources for their sample of low-income urban youth. This pattern fits with Gerard and Buehler's (2004) findings that cumulative risk across multiple domains overwhelms the effects of potential protective factors for youth and with the construct of *protective reactive effects*, defined by Luthar, Cicchetti, and Becker (2000) as the dissipation of protective effects under conditions of overwhelming stress.

More basic and intervention research is needed to determine the contexts in which coping and other protective factors are helpful and harmful. For example, Grant and colleagues found that individually based active coping strategies were, generally, counter-productive for the most severely stressed youth in their low-income urban sample (Grant, McMahon, Carter, & Carleton, in press). However, even the most severely stressed youth could benefit from active strategies if they were used in the context of supportive relationships with adults and connections to protective settings (e.g., family, school, community, or religious organization) (Grant, McMahon, et al., in press). Grant and colleagues are currently building on those findings through the development of a new intervention which teaches low-income urban youth contextually relevant coping strategies and connects them with mentors and protective settings to support their coping efforts (Grant, Farahmand, et al., 2014). This broad approach is consistent with research, reviewed earlier, on the numerous mechanisms through which poverty exerts its negative effects, including reduced interpersonal and community resources. Additional research is needed to evaluate the efficacy and effectiveness of broad approaches such as this one.

Meta-analyses of intervention effects also highlight the important moderating function context can play on effectiveness. In particular, Farahmand and colleagues' recent meta-analyses of mental health interventions targeting youth residing in urban poverty (Farahmand, Duffy, et al., 2012; Farahmand, Grant, Polo, Duffy, & Dubois, 2011) indicate that community-based interventions (.25 /–.11) are more effective than school-based interventions (.08 /–.09). School-based interventions in low-income urban communities were particularly likely to yield negligible or even negative effects if they targeted externalizing outcomes. This pattern is consistent with evidence that stressors particularly common within the context of *urban* poverty (i.e., exposure to community violence) are specifically associated with externalizing outcomes (Grant et al., 2013).

In the short run, these findings suggest that community-based interventions should be prioritized over school-based interventions when targeting externalizing problems affecting low-income urban youth. In addition, there is a need for research on systemic barriers to effective school-based intervention in the context of urban poverty, particularly for externalizing problems. Research is needed to determine what school-based factors within the context of urban poverty compromise the delivery of effective mental health intervention and what strategies might be useful in addressing these negative factors so that, in the long run, we can harness the potential benefit of school-based interventions for youth residing in urban poverty (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011).

FUTURE DIRECTIONS

Earlier we discussed several pathways that appear to be good candidates linking childhood experiences of deprivation with psychological distress and conduct disorders. These pathways included elevated parental stress and subsequent parental harshness and lack of sensitivity as

well as children's own stress responses. One of the primary reasons childhood deprivation appears to be negative for children and possibly extending later into the life course is because of exposure to a higher level of cumulative risk factors, such as family turmoil, violence, chaos, and instability as well as suboptimal physical environmental conditions (e.g., substandard housing, toxins) that often accompany poverty. We also pointed out that increasing evidence points toward compromised executive functioning and less adaptive coping strategies as difficulties accompanying childhoods with less opportunity. Finally, we provided evidence that for stress and executive functioning, very recent work has begun to illuminate the role of brain structure (e.g., smaller hippocampus) and function (e.g., more difficulty regulating negative emotions) in relation to childhood poverty/low SES. Thus, not only are low-SES children apt to be exposed to a higher level of aversive environmental demands, they may also be less capable of coping with the myriad of demands they are confronted with at home, in school, and in the community. Low-SES individuals have higher demands but often lack the intrapersonal or environmental resources to manage those demands (Gallo & Matthews, 2003).

Given what appears to be the central role of parenting in the linkages between poverty and deprived environments for children's mental health (see Figure 4.1), it is worth thinking about other ways in which poverty and low SES environments could alter the parent-child relationship. We noted that although the focus has been on the direct effects of income or SES on parenting behaviors, some work suggests that deprivation may interact with other critical aspects of parents' lives to moderate the effects of SES on parenting behaviors. In addition to expanding the small amount of work noted earlier on social support, religiosity, and chaos as potential moderators of the link between SES and parenting behavior, another topic worth considering is social capital. Many low-SES families, particularly in urban areas, also reside in neighborhoods low in social capital (Leventhal & Brooks-Gunn, 2000; Saegert, Thompson, & Warren, 2001; Sampson, Morenoff, & Gannon-Rowely, 2002). These settings tend to be low in social cohesion and social control, making it difficult for parents to connect with others who can also contribute to the development and well-being of children. Low-income women have smaller and less cohesive social networks than their middle-income counterparts (Evans, Boxill, & Pinkava, 2008). A related aspect of low social capital is the dearth of positive, informal learning and socialization opportunities, such as music, dance, and art; access to museums and other informal learning centers; after-school activities; summer programs; and organized sports and recreational activities. Such resources tend to provide greater opportunities for positive and sustained interactions with other adults and increase the probability of constructive, positive peer interactions (Eccles & Gootman, 2002). There is some evidence that high social capital can buffer some of the ill effects of childhood poverty on adolescent smoking and weight gain (Evans & Kutcher, 2011). Recall also that better classroom practices help low-income adolescents better regulate themselves, which, in turn, lead to better psychological adjustment (Brody et al., 2002).

At the same time, social capital can indirectly support more positive, productive parenting. It provides opportunities to meet and develop friendships with other adults who may have shared values and aspirations, particularly for their children. A richer network of community resources for children and youth also means their parents get some respite from child care. Evans et al. (2008) showed that the negative relation between family income levels and maternal responsiveness in a sample of low- and middle-income 13-year-olds was largely a by-product of high maternal stress and low social resources available to the mother. Each of these factors was associated with lower maternal responsiveness, but the joint pathway of low social resources and high stress was what really mattered. Furthermore, we suspect many low-SES parents feel uncomfortable and possibly even unwelcome at their child's school. Such perceptions, regardless of their accuracy, when coupled with single parenthood and/or nonstandard working hours that may also be variable, make it much less likely that low-SES parents develop relationships with school personnel or cross paths with other parents at their children's school. Parental engagement in school is strongly tied to SES (Evans, 2004). We need to learn about how community social capital can directly influence low-income children's psychological well-being directly as well as affect their parents' abilities to manage the myriad of demands associated with raising a family.

Another contributing risk factor that has not received much attention in the linkages between childhood poverty and the development of psychopathology is stigma and discrimination. Adolescents who are poor feel stigmatized (Fitchen, 1981), which in turn contributes to elevated allostatic load relative to their more advantaged peers (Fuller-Rowell, Evans, & Ong, 2012). This finding is bolstered by the persistent findings that some of the SES-health gradient can be attributed to inequality (Wilkinson & Pickett, 2009) with states or countries having the widest gaps between the rich and the poor also

having the steepest SES-health gradients (Kondo et al., 2009). How inequality translates into ill health is a topic ripe for additional research, and it is likely that stigma, bias, and discrimination play a role in SES and child psychopathology. There is also abundant evidence that racial discrimination is stressful and affects the physical and mental health of children, youth, and their parents (Mays, Cochran, & Barnes, 2007). Racial discrimination also explains some of the covariation between between minority status and ill health (Williams, Mohammed, Leavell, & Collins, 2010). The interplay of lower financial opportunity with stigma and discrimination related to poverty itself along with its interaction with racial minority status on children's mental health is an important topic worthy of much more attention. Wilson, Foster, Anderson, and Mance (2009) investigated the role of racial identity but found it did not moderate the link between poverty and psychological distress among African American youth. Grant and colleagues (2005), however, did show that exposure to violence was a mediator of linkages between poverty and internalizing symptoms among African American adolescents.

It is sobering to consider the potential indirect effects of racism on parenting behaviors in the context of poverty. It is hard to be warm and responsive or to build a wide social network when one has to be worried about how one is perceived by others. This situation is likely compounded by simultaneous efforts to be vigilant about how one's children are faring in school or the larger community because of their racial status. The degree of social isolation because of low-SES status and/or racial minority status likely also intersects with urbanity. One of the striking features of urban poverty is the concentration of low-income, racial minority families in specific neighborhoods. This concentration stands in marked contrast to rural areas, where being poor and/or being non-White makes one a distinct demographic minority (Lichter & Johnson, 2007).

Another important area for further exploration in research on childhood deprivation and the development of psychopathology is the topic of mastery or control. One of the elements inherent in nearly all of the environmental demands low-SES children and their families face is uncontrollability. A large body of literature documents that chronic exposure to negative social (Peterson, Maier, & Seligman, 1993) and physical (Evans & Stecker, 2004) conditions elevate helplessness in children and adults. Chronic experience of helplessness is a well-documented risk factor for depression (Peterson et al., 1993). Poverty and other forms of disadvantage themselves may lead to elevated experiences of uncontrollability producing helplessness. The lower the family's income, the less children believe they have mastery (Bandura, Barbaranelli, Caprara, & Pastorelli, 2001; Battle & Rotter, 1963). Among adolescents and adults, the higher one's income and education, the higher one's perceived control (Specht, Egloff, & Schmukle, 2013). Moreover, income reductions at any point during a 6-year period led to decreased perceived control, independently of baseline income levels (Specht et al., 2013). Furthermore, lower-SES parents are more authoritarian (Hoff et al., 2002) and less likely to encourage self-directedness or autonomy in their children (Kasser, Koestner, & Lekes, 2002; Luster, Rhoades, & Haas, 1989; Whitbeck et al., 1997). Furthermore, in a sample of Head Start children, those faced with a wider array of risk factors in the home environment exhibited more learned helplessness on a standard helplessness protocol (Brown, 2009). In this protocol, participants are given an interesting, age-appropriate puzzle. The index of helplessness is persistence to solve the puzzle. Using a similar protocol, Evans and colleagues (2005) also found that children from ages 9 to13 from low-income households exhibited greater learned helplessness compared to their middle-income peers. Given the prominence of racism and discrimination in the experience of low-income African American children and their families, control is likely an important pathway in thinking about the intersection of race and class as it impacts the mental health of children and youth (Williams et al., 2010).

A few investigators have looked at the potential role of genetic processes to influence outcomes of childhood poverty. Early chronic stress exposure is capable of altering genetic transcription processes (i.e., epigenesis). One research team has examined epigenetic processes in relation to childhood SES. Work by Miller, Chen, and Cole (2009) reveals that early low SES childhoods are related to altered gene expression in the inflammatory response systems (e.g., T cells) as well as in glucocorticoid (i.e., stress hormone) receptor systems (Miller & Chen, 2007; Miller et al., 2009). Heightened reactivity to adverse stimuli is the net effect of these different changes in gene transcription profiles. Recent work by Essex and colleagues (2013) has provided some of the first evidence of differential DNA methylation (affects the protein-encoding portions of a given gene, making it more or less accessible to transcription and expression) in adolescents whose childhoods were marked by high levels of stress and adversity. These epigenetic "marks" on the genome caused by early experience are hypothesized to lead to stable changes in the expression of genes relevant to health and development.

We also know that genetic polymorphisms can alter reactivity to stressful environments, and this insight has recently been applied to childhood SES. In a twin study

with 5-year-olds, additive, genetic effects accounted for about 70% of the variation in resilience for behavioral adjustment in low-SES, resilient children (Kim-Cohen, Moffitt, Caspi, & Tayor, 2004). Moreover, genetic components also carried some of the contribution of maternal warmth to resilience. One genetic polymorphism that has generated considerable interest in clinical psychology is the serotonin transporter genotype (5-HTTLPR) because it appears to relate directly to psychopathology and can alter vulnerability to risk factor exposure. Recent work suggests some possible linkages between this genetic polymorphism and vulnerability to low-SES background. Juveniles from low-SES backgrounds who had the long/long allele of 5-HTTLPR were more prone to narcissism and callous-unemotional traits than youth with the short/short and short/long genotypes, who did not differ in narcissism or callousness as a function of SES (Sadeh et al., 2010). Gene Brody and his colleagues (2012) have been following a sample of low-SES, African American youth from elementary school through young adulthood. Among those at risk, given high levels of poverty-related stressors, a subset of young adults were resilient in terms of good psychological adjustment and academic achievement. One cluster of these resilient young adults, however, manifested very high levels of allostatic load, indicative of chronic physiological stress. The resilient subgroup who did well despite the difficult circumstances in which they grew up appeared to pay a price in the form of very high levels of chronic stress. This physical vulnerability was associated with the short allele genetic polymorphism on the 5-HTTLPR serotonin transporter genotype. Finally, it warrants brief mention that many of the chronic stressors accompanying low-SES childhoods, such as low maternal responsiveness, chaos, and financial pressure, each interact with specific genetic polymorphisms to alter children's vulnerability (Kim & Evans, 2011).

The last future research topic we wish to call attention to is the paucity of a developmental focus in much of the research. As we noted in our overviews of research on childhood SES and psychopathology, very few studies incorporate comparisons of the mental health of children of different ages, let alone follow the same child over time in a longitudinal design (see NICHD, 2005; Schoon et al., 2002; Wadsworth & Achenbach, 2005, for some notable exceptions). There are trends in the literature suggesting that both the age and the duration of poverty exposure matter for children's mental health, indicating that earlier poverty is worse than later poverty and that the longer the duration, the more adverse the impacts (Bolger et al., 1995; Brooks-Gunn, Guo, & Furstenberg, 1993; Macmillan, McMorris, & Kruttschnitt, 2004; Najman et al., 2010; NICHD, 2005; Sacker, Schoon, & Bartley, 2002; Schonberg & Shaw, 2007; Schoon et al., 2002). Furthermore, many epidemiological investigations of SES reveal that social class at birth is a robust predictor of adult morbidity and mortality. These relations hold independently of adulthood SES, and several studies suggest that adult SES has little or no predictive power for health when childhood SES is statistically accounted for (Cohen, Janicki-Deverts, Chen, & Matthews, 2010).

Two particularly elegant demonstrations of the developmental timing of poverty and children's psychological well-being come from two experimental interventions. Costello and colleagues (2003, 2010) evaluated the impacts of increased incomes from the opening of a casino on a Native American reservation comparing Native American and non-Native children who did not receive the income supplements from the casino. The supplements reduced externalizing symptoms in the Native American children, but no changes over the same time period occurred in the comparison group. These same differences maintained for the subjects as adults but only for the youngest cohort who were exposed from an earlier age for a longer time period to the income supplements. Fernald and Neufeld (2008) and Fernald and colleagues (2009) evaluated a conditional cash-transfer poverty reduction program conducted in Mexico (Opportunidades). Essentially parents are given cash supplements contingent on various positive child-rearing practices, such as school attendance and use of preventive health care. Low-income rural children and their families were randomly assigned to the interventions at different time periods but were all enrolled at birth. Eight to 10 years after the intervention, children who had been enrolled 6 months earlier in the program showed more significant improvements in psychological health compared to those who had been enrolled later on. The section titled "Practice and Policy" provides more information on conditional cash transfer programs. Overall, however, our knowledge base for understanding the differential effects of of variations in poverty's timing and duration on children's mental health is thin and does not extend over long periods of maturation. Much more work spanning multiple developmental periods and capturing the timing of income changes needs to be done in order to tease apart the differential and/or interactive effects of developmental timing of poverty and duration of exposure to poverty.

One reason it is important to examine this question more rigorously is because it speaks to the issue of whether there are particular points in development where the adverse impacts of lower financial and social opportunities matter more and then become embedded in the individual,

scarring him or her for life. Or is what really matters the accumulation of multiple insults that recur as one grows up in poverty or in a low-SES household (Shonkoff, Boyce, & McEwen, 2009)? These two models are not mutually exclusive and could both be happening. They do have different implications for interventions. If, for example, there are critical developmental periods during which scarring occurs, interventions occurring prior to these periods may have the largest impacts. If, however, the process of damage occurs over time and continues to build over time, interventions may be helpful at multiple points in development. For example, interventions targeting family income, parental stress, and parenting may be most effective when delivered as early in development as possible, whereas interventions can be added later in the developmental process to directly target older children's self-regulation, EF, and coping skills and to prevent further accumulation of damage.

Developmental issues also intertwine with our presentation of potential, underlying mechanisms to help account for why poverty and low-SES childhoods are so inimical to the development of mental health. For example, if high levels of chronic stress affect different cortical and subcortical areas of the brain at different maturational rates, then we might expect an early critical period to be more consequential for systems that largely mature early in life. In contrast, biological systems that mature over a longer time frame might be more vulnerable to the accumulation of adverse experiences accompanying poverty rather than being age dependent. The PFC and other stress-regulatory regions of the brain, such as the hippocampus, take a longer time to mature than the amygdala (Lupien et al., 2009; Tottenham & Sheridan, 2010). The amygdala is a limbic structure centrally involved in rapid, automated responses to threat, fear, and strong emotions. This way of thinking about poverty, low SES, and child development also has important implications for whether constructs like coping or executive functioning would be expected to mediate the adverse impacts of poverty on mental health or function as moderators, providing protection. Wadsworth, Raviv, Compas, and Connor-Smith (2005) found that coping strategies were more apt to mediate the links between poverty-related stress and mental health among young adolescents but to moderate the same relations for their parents. Mediation would be predicted for systems and processes that mature earlier in life whereas moderation would be predicted for those that come on line later. Consider, for example, the relations between SES and EF functioning in relation to age. As reviewed earlier, low SES tends to directly erode EF among younger children; for adolescents, however, EF often functions as a resource, moderating the ill effects of SES on mental health. A developmental perspective also encourages us to think more about the relative influence of the home environment compared to the larger school and neighborhood environment in the lives of low-SES children. Thus, the impact of poverty directly on parents relative to the impact of poverty on school and community may play out quite differently as a function of child age. Finally, all of our research programs will benefit from better implementation of multiple levels of analysis to bring together converging lines of evidence from the community, neighborhood, family, individual, and genetic realms. An integrated understanding of the risks and sources of resilience in children affected by poverty is likely to lead the best solutions for this social problem that is so very costly, both in terms of human suffering as well as losses of human and economic capital.

Our overarching goal in writing this chapter was to create a compendium of the excellent scholarship that has convincingly demonstrated the critical roles of poverty and low socioeconomic status in the development of most forms of psychopathology. What is quite clear from this review is that we have moved beyond the important but insufficient question of *Does poverty matter for developmental psychopathology?* to the essential question of *How does poverty matter for developmental psychopathology?* The research outlined here on the psychosocial and biological mechanisms of poverty's effects on a child's brain, body, and functioning is substantial, compelling, and exciting because it illuminates numerous processes and pathways that can be targeted in treatment and prevention. The consistency of findings across multiple levels of analysis and inference provides a strong basis on which to urge researchers to explicitly include and explore income and SES variables in developmental psychopathology research—controlling for or covarying the effects of income/SES relegates this critical risk factor to a nuisance variable. It is clear that poverty and low SES are more than a nuisance and instead constitute a very powerful determinant of children's mental health.

INTRODUCTION

Each day approximately three-quarters of a million adults around the world experience the pleasures and profits as well as the trials and tribulations of becoming a new parent. Each reader of this page has had the experience of being parented, and many relive the experience when they parent their own children. Evolutionary theory distinguishes between bringing a new individual into the world and caring for an existing individual, childbearing versus child caring (Bjorklund & Ellis, 2014; Bjorklund, Yunger, & Pellegrini, 2002). Whereas species lower in the phylogenetic hierarchy are principally childbearers, mammals such as *Homo sapiens* tend to be devoted child carers perhaps because the investment in a small number of progeny is great or, altricial, newborn human children are totally dependent on their parents. Human parents are fundamentally invested in their children: their survival, their socialization, and their education. Parents are tasked with preparing children for the physical, economic, and psychosocial situations that are characteristic of the environment and culture in which children must survive and, it is hoped, thrive (Benedict, 1938; Bornstein, 1991, 2012; LeVine, 2003). In consequence, understanding parenting is becoming a high-profile endeavor, and understanding the determinants of healthy and typical as well as unhealthy and atypical parenting is of increasing and compelling interest as well. Although parenting remains a somewhat mystifying subject about which almost everyone has opinions but about which few people agree, parenting study is enjoying popularity today as never before, and consequently a surprising amount of solid science is accumulating about parenting and its determinants.

Adults already know (or think they know) something about parenting by the time they first become parents. Indeed, human beings appear to possess some intuitive knowledge about parenting, and certain characteristics of parenting may be wired into our biological makeup. For example, people almost everywhere speak to babies even though they know that babies cannot understand language, and people even speak to babies spontaneously in a speech

This chapter summarizes selected aspects of my research, and portions of the text have appeared in previous scientific publications cited in the references. This research was supported by the Intramural Research Program of the National Institutes of Health, *Eunice Kennedy Shriver* National Institute of Child Health and Human Development. I thank L. Henry for superb assistance. Address correspondence to: Marc H. Bornstein, Child and Family Research, *Eunice Kennedy Shriver* National Institute of Child Health and Human Development, National Institutes of Health, Suite 8030, 6705 Rockledge Drive, Bethesda MD 20892–7971, U.S.A. E-mail: Marc_H_Bornstein@nih.gov.

register specially reserved for them. However, human beings also acquire important knowledge of what it means to parent children through generational, social, and media images of parenting, children, and family life, knowledge that plays a significant role in helping people formulate their parenting cognitions and guide their parenting practices. For example, parents from different cultures differ in their opinions about all manner of caregiving-related issues, such as the relevance of diverse competencies specific for their children's successful adjustment, the ages they expect children to reach different developmental milestones, and so forth. Direct experiences with children and self-constructed parenting also help formulate parenting attitudes and actions.

What forces affect when and how parents parent? This question of determinants goes to the heart of much of contemporary parenting science. It is the subject matter of this chapter. In consequence, the chapter does not dwell on parenting as a phase of adult development or parenting as an instrumental activity vis-à-vis children and their development. Of course, parents are concerned about themselves as parents, and parents are concerned about the everyday well-being of their children as well as their children's long-term health and growth. Nor does the chapter address the origins of parenting studies, theories of parenting, or arguments for and against parenting effects. For an introduction and overview of these important parenting issues, see the companion chapter in Bornstein (2015).

Rather, this chapter surveys central issues concerning *determinants of parenting*, both normal and typical as well as abnormal and atypical (Cicchetti & Toth, 2009); it pursues the following course. The first section of the chapter briefly overviews, *in seriatim*, cognitions and practices that principally instantiate parenting and then parents, the principal actors in the human drama of caregiving. As a transition to the main focus on the multiple determinants of parenting, the chapter next alerts the reader to a series of methodological concerns useful in understanding and unpackaging determinants of parenting and points to some gaps in the literature that suggest future directions of research. The chapter then turns to the main substance—a review of the determinants of parenting in parents, children, and contexts. The chapter then addresses translational implications and concludes.

PARENTING AND PARENTS

As judged by psychoanalysis, ethology, psychology, and neuroscience, parents engage in a peculiar kind of life's work: Parenting is a delicate blend of altruism, prosociality, devotion, and selflessness, marked by constantly challenging demands, changing and ambiguous criteria, and all too frequent evaluations. Parenting entails both affective components—in terms of commitment, empathy, and positive regard for children—and cognitive components—the how, what, when, and why of caring for children. So, thinking about the determinants of parenting demands multilevel considerations of psychobiology, cognition, emotion, and sociality as well as multidisciplinary considerations of biology, psychology, sociology, and anthropology.

According to a nationwide survey conducted by the National Center for Children, Toddlers, and Families, more than 90% of parents say that, when they had their first child, they not only felt "in love" with their baby but were personally happier than ever before in their lives (Civitas Initiative, Zero to Three, & Brio Corporation, 2000). Parents report relatively higher levels of happiness, positive emotion, and meaning in life than do nonparents (Nelson, Kushlev, English, Dunn, & Lyubomirsky, 2013). Parents find interest and derive considerable and continuing personal reward in their relationships and activities with their children. They report that spending time with their children, especially in recreation or educational child care, ranks among their most enjoyable activities (Krueger, Kahneman, Schkade, Schwarz, & Stone, 2009; Nelson et al., 2013). And they are doing more of it: Bianchi (2000), Sayer, Bianchi, and Robinson (2004), and Aguiar and Hurst (2007) concur that adults in the United States (as elsewhere in the world; Gauthier, Smeeding, & Furstenburg, 2004) are spending more time with their children today than in the past. Notably, mesocortico-limbic dopamine is involved in both reward-related learning and mammalian caregiving (Insel, 2003).

For many, parenthood enhances psychological development, self-confidence, and a sense of well-being. Parenting translates into a constellation of new trusts, provides opportunities for enrichment and learning, and unveils a panorama on the "larger picture" of life. Parenthood also gives adults ample occasion to confront new challenges and to test and display their competencies (Crittenden, 2004). Markus, Cross, and Wurf (1990) learned that feelings of competence as a parent constitute a highly common aspect of the self as desired by adults. More commonly, however, parenting is identified with its instrumental character, as acts of providing for and supporting the biological, physical, intellectual, emotional, and social development of progeny. Human children cannot and do not grow up as solitary individuals, so parents want to know how best to

take advantage of the opportunities parenting affords and cope with parenting's unrelenting demands. Some consider this instrumental construal of parenting a lifelong 24/7/365 job. Parenthood is a major phase and constituent ingredient of mature and generative adulthood, and parenthood is central to childhood, to child development, and to society's long-term investment in children. Thus, we are motivated to know about the meaning and importance of parenthood and parenting and about how parenting develops. First, however, we address two introductory questions. How is parenting expressed, and who parents?

Parenting Cognitions and Practices

Parenting is instantiated in cognitions and practices, what parents think and what they do. Child rearing entails all sorts of mentation and consists of multiple kinds of interactions of parent, child, and context; parents possess attitudes, expectations, and attributions, and they naturally engage their children in a range of diverse activities and do not only or necessarily behave in uniform ways. Parenting appears to be a social construction that judiciously combines personological consistency with situational specificity. Instead of broad styles, it may be more appropriate and valid to conceive of parenting as fine-grained domains of practices and cognitions. Parenting is therefore multidimensional, modular, and specific (Boivin et al., 2005; Bornstein, 2002a, 2006a; Bornstin et al., 2008; Bradley & Caldwell, 1995; E. Skinner, Johnson, & Snyder, 2005) and so supports the identification and empirical focus on relatively independent cognitions and practices. When the chapter turns to determinants of parenting, it is concerned with the determinants of variegated cognitions and practices.

Parenting cognitions have long held a popular place in the study of parenting, and they span a wide array of goals, attitudes, expectations, perceptions, attributions, and actual knowledge about parenthood, about one's own parenting, about childhood, and about one's own child(ren). Cognitions also form a framework within which parents perceive and interpret their children's behaviors. Parenting practices give expression to parenting cognitions and constitute a large measure of children's worldly experience. The contents of human parent-child interactions are dynamic and varied and include multiple obligatory as well as discretionary activities. Parents nurture and protect children, but they also guide children in understanding and expressing proper feelings and emotions, educate children as to actions that are acceptable for the stage of childhood they occupy, and prepare children for adaptation to a wider range of life roles and contexts they will encounter as they grow. Take protectiveness as an expression of parental warmth (i.e., affection, nurturance, and responsiveness). The developmental literature historically treated protectiveness as a unidimensional construct (Parker, 1983; Sargent, 1983). Besides trying to protect their children from physical harm, however, parents also engage in diverse behaviors to protect their children from psychological and social harm (Power, 2004). Not unexpectedly, different kinds of protectiveness show different relations with different domains of child adjustment (Power & Hill, 2008). So parent protectiveness has proved to be better conceptualized as illustrative of the multidimensional, modular, and specific nature of parenting, and the effectiveness of parent protectiveness is better analyzed with respect to its different facets and effects. In practice, of course, parent-child interaction is dynamic, intricate, and meshed, and parents regularly engage in combinations of cognitions and practices. Taken as a totality, parenting cognitions and practices constitute a varied and demanding task set, and adults differ considerably in terms of how they esteem various components of the caregiving repertoire as well as in how successful they are in executing different components.

The attitudes and actions of children's parents, and the environments of caregiving they create, matter in that they shape children and the course of children's academic, emotional, behavioral, and social development (Bates, Schermerhorn, & Petersen, 2012; Belsky & de Haan, 2011; Bornstein, 2015; Collins, Maccoby, Steinberg, Hetherington, & Bornstein, 2000; Domitrovich & Bierman, 2001; Goodnow, 2002; Holden & Buck, 2002; Maccoby, 1992; Roksa & Potter, 2011; Sigel & McGillicuddy-De Lisi, 2002; Stormshak, Bierman, McMahon, & Lengua, 2000; Vandell, 2000). We know this from a long history and wide variety of convergent approaches from correlational designs to experiments to interventions. For example, Patterson and Forgatch (1995) reported substantial correlations between parents' disciplinary and monitoring practices and children's negative and coercive behavior both at home and in out-of-home contexts, and Chilcoat and Anthony (1996) reported significant increases in risk of adolescents' drug sampling for every unit of decrease in parental monitoring after partialing age, gender, and ethnic status. The foregoing studies, although based on correlations, illustrate associations between parenting and child development that transcend a common context and obtain above common-cause third-variable controls (Ganiban, Saudino, Ulbricht, Neiderhise, & Reiss, 2008; Knafo & Jaffee, 2013; Price & Jaffee, 2008).

Longitudinal associations, adoptive parent–adopted child associations, and other emerging conservative strategies that supplant simple zero-order correlations constitute additional design improvements on cross-sectional and genetically related parent-child approaches. For example, higher levels of warm and sensitive parenting predict later decreases in child negative reactivity, even controlling for initial levels (Bates et al., 2012), and higher levels of harsh and controlling parenting predict increases in child negative reactivity, even controlling for initial temperament (Belsky, Fish, & Isabella, 1991; Braungart-Rieker, Hill-Soderlund, & Karrass, 2010). Using an adoption design that differentiates heritable (from biological parent) and environmental (from adoptive parents) effects on the adoptee's behavior, Ge et al. (1996) found that adoptive parents' behavior was associated with the psychiatric status of the adoptee's biological parents and that this association was mediated by the adoptee's behavior: Adoptees born to parents with psychopathologies were more hostile and antisocial, and their adoptive parents used more harsh discipline and were less nurturing and involved (see also O'Connor, Deater-Deckard, Fulker, Rutter, & Plomin, 1998). Apparently having genes of parents with psychopathologies affects adoptees' behavior and thus adoptive parents' parenting as well. Adoptive parent educational achievement is associated with adopted children's schooling (Bjoerklund, Lindahl, & Plug, 2006). Rice et al. (2010) employed a prenatal cross-fostering design, including pregnant mothers who were related or unrelated to their child as a result of in vitro fertilization and surrogacy, to disentangle inherited and environmental influences. Their logic was: If links between prenatal stress and offspring outcome are environmental, the association should be observed in unrelated as well as related mother-child pairs. Associations between prenatal stress and offspring birthweight, gestational age, and antisocial behavior were seen in both related and unrelated mother-offspring pairs, consistent with environmental links being determinative. The association between prenatal stress and offspring anxiety in related and unrelated groups appeared to be due to current maternal anxiety/depression rather than prenatal stress. By contrast, the link between prenatal stress and offspring attention-deficit hyperactivity disorder (ADHD) was present only in related mother-offspring pairs and therefore was likely attributable to genetic factors.

Experimental manipulations advance beyond parent-child correlations in attempts to document causal relations between parenting cognitions or practices and children's development. Animal experiments and natural experiments, designed experiments, and experimental interventions with human beings give evidence of parenting effects. Experiments with animal populations since Harlow's (1958) studies of monkeys raised with contrasting surrogate mothers provide invaluable and unique data about parenting because many informative manipulations are unethical with human beings. Variation in maternal care by rat dams (specifically arched-back nursing and licking and grooming) during the first postnatal week affects endocrine, behavioral, and even cognitive development of offspring: Pups of maternal dams show a decreased stress response, increased glucocorticoid receptor expression and synaptogenesis in the hippocampus, and enhanced spatial memory compared to pups of nonmaternal dams (Fish et al., 2004). The same effects also appear in cross-fostered pups (I. C. G. Weaver et al., 2004), demonstrating that they are not due to genetic inheritance. Notably, these endocrine, behavioral, and cognitive effects persist to maturity.

Experiments that have randomly assigned human families to treatment versus control groups and that intervene with the parents but do not simultaneously treat the children are rare (for obvious reasons), but several have shown that treatment can change parental thinking and action toward children in specified ways and, in consequence, alter child development. For example, intranasal administration of neuropeptides can reach the central nervous system, and oxytocin (OT) is known to play a key role in regulating social behavior and supporting the parent-infant bond (MacDonald & MacDonald, 2010). Naber, van IJzendoorn, Deschamps, van Engeland, and Bakermans-Kranenburg (2010) videorecorded fathers during a play session with their toddlers once following intranasal OT administration and then after intranasal placebo administration. Fathers increased their support for learning and exploration with respect for the child's autonomy following OT administration. Utilizing a double-blind, placebo-controlled crossover design, Weisman, Zagoory-Sharon, and Feldman (2012) observed fathers and their infants twice in a face-to-face still-face paradigm following administration of OT or placebo. OT administration increased fathers' salivary OT and key parenting behaviors that support parent-infant bonding. Moreover, parallel increases were found in infant salivary OT and engagement behavior, including social gaze, exploration, and reciprocity. In other words, OT administration had parallel effects on the treated parent and untreated child.

Interventions with parents have two construals. Near the end of this chapter, interventions are discussed for their translational implications to improve parenting

clinically and to inform policy. Intervention trials also can be interpreted as experimental manipulations that test theoretical models of parenting effects (P. A. Cowan & Cowan, 2002; van Doesum, Riksen-Walraven, Hosman, & Hoefnagels, 2008). An intervention designed to facilitate maternal responsiveness enhanced children's language skills (Landry, Smith, Swank, & Guttentag, 2008); a second to improve parents' behavior support found positive effects on key indicators of children's school readiness (Lunkenheimer et al., 2008); and a third to boost parents' positive behavior practices reduced problem behaviors in young children (Dishion et al., 2008).

Parenting in one generation is consequential because it has manifest instrumental validity for the succeeding generation. Importantly, individual differences in parenting cognitions and practices tend to be stable, meaning that parenting assessed at one point can to a certain degree be assumed to reflect past as well as future parenting. Short-term "test-retest" reliabilities of cognitions ($r = .74$) and practices ($r = .59$) in parents tend to be high (Holden & Miller, 1999). Holden and Miller (1999) meta-analyzed the consistency of beliefs and behaviors of parents (mostly mothers) with both relative standing and mean level change in mind and considering three circumstances: comparisons across time, children, and situations. Consistency was found to depend on circumstance as well as parenting construct, child age, and methodological approach among other moderators. They arrived at diminishing summary levels of child-rearing stability across children ($r = .50$), across time ($r = .45$), and across situations ($r = .26$) and increasing differences across children ($d = .23$), across time ($d = .40$), and across situations ($d = .52$) (see also Bornstein, Gini et al., 2006; Dallaire & Weinraub, 2005; Haltigan, Roisman, & Fraley, 2013; Maas, Vreeswijk, & van Bakel, 2013; Porter & Hsu, 2003, for supporting instance cases since the Holden and Miller meta-analysis).

Parents

Now that the principal attitudes and actions in parenting have been identified, it is appropriate to turn to consider parenting's principal actors. Who parents children? The majority of children throughout the world grow up in family systems with more than one or two significant parenting figure guiding a child's upbringing and socialization, even if the research literature usually focuses on mothers. Mothers and fathers are not children's only caregiving agents. The conception of parenting as a set of cognitions and practices expands the discussion of determinants of parenting beyond biological parents to other related (siblings, grandparents) and unrelated (adoptive, foster, and alloparents) caregivers who may also "socially" parent children (Leon, 2002). This chapter is largely circumscribed to determinants of parenting in parents, although for completeness sake determinants of some nonparental caregiving are briefly described.

Mammals tend generally to be devoted child "carers" (Bjorklund et al., 2002), and almost all mammalian species are matrilocal, the norm in mammalian care falling to mothers (Clutton-Brock, 1991; Wilson, 1975). On this account, maternal care is much more common than paternal care (in mammals, males provide care in less than 5% of species; Moller, 2003). Most observers agree that mothers (and female relatives) normally play the more central role in human child rearing (Barnard & Solchany, 2002; Civitas Initiative et al., 2000; Holden & Miller, 1999; Leiderman, Tulkin, & Rosenfeld, 1977; Weisner & Gallimore, 1977) and in many nonhuman mammalian species (Briga, Pen, & Wright, 2012). The maternal role is better articulated and defined than is the paternal role, and in their own upbringing, women are generally afforded more opportunities to acquire and practice skills that are child centered. Mothers are primarily responsible for home and family, and they are believed to bear a heavier psychic burden in parenting (Barnard & Solchany, 2002; Calzada, Eyberg, Rich, & Querido, 2004; Metsäpelto & Pulkkinen, 2003; Verhoeven, Junger, Van Aken, Deković, & Van Aken, 2007). Even among species where males show considerable parental altruism, they commonly do less caregiving work than females (Wilson, 1975). One finds many more nonresident dads than moms (Sorensen, 1997), for example.

Homo sapiens is an alloparental species, and cooperatively breeding vertebrates (like human beings) often enlist "helpers" who take care of immature offspring who are not their own within the social group (Hrdy, 2009). Among humans, siblings sometimes care for children (Zukow-Goldring, 2002); grandparents often assume central roles in child caregiving (P. K. Smith & Drew, 2002); and numbers of young children around the world normatively participate in diverse types of nonparental nonfamilial care (Clarke-Stewart & Allhusen, 2002). Grandparental help may be indirect or direct. Increased life expectancy, decreased family size, more maternal employment, and the rise of single-parent families have conspired to increase the potential for grandparents (and others) to play greater parts in the lives of their grandchildren (Arber & Timonen, 2012; Dunifon, 2012; Kornhaber, 2002; Tanskanen & Rotkirch, 2014; Witkin, 2012). Approximately 43% of grandparents provide some child care on a regular basis (Lou & Chi, 2012; Stelle, Fruhauf, Orel, & Landry-Meyer,

2010), and in custodial grandparent families, children are reared solely by grandparents (as the result, e.g., of maternal incarceration or other parental problems; Poehlmann et al., 2008).

Many tasks associated with child care can also be purchased in the marketplace. Today children enter that kind of care early, stay for longer periods of time, and change types of care often (Burchinal, Magnuson, Powell, & Hong, 2015). Beginning in the child's first year, about 50% of the children in the United States, for example, experience regular nonparental child care, and by the preschool years, more than 75% of children have experienced some type of child care. As a consequence of contemporary social and cultural forces (mentioned earlier), the use of child care services has burgeoned, and nonparental caregivers have assumed increasing responsibility for meeting children's developmental needs and preparing children for a future in society (Gottfried, Gottfried, & Bathurst, 2002).

It has been argued that mothers and fathers and others do not necessarily share the same "investments" in parenting (Geary, 2000), and human cultures distribute the tasks of child care in different ways (Leinaweaver, 2014). Children's parents and others divide the labor of caregiving, and the content, meaning, and effects of mother-child, father-child, and other-child relationships all have significances. Indeed, researchers have reckoned that, for example, mothers and fathers make independent contributions to children's development (A. Martin, Ryan, & Brooks-Gunn, 2007; Ryan, Martin, & Brooks-Gunn, 2006), children develop attachments to different people (Howes & Oldman, 2001; Howes & Spieker, 2008), and social relationship theory posits that multiple associations are important to children because they meet different developmental needs (Vandell, 2000).

All said, it comes as little surprise that a more extensive body of information has developed about determinants of mothering than about fathering or other caregiving. However, the division of child care implies that developmental science eventually needs to consider determinants in mothers, fathers, as well as multiple other "parents."

Summary

Parenting expresses itself in both the beliefs parents hold and the behaviors they exhibit. Many conceptually separate parenting cognitions and practices have been discerned, and each is developmentally significant. Moreover, many people parent children. With parenting so demonstratively meaningful, we should ask not whether parents matter, but what makes a good parent. Parenting is important; therefore, the determinants of parenting are important.

Parenting is not an activity people normally think of as being especially scientific. Like most things, however, better parenting benefits from greater knowledge and understanding, which in turn depend on theory and research. Happily, there is a science of parenting with developing theory and growing systematic research behind it. The contemporary parenting literature, however incomplete, now contains thousands of studies. This chapter of determinants of parenting is based on that consolidating science of parenting.

SOME METHODOLOGICAL CONSIDERATIONS AND FUTURE DIRECTIONS

Measurement is an importunate challenge in contemporary parenting science (Bornstein, 2010a; Bornstein & Toole, 2010). Hurley, Huscroft-D'Angelo, Trout, Griffith, and Epstein (2014) reviewed the psychometric quality of parenting measures published from 1985 to 2009. Their initial search yielded 164 English-language measures, which was reduced to 25 that supplied some psychometric information. Considering 10 psychometric properties, out of the 25, 7 had no acceptable psychometric properties, 7 had only 1 or 2, 6 had 3 to 4, none had 5 to 6, and only 5 had strong psychometric properties in 7 or more. Only 5 measures provided norming information.

The parenting literature is also encumbered by mixed findings, and empirically there is widespread lack of agreement regarding which assessment methodology may be most effective and valid to use, as observation, test, and interview and questionnaire methods have different strengths and limitations (Bögels & van Melick, 2004; Collett, Gimpel, Greenson, & Gunderson, 2001; Dadds, Maujean, & Fraser, 2003; Gaylord, Kitzmann, & Coleman, 2003; O'Connor, 2002; Reitman, Rhode, Hupp, & Altobello, 2002; Rhoades & O'Leary, 2007). Moreover, which features of parenting are most vital to study presents a central, perennial, and sometimes vexing choice (Bornstein, 2013b). Related empirical concerns focus on the need for measurement invariance of assessments across parent gender, socioeconomic status (SES), and culture (Adamsons & Buehler, 2007; Furman & Lanthier, 2002; L. Huang et al., 2011; Locke & Prinz, 2002; Senese, Bornstein, Haynes, Rossi, & Venuti, 2012; Stolz, Barber, & Olsen, 2005). Additional challenges for the future study of determinants are to acknowledge and rectify the fact that that, up to now, the rapidly developing discipline of parenting research has

focused too narrowly on determinants of mothering to the near exclusion of other caregivers and of multiple family relationships; on selected determinants of parenting, such as SES, to the near exclusion of others, such as religion; on determinants in normative nuclear families, when the world is populated with a bewildering panoply of family compositions (Ganong, Coleman, & Russell, 2015; Perrin, Siegel, & the Committee on Psychological Aspects of Child and Family Health, 2013; Shah, Zao, & Ali, 2011); and on determinants of parenting in the minority (Western, educated, industrialized, rich, and democratic) developed world rather than the majority developing world (Bornstein, 2010b; Henrich, Heine, & Norenzayan, 2010; Tomlinson, Bornstein, Marlow, & Swartz, 2014). Future cutting-edge research designs will also account for assortative mating, control one parent in analyzing determinants on the other parent, and other areas.

Another pervasive critique of contemporary parenting science is that research in the area has not yet adequately addressed determinants of the nuanced complexities of everyday parenting, where the rubber meets the road. Parents multitask; parenting is more than feeding and teaching and being emotionally available. Parenting is planning and organizing (arranging playdates, identifying after-school activities, finding pediatricians) that consumes mental and physical energy and time. Parenting is disambiguating moment-to-moment novel, complex, dynamic, uncertain information associated with children and child rearing. Parenting is expecting of oneself and being expected by others to caregive consistently, appropriately, and effectively. Parenting is being highly motivated to succeed at these many assignments. Using nonparticipant unobtrusive naturalistic observational methods, Radesky and colleagues (2014) captured frequency, duration, and modality of mobile device use versus caregiving of people tending young children eating in fast food restaurants. Caregivers who were highly absorbed with their devices also responded harshly to child misbehavior.

Consumers of the determinants of parenting literature should consider that parenting also affects each putative determinant, and untangling direction of effects is a persistent vexing concern. This field needs to move beyond single-point-in-time cross-sectional determinant-of-parenting studies that leave the direction of parenting determinants ambiguous. Strong evidence that a given factor "determines" parenting would be a Time 1 (T1) determinant–Time 2 (T2) parenting link that (good) controls for the T1 level of the parenting variable in question and (better) also controls for the concurrent T2 association between the putative determinant and the parenting outcome. Such designs are supported by, for example, a partial correlation between T1 determinant and T2 parenting, controlling for T1 parenting or a cross-lag correlation in which the T1 determinant predicts the part of the variance in T2 parenting that remains after controlling for T1 parenting and its concurrent link to the T2 determinant or a comparable regression formulation. (Simple longitudinal precedence is only suggestive of causality; Reiss, 1995.) When is a determinant effective? Consider three possible temporal models of the effectiveness of some determinant of parenting. As described, an antecedent determinant of parenting might be effective and endure, independent of later experience with the determinant and of any earlier contribution of the parenting variable. This antecedent determinant model is consonant with a sensitive period interpretation of determinant effects on parenting (Bornstein, 1989). Alternatively, a determinant could exert a unique influence on parenting only at current points in time that override the effects of antecedent influences. Or, in a cumulative/additive/stable model, a determinant at any one time might not necessarily affect parenting, but meaningful longitudinal relations need to be structured by the determinant continually repeating and aggregating through time. To date, theoretical explanations for specific pathways and directions of associations are weak, and methodologically rigorous studies (e.g., using longitudinal data in conjunction with independent assessments of determinants) continue to be the exception.

The issue of determinants raises the important questions of multicausality. On one hand, many "causes" of parenting naturally covary, so multicollinearity is an issue that merits close attention. For example, youth is associated with less than optimal parenting, perhaps because young parents themselves are still developing executive functions or a sense of self, but people who have children early in their life career are also more likely to have low education and low SES, which adversely affect their parenting. Bandura (1997) defined self-efficacy as personal judgments about one's ability to execute a future course of action and to encompass feelings of competence about one's ability to perform a role or task. Self-efficacy has come to occupy a central role in parenting science and is linked with positive parenting. In Bandura's analysis, efficacy is influenced by a number of factors, including task difficulty, effort expenditure, vicarious experiences, physiological and mood states, social or verbal persuasion, and outcome expectancies that have been formed by past successes and failures. Self-efficacy as much as any construct exemplifies multideterminacy in parenting. As we shall see, Bandura underestimates the case, as a slew

of other factors, from depression to child care experience to social support, likewise co-construct self-efficacy in parents. To identify any one determinant of parenting, it is necessary to covary third-variable confounders.

On the other hand, it is certain that parenting has many determinants, and it is illogical and nonscientific to assert the preeminence of one cause over another when each in its own way contributes to some effect. Within complex developmental systems, it is unlikely that any single factor can be expected to account for substantial amounts of variation. Parenting effects are also conditional and not absolute (i.e., true for all parents under all conditions). More complex conceptualizations that incorporate larger numbers of influential variables will likely explain parenting better than simpler ones with fewer variables. The constructive enterprise is really to understand how all relevant forces might work in concert. Parenting is a multilevel phenomenon and will be better understood eventually by employing evolutionary, biological, comparative, behavioral, and cultural perspectives.

By 1997, Holden reported that more than 30 variables had been identified to empirically influence parenting. The literature concerning endogenous and exogenous sources of influence on parenting has since burgeoned further, but antecedents have typically been studied in isolation, and few investigations evaluate multiple influences simultaneously. Thus, the overlap of different antecedents vis-à-vis the unique contribution that any one may make to parenting remains essentially unexplored. With this limitation in mind, family systems theorists have emphasized the importance of considering the possible independence *and* interdependence of multiple organismic, environmental, and experiential determinants of parenting. Various models of action might obtain: It could be that some determinants compete with each other, others may be additive, and still others interact (Holden & Miller, 1999).

Furthermore, effect sizes for any one determinant-parenting relation, or for contingencies that operate across different components of the family system, might be small in magnitude. This is not a statement about the unimportance of small effects (see Bornstein, 2014) but rather of the need to build models of parenting that focus on the ways small effects might combine.

The number and complexity of determinants have implications for the expression of parenting. Holden and Miller (1999) pointed out that, if parenting is determined by a small number of consistent or operative variables, parenting might be characterized by great similarity. If, however, parenting is determined by a large number of influences or variables that change, parenting might be less consistent.

The still-inadequate situation of contemporary parenting research is therefore ripe for revolution and advancement. In the meantime, the account of determinants of parenting that follows must be understood in light of extant literature, and in weighing the ensuing survey, the reader is best informed by a clear understanding of these several constraints and shortfalls as well as others that arise as successive topics are discussed.

DETERMINANTS OF PARENTING

For heuristic purposes, the considerations of parent, child, and contextual determinants of parenting in this chapter treat each factor as a determinant, and each has been investigated as such. However, in an organized, linked, multicausal system, any element has the potential to moderate both the structure and the impact of other elements in the system.

Suppose (following Bronfenbrenner & Morris, 2006) that parenting is the joint product of four defining properties: Process × Person × Context × Time. *Process* refers to dynamic interactions that the parent experiences. In considering child development, Bronfenbrenner and Morris (2006) gave central attention to "proximal processes," which they posited to be most important. Applied here, such processes would consist of the parent's experiences within microsystems and include social interactions with others and engagement with particular materials in a setting. Characteristics and qualities of the parent *qua person*, factors such as age, gender, personality, and competencies, are posited to determine parenting.

Context refers to nested micro-, meso-, exo-, macro-, and chronosystems which Bronfenbrenner (1979) identified and distinguished in conceptualizing different spheres of influence on an individual. To paraphrase, he defined the microsystem as the pattern of activities, roles, and interpersonal relationships experienced by the parent in face-to-face settings with particular physical and material features. The microsystem also can encompass mass media (television, movies, or the Internet), given that these sources affect a parent's functioning. For example, based on a national U.S. sample of 1,000 parents living with at least one target child 6 to 17 years old whom Romer and his colleagues (2014) exposed to sequences of three pairs of short scenes with either violent or sexual content from popular movies, parents became progressively desensitized to both violence and sex in movies, which may contribute to their increasing acceptance of both types of content for young children.

The parent microsystem is nested under the mesosystem, defined in paraphrase as linkages and processes that take place between two or more settings containing the parent. A mesosystem is in essence a system of microsystems. For example, mothers are likely influenced by information they receive from their support networks (McConnell, Breitkreuz, & Savage, 2011) or when attending a school event affects their parenting (McIntosh, Lyon, Carlson, Everette, & Loera, 2008). The exosystem encompasses linkages between features of the environment the parent does not directly encounter but that guide parenting through their effects on the microsystem and mesosystem. For example, parents' use of computer technology to telecommute rather than work at their workplace illustrates an exosystem setting effect on parenting (Golden, 2012). At the outermost macrosystem level are overarching patterns of beliefs, values, customs, and living conditions. Bronfenbrenner (1979) highlighted the importance of macrosystem constituents, such as religion, social class, and culture. Cutting across these four levels is the dimension of time, the chronosystem, which includes minute-by-minute exposure to various processes, the periodicity of episodes over broader intervals of days or weeks, and even longer life course and historical eras. The chronosystem can be viewed in terms of the comparative salience of proximal processes occurring at different ages (e.g., critical or sensitive periods; Bornstein, 1989) or in terms of persons encountering different macrosystem events at different ages (Elder & Shanahan, 2006).

Bioecological theory provides a rich and generative framework for drawing attention to important active ingredients and features of different determinants and in formulating ways to conceptualize relations between different determinants. A crucial point is that the meso-, exo-, macro-, and chronosystems are not separate from the parent's immediate microsystem. Rather, each system permeates those inferior to it. Moreover, it is important to recognize the bidirectional nature of system linkages. For example, the interplay between parent work conditions and family functioning, a usual exosystem analysis, involves assessments of work→family (work-to-family spillover), where work demands infringe or enhance parent functioning (Hsueh & Yoshikawa, 2007; Krapf, Ursprung, & Zimmerman, 2014), as well as family→work (family-to-work spillover), where parent responsibilities infringe or enhance work performance (Buehler & O'Brien, 2011; Krapf et al., 2014). This system structure is best viewed as hierarchical in nature, with lower-order elements nested within higher-order elements and no one level predominant (Ungar, Ghazinour, & Richter, 2013). Here I adopt this scheme to model the determinants of parenting. A further important consequence of multiple linkages across system levels reinforces the probabilistic nature of parenting, given that the impact of influences from one level can be moderated by characteristics at other linked levels.

A vital step on the path to fully understanding parenting is to evaluate the many forces that structure it. The origins of individual variation in maternal, paternal, and alloparental caregiving, whether of cognitions or practices, are extremely complex, and it has long been explicitly acknowledged that parenting is multiply determined. Contexts (such as evolution, history, ecology; culture, ethnicity, religion, SES; neighborhood, networks, family, situation), children's structural and psychological characteristics, and parents' own biological and psychological characteristics work in tandem to construct a parent. Consistent with a relational developmental bioecological orientation (Belsky, 1984; Bornstein, 2006a; Bornstein et al., 2007; Bronfenbrenner & Morris, 2006; Farnfield, 2008), this vast array of determinants can be grouped roughly (following the logic of hierarchical regression) according to their proximity to the parent from proximal to distal: (a) intrapsychic and intrapersonal characteristics of parents, (b) actual or perceived characteristics of children, and (c) contextual characteristics. A thorough and thoroughly up-to-date meta-analysis sought to quantitatively synthesize what twin and adoption studies have to say about the etiology of parenting (Klahr & Burt, 2014). Unsurprisingly, this meticulous attempt to definitively catalog genetic and environmental sources of parenting identified effects attributable to parent, child, and context. Reasons of space constrain a full accounting of all possibilities, and so this exposition of the determinants of parenting in the three main sources is illustrative rather than exhaustive.

DETERMINANTS IN THE PARENT

Because securing the survival of offspring is fundamental to evolutionary pressure, it is likely that specific biological and psychological characteristics evolved in the service of parenting. Expressions of parenting have been shown to reflect biological and psychological characteristics that equip parents (an even nonparents) to interpret and respond to the kaleidoscopic requirements and responsibilities of parenting. Even if most parents face the formidable challenges of parenthood with some degree of naiveté, parents do not meet the task totally unprepared.

Biological Characteristics

Genetic endowment, neurohormonal activity, and central nervous system structure and function constitute some of the central biological characteristics identified to condition parenting.

Genetics

Behavior genetics (BG) seeks to understand biological sources of variation in human characteristics (Plomin, DeFries, McClearn, & McGuffin, 2008). By studying individuals of varying genetic relatedness (identical and fraternal twins, biological and adopted siblings who share or do not share the same experiences), behavioral geneticists attempt to estimate the amount of variation (heritability; h^2) in characteristics that can be explained by genetic endowment. Heritability denotes inheritance of DNA and refers to the main effect of genetics on individual differences but does not necessarily imply genetic determinism (for discussions of interpretations and misinterpretations of heritability, see Plomin et al., 2008; and Visscher, Hill, & Wray, 2008). BG assumes that sources of variation in a parent characteristic can be separated into independent genetic (G) and environmental (E) components that together (with error variance) add to l00% of the variance in a characteristic. G effects are additive (A) and dominant (D), and E effects are shared (C) and nonshared plus error (E). (E is not usually measured directly but estimated as the residual variance not accounted for by G; see Caspi, Taylor, Moffitt, & Plomin, 2000.)

From a BG perspective, parenting is just another phenotype that is a reflection of nature and nurture and not an eventuality of "pure" nurture (McGuire, 2003). Genetic contributions to parenting are conceptualized as evidence of genotype-environment correlations (*r*GE). Three types of *r*GE processes have been articulated: Passive *r*GE processes occur when family members share both environments and genes; evocative *r*GE processes refer to the extent to which genetically linked traits in individuals elicit responses from others; and active *r*GE processes refer to the extent to which people seek out environments that are correlated with their genetically linked traits. Studies of the heritability of parenting usually focus on passive and evocative processes because active *r*GE processes are difficult to detect in the absence of longitudinal data (McGuire, Segal, & Hershberger, 2012).

Lytton and Gallagher (2002) and McGuire (2003) introduced and discussed BG research on the heritability of parenting beliefs and behaviors. Early BG studies focused on demonstrating that some parenting cognition or practice is heritable; for example, parents' warmth (Neiderhiser et al., 2004). Current studies investigate moderators and mediators of genetic and environmental contributions to parenting (McGuire et al., 2012). Kendler and Baker (2007) meta-analyzed child- and parent-based BG studies of contributions to parenting and found that weighted heritabilities from 12 studies that were child-based were highest for parental warmth (34–37%), then protectiveness (20–26%), and last control (12–17%), and 10 parent-based studies showed higher heritabilities for parental warmth (35%) compared to other parenting dimensions (19–23%). A succeeding review (Klahr & Burt, 2014) arrived at similar conclusions with respect to heritabilities for different dimensions of parenting in mothers and fathers based on child and parent adoption and twin designs.

A full consideration of the BG literature and the controversies it raises is beyond the scope of this chapter. Suffice it to say that empirical and philosophical points have been argued to vitiate many central BG claims (Charney, 2012; Collins et al., 2000; Elman et al., 1996; Gottlieb, 1995; Rose, 1995; Turkheimer, 1998). For example, heritability estimates are often indeterminate and variable (Klahr & Burt, 2014), as estimates fluctuate depending on the dependent construct, source of information, and other methodological factors; genes may function differently in different environments and at different times (Naumova, Lee, Rychov, Vlasova, & Grigorenko, 2013; Szyf & Bick, 2013); and meta-analyses reveal that heredity rarely accounts for as much as 50% of the variation among individuals in a particular population (Klahr & Burt, 2014; McCartney, Harris, & Bernieri, 1990). Furthermore, in genetically informed adoption and twin research, degree of biological relatedness between individuals, not specific molecular markers of genetically linked characteristics, is often the primary focus, and it has proven difficult to identify genes responsible for the heritability of complex traits, such as parenting (Plomin, 2012; Wahlsten, 2012)—although this situation is changing with respect to identifying specific genes (see Bakermans-Kranenburg & van IJzendoorn, 2008; Burkhouse, Gibb, Coles, Knopik, & McGeary, 2011; S. S. Lee et al., 2010; Mileva-Seitz et al., 2011; van IJzendoorn, Bakermans-Kranenburg, & Mesman, 2008). As to how genes might manifest in parenting, it is possible they do so through hormones implicated in childbearing and child rearing or because they contribute to the mental and emotional composition of the parent (both of these determinants of parenting are discussed next). However, contemporary parenting research is concerned with a broader range of questions than concern most heritability studies.

Hormones

The expression of parenting has been linked to hormones that are sometimes homologous in females and males (Bales, 2014; Corter & Fleming, 2002; Reburn & Wynne-Edwards, 1999). In most mammals, postpartum females respond to young differently than do nulliparous (virgin) females (Numan, 2012; Numan, Fleming, & Levy, 2006; Numan & Insel, 2003). Primiparous females are attracted to infants and care for them, whereas virgins typically avoid or reject infants, suggesting that hormonal events involved in parturition prime the brain to be sensitive to a new and unique set of stimuli (Lambert & Kinsley, 2012). Such hormonal changes enter the brain and act on neurons to modify brain function (Numan & Insel, 2003). A "female mammal's physiological state primes and activates neural and neurochemical mechanisms that promote maternal responsiveness [and]... dysregulation of such mechanisms would lead to inadequate maternal behavior" (Numan, 2012, p. 105).

Perhaps the most studied hormone is oxytocin, which promotes prosocial behavior (Galbally, Lewis, van IJzendoorn, & Permezel, 2011) and is known to support the parent-infant bond in mammals (MacDonald & MacDonald, 2010). OT has been implicated in attachment and positive parenting in different species from rodent (Champagne, Diorio, Sharma, & Meaney, 2001) to monkey (Maestripieri, Hoffman, Anderson, Carter, & Higley, 2009) to human (Feldman, Gordon, & Zagoory-Sharon, 2011). Variation in the OT receptor gene is associated with maternal sensitivity (Bakermans-Kranenburg & Van IJzendoorn, 2008). Naber and colleagues (2010) videorecorded fathers during a play session with their toddlers following intranasal OT administration and then after intranasal placebo administration. Fathers increased their support for learning and exploration with respect for the child's autonomy following OT administration. Feldman et al. (2012) assayed OT from adults who were also genotyped for oxytocin receptor (*OXTR*) and *CD38* risk alleles associated with social dysfunction. (*CD38* is an ectoenzyme that mediates the release of brain OT.) Parent-infant interactions were microcoded for touch and gaze synchrony, and participants reported on parental care in childhood. Reduced plasma OT and both *OXTR* and *CD38* risk alleles were related to less parental touch, and parents who reported less parental care showed lower plasma OT, low-risk *CD38* alleles, and less touch, suggesting that peripheral and genetic markers of the extended OT pathway might underpin core behaviors associated with human parenting. In one extension of this work, the same team observed associations between baseline OT levels in mothers and fathers and different parenting behaviors (engagement, affect synchrony, and communication). OT revealed differential associations with sexually dimorphic patterns of parental behavior: Mothers' baseline OT levels were positively correlated with affectionate but not stimulatory contact, whereas fathers' baseline OT levels were positively correlated with stimulatory but not affectionate contact (Feldman, Gordon, Schneiderman, Weisman, & Zagoory-Sharon, 2010; Feldman et al., 2011). Utilizing a double-blind, placebo-controlled crossover design, Weisman, Zagoory-Sharon, and Feldman (2012) observed fathers and their 5-month-old infants twice in a face-to-face still-face paradigm following administration of OT or placebo to the father. OT administration increased fathers' salivary OT and key parenting behaviors that support parent-infant bonding. Moreover, parallel increases were found in infant salivary OT and engagement, including social gaze, exploration, and social reciprocity. In other words, OT administration had parallel effects on the treated parent and untreated child.

Several other neurohormones show associations with parenting cognitions and practices. Decreased cortisol relates to high ratings on control and warmth, decreased emotionality in responding to children, and reduced conflict with children about rules. Mothers with higher cortisol levels are withdrawn and less interactive with children (Flinn et al., 2012). Fathers' cortisol levels are elevated at home on evenings that follow more stressful interactions with supervisors and with coworkers (Repetti, Robles, Reynolds, & Sears 2012; Saxbe, Repetti, & Nishina, 2008). Sprengelmeyer et al. (2009) implicated the likely involvement of estrogen and progestogen in mothers' emotional responses to baby faces. They suggested that neural substrates involved in reward processing and maternal behavior are possible candidate structures linked to these processes (Panksepp, 1998). Increases in prolactin (PRL) levels have been implicated in the expression of parenting in females as well as males, and fathers have higher PRL levels than nonfathers (Gettler, McDade, Feranil, & Kuzawa, 2012). Variation in the vasopressin receptor 1A (AVPR1A) is associated with maternal focused support (Avinun, Ebstein, & Knafo, 2012).

Whereas estradiol plays a role in regulating maternal behaviors in female animals, the conversion of testosterone (T) into estradiol is believed to be involved in regulating paternal behavior in male animals (Trainor & Marler, 2001, 2002) and may constitute an endocrinological basis of paternal care (Fernandez-Duque, Valeggia, & Mendoza, 2009). Human fathers show different peripheral steroid hormone levels compared with childless men (Storey,

Walsh, Quinton, & Wynne-Edwards, 2000). In men, T is elevated during mate acquisition (and conspecific competition) but downregulated in parenting (Gettler, McDade, & Kuzawa, 2011). A large representative study in the Philippines showed that, among single nonfathers, men with high waking T were more likely to become partnered fathers by the time of follow-up 4.5 years later. Men who became partnered fathers then experienced large declines in waking and evening T, declines that were significantly greater than declines in single nonfathers (Gettler, McDade, Feranil, & Kuzawa, 2011). Men with higher T levels report less sympathy in response to an infant cry (Fleming & Li, 2002), and fathers with higher T engage in less caregiving (Alvergne, Faurie, & Raymond, 2009; Kuzawa, Gettler, Muller, McDade, & Feranil, 2009).

In considering the possible implications of pregnancy-related hormones and other caregiving-involved hormones, it is well to remember that many individuals who do not give birth to children—fathers, grandparents, in-laws, adoptive parents—not only parent them but come to love and develop strong emotional bonds with them too (Rilling, 2013).

The Nervous Systems

Just as genes and hormones are wrapped up in parenting, so are the structure and function of the autonomic and central nervous systems (Bridges, 2008; Brunton & Russell, 2008; Numan & Insel, 2003). Esposito and his colleagues (2014) measured autonomic physiological arousal using the novel technique of infrared thermography while Italian and Japanese adults viewed unfamiliar infant and adult faces of ingroup versus outgroup members. Both Italian and Japanese showed significant physiological activation (increase of facial temperature) for both ingroup and outgroup infant faces. Arousal responses to infants are mediated by the autonomic nervous system. These same investigators also used three convergent methodologies – Galvanic Skin Response (GSR), cardiac dynamics via Inter-Beat Interval (IBI), and right hand temperature change (RHTC) in fathers of typically developing children and non-fathers listening to the cries of infants later diagnosed with ASD compared to typical infant cries and laughter. They found that fathers and non-fathers alike show greater negative responses (increased GSR) to ASD compared to typical infant cries and laughter. Fathers showed higher IBI and greater RHTC than non-fathers while listening to typical and atypical cries. Thus, fathers and non-fathers show emotional arousal mediated by sympathetic activation while listening to cries of children with ASD (Esposito et al., 2015).

Parenthood is known to alter the adult brain (Barrett & Fleming, 2011; Bornstein, 2013a; P. Kim et al., 2010a; Leuner, Glasper, & Gould, 2010; Rilling, 2013). For example, Bornstein, Arterberry, and Mash (2013) found that just 3 months of exposure to their own infant's face changes the visual cortex evoked response potential (ERP) in new mothers. Nonhuman animal studies show that the mammalian forebrain plays an important part in the expression of reproductive behavior and specific behaviors during nursing and care of offspring, ones that are different in female and male animals and are reflected in functional and morphologic sex differences in neural forebrain circuitry (Champagne et al., 2001; Corter & Fleming, 2002; Sheehan & Numan, 2002; Simerly, 2002). The physiological state associated with parturition causes a functional rerouting of the brain circuits over which infant stimuli are processed. In virgins, infant stimuli have a negative valence and activate neural circuits that regulate avoidance and defensiveness, resulting in antisocial responses. Such mechanisms prevent the virgin from caring for young when she is not lactating. In postpartum females, infant stimuli have a positive valence and activate neural circuits that regulate attraction, approach, and acceptance behaviors (prosocial maternal responses).

In humans, the neuroscience of parenting is a cresting area of research interest (Bornstein, 2013a). Using visual (usually face) and auditory (usually cry or laugh) stimuli (of own and unfamiliar infants and children), imaging studies from electroencephalography to ERP to magnetoencephalography to functional magnetic resonance imaging have begun to expose neural activation patterns in specific regions of the brain that are associated with select parenting cognitions and practices leading to incipient models of a complex brain network hypothesized to mediate human parenting (Swain, Lorberbaum, Kose, & Strathearn, 2007). Since Bartels and Zeki (2000, 2004), programmatic research with own versus other baby photographs and videos (Bornstein et al., 2013; Leibenluft, Gobbini, Harrison, & Haxby, 2004; Noriuchi, Kikuchi, & Senoo, 2008; Ranote et al., 2004; Strathearn, Li, Fonagy, & Montague, 2008; Swain, Leckman, Mayes, Feldman, & Schultz, 2006) and with cries of own infant versus standard cries versus control noises (De Pisapia et al., 2013; Ranote et al., 2004; Venuti et al., 2012) has revealed enhanced activations in regions of mothers', fathers', and nonparents' brains associated with empathy, responsiveness, and emotion recognition and evaluation. Human mothers show neural activation in limbic forebrain structures in response to infant crying compared with neutral sounds (Lorberbaum et al., 1999) and bilateral activation of the

orbitofrontal cortex while viewing pictures of their own versus unfamiliar infants (Nitschke et al., 2004). First-time mothers activate mirror-neuron regions of the brain more strongly when observing and empathizing with their own compared with unknown infants (Lenzi et al., 2009). Connecting brain activation with cognitions, mothers viewing smiling pictures of their own versus unfamiliar infants yields brain activation that is correlated with pleasant mood ratings and affective responses to their infant (Nitschke et al., 2004). When Laurent and Ablow (2012) investigated depression-related differences in primiparous mothers' neural responses to their own infant's distress cues using functional neuroimaging, they found that nondepressed mothers activated to their own infant's cry greater than to a control sound in a distributed network of paralimbic and prefrontal regions, whereas mothers diagnosed with major depressive disorder failed to show activation. Depressed compared to nondepressed mothers also showed less striatal (caudate, nucleus accumbens) and medial thalamic activation. Experience-independent and experience-dependent neuroplastic alignments of the human brain likely subserve the biological requirements of child care, securing offspring survival and well-being and perhaps fostering reproductive fitness in subsequent generations (Bornstein, 2013a; P. Kim et al., 2010b; Rilling, 2013).

Papoušek and Papoušek (2002) advanced the notion that some parenting is likely hardwired in human beings. Intuitive parenting involves responses that are developmentally suited to the age and abilities of the child and that likely have the goal of enhancing child adaptation and development. Parents regularly enact intuitive parenting programs in an unconscious fashion; such programs do not require the time and effort typical of conscious decision making; and, being more rapid and efficient, they utilize less attentional reserve. An example of such intuitive parenting is child-directed speech (Soderstrom, 2007) whose special characteristics vary from adult-directed speech along prosodic, simplicity, redundancy, lexical, and content dimensions. Cross-cultural study attests that child-directed speech is (essentially) universal (Jacobson, Boersma, Fields, & Olson, 1983; Snow, 1977; but see Ratner & Pye, 1984). When communicating with their children, even deaf mothers modify their sign language the way hearing mothers use child-directed speech (Erting, Prezioso, & Hynes, 1994). Indeed, parents find it difficult to resist or modify such intuitive behaviors, even when asked to do so (Trevarthen, 1979). Additional support for the premise that such interactions with children are intuitive comes from observations that nonparents (males and females) who have little prior experience with children modify their speech as parents do when in the presence of a young child and even when asked to imagine speaking to one (Jacobson et al., 1983). Many parenting cognitions and practices are likewise unconscious, habitual, and possibly thoughtless, and they are enacted by parents and nonparents alike (Senese et al., 2013).

Psychological Characteristics

In addition to these (and possibly other) biological characteristics, a variety of psychological characteristics in the parent has been identified that shape parenting. They include the gender, age and stage, health status, cognition (including parenting cognitions), personality, intergenerational transmission and family of origin, and experiences of the parent.

Gender

Parent gender is a perennially important topic (Bornstein, 2013b), especially as the role of fathers has become more widely recognized (Ribas & Bornstein, 2005). Some salient distinctions between mothering and fathering already have been drawn. Mothers and fathers hold some similar and some different ideas about parenting and appear to interact with and care for children in some convergent and some complementary ways; that is, they tend to divide some of the labor of caregiving and engage children by modeling different orientations and emphasizing different types of interactions. Mothers are more often involved in direct caregiving and typically provide children with more close emotional support, whereas fathers often provide more informational and material support and involve children more in leisure activities (Collins & Russell, 1991; Parke & Buriel, 2006; Steinberg & Silk, 2002). Mothers tend to be more knowledgeable about children's friendships and their social network than fathers; fathers are more likely to be perceived as relatively distant authority figures who may be consulted for objective information (such as help with homework) but who are less frequently sought out for relationship support or guidance (such as help for problems with friends) than mothers (Updegraff, McHale, Crouter, & Kupanoff, 2001; Waizenhofer, Buchanan, & Jackson-Newsom, 2004). Boivin and colleagues (2005) analyzed the factor structure of a self-administered questionnaire designed to assess 2,122 mothers' and 1,829 fathers' self-efficacy, perceived impact, hostile-reactive behaviors, and overprotection vis-à-vis their young infants. The two parents did not differ with respect to perceived parental impact, but these researchers found significant

gender differences in other parenting self-perceptions. Mothers were more worried about the health and safety of their infants and felt more effective as parents than did fathers, and fathers were more prone to hostile-reactive behaviors than mothers. Across nine countries, mothers report more progressive parenting attitudes than fathers, and fathers report more authoritarian attitudes than mothers (Bornstein, Putnick, & Lansford, 2011). However, mothers and fathers may differ in their consistency, favoring mothers (Belsky, Taylor, & Rovine, 1984; Lytton & Zwirner, 1975).

Anticipating evolutionary considerations discussed toward the conclusion of this chapter, the bias toward caregiving in women could be evolutionally advantageous, considering that women are primary caregivers of children in most societies (Eibl-Eibesfeldt, 1989). Evolutionary psychology attributes these consistent differences in mothering and fathering among mammals principally to maternal internal gestation and obligatory postpartum suckling (Clutton-Brock, 1989). Differences in the relative costs and benefits of producing offspring are argued to play key parts in understanding the evolution of gender differences in reproductive strategies and in parental investment (Trivers, 1972): The gender with the lower potential rate of reproduction invests more in parenting efforts (Clutton-Brock & Vincent, 1991).

Age and Stage of Life

The average age at first birth in the United States is 26.0 years. The contemporary demographics of parturition in the United States indicate that the rate of teenage (15–19 years) motherhood is epidemic (273,105 live births in the United States in 2013; CDC/National Center for Health Statistics, 2015), as approximately 1 in 3 adolescent women becomes pregnant by the end of her nineteenth year. At the same time, increasing numbers of adult women are delaying conception, extending the age range for pregnancy and birth (J. A. Martin et al., 2013). In 2011, for the first time on record, for example, birth rates in Canada were higher for women in their late 30s than in their early 20s. These demographic trends might be ascribable to several factors that contribute to the decision to bear a child and so to parent (Golombok, 2002, 2013), and they apply to first-time parenthood. Parents also age as their children do, and they encounter their own life challenges along the parentway. For example, the typical parent may be 40 years of age or older when her or his first child enters adolescence, and parents at midlife often encounter unique developmental needs brought on by their own passage into midlife at the same time as their children (Bornstein, Jager, & Steinberg, 2012). This period in the family life cycle sometimes proves to be a low point in parents' marital and life satisfaction as well as a period of heightened risk for divorce (Gecas & Seff, 1990; Gottman & Levenson, 2000).

These demographic trends, in turn, raise questions about specific associations that may obtain between age or stage of life and parenting. It was once standard to believe that optimal childbearing takes place between about 20 and about 30 years of age (Rindfuss & Bumpass, 1978) and support for this ∩-shaped function still prevails (McGrath et al., 2014). Rossi (1980) proposed a "timing-of-events" model that suggests that having a child when very young or very old might represent "off-time" versus "on-time" variations in childbearing that result in decreased social reinforcement and lead to curvilinear relations between age and parenting. For example, teenage and older mothers tend to report higher levels of parenting stress compared to mothers in their 20s and early 30s (Östberg & Hagekull, 2000).

Whether and how parent chronological age relates to parenting cognitions or practices appears to depend on specifics of the assessment. For some parenting variables, age does not seem to matter. Mothers of all ages possess implicit beliefs (Holden & Buck, 2002), and mothers of all ages engage equally in child-directed speech (Papoušek & Bornstein, 1992). For many other forms of parenting, however, age matters a lot. The biopsychosocial impacts of early childbirth are fairly well established. Adolescent mothers experience more pregnancy and delivery problems, bear less healthy babies, express less desirable or realistic child-rearing cognitions, hold less realistic expectations about child development, and parent using less favorable practices than do adult mothers (Berlin, Brady-Smith, & Brooks-Gunn, 2002; Bornstein & Putnick, 2007; Bornstein, Putnick, Suwalsky, & Gini, 2006; Coley & Chase-Lansdale, 1998; Demers, Bernier, Tarabulsy, & Provost, 2010; Moore & Brooks-Gunn, 2002; Pomerleau, Scuccimarri, & Malcuit, 2003; Schlomer & Belsky, 2012). For example, in a multivariate analyses that compared adolescent (≤19 years) and adult (≥26 years) mothers, controlling for sociodemographic and other human and social capital factors, Y. Lee (2009) found that adolescent mothers were more psychologically and physically (spanking) aggressive. Lewin, Mitchell, and Ronzio (2013) used the nationally representative Early Childhood Longitudinal Study-Birth cohort data set to compare parenting practices of adolescent mothers (<19 years), emerging-adult mothers (19–25 years), and adult mothers (>25 years) when their children were 2 years of age. Controlling for socioeconomic differences,

adolescent mothers exhibited less supportiveness, sensitivity, and positive regard than emerging adult mothers, who exhibited less than adults. Adolescent and emerging-adult mothers reported equivalent frequencies of spanking and use of timeout, significantly more than adult mothers.

Some effects of aging on parenting are thus clear cut, but others not. A 35-year-old woman has a 1 in 400 chance of conceiving a child with Down syndrome, and this likelihood increases to 1 in 110 by age 40 and then to approximately 1 in 35 by the age of 45 (National Down Syndrome Society, http://www.ndss.org/). Tending and rearing children are physically challenging, and older primiparas may possess relatively diminished physical capacities to meet those demands (Mirowsky, 2002). However, older mothers are more likely to adhere to good diets and gain weight appropriately during pregnancy, to begin prenatal care in the first trimester of pregnancy, and to avoid toxins (smoking and alcohol) during pregnancy. Age is often conceived of as a marker for maturity, perspective, and patience; older-adult mothers tend to possess more experience and information and may feel more psychologically ready to assume the many responsibilities of child rearing. In the view of some, mothers' readiness to be a parent is determined by competency and maturity as measured by her age at childs' birth (Garrett, Ferron, Ng'andu, Bryant, & Harbin, 1994). The more mature and experienced mothers are, the more appropriate and propitious (it is commonly believed) their parenting beliefs and behaviors are likely to be (Bornstein, Putnick, & Suwalsky 2012; Demers, Bernier, Tarabulsy, & Provost, 2010). Even after controlling for SES, maternal education, ethnicity, intelligence, social desirability of responding, and child age and language competence, older mothers direct more praise and physical affection toward their toddlers than do younger mothers (Bornstein & Putnick, 2007). A study of European American mother-child dyads found that older mothers were more sensitive and optimally structuring with their infants and toddlers than were younger mothers (Bornstein, Putnick, & Suwalsky, 2012).

Fathers' age matters as well in these and other ways. A monotonic association obtains between advancing paternal age and risk of autism spectrum disorders (ASD) in children (Reichenberg et al., 2006), for example, and a study of genome-wide mutation rates by sequencing the entire genomes of a sample of Icelandic parent-offspring trios revealed that the diversity in mutation rate of single nucleotide polymorphisms is dominated by the age of the father at a child's conception, implicating increases of about two mutations per year (Kong et al., 2012). Advancing paternal age is specifically associated with increased genetic mutations during spermatogenesis, which may cause psychiatric morbidity in offspring. A population-based cohort study of all people born in Sweden from 1973 to 2001 ($N = 2{,}615{,}081$) revealed that paternal age is associated with increased risk of some psychiatric disorders (ASD, psychosis, and bipolar disorders) but decreased risk of the other indexes of morbidity. In another within-sibling comparison, offspring of fathers 45 years and older were at heightened risk of ASD, ADHD, psychosis, bipolar disorder, substance use problems, failing a grade, and low educational attainment compared with offspring of fathers 20 to 24 years old (D'Onofrio et al., 2014).

Of course, age is a "social address" (Bronfenbrenner & Crouter, 1983), and age usually stands only as a proxy for underlying processes. More proximal intrapersonal factors likely play the meaningful roles in parenting, and it is possible to identify some critical developmental phenomena that would help to mark mature caregiving. For example, developing executive functions (discussed later) coordinate metacognitive processes through monitoring and controlling the use of knowledge and strategies that redound positively to parenting (Barkley, 2012; Yeager & Yeager, 2013).

Health Status

To parent well, a parent's own needs must be met. When women are inadequately nourished, for example, their health and social development may be compromised, and their abilities to bear and rear healthy children are jeopardized (Houck, Rodrigue, & Lobato, 2007). Malnourished women fall ill more often, and they have smaller babies, whereas women whose diets are rich in protein have fewer complications during pregnancy, transit shorter labors, and bear healthier babies. Deficiencies in zinc, folic acid, and protein have been linked to central nervous system dysfunction, prematurity, and low birthweight (Keen, Bendich, & Willhite, 1993). In many regions of the developing world, malnutrition is a chronic problem (UNICEF, 2006), but this problem is not limited to poor countries. The U.S. Special Supplemental Food Program for Women, Infants, and Children (WIC) provides food packages, nutrition education, and health care to low-income pregnant women and new mothers. More than 8 million people receive WIC benefits each month (Lino, 2013). Severe malnutrition in early pregnancy (especially lack of folic acid, a B vitamin) increases the risk of neural tube defects, such as spina bifida, in which the spinal cord does not close completely, or anencephaly, in which part of the brain does not develop. Malnutrition later in pregnancy is associated with low birthweight. But the long-term prognosis for children chronically malnourished in utero is not entirely

bleak. If children receive nutritious diets before age 2, they can rebound. Near the end of World War II, western (but not northern or eastern) Holland endured a food blockade that provided an unfortunate but important natural experiment in maternal health. Unlike other famines, the so-called Dutch Hunger Winter struck during a precisely circumscribed time and place and in a society that kept comprehensive and meticulous health records. As a result, researchers later identified children who were exposed to fetal malnutrition in different trimesters and could follow them through adolescence and well into adulthood. In general, children born during this time of famine did not suffer pervasive long-term physical or mental disabilities (Hoek, Brown, & Susser, 1999; Susser, Hoek, & Brown, 1998). Relative to those who received proper nutrition, however, malnourished children suffered more nervous system congenital abnormalities as well as increased risk of schizophrenia.

Health effects are not restricted to mothers. Diet folate deficiency is associated with giving birth to a child with a birth defect. Male mice that were fed a diet containing less than 15% of the recommended amount of folate for their lifetime (from the time they were fetuses through to their reproductive maturity) showed deficiencies in fertility as well as litter offspring with approximately 30% more birth defects than controls (Lambrot et al., 2013).

Cognition

Parents' attentiveness, intelligence, mental functioning, and (as we see later) even memories of their own childhood help to create a "strategy frame" or "affective lens" that influences parenting (Putallaz, Costanzo, & Smith, 1991). Attention at neurobiological levels is heightened in new mothers (Purhonen, Valkonen-Korhonen, & Lehtonen, 2008); policewomen report enhanced vigilance following the birth of their first child (Fullgrabe, 2002); and women's improved attentional processing of infant emotions during pregnancy relates to their later relationships with their infant (Pearson, Lightman, & Evans, 2011). Analyzing data from the Massachusetts site of the National Institute of Child Health and Human Development (NICHD) Study of Early Child Care and Youth Development, Mulvaney, McCartney, Bub, and Marshall (2006) learned that mothers' verbal intelligence predicted the effectiveness of their scaffolding collaborations with children (which in turn uniquely predicted later cognitive capabilities of the children).

Executive functions include self-regulation, sequencing, flexibility, response and inhibition, planning, and organization of behavior (Butterfield, Albertson, & Johnston, 1995; Denckla & Reiss, 1997; Eslinger, 1996). The orderly approach to problems, maintenance of problem solving sets for future goals, control processes for organizing behavior over time, flexibility and effectiveness of verbal self-regulation, skillful use of strategy, and behaviors that alter the likelihood of later events are all executive functions . . . and describe well the requirements of parenting. Grattan and Eslinger (1992) suggested that mental flexibility and perspective-taking are cognitive prerequisites to empathic understanding; impulse control, temporal integration, and synthesis of multiple pieces of information are cognitive prerequisites to identity formation; and symbolic thinking, weighing alternative possibilities, and considering consequences among alternatives are cognitive prerequisites to moral maturity. Thus, executive functions exert powerful and pervasive influences on social behavior, and immaturity or impairment of executive function can lead to demanding and self-centered behavior, lack of social tact and restraint, impulsive speech and actions, disinhibition, apathy and indifference, and absence of empathy, all of which are hallmarks of dysregulated parenting.

The neuropsychological underpinnings of executive functions are usually assigned to the prefrontal cortex and its extended networks (Pennington, Bennetto, McAleer, & Roberts, 1996). Notably, individuals with localized prefrontal injury display poor parenting (Eslinger, Grattan, Damasio, & Damasio, 1992). Consider patient DT, who:

> proved unable to anticipate and meet her child's needs, such as planning meals, changing clothing, and providing nurturance and comfort. . . . Her performance [was] erratic, impulsive, and marked by poor follow through on required tasks, failure to learn from mistakes, and very negative reactions to criticism. . . . She [had] very limited capacity for empathic understanding, inadequate identity development, difficulties in vocational adjustment, and a concrete level of moral reasoning. (Grattan & Eslinger, 1992, p. 185)

DT shows how the want of executive functions profoundly undermines parenting in an individual who otherwise possesses normal motor and sensory functions and broadly normal intellect, perception, language, and memory. To this point, it is important to note that the prefrontal cortex shows a prolonged course of development, with changes in synaptic density detectable even into the mid-20s (Shaw et al., 2006), and so could very well underlie the well-known challenges commonly associated with adolescent parenting. As indicated earlier, teenage mothers display notable parenting deficits (Loeber, Burke, Lahey, Winters, & Zera, 2000). Younger mothers score lower than older mothers on a construct called cognitive readiness

to parent (aggregated knowledge of child development, parenting attitudes, and parenting style), and cognitive readiness to parent predicts parenting, at least during infancy (Whitman, Borkowski, Keogh, & Weed, 2001), and accounts for relations between early maternal interactions and 1-year attachment status (Lounds, Borkowski, Whitman, Maxwell, & Weed, 2005).

Parenting Cognitions

As reviewed earlier, parenting cognitions come in many flavors and are generally believed to serve many functions: They affect parents' sense of self, help to organize parenting, and mediate the effectiveness of parenting. Cognitions help to structure parents' practices and determine how much time, effort, and energy to expend in parenting. To begin at the beginning, however, cognitions instigate whether to become a parent. Because of the widespread availability of contraception and assisted reproductive technologies, decisions to bear and rear children are elective. Changing cultural mores also permit (15%–19% and increasing) people to remain voluntarily childless (Letherby, 2002; Livingston & Cohn, 2010). Today, the rates of unintended and intentional pregnancies are about the same (~50% of each in the United States; Finer & Zolna, 2011). Notably, unplanned pregnancies are associated with many poorer forms of parenting (Treyvaud, Rogers, Matthews, & Allen, 2010), including increased likelihood of perinatal mood problems and reduced well-being in the postpartum period (Grussu, Quatraro, & Nasta, 2005; Lachance-Grzela & Bouchard, 2009; Yanikkerem, Ay, & Piro, 2013), less time and attention paid to infants (Barber, Axinn, & Thornton, 1999), and more negative parenting (East, Chien, & Barber, 2012).

How parents see themselves vis-à-vis children generally can lead to their expressing one or another kind of affect, thinking, or behavior in child rearing. According to the Civitas Initiative et al. (2000) survey, for example, 90% of new parents in the United States have confidence in their abilities and think of themselves generally as good parents. Parents with a low perceived balance of power within the caregiving relationship may see unresponsive children as behaving with intent, an interpretation that easily fosters in parents a sense of helplessness and ultimately anger (Bugental & Happaney, 2004). Especially salient self-perceptions of parents have to do with their feelings of competence in the role of caregiver, satisfaction gained from caregiving, investment in caregiving, and balance of caregiving with other social roles. Most is known about parenting competence (Bornstein, Haynes, et al., 2004; Bornstein, Hendricks, et al., 2003). Among low-income families, mothers with lower levels of belief in parents as teachers are less likely to elaborate appropriately with their children during shared book reading (DeBaryshe, 1995). Functionally, perceptions of competence in parenting are associated with parents' use of effective parenting strategies (Johnston & Mash, 1989; Teti & Gelfand, 1991). Self-efficacy theory posits that adults who evaluate themselves as competent, who know what they can do, and who understand the likely effects of their actions will, as parents, more likely act as constructive partners in their children's development (Bandura, 1986, 1989; Coleman & Karraker, 1998; Conrad, Gross, Fogg, & Ruchala, 1992; King & Elder, 1998). Eccles and Harold (1996) reported that parents' confidence in their ability to influence their children's academic performance and school achievement is associated with parents' school involvement and predicts parents' helping with their children's academic interests (Epstein & Sanders, 2002; see, too, Hoover-Dempsey & Sandler, 1997). Mothers who consider themselves efficacious and competent in their role as parents tend to be more responsive and empathic and less punitive and hold more appropriate developmental expectations (De Haan, Prinzie, & Deković, 2009; Meunier, Roskam, & Browne, 2011). Parents who believe that they can or cannot affect characteristics in children likely act accordingly. The Civitas Initiative et al. (2000) reported that approximately 25% of parents in the United States thinks that a baby is born with a certain level of intelligence that cannot be increased or decreased by how parents interact with the baby. How parents see their own children has specific consequences as well, of course. Mothers who regard their child as being difficult, for example, are less likely to pay attention or respond to their child's overtures (Putnam, Sanson, & Rothbart, 2002).

Other prominent parenting cognitions likewise influence parenting. *Attitudes* refer to an individual's predispositions, reactions to, or affective evaluations of the supposed facts about an object or situation. *Expectations* about a child as well as developmental norms and milestones—when a child should achieve a particular skill—affect parents' appraisals of their child and their parenting. Expectations also generally bias observations so that information consistent with the expectancy is more likely to be attended to, processed, and acted upon. Jamaican mothers expect their children to sit and to walk early, whereas Indian mothers living in the same city expect their children to crawl later. In each case, children's actual attainments of developmental milestones accord with their mothers' expectations (Hopkins & Westra, 1989, 1990). *Attributions* are interpretations of causations of events

and behaviors, and parenting attributions refer to assigned meanings and definitions of a child's behavior and so can affect parents' caregiving practices (Bugental & Happaney, 2002). Parental attributions typically distinguish between the internal (intentional) and the external (situational). An internal attribution might refer to parental interpretations of a child's behavior as dispositional and deliberate, whereas an external attribution might refer to parental interpretations of a child's behavior as contextual, transitory, and even accidental (Coplan, Hastings, Lagacé-Séguin, & Moulton, 2002). In certain circumstances, parents might believe a child is behaving purposefully, when the child's behavior may in fact be developmentally typical. For example, higher levels of internal attributions of child misbehaviors are more prevalent among neglectful, abusive, and authoritarian mothers (Z. Wang, Deater-Deckard, & Bell, 2013). Investment in, involvement with, and commitment to children is foundational to positive child rearing; indeed, Baumrind and Thompson (2002) defined ethical parenting "above all [as] requiring of parents enduring investment and commitment throughout their children's long period of dependency" (p. 3). Invested parents are more responsive and view their children more positively (Greenberger & Goldberg, 1989). In turn, parental investment in children's lives and parental responsibility for children's care help to ensure that parents provide children with medical attention, physical activity, and proper nutrition they require for wholesome development (Cox & Harter, 2003). Finally, how parents balance their multiple roles in life—parent, spouse, and employee—reflects on their effectiveness in those diverse roles, including their parenting (Perry-Jenkins, Repetti, & Crouter, 2000). Mothers who are happy with their roles are more accepting of their children (Stuckey, McGhee, & Bell, 1982). Parenting satisfaction affords a sense of well-being in the parenting role that translates to positive emotionally available parent-child interactions (Bornstein, Putnick, et al., 2012).

Whereas goals, attitudes, and other similar cognitions may or may not be factual, parenting knowledge draws on the science base as well as social construction and is thought to be valid and reliable by members of the clinical and research communities (Bornstein et al., 2010). Parenting knowledge of child rearing and child development encompasses many domains, including fulfilling the biological and physical as well as socioemotional and cognitive needs of children as they develop, understanding of normative child development, and awareness of practices and strategies for maintaining and promoting children's health and coping effectively with children's illness (Bornstein & Cote, 2004b; Scrimin et al., 2009). The general state of parents' knowledge affects their everyday decisions about their children's care and upbringing and guides parents' decisions about how to maintain child health and when and how to seek care if children fall ill (Hickson & Clayton, 2002; Melamed, 2002; Zuckerman & Keder, 2015). Parenting knowledge equips parents with information they need to interpret children's abilities and accomplishments and to tailor their interactions accordingly. In turn, parenting knowledge is associated with enhanced parental self-perceptions of competence, satisfaction, and investment in parenting (Bornstein, Hendricks, et al., 2003). For example, the relation between parental self-efficacy and parenting competence is moderated by parenting knowledge: Parental self-efficacy and parenting competence are positively associated when parenting knowledge is high; by contrast, self-efficacy and competence are inversely associated when knowledge is low (Hess, Teti, & Hussey-Gardner, 2004). Parents who harbor unrealistic developmental expectations that are not informed by accurate knowledge experience greater stress as a result of mismatches between expectations and actual child behaviors (Teti & Gelfand, 1991), whereas knowledgeable parents have more realistic expectations and are more likely to behave in developmentally appropriate ways with their children (Grusec & Goodnow, 1994). Mothers' specific knowledge of child rearing and child development explains variations in their emotional relationships with children (Bornstein, Putnick, et al., 2012). Safety is measured in terms of awareness of health care, the identification and treatment of illnesses, and accident prevention, and these beliefs guide parents' decisions about how to maintain child health. Using the prospective longitudinal study data set of a low-birthweight preterm cohort from the multisite Infant Health and Development Program, Benasich and Brooks-Gunn (1996) found that maternal knowledge of child development and child rearing conditioned the quality and structure of the home environment mothers provided (which in turn affected child cognitive and behavioral outcomes). Sudden infant death syndrome (SIDS) is the leading cause of reported neonatal mortality in the United States (http://www.cdc.gov/sids/), and sleeping prone or on too-soft bedding that may cover an infant's mouth and nose increases the likelihood of asphyxiation (Scheers, Rutherford, & Kemp, 2003). Still, approximately 20% of parents place infants ages 1 to 3 months on their stomachs during sleep (Gibson, Dembofsky, Rubin, & Greenspan, 2000).

In all these different ways, parents' cognitions can lead to different transactions with children. In what may be

called the standard model of parenting (widely assumed but seldom appropriately tested), parents' cognitions are hypothesized to prompt or direct parents' practices and, ultimately, children's development. That said, relations between beliefs and behaviors are historically an unsettled area in social psychology (Armitage & Conner, 2001; Festinger, 1964; Green, 1954; LaPiere, 1934; Wicker, 1969), and relations between parental beliefs and behaviors specifically are equally elusive (Bornstein, Cote, & Venuti, 2001; Coleman & Karraker, 2003; Cote & Bornstein, 2000; Holden, 2002; S. G. Miller, 1988; Okagaki & Bingham, 2005; Sigel & McGillicuddy-De Lisi, 2002). Many researchers have reported no relations between mothers' professed parenting attitudes and their activities with their children (Cote & Bornstein, 2000; McGillicuddy-De Lisi, 1992), where others have reported associations between parents' beliefs and behaviors that are relatively weak or positive but nonsignificant (Coleman & Karraker, 2003; Mantzicopoulos, 1997; Sigel & McGillicuddy-De Lisi, 2002).

Those parenting beliefs and behaviors whose consonance has been evaluated have often been very general, giving little reason to expect an association. When more circumscribed and conceptually corresponding cognition-practice domains are studied, however, some maternal child-rearing beliefs have been found to relate to some self-reported or observed child-rearing behaviors, supporting expected links in the putative standard model causal chain (Coplan et al., 2002; K. Y. Huang, O'Brien Caughy, Genevro, & Miller, 2005; Kinlaw, Kurtz-Costes, & Goldman-Fraser, 2001; Strassberg & Treboux, 2000). For example, the Benasich and Brooks-Gunn (1996) study just reported found that maternal knowledge of child development and child rearing conditioned the quality and structure of the home environment mothers provided, which in turn affected child cognitive and behavioral outcomes. The strength of the association between parents' cognitions and practices appears to depend, therefore (at least in part) on alignment of conceptual links between the respective contents of their beliefs and their behaviors, as for example between authoritarian attitudes and discipline strategies and between intuitions about parenting effectiveness and competence. European American mothers endorse the importance of independence and self-assertiveness when asked to describe their ideal child, whereas Latina mothers accentuate obedience and respect for theirs (Harwood, Leyendecker, Carlson, Asencio, & Miller, 2002; Tamis-LeMonda & McFadden, 2010). In accord with these expressed values, in real-time interactions, U.S. mothers encourage their children to feed themselves as early as 8 months of age, whereas Latina mothers hold their children close on their lap and control feeding from start to finish.

In brief, beliefs do not always map to behaviors directly, but the two coexist in complex ways, and meaning assigned to each is critical (Bornstein, 1995). Parenting beliefs provide parents with a framework for interpreting their children's behaviors, guiding parents' interactions with their children and determining the activities and opportunities that parents supply. Ethnographic interviews of mothers with infants between the ages of 2 and 18 months revealed that some mothers avoid using physical punishment with infants because they believe that infants are not able to clearly understand right and wrong, whereas other mothers believe that infants can misbehave intentionally and need to be punished to stop their bad behavior and learn to respect the mother's authority. Subsequent quantitative analyses revealed that mothers who expressed concerns about bad behavior and spoiling interacted less positively with their infants (Burchinal, Skinner, & Reznick, 2010).

It is especially noteworthy how early cognitions may function in the development of parenting. Siddiqui and Hägglöf (2000) found that mothers' antenatal attachment expectancy toward their unborn child predicted mothers' sensitivity at 3 months postpartum (see also Thun-Hohenstein, Wienerroither, Schreuer, Seim, & Wienerroither, 2008). Similarly, Haltigan and colleagues (2014) determined that mothers' attachment representations assessed prenatally predicted observed maternal sensitivity at 6 months postnatally. Using an equivalent longitudinal design, Dayton, Levendosky, Davidson, and Bogat (2010) learned that mothers who professed affectively disengaged prenatal representations of their children were at 1 year more behaviorally controlling; mothers whose representations were affectively distorted were hostile; and mothers with balanced representations demonstrated more positive parenting.

Personality

Two general orientations have guided theory and research linking personality to parenting: One concerns a factor structure thought to compose normal personality, and the other concerns more specific personality characteristics, from anxiety and stress to depression and psychopathology. Sigmund Freud (1949), the father of psychoanalytic theory, speculated that a parent's personality would determine the nature of parenting as well as the parent-child relationship and the child's development. Another consistent theme among psychoanalytic theorists is that, if

parents' emotional needs are not met during the course of their own development, then their own psychological makeup would reflect in their parenting (Cohler & Paul, 2002; Holden & Buck, 2002). Anna Freud (1955/1970) described mothers who rejected their children, sometimes due to psychosis but more often because of their own neurotic conflicts.

Personality therefore has a significant part to play in parenting: "One cannot take the 'person' out of the parent" (Vondra, Sysko, & Belsky, 2005, p. 2). Contemporary views derived from personality psychology assert that some parenting cognitions and practices reflect general and stable personality characteristics (Belsky & Barends, 2002). Bronfenbrenner and Morris (2006) opined that personality factors constitute person "force characteristics" likely to influence children's development because personality affects parenting directly and because it colors other social contextual factors that influence parenting, including spouse selection and marital relationships.

Personality is currently conceptualized as a profile of five broad-band factors (the so-called Big Five), each with lower-level facets (McAdams & Pals, 2006), that may be "universal" (Allik & McCrae, 2004; McCrae et al., 2005). *Openness to Experience* reflects a tendency to have a broad perspective and to approach life in intelligent, creative, philosophical, and inquisitive ways. Mothers who are more open are also more emotionally expressive with their children (C. L. Smith et al., 2007). *Neuroticism* reflects a proneness to psychological distress, unrealistic ideas, excessive cravings or urges, maladaptive coping responses, and a perturbable, insecure, and vulnerable orientation to life. Mothers who are neurotic display high levels of negative affectivity toward their children, are less responsive to their children's needs, engage in more physical and verbal power assertion, and are less encouraging of their children's autonomy (Clark, Kochanska, & Ready, 2000). Kotov, Gamez, Schmidt, and Watson (2010) reported that Neuroticism shows associations with internalizing and externalizing psychopathology (see also Decuyper, De Pauw, De Fruyt, De Bolle, & De Clereq, 2009; Ruiz, Pincus, & Schinka, 2008). Likewise, more neurotic fathers are more negative with their children, whereas less neurotic fathers seem to be less behaviorally and emotionally involved with theirs (S. Wang, Repetti, & Campos, 2011). *Extraversion* reflects the quantity and intensity of interpersonal interaction, activity level, need for stimulation, and capacity for joy, control, and assertiveness. Extraverted mothers are more nurturant and supportive of their children's autonomy (Clark et al., 2000; Losoya, Callor, Rowe, & Goldsmith, 1997; C. L. Smith et al., 2007) but also more controlling (i.e., power assertive and forceful in disciplinary style) than those who are less extraverted (Clark et al., 2000; Kochanska, Clark, & Goldman, 1997). *Agreeableness* reflects an interpersonal orientation in feelings, thoughts, and actions along a continuum from compassion to antagonism, the high end of which is characterized as cooperative, trusting, and warm. Agreeable mothers express higher levels of positive affect, support, and warmth with their children, are more sensitive and responsive to their children's needs, and are less likely to be affectively negative, uninvolved, and overreactive than less agreeable mothers (Belsky, Crnic, & Woodworth, 1995; Browne, Meunier, O'Connor, & Jenkins, 2012; de Haan, Prinzie, & Deković, 2009; Kochanska et al., 1997; C. L. Smith et al., 2007). Finally, *Conscientiousness* reflects the extent to which a person is well organized, responsible, decisive, dependable, hardworking, and even ambitious. Conscientious mothers provide more structure and use less forceful disciplinary styles than less conscientious mothers; however, conscientiousness is also associated with restrictive and overcontrolling child rearing (Clark et al., 2000; Neitzel & Stright, 2004; Verhoeven et al., 2007).

A burgeoning literature explores relations between one or more of the Big Five and parenting (e.g., Koenig, Barry, & Kochanska, 2010), and a critical mass has accumulated to allow Prinzie, Stams, Dekovic, Reijntjes, and Belsky (2009) to conduct a meta-analysis that examined associations between parental personality and parenting practices. Results revealed only modest associations between parental personality and parenting warmth, behavioral control, and autonomy support. Additionally, this meta-analysis showed that several moderators (e.g., parent age) explained variability among effect sizes reported across individual studies.

Only a small number of studies has assessed all five personality factors in relation to parenting cognitions and/or parenting practices, controlling for one another. Factor analysis of a personality inventory completed by a community sample of European American mothers of firstborn 20-month-olds who also responded to multiple measures of parenting cognitions (knowledge, self-perceptions, and reports about behavior) and observed in interaction with their children for diverse parenting practices (language, sensitivity, affection, and play) replicated extraction of the Big Five personality factors and showed, controlling for sociodemographic characteristics, that the five personality factors (as variables and in patterns as clusters) related differently to diverse parenting cognitions and practices (Bornstein, Hahn, & Haynes, 2011). In a parallel

cross-cultural study, mothers of firstborn 20-month-olds from seven countries (Argentina, Belgium, Israel, Italy, Japan, South Korea, and the United States) completed all the same procedures (Bornstein et al., 2007). The Big Five factor structure was extracted when the cross-cultural personality data were analyzed, and again the Big Five were found to relate differently to diverse parenting cognitions. Likewise, C. L. Smith et al. (2007) examined longitudinal relations among maternal personality, emotional expressions, and parenting sensitivity and intrusiveness: Conscientiousness and Agreeableness were positively associated with observed positive emotional expressions at T1, and Agreeableness, Openness to Experience, and Extraversion at T1 were positively related to positive emotional expressions at T2. Maternal positive emotional expressions at T1 and T2, in turn, were associated with more sensitive parenting observed at T3. In addition to first-order associations between maternal personality and maternal parenting, other factors (e.g., emotional expressiveness) may constitute possible pathways for explaining second-order relations between personality and parenting. Maternal personality in the normal range is often neglected in parenting research, but it appears to be operative in everyday parenting.

Other specific features of normal personality favorable to good or poor parenting likely include empathic awareness, predictability, nonintrusiveness, and emotional availability. Lack of self-centeredness and adaptability might also be especially pertinent to parenting; so, parents who are more focused on relieving their own discomfort may resort to insensitive parenting strategies, such as minimization and punishment, and become dysregulated and try to end a child's distress abruptly (Fabes, Poulin, Eisenberg, & Madden-Derdich, 2002). Some states of mind, perhaps in the normal range but still troubling, are regularly identified with poor parenting (Whisman & Baucom, 2012; Zahn-Waxler, Duggal, & Gruber, 2002). Mood is one, and mood states predict parenting self-efficacy (Leerkes & Burney, 2007; Porter & Hsu, 2003; C. M. Weaver, Shaw, Dishion, & Wilson, 2008). Stress, in its many forms, has a rich history of untoward influence on multiple aspects of well-being in parenting (Crnic & Low, 2002; Deater-Deckard, 2004). The upbringing of children is highly emotional for both parents and children (Pomerantz, Wang, & Ng, 2005). Adult adaptability is likely vital, not only in the first few months, when infants appear unpredictable and undifferentiated, but through adolescence. Mothers and fathers report increased parenting stress across their child's transition to adolescence, and stress seems to arise from parent-adolescent interactions rather than qualities of the parent or the child per se (Putnick et al., 2010).

Stress, as in coping with daily hassles, predicts less maternal positivity (Crnic & Low, 2002); for example, depressed mothers experience more parenting stress (Coyl, Roggman, & Newland, 2002), and stress likely negatively affects parenting through disruptions in the parent-child relationship (Ciciolla, Crnic, & West, 2012; Crnic, Gaze, & Hoffman, 2005). Parenting stress is related to specific parenting behaviors (Putnick et al., 2008), and the stability of stress over time likely maintains adverse influences (Östberg, Hagekull, & Hagelin, 2007). Stress is also commonly related to diminished psychological well-being in parenting (Deater-Deckard, 1998). Abidin (1992) conceptualized parenting stress as resulting from many different relationships and contexts. Parents who are more stressed in the parenting role are more likely to behave in an authoritarian manner (Tan, Camras, Deng, Zhang, & Lu, 2012), whereas parents who report low levels of stress are more likely to be authoritative (Woolfson & Grant, 2006). Less stressed parenting is linked with better parent-adolescent communication (Joshi & Gutierrez, 2006), whereas more stressed parenting is associated with harsh discipline (Anjum & Malik, 2010; Fang, Wang, & Xing, 2012; Pinderhughes, Dodge, Bates, Pettit, & Zelli, 2000) and, under chronically high conditions, even with child abuse (Taylor, Guterman, Lee, & Rathouz, 2009).

It has been argued that self-centered parents would be less likely to put children's needs before their own (C. P. Cowan & Cowan, 1992; Dix, 1991), so that women who are more preoccupied with themselves, as measured by physical and sexual concerns, likely display less effective parenting (Grossman, Eichler, & Winikoff, 1980). Still other possibly untoward characteristics include "parenting perfectionism"—the degree to which parents hold excessively high standards (M. A. Lee, Schoppe-Sullivan, & Kamp Dush, 2012; Snell, Overbey, & Brewer, 2005). Whereas psychological well-being is associated with parenting competence (Fujiwara, Okuyama, & Izumi, 2012), psychological distress (anxious or depressive symptomatology short of outright psychopathology) appears to undermine parenting. Maternal anxiety predicts self-reported diminished warmth toward children (Drake & Ginsburg, 2011), and anxious mothers may be disengaged or intrusive and overstimulating (Feldman, Granat, Pariente, Kanety, Kuint, & Gilboa-Schechtman, 2009; Kertz, Smith, Chapman, & Woodruff-Borden, 2008; for a meta-analysis, see van der Bruggen, Stams, & Bogels, 2008). For example, mothers who are anxious or angry in response to their infant's crying may misread these distress

cues or believe that crying is a nuisance that interferes with their own goals, and so are unlikely to respond sensitively when their infants are distressed because they prioritize their own needs over those of their infants.

Whether fleeting, as in response to transient economic circumstances or even the birth of the baby, or chronic, depression affects parenting adversely (Field, 2010; Lovejoy, Graczyk, O'Hare, & Neuman, 2000; Murray, Halligan, & Cooper, 2010; Zahn-Waxler et al., 2002). Epidemiologically, postnatal depression is surprisingly common with a prevalence of 10% to 15% (Gavin et al., 2005). Heron and colleagues (2004) even found that 44% of women with postpartum depression (and 36% of the women with postpartum anxiety) did not experience depression (or anxiety) in pregnancy. Depressed mothers fail to experience—and convey to their children—much happiness with life. Depression's associated mood disturbance, worry, and rumination compromise mothers' ability to attend, diminish their responsiveness, and discoordinate their interactions with infants and children (Dix & Meunier, 2009; Manian & Bornstein, 2009; Murray et al., 2010; Pearson et al., 2012; Stein et al., 2012). Mothers who present with depression likely show increased negative affect and cognitions, apathy and lack of energy, and decreased engagement with children (Campbell, Matestic, von Stauffenberg, Mohan, & Kirchner, 2007; Kertz et al., 2008; Mertesacker, Bade, Haverkock, & Pauli-Pott, 2004; Niccols & Feldman, 2006; van Doesum, Hosman, Riksen-Walraven, & Hoefnagels, 2007). Overall, meta-analysis of this literature points to small but significant associations between maternal depression and negative (coercive, intrusive) and disengaged (withdrawn, uninvolved) parenting (Lovejoy, Graczyk, O'Hare, & Neuman, 2000).

As with other psychological symptomatology, the effects of depression are not exclusive to mothers. Prenatal and postpartum depression manifest in about 10% of men (Paulson, Bazemore, & Sharnail, 2010); postpartum paternal depression is predicted by maternal depression (Goodman, 2004; Wee, Skouteris, Pier, Richardson, & Milgrom, 2011); and depression exerts untoward effects on paternal parenting as it does on maternal parenting (R. N. Davis, Davis, Freed, & Clark, 2011; Wilson & Durbin, 2010). Happily, most cases of postpartum depression remit; unhappily, treatment of depression in those who do not is less than successful in repairing parent-child relationships (Forman et al., 2007).

Outright psychopathology, such as mental illness, phobias, substance abuse, and antisociality, seriously impairs thinking, affect, and behavior, and consequently parenting cognitions and practices. Vesga-López et al. (2008) estimated prevalences of postpartum psychopathologies to range from 12% for substance use to 15% for mood disorders. Fewer studies of psychopathology and parenting populate the literature (Berg-Nielsen, Vikan, & Dahl, 2002). However, mothers diagnosed with major psychopathologies display detached parenting, spend less time with their children, show less affection, and provide less structure (Brook, Brook, Ning, Whiteman, & Finch, 2006; Champion et al., 2009; Gerdes et al., 2007); and mothers who engage in antisocial behavior are, on the one hand, less likely to employ optimal parenting practices (Jaffee, Belsky, Harrington, Caspi, & Moffitt, 2006) and, on the other hand, more likely to demonstrate hostility toward children (Bosquet & Egeland, 2000) or even abuse them physically (Kim-Cohen et al., 2006a).

Intergenerational Transmission and Family of Origin

Winnicott (1948/1975) and Spitz (1965/1970) detected the roots of aggressive, impulsive, immature, self-centered, and self-critical caregiving in parents' own experiences growing up. Likewise, Bowlby (1969) and successive attachment theorists subsequently proposed that, arising out of their early interpersonal experiences with caregivers, young children develop "internal working models" of their caregivers that incorporate both sides of the caregiver-child relationship. Attachment theory asserts that, on the basis of repeated experiences of characteristic patterns of interaction, children develop expectations regarding the nature of social interactions that endure long after they depart their family of origin. Representations of interactions with parents thus model individual differences in attachment security in childhood and reverberate at later ages in associations with others (Fraley & Shaver, 2000; Mikulincer, Shaver, & Pereg, 2003) as, for example, in the quality romantic relationships (Dekovic & Meeus, 1997) and in own parenting. For instance, evidence from nonhuman animal research shows that the experience of being neglected or abused can affect infant brain development, with the result that inadequate parental behavior is exhibited in adulthood (Champagne, 2008; Maestripieri, 2005; Numan & Insel, 2003; Numan & Stolzenberg, 2009). Mothers with lower maternal care in childhood have larger gray matter volumes in key brain areas related to parenting and show lower activation there in response to infant cries; members of high-risk families fail to show patterns of activation in brain regions associated with empathy and collaborative behavior (Atkinson, 2012; P. Kim et al., 2010b).

Intergenerational continuities in parenting have been detected in many different mammalian species, including

rats, rhesus monkeys, and human beings (Conger, Belsky, & Capaldi, 2009; Jensen & Champagne, 2012). A lay belief supported by an emerging science is that the way parents rear their offspring results to a significant degree from the child-rearing parents experienced when they were growing up (Conger, Schofield, & Neppl, 2012). In animals, the quality of parental care received in infancy is a significant predictor of offspring and even grand-offspring parental behavior, suggesting that intergenerational effects persist (Jensen & Champagne, 2012). Parenting styles are often similar from one generation to the next. In laboratory rats, mothers, daughters, and granddaughters lick and groom their litters at similar frequencies (Champagne & Meaney, 2007), and cross-fostering studies support the hypothesis that the behavioral transmission of maternal behavior is not dependent on the transmission of specific DNA variants (Champagne et al., 2003). A mother's reported family-of-origin emotional expressiveness is important to understanding the manner in which she socializes emotion in her child. Baker and Crnic (2005) examined the role of mothers' reports of their family histories of emotional expressiveness for the manner in which they socialized emotion in their children: Systematic relations between reports of family-of-origin expressiveness and current parenting emerged for certain forms of expressiveness.

Through intergenerational transmission, via interlocked genetic and experiential pathways, purposefully or unintentionally, then, one generation (G1) appears to influence the parenting beliefs and behaviors of the second generation (G2) and thus the experiences and even child rearing of the third generation (G3). Fraiberg, Adelson, and Shapiro (1975) once referred to these inspirations as "ghosts in the nursery." In two early studies, Ruoppila (1991) reported significant correlations between grandparental and parental child rearing in a Finnish sample, and Vermulst, de Brock, and van Zutphen (1991) documented similarities in parental functioning across generations in a Dutch sample. Maritally dissatisfied couples are more likely to have had unhappily married parents (Amato & Booth, 2001); marital violence in the family of origin tends to repeat in the successive generation (Stith et al., 2000); and when parents abuse their children, their children are at risk of repeating abuse as parents with their own children (Cicchetti, Toth, & Maughan, 2000; Newcomb & Locke, 2001; Pears & Capaldi, 2001). Kovan, Chung, and Sroufe (2009) provided a "longitudinal" illustration of intergenerational transmission when they recorded interactions of parents (G1) and their 2-year-olds (G2) and then waited and recorded interactions of those 2-year-olds as parents (G2) of their own 2-year-olds (G3). Even accounting for confounds, a relatively strong correspondence emerged in parenting between generations. A variety of studies now documents similarities across generations for harsh parenting (Capaldi, Pears, Patterson, & Owen, 2003; DiLillo & Damashek, 2003) and poor supervision (C. A. Smith & Farrington, 2004) as well as for positive (Hofferth, Pleck, & Vesely, 2012; Thornberry, 2005; Thornberry, Freeman-Gallant, Lizotte & Krohn, 2003) and constructive caregiving (Z. Chen & Kaplan, 2001; Kerr, Capaldi, Pears, & Owen, 2009). Using data from grandparents (G1) and parents (G2), Bailey, Hill, Oesterle, and Hawkins (2009) examined continuity in parental monitoring and harsh discipline across generations. Parental monitoring and harsh discipline demonstrated continuity from G1 to G2. Thus, parenting in G1 vis-à-vis G2 predicts parenting in G2 toward G3.

Attachment is lifelong (Mikulincer & Shaver, 2010), and the Adult Attachment Interview (AAI; George, Kaplan, & Main, 1985) assesses an adult's (G2) model of his or her own relationships with his or her parents (G1). Unsurprisingly, adult attachments are conceptualized as relatively stable patterns of feelings, thoughts, and behaviors that characterize a person's current close relationships (Shaver & Mikulincer, 2002). For example, attachment avoidance reflects discomfort with closeness and intimacy. People who avoid try to minimize their distress, are uncomfortable depending on others or having others depend on them, and are reluctant to disclose feelings or information to relationship partners that might suggest vulnerability (Mikulincer & Shaver, 2010; Shaver & Mikulincer, 2002). Adult attachment insecurity, particularly avoidance, is associated with more negative responses to infant distress in females (Leerkes & Siepak, 2006) and less sensitive and comforting responses to children in mothers (Edelstein et al., 2004).

Strong predictive links have emerged between the G2 mother's AAI classification vis-à-vis parents in G1 and the G3 child's attachment with the G2 mother (P. K. Smith & Drew, 2002). G2 mothers who report having secure and realistic perceptions of attachments to their G1 mothers, for example, are themselves more likely to behave sensitively with their G3 children and have securely attached G3 children (Cummings & Cummings, 2002). Van IJzendoorn (1995) reviewed AAI studies and reported 75% concordance between the parent's autonomous/nonautonomous classification and a child's secure/insecure classification in Ainsworth's Strange Situation. Indeed, some claim that G2 maternal attachment to her primary G1 caregiver is a better predictor of her parenting skills than G2 representations of her G3 child or experiences directly with

the G3 child (Biringen, Matheny, Bretherton, Renouf, & Sherman, 2000). Thus, adults' caring for their offspring may have roots in their own early-life experiences with primary caregivers such that people who experienced quality parenting as children may express stronger compassion and altruistic behaviors towards others. This conclusion is supported by the continuity of parent-infant attachment styles into adult relationships (Fraley, 2002).

Parents appear to draw on the legacy of their families of origin for models of parenting, often emulating the same patterns of parenting and couple interaction they were exposed to as children, so mothers' positive memories of their family of origin's coparenting relationship are associated with their own supportive approach (Stright & Bales, 2003). For obvious reasons of longitudinality, the field of parenting in human beings has made only modest progress on what is an extraordinarily challenging problem: namely, establishing that patterns of parenting in G1 are internalized and carried forward to be reactivated in G2. Just collecting two or three generations of data is formidable, so it is to be expected at this stage that the field is far from settled on the mediational processes by which parenting transmits intergenerationally. Both genetic and experiential pathways of various types have been proffered. For example, a parent's experiences with and memories of his or her own parents may reverberate in his or her own parenting via direct (possibly ascribable to G2's observational learning of G1 parenting) or indirect (experiencing G1 parenting as a child affects mature behaviors in interaction with others, including one's own children) means (Campbell & Gillmore, 2007; Capaldi et al., 2003; van IJzendoorn, 1992). Whether the epigenetic activation of maternally related genes is transmitted across multiple generations of female offspring is not known, but cycles of parenting clearly repeat across multiple generations (Bower-Russa, Knutson, & Winebarger, 2001; Champagne, 2010; Gonzalez, Lovic, Ward, Wainwright, & Fleming, 2000; Kaffman & Meaney, 2007; Veenema, 2009).

A prospective, intergenerational study considered multiple influences on fathers' constructive parenting. Fathers in G2 were recruited as boys on the basis of neighborhood risk for delinquency, and they were assessed through early adulthood. The fathers' parents (G1) and the G2 mothers of G3 children were also studied. A multiagent, multimethod approach measured G1 and G2 constructive parenting (monitoring, discipline, warmth, and involvement) and G2 positive adolescent adjustment. Path modeling supported direct transmission of G1 constructive parenting of G2 in late childhood to G2 constructive parenting of G3 in middle childhood. G1 parenting also indirectly influenced G2 parenting through G2 positive adjustment. G1 parenting influenced G2 parenting in both early and middle childhood of G3. Positive father involvement in terms of caring for the child and sharing decision making when sons are young is associated with warmer and more positive parenting of their young children by the same sons as parents themselves in young adulthood; even in a high-risk sample, young men whose fathers were involved became better fathers to their own children (Hofferth et al., 2012). These intergenerational continuities in parenting persisted, even when additional influences were considered.

Transmission pathways of constructive parenting are maintained, in part, by engendering positive adjustment in offspring (Kerr et al., 2009). Two important questions in this literature ask, first, whether similar intergenerational continuities obtain for positive as well as negative aspects of parenting and, second, what types of processes or mechanisms might account for these associations (Conger et al., 2012). Using observer reports of parent-child interactions in the home, Neppl, Conger, Scaramella, and Ontai (2009) evaluated G2 parenting of their G3 children. With regard to the first question, these researchers found continuities between G1 and G2 harsh parenting (angry, hostile, and uncaring behaviors) and between G1 and G2 positive parenting (interest, concern, and clear communication). However, G1 positive parenting did not predict G2 harsh parenting after controlling for harsh parenting in G1. These findings help to identify specific mediating pathways that might explain intergenerational continuities in both styles of parenting, and they are consistent with earlier research demonstrating that negative parenting behaviors in G1 are related to the same behaviors in G2 through more general conduct problems of G2 parents (Caspi & Elder, 1988). Neppl and her colleagues (2009) also showed that G1 harsh parenting predicted G2 externalizing or antisocial behaviors, which then led to G2 harsh parenting. That is, when G2 youth experienced harsh parenting as adolescents, they were more likely to engage in antisocial behaviors during late adolescence and early adulthood, and these antisocial tendencies were directly related to their harsh parenting behaviors with their children. The authors proposed that positive or constructive parenting by G1 would be related to the same type of parenting in G2 through the competencies that positive parenting promotes during childhood and adolescence. G2 academic attainment mediated the relations between G1 and G2 positive parenting. Externalizing behaviors did not mediate continuity in positive parenting, and academic attainment did not mediate continuity in harsh parenting. It appears

that these intergenerational continuities are explained by processes or mechanisms specific to the type of parenting being considered. Conger (2013) showed that continuity in harsh parenting is partly a function of the partners that one chooses. People who have been harshly parented in childhood are more likely to partner with those who parent harshly, which in turn increases the parent's own risk of harsh parenting.

In brief, specific styles of parenting demonstrate continuity across generations. A special section of *Developmental Psychology* (Conger et al., 2009) was devoted to the issue of the intergenerational transmission of parenting, including evidence regarding the intergenerational transmission of positive parenting and developmental mediators that seem to be involved in that transmission. Evidence for intergenerational continuity in parenting has emerged as robust across diverse study samples, types of measurement, lengths of time, and after consideration of a variety of confounders. These studies also raise important questions about genetic and epigenetic processes that might contribute to similarities and dissimilarities in parenting across generations.

Epigenetics and Parent Experiences

Epigenetics constitute regulatory layers "on top of" DNA that may be experiential and modulate gene expression. For example, male mice learned to fear the smell of cherry blossoms (through associative conditioning with foot shocks); they were then mated with females. Their offspring, raised to maturity without ever having been exposed to the scent of cherry blossoms, demonstrated fearfulness the first time they were exposed to cherry smell and had a lower threshold for cherry blossom detection, and their brains had more neurons devoted to the scent. Moreover, the pups of females artificially inseminated with sperm of fear-conditioned father mice showed similar effects (Dias & Ressler, 2014). Thus, characteristics outside DNA appear to be inherited from parents (see also Vassoler, White, Schmidt, Sadri-Vakili, & Pierce, 2012).

Summary

Likely most proximal to parenting are determinants in the parent, including biological characteristics of the parent (such as genetic endowment, hormonal activity, and nervous system structure and function) as well as psychological characteristics (such as the parent's gender, age and stage of life, health status, cognitions, personality, family of origin, and perhaps parents' own idiosyncratic experiences). All of these factors (and others in the child and context detailed in the next sections) need to be taken into consideration when attempting to divine sources of individual differences in parenting cognitions and practices in mothers, fathers, and other child caregivers.

DETERMINANTS IN THE CHILD

When rat dams are given a choice between a chamber that has been associated with pups and one where they may receive an injection of cocaine, there is a period of time after parturition when new dams prefer the company of pups and succumb to power of offspring, spurning even the allure of narcotics (Mattson, Williams, Rosenblatt, & Morrell, 2001; Pereira, Seip, & Morrell, 2008; Seip & Morrell, 2007).

Thinking about parent-child relationships naturally highlights parents as agents of child socialization, and there is ample evidence, especially in the early years, that, between parents and children, children have little agency and parents exert more sway (Kochanska & Aksan, 2004; Maccoby, 1992; Vygotsky, 1978). There is initially asymmetry between parent and child contributions to parenting, but children from infancy affect parents. Parenting is a two-way street, and it has long been appreciated that development in children is a catalyst for transformations in parenting (Baldwin, 1946) and that children actively select, modify, interpret, and create their own environments, including their parenting (Bell, 1968; Scarr & Kidd, 1983). As the child ages, the parent-child relationship becomes more mutual and less hierarchical, providing adolescents and adult children with opportunities that help to redefine their relationships with their parents (Bornstein, Jager, et al., 2012). Contemporary theorizing readily acknowledges the effects of children on parents (Bell, 1968, 1970; Sameroff, 2009). Often what parents think or do depends on many child factors, and subtle as well as not-so-subtle biological and physical, psychological, and social characteristics of children influence parenting (Hodapp & Ly, 2005; Karraker & Coleman, 2005). Child effects answer the manifest behavioral adjustments parents make to children's age and gender and appearance, temperament, and activity. Child effects have several construals; from attachment theory, they signal need for care or alternatively they prompt or cause parenting (Sroufe, 1985). Some child effects are universal and common to all children; others are unique to a particular child or child-related situation. In early childhood, maternal sensitivity is in part defined by the reciprocal nature through which parents respond to their children, suggesting flexibility in parenting

practices to adjust to minute-by-minute demands of a situation (Ciciolla et al., 2012). The extent to which parents are sensitive depends on how well they are able to mold their responses and interactions to the needs of the child (Ainsworth, 1969; Leerkes, Blankson, & O'Brien, 2009); thus, determinants in the parent and in the child interact.

From the start, the birth of a child stirs the emotions and rivets the attention of adults. By their very coming into existence, children alter the sleeping, eating, and working habits of their parents; and they change who parents are and how parents define themselves. Moreover, parent and child activities are characterized by intricate patterns of mutual attunement and transaction (Bornstein, 2009, 2013a). Infants cry to be fed and changed, and when they wake, they let parents know they are ready to play and to learn; through social referencing and attachment relationships, infants and young children regularly deploy parents as agents. Many parenting initiatives are proactive; very often, however, parents behave reactively. When Anderson, Lytton, and Romney (1986) experimentally paired conduct-disordered boys with mothers of normal boys, the mothers behaved negatively. Adolescent problem behaviors may more powerfully determine parenting practices than parenting practices provoke subsequent adolescent problem behaviors (Huh, Tristan, Wade, & Stice, 2006).

Bell (1968; Bell & Harper, 1977) was among the first developmental theorists to emphasize the key role that bidirectional effects play in child socialization. By virtue of their unique characteristics and propensities—genetic endowment, physical features, state of arousal, perceptual awareness, cognitive capacity, emotional expressiveness, and individuality of temperament and personality—children actively contribute to the parenting they receive. Children influence which experiences they will be exposed to, and they interpret and appraise those experiences and so (in some degree) determine how their experiences affect them. Even within the same family and home setting, parents do not behave toward their different children in the same way, parenting is not perceived by different children in the same way, and parenting does not affect different children in the same way (Suitor et al., 2009; Turkheimer & Waldron, 2000). Some researchers have pointed to the relatively important role of children's perceptions of parenting in examining effects of parenting (Barry, Frick, & Grafeman, 2008). For example, Demo, Small, and Savin-Williams (1987) found that children are influenced more by their perceptions of parental practices and less by the actual practices.

The mere presence of offspring can be efficacious. When Kenkel et al. (2012) exposed reproductively naive male prairie voles (*Microtus ochrogaster*) to infants or control manipulations and measured plasma concentrations of OT, they found that simple pup exposure increased activation of neurons that stained for OT. Becoming or being a parent affects adults, females and males alike. Males in the biparental marmoset species *Callithrix jacchus* engage in high levels of parenting and express enhanced circulating reproductive hormones, such as arginine vasopressin. The brains of first-time and experienced marmoset fathers have greater abundance of arginine vasopressin V1a receptors and greater density of V1a receptor-labeled dendritic spines on pyramidal neurons in prefrontal cortex than nonfathers (Kozorovitskiy, Hughes, Lee, & Gould, 2006). Woller et al. (2012) examined the release of several reproductive neurocrines, including OT and PRL, in cultured explants of the hypothalamus of paternally experienced male marmosets compared to naive paternally inexperienced males. OT and PRL levels were higher than levels found in inexperienced males, suggesting that paternal experience prompts secretion of neurocrines in a male biparental primate.

Biological Characteristics

Physical features of children likely affect parents everywhere, perhaps in similar ways. By 18 to 20 weeks of gestation in their first pregnancy (16–18 weeks in repeated pregnancies), fetuses are felt to move in utero ("quickening"), a significant marker in the lives and psyches of the child's parents (Cunningham et al., 2010). Newborns have large heads dominated by disproportionately large foreheads, widely spaced relatively large eyes, small snub noses, exaggeratedly round faces, and weak chins. The ethologist Lorenz (1935/1970) hypothesized that these physiognomic *Kindchenschema* incite adults to express nurturant reactions. Adults are biased to respond quickly to human infant faces in positive ways (Esposito et al., 2015; Parsons, Young, Kumari, Stein, & Kringelbach, 2011; Senese et al., 2013) and are strongly motivated to caregive by them (Glocker et al., 2009a), just as human infant faces increase activation in select brain regions associated with empathy and responsiveness (Caria et al., 2012; Glocker et al., 2009b). Cuteness in infant faces modulates mother-infant interaction (Langlois, Ritter, Casey, & Sawin, 1995), and cuter babies are rated as more friendly, cheerful, likable, healthy, and competent (Casey & Ritter, 1996; Karraker & Stern, 1990; Ritter, Casey, & Langlois, 1991; Stephan & Langlois, 1984). A female's willingness to adopt a baby (Volk & Quinsey, 2002) and a mother's sensitivity toward a baby (Langlois et al., 1995)

in part reflect facial cuteness. Viewing a picture of one's own child activates brain areas associated with reward and motivation (Mascaro, Hackett, & Rilling, 2013).

Idiosyncratic characteristics of individual children are no less stimulating to parents. Every child is an original, and general developmental functions in children unfold in the context of wild individual variation. Some individual differences are rooted at deep biological levels. For example, a polymorphism of the *DRD*4 gene is associated with disorganized attachment (Gervai et al., 2005; Lakatos et al., 2000, 2002). Among carriers of the 7-repeat *DRD4* allele, there is no relation between quality of maternal communication and infant attachment; however, a strong relation exists between maternal disrupted communication and attachment in infant carriers of the *DRD*4 7-repeat genotype. That is, an individual-differences genetic trait in the child moderates the relation between maternal caregiving and infant attachment (Gervai et al., 2007). Similarly, low maternal sensitivity in infancy predicts higher levels of mother-reported externalizing behavior problems at 2 to 3 years of age but only if infants carry the 7-repeat allele of the *DRD4* gene (Bakermans-Kranenburg & van IJzendoorn, 2006). Caspi and colleagues (2002, 2003) reported that the relation between childhood maltreatment and later psychological maladjustment is moderated by genetic factors. The functional polymorphism of the regulatory region of the monoamide oxidase A (*MAOA*) gene moderates the relation between early maltreatment and later antisocial behavior, and a regulatory polymorphism of the serotonin transporter (5-*HTT*) gene moderates the effect of early maltreatment on adult depression (see also Foley et al., 2004; Kaufman et al., 2004; Kim-Cohen et al., 2006b). O'Connor et al. (1998) identified two groups of adoptees: one at genetic risk for antisocial behavior (their biological mothers had a history of antisocial behavior) and the other not at risk. At several points during the adoptees' childhood, O'Connor et al. assessed the children's characteristics and the adoptive parents' child-rearing methods. Children carrying a genetic risk for antisocial behavior were more likely to receive negative socialization from their adoptive parents. Jaffee, Caspi, Moffitt, and Taylor (2004) found that 5-year-old twins' experience of corporal punishment was mediated by the same genetic factors that predisposed them to aggressive and oppositional behavior; children's antisocial behavior evoked physical maltreatment. Likewise, Pener-Tessler et al. (2013) learned that boys' self-control mediated the association between their serotonin transporter gene polymorphism (5-*HTTLPR*) genotype and their mothers' positivity (warmth, autonomy support, responsiveness) toward them: Boys who carried the short allele of 5-*HTTLPR* exhibited higher levels of self-control and received higher levels of positive parenting.

Other biological characteristics of children, even if seemingly hidden, appear to affect parents. Vagal tone indexes heart rate and breathing changes and, as a physiological marker of emotion regulation, estimates parasympathetic nervous system influences on the heart. Mothers are concordant with their children in vagal tone (Bornstein & Suess, 2000), and higher vagal tone (more parasympathetic regulation) in children predicts more supportive and less restrictive mothering, even controlling for earlier mothering (Kennedy, Rubin, Hastings, & Maisel, 2004).

Normal development may be nonlinear in nature, stalling sometimes or even regressing temporarily (Bever, 1982; Harris, 1983; Strauss & Stavey, 1982). Parenting a child is thus akin to trying to judge a moving target, the ever-changing child developing in fits and starts at his or her own pace. Interest in the origins and expression of their child's individuality occupies a central position in parental thinking. Twin, adoption, and sibling studies indicate that child temperament and developmental competence are both instrumental in affecting the nature of parenting (Plomin, Reiss, Hetherington, & Howe, 1994). A persisting parenting challenge is that, at base, parents are constantly trying to divine what is inside their children's heads, what they want, what they know, how they feel, and what children will do next vis-à-vis the people and things around them. Thus, parents seem constantly in search of patterns, often inferring them on the basis of single transient events. For example, the ages at which individual children achieve a given developmental milestone typically vary enormously (some children say their first word at 9 months, others at 29 months), just as children of a given age vary dramatically among themselves on nearly every index of development (at 20 months, some toddlers speak 1 word, some 487; Bornstein et al., 2004). Of course, when and how their children talk, reach puberty, and so forth exercise strong psychological and behavioral impacts on parents.

Psychological Characteristics

Individual-difference characteristics of children stimulate parenting beliefs and behaviors, which then influence children's adjustment and development. Goldberg (1977) usefully taxonomized three salient child characteristics that affect parents: responsiveness, readability, and predictability. *Responsiveness* refers to the extent and quality of child reactivity to stimulation; *readability* refers to the definitiveness of child behavioral signals; and *predictability* refers

to the degree to which child behaviors can be anticipated reliably. Each child varies along each of these dimensions and manifests a unique profile of these characteristics (and others) that will influence parenting. For example, an "easily read" adolescent produces unambiguous cues that allow parents to recognize the adolescent's state quickly, interpret signals promptly, and thus respond appropriately.

Age and Stage

Some aspects of parenting are frequent or significant from the get-go and wane as children develop; others wax in importance over the course of child development. There is a general reduction in time devoted to parenting activities, especially caregiving, as children grow and develop and puberty distances adolescents from their parents. Parents of younger children (0–6 years) spend twice as much time in child care activities as do parents of older children (6–17 years; U.S. Bureau of Labor Statistics, 2013), and the sheer frequency with which children are exposed to parent cognitions and practices changes markedly from infancy to adolescence (Bradley, Corwyn, McAdoo, & García Coll, 2001). Child age predicts maternal reports of their own positive and negative parenting in a Canadian cohort study of children aged 4 to 11 years (Jenkins, Rasbash, & O'Connor, 2003) as it does parental reports as well as observations of parenting (Browne et al., 2012). As their susceptibility to peer influences peaks, adolescents experience a concomitant decline in susceptibility to parental influence, more and more determine how much time they spend with their parents, and the extent to which their parents are involved in and know about their lives outside the family (Bornstein, Jager, et al., 2012; Kerr, Stattin, Biesecker, & Ferrer-Wreder, 2003). Mothers and fathers alike report increased parenting stress across their child's transition to adolescence (Putnick et al., 2010), and adolescents and parents contest control over different types of issues as adolescents age (Smetana & Villalobos, 2009). Younger adolescents tend to endorse parental responsibility and care, whereas older adolescents tend to justify expression of rights with appeals to personal choice and rights (Cherney, 2010). Thus, adolescents come to consider some behaviors and actions to fall outside the bounds of parental regulation (Smetana, 2000), such as personal issues (e.g., hairstyle or favorite food), multifaceted issues (containing aspects of both personal and conventional domains), and prudential issues (involving potential harm to an actor). Parents, by contrast, continue to view these issues as within the scope of their authority, defining them as social conventions or matters of safety. These discrepant interpretations can lead to increases in everyday conflicts that ultimately serve as opportunities for adolescents and parents to renegotiate boundaries of authority (Smetana & Villalobos, 2009). Adolescents reportedly experience negative moods more often than either children or adults (Larson & Asmussen, 1991; Larson, Csikszentmihalyi, & Graef, 1980; Larson & Lampman-Petraitis, 1989), and the increase in negative affect during adolescence challenges parents of teenagers. One cross-sequential study that spanned ages 6 through 18 reported that positive aspects of parenting decreased markedly through middle adolescence even though parent-child communication changed little (Loeber et al., 2000). As a result, parents need to calibrate their reactions to adolescents' emotions.

Young children's interactions with their context are normally controlled by their parents, whereas older children and adolescents may engage more closely with other people, institutions, and physical aspects of their contexts (Leventhal, Dupéré, & Shuey, 2015). For example, children's developmental status makes different neighborhood social processes more or less salient for their parents (Skinner et al., 2014). Neighborhood social cohesion may be more important for parents when their children are young because of parenting demands, but parents may become more focused on neighborhood disorder as their children age and have greater direct exposure to neighborhoods.

Parents adjust relative to both child age and stage and child capacity and performance (Bellinger, 1980). Children's achieving certain milestones—standing upright and walking, for example—completely alters the nature and quality of adult caregiving (Campos et al., 2000), just as do many other rites of passage, such as children going to school for the first time, receiving communion or getting bar or bat mitzvahed, driving and dating, attending college, getting married, and all the events in between. With each such child development, parenting changes in some corresponding ways. Parents talk to the walking as opposed to the crawling toddler differently, just as they interact with the pubertal adolescent differently from the prepubertal. It is an understatement to say that adolescents' initiation of dating and sexual relationships have consequences for parents. Sensitive parents tailor their parenting to match their children's developmental progress (Adamson & Bakeman, 1984; Carew, 1980), for example, by providing more didactic experiences as children become more competent (Bornstein & Tamis-LeMonda, 1990; Bornstein et al., 1992; Klein, 1988). Mothers of infants in many cultures use affect-laden speech, but as their young children achieve more sophisticated levels of motor exploration and cognitive comprehension, mothers increasingly orient, comment, and prepare them for the world outside

the dyad by infusing maternal speech to children with increasing amounts of information (Bornstein et al., 1992). The mean length of mothers' utterances tends to match the mean length of those of their 12- to 32-month-olds (McLaughlin, White, McDevitt, & Raskin, 1983).

Childhood is change—development involves rapid growth in biological, mental, emotional, and social spheres; understanding, anticipating, and responding to these dynamic changes continuously challenge parents. Parents need to know about and keep vigilant to all the complications and subtleties associated with their child's development. With each child advance, parenting changes in some corresponding ways. Individual parents seem to maintain their standing relative to one another from day to day: Parents who talk to their children more on Monday likely talk to their children more on other days of the week. Over longer periods, of course, group mean levels in parenting change, and they certainly do so in response to children's development. Thus, stability does not negate age-appropriate parenting. Nonetheless, keeping an eye on a toddler in the park when the child is beginning to walk and giving a cell phone to a teen who is beginning to drive a car appear superficially different but may be conceptually similar in the sense of reflecting continuity in parental monitoring. As Holden and Miller (1999, p. 243) concluded, "the nature of child rearing is simultaneously enduring and different."

Birth Order

Survival rates for primate infants are higher among experienced multiparas compared with primiparas (Hrdy, 2009). For example, 63% of baboon infants of experienced mothers survive versus 29% of infants born to first-time mothers (Altmann, Hausfater, & Altmann, 1988). In human beings, multiparas report higher self-efficacy than primiparas (Fish & Stifter, 1993).

Although a substantial proportion of developmental science has been constructed on mother-firstborn relationships (Hoffman, 1991), roughly 80% of families in the United States will have more than one child (Dye, 2010), and most children in the United States grow up with siblings (Kreider & Ellis, 2011). Family structure, especially parity, has been thought to play a signal role in the development and expression of individual differences in parenting at least since Francis Galton (1874) and Alfred Adler (1928). A dramatic change in family dynamics takes place when a second baby is born into the family, and parenting differs in some ways for first- versus laterborns (J. Dunn & Plomin, 1990; Sulloway, 1996). Mothers engage, respond, stimulate, talk, and express positive affection more to first- than to laterborns, even when first- and laterborns show no differences in their behavior, indicating that some parenting does not (necessarily) reflect child behavior but parity (Belsky, Gilstrap, & Rovine, 1984). Combined with variation in genetic makeup, within-family variation in parental thinking and treatment is a potent factor in accounting for why children in the same family differ from one another (Caspi et al., 2004). This line of thinking culminates in parental differential treatment (Solmeyer, Killoren, McHale, & Updegraff, 2011) of siblings, which occurs when siblings are recipients of different child-rearing cognitions and practices. Parental differential treatment follows from children's individual characteristics (e.g., gender, age, personality, or special needs) and because of parental characteristics and family functioning (e.g., favored child versus scapegoat; McHale & Pawletko, 1992; Mekos, Hetherington, & Reiss, 1996). Thus, a parent may feel more affinity with or be more effective with one child than another. Parental differential treatment implies that parents do not have the same attitudes or act towards all of their children simularly. Indeed, there is research that supports the supposition that parents' cognitions and practices are less favorable in families with greater numbers of children (Furman & Lanthier, 2002).

Gender

Although there is evidence that parenting girls and boys is surprisingly similar in many ways (Bornstein et al., 2015; Hyde 2005, 2014; Lytton & Romney, 1991), child gender broadly organizes many parent descriptions, impressions, and expectations of children from the start of life (Bornstein, 2013a): Parents tend to interact with children differently by child gender. Classic "Baby X" studies (where the gender of the infant is not known to study participants) in the United States have shown that unidentified infants are judged more frequently to be male (Condry & Condry, 1976; J. Z. Rubin, Provenzano, & Luria, 1974; Seavey, Katz, & Zalk, 1975) and that parents conceive of and behave toward infants differently depending on whether they think they are interacting with a girl or a boy (Seavey et al., 1975; Sidorowicz & Lunney, 1980). Newborn nurseries provide uniformly gender-appropriate blankets, accessories, and the like; baby showers carefully respect child gender; and infants are fastidiously dressed in gender-appropriate clothing (Shakin, Shakin, & Sternglanz, 1985). Parents have been reported to purchase gender-stereotyped toys for their children within a few months of the child's birth—prior to when children could express gender-typed toy preferences themselves (Pomerleau, Bolduc, Malcuit, & Cossette, 1990). Mondschein,

Adolph, and Tamis-LeMonda (2000) found that mothers of 11-month-old boys would overestimate how well their babies could crawl down a sloped pathway, whereas mothers of 11-month-old girls would underestimate how well their babies could do, even when subsequent tests of crawling ability on the sloped path revealed no sex differences in infant crawling. Later, parents speak more frequently about emotions with their girls than with their boys, they speak about emotions differently, and they differentially reward and punish different emotions in daughters versus sons (Garside & Klimes-Dougan, 2002). Mothers respond differently to their "difficult" sons than to their "difficult" daughters, even when boys and girls do not differ on an independent measure of difficulty (Else-Quest, Hyde, Goldsmith, & Van Hulle, 2006). Daughters are apt to engage in more relational and less autonomous play than boys, possibly fostering more sensitive responding from mothers (Ruble, Martin, & Berenbaum, 2006). Continuing on in development, although parents encourage participation in sports with no gender differences, parents are more likely to encourage participation in youth organizations, religious activities, and summer situations with sons than with daughters and are more likely to encourage participation in art programs with daughters than with sons (MacDonald & Parke, 1984). Parents also tend to give adolescent boys more decision making leeway (Daddis & Smetana, 2005), whereas adolescent girls report more stringent rules regarding socializing with friends, and caregivers are more likely to become involved in peer relationships because of misbehavior of their sons than of their daughters (Greene & Way, 2005; Way & Greene, 2006). Parents also appear to be more consistent in the ways they socialize their daughters than in the ways they socialize their sons (McGue, Elkins, Walden, & Iacono, 2005). For example, Kagan and Moss (1962) reported a higher cross-time correlation ($r = .77$) for maternal control of girls than boys ($r = .24$). Gender stereotypes influence parents' reports of adolescent problems; consequently, parental attributions reflect their differential expectations for boys versus girls (Bornstein, Putnick, et al., 2011; Bugental & Happaney, 2002; Lansford et al., 2011). Although conflicts with parents reportedly increase in intensity as warmth decreases across adolescence, these changes appear to be greater for girls than boys (McGue et al., 2005).

Girls may spend more time with their mothers than do boys, becoming closer and more positively involved with them (Bornstein et al., 2008; Clarke-Stewart, 1973). Girls are recipients of greater warmth than boys (Atzaba-Poria & Pike, 2008), more positive parenting practices (Lloyd & Devine, 2006), and less harsh parenting and physical punishment (Lytton & Romney, 1991). In addition, girls are yelled at and smacked by their parents less often than boys are. Of particular relevance here is that a meta-analysis by Lytton and Romney (1991) found stronger effect sizes for parental physical punishment (strongly associated with parent rejection) for boys than for girls. Studies also have shown differences in the quality, pattern, and impact of mother-child and father-child interactions. All that said, the specific mechanisms that drive the influences of child gender on parenting cognitions and practices remain largely unknown (Ciciolla et al., 2012) as do the parenting dynamics of gender-same versus gender-different siblings (Jenkins et al., 2003).

Health Status

Child medical risk factors, such as low birthweight, prematurity, illness, developmental disability, and ASD, to name only a few, are associated with parenting stress (Eisengart, Singer, Fulton, & Baley, 2003; Goldberg & DiVitto, 2002; Hodapp, 2002; Kuhn & Carter, 2006; Saigal & Doyle, 2008; Zuckerman & Keder, 2015), and (unsurprisingly) the more severe the child's symptoms, the greater the parenting stress (Williford, Calkins, & Keane, 2007). Even multiple births pose problems (Damato, 2005; Lytton & Gallagher, 2002). Early developmental risk, such as prematurity and developmental delay, is associated with increased negative emotionality and behavior problems, less competent social interactions, and unclear emotional expression (Boström, Broburg, & Hwang, 2010; Feldman, 2007). In turn, these circumstances and behaviors are associated with greater parenting stress and more psychological distress in the parents (Baker, Blacher, Crnic, & Edelbrock, 2002; Baker, Blacher, & Olsson, 2005), perhaps resulting in the lower levels of maternal sensitivity often reported in families of children with developmental challenges (Feldman, 2007; Fenning, Baker, Baker, & Crnic, 2007; Niccols & Feldman, 2006). Preterm children have difficulty regulating interpersonal engagements, as evidenced in their increased gaze aversion, decreased play, and lower levels of joint attention: in compensation, mothers of preterms are more active and directive (Goldberg & DiVitto, 2002; Winstanley et al., 2015). Similarly, children's problem behaviors affect parents: For example, children's cry-fuss/sleep problems contribute to maternal depression and stress, and repeated problems have the greatest impact (St. James-Roberts, 2008). Mothers of children with developmental delay are less sensitive than mothers of typically developing children, especially under conditions of challenge (Ciciolla et al., 2012; Niccols & Feldman, 2006). If, as the Centers for Disease Control and

Prevention's Autism and Developmental Disabilities Monitoring Network Surveillance Year 2010 Principal Investigators (2014) estimate, about 1 in 68 children in the United States is diagnosed with an ASD, consider the range of parenting challenges numerous parents now face.

Cognitive Development

Mother-child dyads from the Massachusetts site of the NICHD Study of Early Child Care and Youth Development participated in a home-based instructional task through which their scaffolding effectiveness was assessed. Cognitive characteristics of both mothers and children, as well as dyadic characteristics from infancy, were examined as predictors of effective dyadic scaffolding when the children were in first grade. Children's early mental development predicted the effectiveness of parent scaffolding collaborations over and above children's concurrent cognitive capabilities (Mulvaney et al., 2006). Likewise, toddlers who demonstrate more effortful control at age 18 months evoke more frequent use of cognitive tactics in their mothers in a teaching task at 30 months, controlling for initial values, and their effortful control at 30 months predicts mothers' cognitive orientation at 42 months (Eisenberg et al., 2010). More generally, the effectiveness of much parenting (e.g., discipline that emphasizes communication and reasoning) depends on children accurately construing parents' communications (Grusec & Goodnow, 1994).

Reciprocally, simple child inattentiveness alters observed parenting (Browne et al., 2012), and mothers of children with a cognitive impairment are characterized as less sensitive and are more likely to engage in directive behaviors (Atkinson et al., 1999; Fenning et al., 2007; Moran, Pederson, Pettit, & Krupka, 1992; Niccols & Feldman, 2006). Children with early developmental delay in cognitive functioning are especially at risk of showing increased negative emotionality and behavior problems; in turn, these behaviors are associated with greater parenting stress and more psychological distress in their parents (Baker et al., 2002; Baker et al., 2005). Families face additional challenges when rearing children with impairments related to education, adaptive behavior, discipline, and the potential need for long-term care (Hodapp, 2002).

Temperament and Personality

There is growing correlational and experimental evidence to suggest that child temperament and behavior influence parental cognitions and practices (Bates & Pettit, 2014). When, as mentioned earlier, Anderson et al. (1986) paired conduct-disordered boys with mothers of conduct-disordered boys and with mothers of normal boys, conduct-disordered boys elicited negative parenting practices from both sets of mothers. Clearly, in this experimental setting, which controls for genetic effects, temperament and personality characteristics of the child contributed to the parenting displayed. Across the infant's first year, evidence for bidirectional relations between infant temperament and parenting emerge. Infants who score low on a smiling and laughing temperament scale from ages 4 to 12 months have mothers who use more negative parenting (more mother-reported lax, overreactive, and overtalkative discipline) at 18 months, controlling for earlier mother personality (Bridgett, Laake, Gartstein, & Dorn, 2013), and having a temperamentally easy child or perceiving a child as temperamentally easy (relatively happy, predictable, soothable, and sociable) enhances mothers' feelings of competence and efficacy (Cutrona & Troutman, 1986; Dixon & Smith, 2003; Porter & Hsu, 2003; Putnam et al., 2002) and promotes warmer and more responsive parenting, whereas challenging children evoke parenting stress and harsh parenting (Balge & Milner, 2000; Deater-Deckard & Dodge, 1997; Gershoff, 2002; Mammen, Kolko, & Pilkonis, 2002; Rodriguez & Green, 1997).

Difficult temperament reflects a child's tendency to react to stressors with negative emotions, including anger, irritability, fear, or sadness (Mertesacker et al., 2004; Rothbart, 2011). Early infant difficultness is associated with more parenting stress and less supportive coparenting across time. Paulussen-Hoogeboom, Stams, Hermanns, and Peetsma's (2007) meta-analysis revealed that child negative emotionality tends generally to be associated with lower parental warmth (in infancy and for high-SES families, negative emotionality may be associated with higher levels of parental warmth; Bates, Olson, Pettit, & Bayles, 1982; Crockenberg, 1986). One study (with autoregressive controls) found that high levels of infant distress at 1 year predicted reductions in mother supportive parenting from 1 to 2 years (Scaramella, Neppl, Ontai, & Conger, 2008). Children with more difficult temperaments often require more external, parental support and usually are recipients of less sensitive parenting (Belsky, 1984; Ciciolla et al., 2012). More generally, child temperament and behavioral styles that challenge parents may elicit harsher, less sensitive parenting behavior (Mills-Koonce, Propper, & Al-Yagon, 2007; Neppl et al., 2009; van den Boom & Hoeksma, 1994), although it is possible (albeit controversial) that negative emotionality also promotes more sensitive parenting in some situations (Leerkes & Crockenberg, 2002). Unsociable infant temperament predicts diminished maternal self-esteem (Farrow & Blissett,

2007), and child negative affectivity and conduct problems predict maternal reports of their own parenting as well as observations of parenting (Browne et al., 2012; Jenkins et al., 2003). Not unexpectedly, parents become warmer and less hostile in response to positive child and adolescent development and less warm in response to problematic child and adolescent functioning (L. R. Williams & Steinberg, 2011). Children's fearfulness and inhibition predict more maternal warmth, even controlling for earlier parenting (Lengua, 2006; Lengua & Kovacs, 2005). Parents' perceptions of child shyness at age 2 predict lower levels of parents' self-reported encouragement of child independence at age 4, even controlling for initial levels of encouragement of independence and stability in child shyness (K. H. Rubin, Nelson, Hastings, & Asendorpf, 1999). High child social wariness at 18 months predicts lower levels of structured parenting at 27 months, even controlling for parenting at 18 months and for changes in child social wariness (Natsuaki et al., 2013); this particular study used adoptive children and their parents, thereby ruling out a shared-genes explanation for the child temperament effect.

Children's developing personality continues to exert effects on parents. Using cohort-sequential latent growth curve modeling, Van den Akker, Deković, Asscher, and Prinzie (2014) studied mean-level personality development in children from 6 to 20 years of age and longitudinal bidirectional associations between child personality and maternal overreactive and warm parenting. In their 5-wave study, child personality predicted changes in both aspects of parenting.

As every parent knows (too well), children's social successes lighten parents' burdens and hearten them, just as children's social difficulties stress and distress parents. Parents worry about their adolescents' participation in delinquent activities (Pasley & Gecas, 1984). If adolescents turn to deviant peers and increase their involvement in antisocial activity, parents often disengage (Dishion, Nelson, & Bullock, 2004; Dishion, Poulin, & Medici Skaggs, 2000). Thus, in response to children's antisocial behavior, negative parental control increases, and positive parent behaviors decline (Albrecht, Galambos, & Jansson, 2007; Ge et al., 1996; Reitz, Dekovic, & Meijer, 2006; Rueter & Conger, 1998; Stice & Barrera, 1995). Adolescents' antisocial behavior disrupts effective parenting, and parents become hostile and rejecting in the face of adolescent delinquency (Conger & Ge, 1999; Conger & Simons, 1997). Some authorities have argued that the impact of adolescent deviance on parenting is stronger than that of parenting on deviance (Albrecht et al., 2007; Jang & Smith, 1997; Kerr & Stattin, 2003). In brief, child temperament plays a pervasive role in family processes (E. F. Davis, Schoppe-Sullivan, Mangelsdorf, & Brown, 2009).

Behavior

Children's behaviors are important for adults' evaluations of children, and children's behaviors affect their parents in all sorts of ways. For example, mothers' disciplinary responses depend on the nature of the child's transgression more than their belief about how to discipline the child (Grusec & Kuczynski, 1980). Parents readily change their child-rearing practices in the face of children's behaviors (Holden, Thompson, Zambarano, & Marshall, 1997). From the moment of birth, certain baby signals effectively influence parenting: Infant cries motivate adults to approach and soothe (Ainsworth, Blehar, Waters, & Wall, 1978; Del Vecchio, Walter, & O'Leary, 2009; Konner, 2010; Soltis, 2004; Stallings, Fleming, Corter, Worthman, & Steiner, 2001), and their smiles encourage and reward adult proximity (Eibl-Eibesfeldt, 1989; Konner, 1991). Indeed, as to be expected in an alloparental species such as ours (Hrdy, 2009), child stimuli that activate parental brain systems in mothers (Rilling, 2013) activate many of the same parental brain systems in fathers (Kuo, Carp, Light, & Grewen, 2012; Wittfoth-Schardt et al., 2012) and nonparents (Caria et al., 2012; Glocker et al., 2009a). Infant distress and nondistress cues may prompt different schema that influence how parents feel and behave in the moment. Infant cries likely activate attachment-related schema and memories of the manner in which parents' own emotional needs were or were not met in childhood, which in turn affect how aversive parents find crying, the manner in which they perceive infant cry signals, and their underlying beliefs about infants' emotions and how best to respond to them (Leerkes & Crockenberg, 2006; Leerkes, Parade, & Burney, 2010). The extent to which parent sensitivity to infant distress is distinct from sensitivity to nondistress or that both are dimensions of general sensitivity is important theoretically as well as practically. That is, if the two are distinct, they likely have different origins and may be related to different domains of child adjustment. And, if the two are distinct, intervention efforts could be developed to target the most relevant domain of parenting given the problem at hand (Leerkes, Weaver, & O'Brien, 2012).

Hearing a baby cry decreases T in men when coupled with nurturant responses (van Anders, Tolman, & Volling, 2011), and aggressive behavior elicits harsh parenting (Anderson et al., 1986; Larzelere, 2000), whereas disclosures of information improves parental monitoring (Kerr & Stattin, 2000; Stattin & Kerr, 2000). Adolescents who disclose to their parents about their lives are more likely

to have parents who refrain from reacting negatively (with sarcasm, judgment, or ridicule) to their spontaneous disclosures, and informed parents tend to be trusting parents (Kerr & Stattin, 2000; Kerr, Stattin, & Trost, 1999).

Responsibility, independence, and freedom accompany child growth. The normal drive of the child and adolescent to establish her- or himself as a separate individual may clash with parents' desires to maintain dependence and inculcate their own values.

Relationships

Parent and child exist in a dyadic relationship, and the nature of their relationship has implications for parenting. As Maccoby (1992) long ago reflected, child rearing is an interpersonal activity that reflects the constant interplay and coordination of (at least) two individuals. Mother-child dyadic characteristics in infancy predict scaffolding when children are in first grade (Mulvaney et al., 2006). Stress derived from the mother-child relationship is associated with higher levels of neglect and affective withdrawal (Suchman & Luthar, 2001). The more rewarding their mutual interactions are, the more motivated are parents to seek quality interactions with their children again (Teti & Candelaria, 2002).

Summary

Concurrent and predictive correspondences define the mutual influences that parent and child continuously exert on one another. The principle of transaction in development acknowledges that experiences shape the characteristics of the individual through time but that the characteristics of an individual shape his or her experiences (Bornstein, 2009; Sameroff, 2009). By dint of their unique characteristics and propensities—state of arousal, physical health, perceptual awareness, cognitive competence, emotional expressiveness, and individuality of temperament and personality—children actively contribute to their parenting and to producing their own development. Children influence which experiences they will be exposed to, and they interpret and appraise those experiences and so (in some degree) determine how those experiences will affect them. Child and parent bring distinctive characteristics to, and each is believed to change as a result of, their interactions; both parent and child then enter the next round of interaction as changed individuals. For example, child temperament and maternal sensitivity operate in tandem to affect one another and eventually the later development (e.g., attachment status) of the child (Rothbart, 2011); parental psychological control and adolescent depressive symptoms exert reciprocal effects (Soenens, Luyckx, Vansteenkiste, Duriez, & Goossens, 2008); parents' use of corporal punishment predicts subsequent child behavior problems, while children with more behavior problems elicit more corporal punishment from their parents (Lansford et al., 2011); and mothers' and fathers' harsh verbal discipline provokes increases in adolescent conduct problems and depressive symptoms as adolescent misconduct elicits increases in mothers' and fathers' harsh verbal discipline (M. T. Wang & Kenny, 2014).

Historically, it has been easy to assume that parents (and other adult socializers) are responsible for, say, gender-differentiated conduct in children. However, it is also the case that daughters elicit more feminine stereotypes and sons more masculine ones. Child effects on parents are in play and coexist with parent effects on children, and these mutual influences interact to consolidate socialization in children (Bornstein, 2013a). Another implicit assumption in parenting studies is that the effects of equivalent parenting are similar for all children. However, there is no reason to expect that a given parenting cognition or practice exerts the same effect on every child, and studies that pool parenting effects across children with different competencies, temperaments, and so forth might obscure child and parenting effects alike. A given parental cognition or practice likely has different effects on children with different temperaments. For example, Kochanska (1995, 1997) found that maternal responsiveness and the formation of a close emotional bond with the child fostered the development of conscience in bold, assertive children, whereas maternal gentle parenting techniques that deemphasized power assertion were more effective with shy, temperamentally fearful children.

In making attributions about their behavior and in creating opportunities and environments (or in failing to do so), parents are often influenced by and respond to their children's characteristics (Bugental & Happaney, 2002; De Los Reyes & Kazdin, 2005). Furthermore, from early infancy children recognize their parents; show preferences for their sights, sounds, and smells; and over the course of just the first year of life, children develop deep and lifelong attachments to sensitive and responsive parents (Bornstein, Arterberry, & Lamb, 2014). In essence, then, children's parents receive a great deal "in kind" for their hard work and commitment: They are often recipients of unconditional love, and through their children they access immortality. In lieu of interpreting the link between warm parenting and adolescent adjustment to indicate an impact of parental warmth on adolescent well-being, it is equally reasonable to conclude that well-adjusted teens elicit warm

parenting from their mothers and fathers (Kerr et al., 2003). Parents likely adjust to child behavior as much as they likely produce it.

In the end, effects in socialization run in both directions—parent to child and child to parent—and this consistency is mutually reinforcing. Parents and their children co-construct parenthood. Phonemes are the meaningful sound units of speech in a language, and they are constructed of subelements (so-called distinctive features). Jakobson (1941/1969) observed that the ontogenetic order of appearance of distinctive features in a Babel of languages including English, Swedish, and Japanese may be relatively fixed. Infants first produce front oral-cavity consonants (/m/, /p/) and mid- to back-vowels (/a/). Consonant-vowel combinations of these pairs are therefore frequently the earliest phonemes to appear in infant vocalizations. A well-known but nonetheless intriguing fact related to the ontogeny of vocalization is that two of these early and frequently appearing pairs, /ma/ and /pa/, tend to acquire particular meaning quite early in life. Murdock (1959) tallied the use of front-consonant/back-vowel phonemes as parental descriptors in 1,072 languages and compared their frequency with other combinations (e.g., front-consonant/front-vowel, back-consonant/back-vowel, etc.) Fifty-seven percent of languages use the early-appearing front-consonant/back-vowel class of infant sounds for initial parental kin terms. In short, parents around the world appear to adopt their infants' very first utterances as names for their own parenting role.

DETERMINANTS IN THE CONTEXT

In addition to biological and psychological factors in themselves and their children, diverse contexts condition and channel cognitions and practices of parents. *Context* refers to "any event or condition outside the organism that affects or is affected by a person's development" (Bronfenbrenner & Crouter, 1983, p. 359). The contexts of parenting are complex, multidimensional, and structurally organized into levels that are linked with each other. Contexts influence parent characteristics, and parent characteristics influence their contexts. Rather than considering parent and context in isolation, there needs to be simultaneous consideration of both parent and context. Here, for convenience sake and heuristic purposes, I distinguish three kinds of contexts in which parenting is embedded and which together encompass contextual determinants of parenting. They are proximal contexts, social group contexts, and distal contexts. Proximal contexts include situation and demand, family structure and system, support networks, employment status, and neighborhood residence; social group contexts include SES, religion, ethnicity, and culture; and distal contexts include ecology, history, and even evolution. All these contexts encourage or discourage diverse patterns of parenting attitudes and actions, and so all are meaningful determinants to parenting.

Proximal Contexts

Some prominent proximal context determinants of parenting include situations in which parents find themselves with children, tasks parents must accomplish, and immediate demands on parents as well as family structure and family systems, support networks that surround parents, their employment, and the neighborhoods where they live. Each is discussed in this section.

Situation, Task, and Demand

The supermarket checkout line is a more challenging context for the exercise of parental authority than is the playground (Lecuyer-Maus, 2000). Although parenting cognitions and practices are relatively stable (in terms of rank-order consistency), both are flexible and can and do vary with situation, task, and demand (qualitatively and in terms of mean level; Bornstein et al., 2006; A. L. Miller et al., 2002). Thus, parental behavior is normally highly situation specific, and parents believe that they need to modify their attitudes and actions relative to specifics of their situation (e.g., Catron & Masters, 1993; Dix & Reinhold, 1991; Grusec & Kuczynski, 1980). Recall that Holden and Miller's (1999) meta-analysis showed that cross-situation parenting stability was lowest of three circumstances and change was greatest. Low-challenge situations (e.g., unstructured play) prompt one kind of parenting (P. J. Miller, Wang, Sandel, & Cho, 2002), as emotional and instrumental demands are relatively minimized (Ciciolla et al., 2012), but the degree to which parents are challenged during interactions affects their practices, as parents must make additional effort to remain calm and regulated under more taxing conditions (A. L. Miller et al., 2002; P. J. Miller et al., 2002). For example, maternal sensitivity during free play is lower than during bathing (Joosen, Mesman, Bakermans-Kranenburg, & van IJzendoorn, 2012). Maas et al. (2013) examined effects of situational variables on mothers' interactions at home with their 6-month-olds. They found that levels of interactive practices of mothers (e.g., sensitivity, stimulation) varied systematically across situations of free play, face-to-face play, and diaper change: During free play,

mothers showed the highest levels of stimulation toward their infants; face-to-face interactions evoked more positive responsiveness; and in the goal-oriented diaper change situation, mothers hardly stimulated their infants and showed less positive regard. Likewise, mothers of children with and without developmental delay show similar levels of maternal sensitivity during free play; however, during a challenging task, mothers of children with developmental delay display lower levels of maternal sensitivity (Ciciolla et al., 2012). Maternal sensitivity during early childhood is therefore influenced by both the parenting context and specific child characteristics. Developmental risk and situation significantly contribute to the expression of maternal sensitivity, but their contributions depend on demands.

Chaotic (unpredictable, nonroutine, inconsistent) environments (often but not always associated with poverty) undermine parenting self-efficacy and involvement, generate marital and parental stress, and undermine support and parent-child relationships (Corpaci & Wachs, 2002; Evans, 2004, 2006; Evans, Gonnella, Marcynyszyn, Gentile, & Salpekar, 2005; Wachs & Camli, 1991) and so child health and development (directly and indirectly). Household chaos describes an environment that is high in noise and low in regularity and routines and has been associated with caregivers who are less likely to monitor children's activities and resort more often to inconsistent discipline and physical punishment (Wachs, 2005). All these sorts of contextualization further support the view of parenting as multidimensional, modular, and specific.

Few studies have attempted to manipulate parenting demands within parent-child interactions by specifically contrasting interaction contexts (S. E. Martin, Clements, & Crnic, 2002; Mills-Koonce et al., 2007; Pianta, Sroufe, & Egeland, 1989). However, studies which have indicated that the demands on parenting interact with other contextual factors. Perhaps most revealing of demand effectiveness on parenting are experimental treatments or interventions in which parents are assigned randomly to a treatment/intervention (versus a control) where beliefs and behaviors of parents change. Experiments can modify parenting cognitions and practices (Forgatch & DeGarmo, 1999). Belsky, Goode, and Most (1980) found that reinforcing mothers' didactic interactions with their young children during play in an experimental group resulted in increases in mothers' didactic interactions (and in higher exploratory play in children) compared to a control group. Van den Boom (1994) trained low-SES mothers to respond sensitively to their children and in this way modified mothers' negative responses to child irritability (and reduced avoidant attachment in distress-prone children). Recall that Slep and O'Leary (1998) demonstrated that mothers could be led to believe that their children misbehaved intentionally, and they subsequently responded to their children with more negative affectivity and harsher discipline than mothers who were led to believe that their children misbehaved accidentally. And Stein et al. (2012) primed mothers to worry or ruminate and thereby evoked more negative thoughts, higher thought recurrence, and more self-focus and so inhibited their responsiveness and vocal interaction.

As pointed out earlier, intervention trials can be interpreted as experimental manipulations that test parenting effects (P. A. Cowan & Cowan, 2002; DeGarmo, Eddy, Reid, & Fetrow, 2009; Dishion et al., 2008; Lunkenheimer et al., 2008; van Doesum, Riksen-Walraven, Hosman, & Hoefnagels, 2008). For example, Forgatch, Patterson, and DeGarmo (2005) found that fidelity to a therapy intervention protocol predicted change in parents' practices (and children's behavior). Experiments and interventions show that situation, task, and demand alter parenting.

Family Structure

Parenting is influenced by family configuration broadly construed. For example, marital status and father presence in the home moderate maternal emotional relationships with young children (Bornstein, Putnick, et al., 2012). Single-parent families typically experience less optimal interactions than do families consisting of two biological parents (Loeber et al., 2000; Sawhill, 2014). Single parenthood (Marquardt, Blankenhorn, Lerman, Malone-Colón, & Bradford Wilcox, 2012; Weinraub, Horvath, & Gringlas, 2002) and parents' separation and divorce (Hetherington & Stanley-Hagan, 2002) disrupt parenting and upset, change, and complicate family processes, as do subsequent transitions to stepparent or foster parent status (Haugaard & Hazan, 2002; Hofferth & Anderson, 2003). Notable in this connection is the incidence of child abuse in the stepparent population (Daly & Wilson, 1988). Many other vicissitudes of life (e.g., economic change) alter family structure and reverberate in changed parenting (Duncan, Magnuson, & Votruba-Drzal, 2015; Ganong et al., 2015).

A common yet still enthralling change in parenting occurs when a second baby is born into the family. As reviewed earlier, parents treat their second-born children in many ways differently than they treat their firstborn children (Sulloway, 1996), even when first- and laterborns show no differences in behavior, indicating that some maternal behaviors reflect family structure (parity), and not child effects (Belsky et al., 1984). As reviewed earlier as well, experience in parenting matters, and mothers are

prone to rate their firstborns as more temperamentally difficult (Bates, 1987), perhaps because first-time mothers are less at ease with their children and tend to perceive them as more demanding. Multiple births per se tax parenting (Bornstein & Ruddy, 1984). Parents of twins versus singletons show differences in mean levels of parenting: Parents of twins feel less effective as parents, show less concern about the health and safety of their infants, and are more likely to use hostile-reactive behaviors than parents of singletons (Boivin et al., 2005).

Evolutionary thinking suggests that parental effort expended on each successive offspring will decrease, resulting in smaller and less nourished offspring, a pattern that has been found in many different species ranging from invertebrates to birds to mammals (Mendl, 1988; Trumbo, 1996). The quality-quantity trade-off is documented in human beings in preindustrial societies, where larger family size has been linked to poorer growth and survival outcomes of children (Strassman & Gillespie, 2002), and in Western societies, where larger family size is associated with less direct parental involvement in key child care activities (Lawson & Mace, 2009). A Canadian cohort study showed that family size predicts maternal reports of their own parenting (Jenkins et al., 2003).

Family Systems

In a sense, the family system is another example of a situation effect on parenting. Parenting does not occur in a vacuum. It can be influenced by the presence of others; for example, fathers are more demanding of their sons when observed with their wives compared with father-son dyads alone (Buhrmester, Camparo, Christensen, Gonzalez, & Hinshaw, 1992). Thus, parents behave one way when interacting one on one with a child but another when the whole family is together (Cox & Paley, 2003; Deal, Hagan, Bass, Hetherington, & Clingempeel, 1999). Considerations of context and parenting necessarily invoke a family systems perspective. In family systems theory, what transpires in parenting is governed not only by the characteristics of the individual parent or child but also by patterns of transaction between the parent and others (Bornstein & Sawyer, 2005; Cox & Paley, 2003). Parenting develops and expresses itself in a family system that functions as an organized whole, composed of interdependent elements or subsystems that include individual parents as well as relationships among parents and others. Each element or subsystem within the family both affects and is affected by other elements; a change in any one element of the system can lead to changes in others. How responsive a mother or father may be at any given moment, for example, is determined not only by that parent's characteristic warmth and a child's characteristic responsiveness but also by the patterns the two parents have created jointly and therefore come to expect in their relationship.

Moreover, a full family systems approach examines parenting in the context of all relationships within the family as well as relations between the family and its many enveloping social and distal contexts (such as socioeconomic class and culture, discussed shortly). For example, mothers who report supportive relationships with "secondary parents" (grandparents and the like) are more competent and sensitively responsive to their children than mothers lacking such relationships (Grych, 2002). Fathers' education predicts the quality of mother-child engagements (Tamis-LeMonda, Shannon, Cabrera, & Lamb, 2004). Reciprocally, conflict between spouses may cause parents to miss the sometimes-subtle signals children use to communicate their needs. For their part, even 1-year-old children are less likely to socially reference their maritally dissatisfied father for information or clarification in the face of stress or ambiguity than are peers of maritally satisfied fathers (Parke, 2002).

Reflecting a family systems perspective, marital relationships affect the quality of parenting (Grych, 2002; Tamis-LeMonda & Cabrera, 2002), just as the way parents work together as a coparenting team has multiple far-reaching consequences for parenting (Teubert & Pinquart, 2010). *Coparenting* refers to ways that parents (or parental figures) relate to each other in the role of parent (McHale et al., 2002; McHale & Lindahl, 2011; Van Egeren & Hawkins, 2004). Coparenting comprises multiple interrelated components: agreement or disagreement on child-rearing issues; support or undermining of the parental role; and joint management of family interactions (Feinberg, 2003). Mutual emotional support and validation, modeling and sharing parenting skills, and buffering marital conflict or dissatisfaction from spilling over into relationships with children constitute some of the ways coparenting functions to moderate parenting. A coparent who has a positive and supportive relationship with a child tends to diminish the likelihood that the second parent will behave in a hostile manner toward the child (Conger et al., 2012).

Another illustration of the moderating effects of family systems on parenting occurs when mothering interprets and conditions fathering, as mothers frequently act as gatekeepers to children's fathers (and other caregivers), encouraging or discouraging others' involvement in child rearing (Allen & Hawkins, 1999; Cannon, Schoppe-Sullivan, Mangelsdorf, Brown, & Sokolowski,

2008). Marital dissatisfaction predicts maternal reports of their own positive and negative parenting (Jenkins et al., 2003). More generally, gatekeeping refers to how each parent regulates the other's interactions with the child (Fagan & Barnett, 2003; Rane & McBride, 2000). In certain circumstances, fathers may be more involved with their children, as when mothers are more satisfied with paternal caregiving and assess fathers to be more competent at caring. Many (but not all) paternal influences on children are indirectly mediated through the father's impact on the mother (A. J. Walker & McGraw, 2000). Thus, maternal encouragement is linked to augmented father involvement in child rearing ("gate opening"; Schoppe-Sullivan, Brown, Cannon, Mangelsdorf, & Sokolowski, 2008), and maternal discouragement with diminished father involvement in child rearing ("gate closing"; Meteyer & Perry-Jenkins, 2010; Trinder, 2008). Many additional aspects of marital relationships affect the quality of mother-child and father-child relationships (Gable, Crnic, & Belsky, 1994; Fincham, 1998; Tamis-LeMonda & Cabrera, 2002).

Support Networks

Beyond the nuclear family system, all families are also embedded in, influence, and are themselves affected by larger social systems. These social systems include formal and informal support networks. Integration or isolation from potential support networks facilitates or hampers parenting. *Support* refers to psychological and tangible resources available to individuals through their relationships with family, friends, neighbors, work associates, and others. Normally, helpful support networks have positive effects on parents.

Support from family members and other groups is associated with a successful transition to parenthood (Bird, Peterson, & Miller, 2002; Elek, Hudson, & Bouffard, 2003). Mothers in supportive relationships are less harried and less overwhelmed, have fewer competing demands on their time, and, as a consequence are more available to their children and are more competent and sensitively responsive to their children than are mothers lacking such relationships (Crnic & Greenberg, 1990; Grych, 2002). A generalized benefit of support could occur because social networks provide parents with regular positive experiences and so bolster overall well-being, because supports provide a sense of predictability and stability in one's life situation and recognition of self-worth and because supports buffer stress and mental health issues in parents (Bird et al., 2002). Members of support networks can also teach and encourage parents in more developmentally appropriate caregiving.

Several significant questions have motivated work in area of parenting supports. One concerns sources of support. In the Civitas Initiative et al. (2000) national survey, 70% of mothers of children under 3 reported that they relied on their spouse and 66% on their mothers for support. As noted previously, marital status and father presence in the home are critical to the young mother's well-being (L. D. Brown, Goslin, & Feinberg, 2011) and account for the quality of maternal emotional relationships with children (Bornstein, Putnick, et al., 2012). Emotional and child care support from a spouse (if not from other family members) are associated with well-being, greater life satisfaction, and more positive affect and competence (DeLongis, Capreon, Holtzman, O'Brien, & Campbell, 2004). Levitt, Weber, and Clark (1986) confirmed the importance of support from her spouse for mothers' well-being in intact families and extended the impact of that support to variation in the infant-mother relationship. In fact, intimate support from husbands appears to have the most general positive consequences for maternal competence (Crnic, Greenberg, Ragozin, Robinson, & Basham, 1983). When their children were 1, 3, and 5 years of age, parents reported on the emotional supportiveness they received from the other parent as well as their relationship status. Latent growth curve models revealed that, for both mothers and fathers, supportiveness was high at birth and perceived supportiveness at 1 year predicted supportiveness over time (Howard & Brooks-Gunn, 2009).

Friends and relatives constitute other major sources of information and support for new parents, especially those with little child-rearing experience. In the Civitas Initiative et al. (2000) survey, 54% of mothers reported that they relied frequently on their child's doctor/pediatrician, 25% on nurses, and 20% of child care providers for information and advice. Health care professionals are less immediately accessible, but comprise an important reserve for all ages and social classes of parent. They are consulted most often about emergent or specific medical problems (Hickson & Clayton, 2002; Hulbert, 2003). At the same time, parents report that many anticipatory guidance topics are not covered in well-child visits and that, even after such visits, they can still use more information (Sanghavi, 2005). When parents were asked whether they had any developmental, behavioral, or health concerns about their child, and whether they shared those concerns with a professional, 29% reported at least one serious concern, and more than 20% had failed to share that concern (Golan et al., 2008). To establish social support networks for information about child rearing, middle-class American parents

typically consult professionals, books, and magazines as well as relatives and friends (Clarke-Stewart, 1998; Young, 1991). Mothers in other social classes and cultures vary from this "high-brow" mode of data collection, however. Informal supports appear to be especially important for ethnic minority families (Burton & Jarrett, 2000). Both informal support systems (the extended family) and formal ones (schools, child care, parent education programs, and professionals) influence parenting (Cochran & Niego, 2002).

A second question in this literature concerns the types of support and the relative importance of the objective amount of support available to parents versus parents' perceptions of support. Support may be emotional, instrumental, or informational (Crockenberg, 1988). Quantitatively, more child care support is associated with higher-quality face-to-face interactions on the part of mothers (L. Levine, García Coll, & Oh, 1985). The more support adoptive parents receive (and the higher their expectations of life with a child), the more satisfaction they feel after their child arrives. Greater perceived support (both global and parenting support in particular) has been linked to lower levels of parenting stress, more positive parenting and relationships with children (Bonds, Gondoli, Sturge-Apple, & Salem, 2002; Izzo, Weiss, Shanahan, & Rodriguez-Brown, 2000; Suzuki, Holloway, Yamamoto, & Mindnich, 2009), and fewer negative interactions with children (Ensor & Hughes, 2010). Hashima and Amato (1994) found in a nationally representative sample that mothers' perceived social support was negatively associated with punitive and other negative parenting behaviors. The majority of existing research links global perceptions of support to indicators of parenting competence and suggests that it may matter more that parents feel support of some sort from some source than the specific amount, type, or source of support. D. M. Lee and Colletta (1983) studied support-parenting relations in adolescent parents with young children. Mothers who were satisfied with their support reported that they were more affectionate with their children, whereas mothers who were dissatisfied with their support reported more hostility, indifference, and rejection of their children. Mothers' social support moderates the effects of daily hassles of parenting (Crnic & Greenberg, 1990).

Parenting researchers have identified multiple antecedents of parenting knowledge *qua* a support (Cochran, 1993; Goodnow & Collins, 1990). Clarke-Stewart (1998), for example, reported that books and magazine articles were a popular source of advice about general child development, and their most frequent users were first-time and middle-class parents (Deutsch, Ruble, Fleming, Brooks-Gunn, & Stangor, 1988). Friends and relatives constitute a major base of information for younger parents with little parenting experience (Belsky, Youngblade, & Pensky, 1989). Mothers' own knowledge tends to relate to their formal, objective experience—exposure to books and manuals, pediatricians, and courses about child rearing—whereas previous informal or subjective experience with children (through babysitting or professional services alone) has been found to correlate not at all or even negatively with parenting knowledge (Frankel & Roer-Bornstein, 1982; MacPhee, 1981).

Today, advice on parenting from outside the family abounds. It begins well before the birth of a child in so-called preconception care whose goal is to reduce the risk of adverse effects for women, fetuses, and neonates by optimizing women's health and knowledge before planning and conceiving a pregnancy (American College of Obstetricians and Gynecologists, 2005; http://www.cdc.gov/preconception/index.html). And it can be found in professional compendia that provide comprehensive medical treatises of prenatal, perinatal, and postnatal development, such as *A Guide to Effective Care in Pregnancy and Childbirth* (Enkin, Keirse, Chalmers, & Enkin, 2000) and *The A to Z of Children's Health: A Parent's Guide from Birth to 10 Years* (Friedman, Saunders, & Saunders, 2013); in now-classic how-to books, such as *Dr. Spock's Baby and Child Care* (Spock & Needlman, 2013), *Your Baby and Child* (Leach, 2012), and *What to Expect When You're Expecting* (Murkoff & Mazel, 2008); in practical guides, such as *Baby Care Basics* (Friedman & Saunders, 2015) and *Teach Your Children Well* (M. Levine, 2013); in evidence-based academic compilations, such as the *Handbook of Parenting* (Bornstein, 2002b) and *Parenting: A Dynamic Perspective* (Holden, 2009); as well as in innumerable popular periodicals that overflow magazine racks in supermarkets, airports, and bookstores.

Internet, blogs, and other social media regularly inform parenting and allow parents to both give and receive support (Brady & Guerin, 2010; Doty, Dworkin, & Connell, 2012). Parents report using these platforms to share thoughts and ideas about parenting as well as normalize their experiences as a parent by trying to determine whether or not circumstances, symptoms, or behaviors they experience are typical and expectable (Drentea & Moren-Cross, 2005; Kirby, Edwards, & Hughes, 2008). Parents often end discussion board posts with "Is this normal?" to solicit other parents' experiences. Parents use the Internet primarily for information seeking (Nichols, Nixon, Pudney, & Jurvansuu, 2009; S. K. Walker, Dworkin, & Connell,

2011) and more specifically for gathering parenting information (Bernhardt & Felter, 2004; Blackburn & Read, 2005; Madge & O'Connor, 2006; Radey & Randolph, 2009; Tuffrey & Finlay, 2002; Warren, Allen, Okuyemi, Kvasny, & Hecht, 2010). Parents report using the Internet to help them improve how they spend time with children (26%), care for children's health (19%), and learn new things (73%; Allen & Rainie, 2002). When parents search for information online, they often seek information related to their child's normative development, specific medical diagnoses, or strategies for developmentally appropriate parenting (Bernhardt & Felter, 2004; Tuffrey & Finlay, 2002). Overall, parents report more confidence and a greater sense of empowerment in their role as a parent as a result of gathering information online (Madge & O'Connor, 2006). For example, many parents use social media to ascertain other how other parents arrive at medical decisions regarding their children (Brady & Guerin, 2010). Parents often use the Internet to find and communicate with other parents who are in situations similar to their own (Tuffrey & Finlay, 2002). Parents of children with ASD, for example, utilize e-mail to validate one another's concerns, help each other cope with uncertainty, and make sense of their experiences as a parent of a child with autism (Huws, Jones, & Ingledew, 2001).

In addition to parent education, parents access and report positive effects from online prevention and intervention programs (Lansford & Bornstein, 2007). In an evaluation of a 6-month computer-mediated social support online community targeting young, single parents (Dunham et al., 1998), 42 women accessed the online network over 16,000 times and provided social support to each other through online discussion fora. This online resource provided an environment for developing close personal relationships and creating a sense of community. Overall, single mothers who participated reported that they felt decreased parenting stress. In an experimental study of over 800 Singaporean parents with children under the age of 6, parents who accessed an online program providing information about children's development and tips for interacting with children increased in knowledge of children's speech and communication skills, children's social skills, and children's intellectual development. Parents who participated in the online program also reported feeling more confident that they were achieving their goal of being a successful parent (Na & Chia, 2008). First-time fathers who participated in an online intervention also reported significantly higher parenting self-efficacy scores than fathers in a comparison group (Hudson, Campbell-Grossman, Elek, Fleck, & Shipman, 2003). This New Fathers Network showed promise for being a successful intervention for providing nursing care knowledge to first-time fathers during the transition to parenthood.

Employment Status

Most parents work outside the home (Repetti & Wang, 2014). The nature of the workforce has changed dramatically; for example, the proportion of U.S. American mothers participating in the labor force increased from approximately 1 in 3 in 1950 to almost 2 in 3 in 2010 (U.S. Department of Labor, 2011). How individuals balance their roles in life, such as parent and employee, reflects in their effectiveness in those roles (Perry-Jenkins, Repetti, & Crouter, 2000). As noted earlier, mothers' role balance has more impact on child development than mothers' work status per se (Lerner & Galambos, 1985, 1986). Mothers who are unhappy with their work roles are more rejecting of their children, for example (Stuckey et al., 1982; Yarrow, Scott, De Leeuw, & Heinig, 1962). However, work can be affirming and have positive consequences for parenting. For example, in a sample of Korean mothers with infants, employment (both for consistently working mothers as well as for those transitioning to employment) was associated with fewer depressive symptoms and higher self-esteem, which in turn contributed to a warmer and more responsive parenting style (J. Kim & Wickrama, 2013). Thus, research tends to support a positive association between the balance struck by positive features of employment and parenting. Here, coparenting again enters the picture as a way for working women and men to balance their job and home lives (Sandberg, 2013).

Overwork and difficulties at work, however, seem to undermine good parenting. Parents tend to reduce their levels of social engagement and expression of emotion after more demanding days at work (Repetti & Wang, 2014). Video recordings of the daily reunions of employed mothers and their preschool children at a work-site daycare center over the course of a week revealed that mothers spoke less and were less emotionally engaged (e.g., there were fewer observations of caring and loving/warm behavior) following more stressful work days (Repetti & Wood, 1997). There is also evidence for short-term increases in irritability, displays of anger, and use of discipline with children after difficult days at work (Repetti, 1994). Elevated levels of negative job spillover are linked to increased use of harsh discipline in fathers (Atzaba-Poria & Pike, 2008). Fathers are less likely to know about their children's experiences and activities if they describe their jobs as highly demanding or as interfering with family life (Bumpus, Crouter, & McHale, 2006), and those who work long hours and carry high workloads have more

conflictive and less positive relationships with their adolescents (Crouter, Bumpus, Head, & McHale, 2001). More negative work environments predict more intrusive and negatively valenced parenting behavior (Costigan et al., 2003). Thus, parents' work demands impinge on family functioning (Hsueh & Yoshikawa, 2007), just as family responsibilities impinge on parents' work performance (Buehler & O'Brien, 2011). Moreover, the impact on children of one parent's work conditions also depends on how the other parent (or partner) accommodates (Barnett & Gareis, 2007).

More stressing still among women and men alike, unemployment, employment difficulties, and low earnings erode parents' positive connections to their children (Bianchi & Milkie, 2010). Indeed, at a macrosystem level, fertility itself declines in times of rising unemployment (Sobotka, Skirbekk, & Phillipov, 2011; Yule, 1906; Silver, 1965; Macunovich, 1996; R. Lee, 1990). Black, Kolesnikova, Sanders, and Taylor (2013) assessed the magnitude of long-term effects on completed fertility during the 1970s coal boom that increased male workers' incomes in coal regions of the United States and realized that that coal boom increased the completed fertility of affected cohorts by 3% while incomes were permanently increased by 6%. Analyzing more than 140 million birth records from the U.S. Vital Statistics natality data for the period 1975 to 2010, Currie and Schwandt (2014) detected short- and long-run negative responses of fertility to changes in the unemployment rate: Cohorts of women who faced high unemployment during their early 20s postponed fertility and had fewer children.

Neighborhoods

Neighbors may share norms and expectations for parenting and a collective willingness to implement both, even in the absence of close personal ties (Leventhal et al., 2015). Neighborhoods affect parents and parenting in many different ways: Neighborhoods likely influence parenting, parenting may mediate neighborhood characteristics on children, and neighborhoods can moderate parenting effects.

First, the character of their neighborhood matters for parents (Franco, Pottick, & Huang, 2010; Guterman, Lee, Taylor, & Rathouz, 2009; Molnar, Buka, Brennan, Holton, & Earls, 2003; Skinner et al., 2014). Parents who live in more disadvantaged neighborhoods experience greater depression, more stress, and worse physical health (Franco et al., 2010; Guterman et al., 2009), all of which are associated with less warm and consistent parenting and strained family relationships (Conger & Donnellan, 2007; Elder, Eccles, Ardelt, & Lord, 1995; Leventhal & Brooks-Gunn, 2005; Ludwig et al., 2012). Parents who move to middle-class neighborhoods, compared with parents who stay in low-income neighborhoods, monitor their children less stringently and are less restrictive in their control and discipline (Briggs, Popkin, & Goering, 2010). Parents who are overwhelmed and stressed by their neighborhood fail to buffer their children from the negative aspects of the neighborhood. However, neighborhood-SES associations with parenting are complex, and (as discussed later) neighborhood affluence can also undermine parenting. However, research also shows that neighborhood social processes are associated with parents' well-being, cognitions, and practices separate and apart from SES. Neighborhood social processes and parenting are nuanced and potentially moderated by structural features. For example, lower neighborhood social cohesion is associated with greater parental depression (Kohen, Leventhal, Dahinten, & McIntosh, 2008), but higher neighborhood informal social control appears to aggravate the negative association between parenting strain and parents' feelings of personal control (Carpiano & Kimbro, 2012).

Second, parenting cognitions mediate links between neighborhood characteristics (social cohesion; Kohen et al., 2008; or disorder; Mrug & Windle, 2009) and parenting practices as well as children's development. In this sense, parenting may serve as an indirect pathway for the effects of neighborhoods on parents themselves or on their children. For example, neighborhood quality predicts parental efficacy, parental efficacy predicts reported parental involvement and monitoring, and both predict academic and socioemotional adjustment of adolescents (Shumow & Lomax, 2002). Parents are less likely to allow their children to spend time outside in neighborhoods that are less safe, restricting their children's options for out-of-school-time physical activity (Schreier & Chen, 2012). Parental victimization by community violence and life stressors (parental strain) predict depressive, anxious, and hostile symptoms (parental mental health), which predict parental knowledge of their children's activities and child disclosure (parenting practices; Borre & Kliewer, 2014).

Last, parenting appears to matter differently in different contexts. That is, specific combinations of parenting and neighborhood attributes interact to influence children's development. Thus, neighborhoods and parenting may be risk or protective factors, or neighborhoods may be a risk factor and parenting a protective factor, or vice versa (Cicchetti, 2010; Simons et al., 2002; Werner, 1995). Parenting and neighborhoods sometimes work in the same direction, for better or for worse. For example, negative, ineffective, or uninvolved parenting may threaten children's

development in the context of high-risk neighborhoods (Roche, Ensminger, & Cherlin, 2007), and lower monitoring and permissive parenting in less safe neighborhoods and those with less residential stability and more disorder are detrimental for children (Beyers, Bates, Pettit, & Dodge, 2003). Similarly, harsh and inconsistent parental discipline in disadvantaged neighborhoods are associated with conduct disorder in children (Brody et al., 2003). By contrast, parenting strengths (e.g., use of authoritative control strategies) in neighborhoods where authoritative parenting is the norm may benefit children (Fletcher, Darling, Steinberg, & Dornbusch, 1995; Simons, Simons, Burt, Brody, & Cutrona, 2005). However, parental warmth, monitoring, and engagement can act as buffers in the context of low-SES or high-crime or disordered neighborhoods (Dearing, 2004; Rankin & Quane, 2002; Roche & Leventhal, 2009), just as neighborhood disadvantages can overcome advantages of typically beneficial parenting (Simons et al., 2002) or ineffective parenting is less problematic in the context of supportive neighborhoods (Browning, Leventhal, & Brooks-Gunn, 2005).

The "goodness of fit" between parenting cognitions and practices and neighborhood characteristics conditions parenting, and the match between the two may also depend on parents' individual attributes (Carpiano & Kimbro, 2012) or ethnicity (Dearing, 2004; Lamborn, Dornbusch, & Steinberg, 1996) or other factors. For example, in high-SES neighborhoods, authoritarian parenting is associated with earlier sexual initiation, but high parental authoritarian control is associated with delayed sexual initiation in youth from low-SES neighborhoods (Roche et al., 2005). The outcome matters as well to the meaning of parenting in context. Authoritarian parenting is detrimental for children's behavior in the context of disadvantaged neighborhoods (Roche et al., 2007; Roche, Ghazarian, Little, & Leventhal, 2011), but it is also associated with favorable academic outcomes (Dearing, 2004). A survey queried 3,115 adults living in 13 different neighborhoods in Texas to rate the effectiveness of different discipline strategies. Neighborhood conditions were related to the endorsement of yelling and threatening, time out and withdrawal of privileges, and explaining to children why certain behaviors are unacceptable, but they were not related to the endorsement of physical discipline. However, these associations differed by ethnicity. Neighborhood cohesion and collective efficacy were associated with decreased endorsement of yelling/threatening for African Americans and U.S.-born Latin Americans, and decreased endorsement of time out and withdrawal of privileges for European Americans. Neighborhood physical disorder, social disorder, and fear were associated with increased endorsement of time out and withdrawal of privileges among European Americans but were not associated with the endorsement of these strategies among ethnic minorities. Thus, parents' attitudes are structured by community context, but the influence of neighborhood conditions on parenting attitudes may differ for different ethnic groups (O'Brien, Caughy, & Franzini, 2005).

Parents in impoverished neighborhoods enforce a variety of rules regarding children's peer relationships presumably to avert their children from the adverse effects of risky peers (Leventhal et al., 2015). For example, parents have rules about where adolescents may meet and regulations constraining the amount of contact they may have with peers. Following a change of residence, parents report that they engage in consulting strategies, such as talking with their adolescents and encouraging them to participate in peer activities (Vernberg, Beery, Ewell, & Absender, 1993).

Social Group Contexts

Parents everywhere presumably want physical health, academic achievement, social adjustment, and economic security for their children (however those goals may be instantiated). It is likely, then, that even people in different social classes, professing different religions, belonging to different ethnicities, and from different cultures profess some similar general characteristics and competencies about parenting and wish to see and to promote some similar general characteristics and competencies in their offspring. Despite strong emphases on cultural differences, many cross-cultural studies of parent cognitions and practices report widespread similarities. In examples of the former, Mesman et al. (2015) sampled 751 mothers in 26 cultural groups from 15 countries around the globe and found strong convergence between maternal beliefs about the ideal mother and attachment theory's description of the sensitive mother across groups; Tulviste, Mizera, De Geer, and Tryggvason (2007) reported that child-rearing goals of mothers of 4- to 6-year-olds from Estonia, Finland, and Sweden were similar in all highly valuing self-maximization; Tudge and colleagues (1999) learned in a comparative study of parental values and beliefs in Estonia, Russia, the United States, and South Korea that middle-class mothers in all cultures were more likely to stress the importance of self-direction than the working-class mothers; and Posada and colleagues (1995) discovered that maternal beliefs about ideal child behavior were similar across seven Western and non-Western

countries and overlapped with attachment theory's notion of the secure-base phenomenon. African American, Dominican immigrant, and Mexican immigrant mothers in the United States reported the qualities they deemed desirable or undesirable in children age 1, 14, and 24 months. Mothers spontaneously referred to a common set of qualities, including self-maximization and connectedness; most mothers approved of desirable qualities, such as achievement, and disapproved of undesirable qualities, such as improper demeanor (Ng, Tamis-LeMonda, Godfrey, Hunter, & Yoshikawa, 2012).

In the practices domain, Bornstein, Putnick, Cote, Haynes, and Suwalsky (2015) examined rates, interrelations, and contingencies of vocal interactions in 684 mothers and their $5^1/_2$-month-old infants in diverse communities in 11 countries (Argentina, Belgium, Brazil, Cameroon, France, Israel, Italy, Japan, Kenya, South Korea, and the United States). Although they found that rates of mothers' and infants' vocalizations varied widely across communities, mothers' vocalizations to infants were consistently contingent on the offset of the infants' nondistress vocalizing, as infants' vocalizations were contingent on the offset of their mothers' vocalizing, and maternal and infant contingencies were significantly correlated. Thus, some parents' cognitions about their parenting and their children and some parents' practices are likely universal. Parenting presents the prospect of contributing to the development of a new life, and if there are universal values in this world, it is probable that nurturing, and not abusing, children falls among them. Similarities in parenting cognitions and practices could reflect evolutionary or biological bases of caregiving, the historical convergence of parenting styles, or the increasing prevalence of monistic parenting patterns through migration or dissemination via mass media.

Even where ultimate goals may be similar, however, social classes, religions, ethnicities, and cultures may differ in proximal ways to achieve them (Bornstein, 1995). Furthermore, the parenting beliefs and behaviors of one's own social group may seem natural but may actually be rather unusual when compared with those of other groups. Thus, SES, religion, ethnicity, and culture constitute social groupings each of which likely conditions parenting. That is, all social classes, religions, ethnicities, and cultures prescribe certain beliefs and behaviors in their members and proscribe others (Maccoby, 2000). For parents, some prescriptions and proscriptions, such as the requirement that parents nurture and protect their offspring, are (as suggested) essentially universal. Others, such as what kinds of emotions can be expressed in public, vary from one social group to another, and social group variation in beliefs and behaviors is always impressive. For example, parents in some cultures talk to babies and see them as interactive partners (Bornstein et al., 2015), whereas parents in other cultures think that it is senseless to talk to babies (Ochs, 1988). Different social groups possess parenting ideas, approach parenting tasks, and value parenting outcomes differently (Cote, Bornstein, Haynes, & Bakeman, 2008; Goodnow & Lawrence, 2015). For these reasons, parents from different social groups differ in their opinions about the significance of specific competencies for their children's successful adjustment, differ in the ages they expect children to reach different milestones or acquire various competencies, and so forth. Specific goals arise, in part, out of unique expectations of adult members of specific social groups. In turn, distinct belief systems provide parents with a framework for interpreting their children's behaviors, guiding their interactions with their children, and determining the activities and opportunities that they supply for their children's development. Here I emphasize parenting differences across social group contexts.

Three additional considerations are preliminary to this discussion of social group membership vis-à-vis parenting. In some respects, SES and ethnicity, and ethnicity and culture, overlap, but in other respects they differ. Here I distinguish each. The reader needs to recognize that much of the extant literature addressing ethnicity has confounded SES and vice versa. Moreover, one ethnicity or different ethnic groups may inhabit the same place, but different cultural groups normally populate different parts of the world. Although not an exclusive definition (Bornstein, 2006b; LeVine, 2003), research sometimes succumbs to the mistaken tendency to lump across SES and ethnicity or ethnicity and culture, but each is heterogeneous, and across social classes, religions, ethnicities, and cultures, different parenting beliefs, different parenting behaviors, and (not unexpectedly) different patterns of child development prevail. There follows a brief overview of some central considerations about social group membership determinants of parenting. In the context of the exosystem ring of Bronfenbrennerian pressures, the order of social groups cited is arbitrary.

Socioeconomic Status

SES comprises income, education, and occupation of householders and is broadly influential in parenting (Bornstein & Bradley, 2003). Although parents in different strata behave similarly in certain ways, SES orders a wide variety of cognitions and practices of parents toward children as it does the home environment (Bornstein, Hahn, Suwalsky, &

Haynes, 2003; Bradley & Corwyn, 2002; Hoff, Laursen, & Tardif, 2002). SES-related variation in parenting is diverse, conditioning the likelihood that parents serve their children spinach, display warmth in child rearing, and read books on child care. For example, using data from the Infant Feeding Practices study, which tracked the diets of more than 1,500 infants until age 1, Wen, Kong, Eiden, Sharma, and Xie (2014) found considerable differences in the solid foods mothers from different socioeconomic classes fed babies. Specifically, less-educated mothers from poorer households resorted to diets high in sugar and fat, whereas more-educated mothers from more resourced households adhered to diets that more closely followed infant feeding guidelines.The immediate consequence of poor infant diets is early weight gain and stunted growth. In the longer-term, the Infant Feeding Practices study analyzed data for the same children at age 6 and reported that infant feeding patterns translated into similar childhood eating habits.

Parental education is a key factor in SES (Bornstein, 2003; Bornstein, Hahn, Suwalsky, & Haynes, 2003). It is likely that lower education levels are tied to poorer awareness of proper nutrition and infant feeding practices. That is, if parents lack a proper understanding of what infants should eat and how important proper nutrition is for child health, they may not select healthy foods when less healthy ones are more convenient. When Duncan and Brooks-Gunn (1997) statistically controlled for household income and other demographic characteristics, they found higher levels of maternal education were associated with better cognitive and educational outcomes in children. More educated parents are more likely to turn to professionals (e.g., doctors, nurses) and immediate family (e.g., spouses, parents) for parenting information and advice than are less educated parents. Parents with fewer years of education are more likely to consult extended family (e.g., grandparents, aunts/uncles) for advice than are more educated parents. Lower-SES mothers refer to books or other written materials less readily as sources of information about child rearing and child development, whereas middle-SES mothers report that reading material is their primary source of information (Furstenberg, Brooks-Gunn, & Chase-Lansdale, 1989; Hofferth, 1987; Young, 1991), and they seek out and absorb expert advice about child development (Lightfoot & Valsiner, 1992). Parents with more education possess more formal knowledge about child development norms and theories and about parenting practices (Bornstein et al., 2013; Conrad, Gross, Fogg, & Ruchala, 1992; Palacios & Moreno, 1996; Parks & Smeriglio, 1986). They have more knowledge about factors that reduce the risks of illness, and they implement practices at home to improve health. More educated parents not only spend more time with their children (Guryan, Hurst, & Kearney, 2008) but use that time differently in that they read to their children more frequently (Raikes et al., 2006) and speak to their children drawing on more sophisticated language and literacy skills (Arriaga, Fenson, Cronan, & Pethick, 1998; Hoff, 2003; Rowe, Pan, & Ayoub, 2005).

Less educated mothers tend to stress traditional child-rearing goals more than mothers with higher levels of education (Tulviste et al., 2007). Similar dynamics obtain in fathers: Less educated Estonian and Finnish fathers are more likely to name desired characteristics related to conformity than more educated fathers. Educational level also drives mothers' expectations of when children should reach developmental milestones (P. D. Williams, Williams, Lopez, & Tayko, 2000). Higher-SES mothers generally give earlier age estimates for children's attainment of developmental milestones than lower-SES mothers (Mansbach & Greenbaum, 1999; von der Lippe, 1999). When Filipino mothers of preschool-age children were asked to estimate the age at which their child would acquire a variety of cognitive, psychosocial, and perceptual-motor skills (P. D. Williams et al., 2000), mothers with higher educational attainment had earlier expectations for children's cognitive and psychosocial development (e.g., emotional maturity, independence). Education also influences parental values for children. People with no more than a high school education tend to put more emphasis on teaching children obedience, religious faith, and being well mannered, whereas college graduates tend to place higher priority on teaching children empathy, curiosity, tolerance, and persistence (Doherty, Funk, Kiley, & Weisel, 2014).

In short, the positive characteristics of caregiver (especially maternal) education vis-à-vis parenting are profound and pervasive. In developing nations, maternal education, net of other family socioeconomic indicators, is positively related to mother's own health care utilization as well as the nutritional status and health care utilization for her children (Abuya, Ciera, & Kimani-Murage, 2012; Ahmed, Creanga, Gillespie, & Tsui, 2013; Burchi, 2012). Using UNICEF's Multiple Indicator Cluster Survey, Bornstein, Putnick, Bradley, Lansford, and Deater-Deckard (2015) explored relations among mother education, household resources, and infant growth in 117,881 families living in 39 low- and middle-income countries. Mother education led to improved infant growth through availability of household resources. Unfortunately, in many low- and middle-income countries around the globe, instructional

capital in the form of maternal education is limited: In 39 low- and middle-income countries, for example, the median years of education for women aged 25 and over was only 5.17 in 2010 (Barro & Lee, 2010).

Conversely, low SES and poor education are risk factors in parenting (and children's development). Low SES adversely affects mothers' psychological functioning and is associated with resort to harsh or inconsistent disciplinary behaviors (Atzaba-Poria & Pike, 2008; Pinderhughes, Dodge, Bates, Pettit, & Zelli, 2000). Parents who enjoyed fewer years of formal education and those with lower income hold less favorable attitudes about parenting in general (e.g., Clément & Chamberland, 2009; Pinderhughes, Dodge, Bates, Pettit, & Zelli, 2000) and sensitivity in particular (Emmen et al., 2012), and show a lower quality of actual parenting behaviors (e.g., Mesman et al., 2012). Around the globe, low- compared to middle-SES parents typically provide children fewer opportunities for variety in daily stimulation, have less appropriate play materials on hand, and engage in less total stimulation (Bornstein & Putnick, 2012). Significantly, working-class mothers converse with their children less, and in systematically less sophisticated ways, than do middle-class mothers (Hart & Risley, 1995; Hoff, 2003). These social class differences in maternal speech to children are widespread: In Israel, for example, middle-class mothers talk, label, and ask "what" questions more often than do lower-class mothers (Ninio, 1980).

Parents in higher socioeconomic strata also change more flexibly and more rapidly in response to changes in developmental theory than do parents in lower socioeconomic strata (Bronfenbrenner, 1958). Lower-SES parents believe they have less control over the outcome of their children's development than do higher-SES parents (Elder et al., 1995; Luster, Rhoades, & Hass, 1989). Kohn (1963, 1969, 1979) hypothesized that social class differences in the requirements and expectations of fathers' jobs were related to differences in fathers' goals and expectations for their children. Lareau (2003) illustrated that lower-income parents adopt a more "natural growth" approach to child development, where they do not attempt to fill leisure time with structured activities, as is more typical of middle- and higher-income parents.

Overall, financial and social stresses sap the general well-being and health of parents and demand attention and emotional energy from them (Magnuson & Duncan, 2002). In McLoyd, Aikens, and Burton's (2006) analysis, stresses on impoverished parents stemming from day-to-day struggles to find the resources to pay for food and rent, and the stresses of trying to cope with living in crowded housing and deteriorated, dangerous neighborhoods, undermine parenting skills and contribute to disorganizing family life (Toldson & Lemmons, 2013). Economic stresses thus erode parenting skills (Conger, Ge, Elder, Lorenz, & Simons, 1994) and reduce parents' attentiveness, patience, and tolerance toward children (Crnic & Low, 2002). Stress on parents is associated with decreased sensitivity to child cues, more negative feelings toward children, and harsh parenting styles (Sevigny & Loutzenhiser, 2010).

Parenting in the upper class is not immune from disadvantage, however (Luthar, 2003; Luthar & Barkin, 2012; Luthar & Latendresse, 2005; Racz, McMahon, & Luthar, 2011). Affluence is sometimes associated with parents' lower social support and higher alcohol use (Briggs et al., 2010; Chuang, Ennett, Bauman, & Foshee, 2005; Fauth, Leventhal, & Brooks-Gunn, 2008). As we see, the economics of the family is open to future study (Duncan & Magnuson, 2002). For example, standard economic theory (Becker, 1960) asserts that children are "normal goods" and fertility increases with income. However, higher female wages also make children more expensive, because childbearing and rearing have costs in terms of income lost. Empirical research supports these opposing forces (Aaronson, Lange, & Mazumder, 2011; Black, Kolesnikova, Sanders, & Taylor, 2013; Brueckner & Schwandt, 2014; Schaller, 2012).

Religion

Religion plays an central role in shaping core values and beliefs regarding family life, and aspects of religion are likely formative influences in parenting (Bengston, 2013; Gaunt, 2008; Mahoney, 2005; Mahoney, Pargament, Tarakeshwar, & Swank, 2008; Wilcox, 2002). A 2012 Gallup global poll reported that nearly 60% of the world's population self-identified as "religious" (WIN-Gallup, 2012). Most U.S. Americans describe themselves as religious (Mahoney, 2010), and 37% of all those with a religious affiliation (60% of White evangelical Protestants) in the United States say that religious faith is among the most important qualities to teach children (Doherty et al., 2014). (By contrast, just 3% of those who are unaffiliated say religious faith is among the most important qualities to instill.) In the United States, too, those with religious affiliations (particularly White evangelical Protestants) are also more likely than the religiously unaffiliated to prioritize obedience and being well mannered and somewhat less likely to say creativity, curiosity, or tolerance is important.

That said, religion is an understudied determinant of parenting. In actuality, scholars have distinguished

religiousness and spirituality as related but separate forces in parenting and family life (King & Boyatzis, 2015). Religiousness tends to refer to the extent to which an individual has a relation with a particular institutionalized religion (and is measured by, e.g., attendance at religious services), whereas spirituality is conceptualized in terms of an individual's personal quest for understanding answers to ultimate questions about life (and is measured by, e.g., perceptions of transcendence). Questions about religiousness tend to predominate in the extant literature and are usually global (Bartkowski & Xu, 2010) and too frequently overlook personal meanings derived from religious involvement (Mahoney, 2010; Mahoney et al., 1999; Volling, Mahoney, & Rauer, 2009).

Parents who are religious are likely to manifest their values and beliefs through everyday interactions with others, including family members. Indeed, if religion guides parenting, we would expect somewhat rigid and less flexible caregiving because fixed factors, such as a religious creed, and not others, such as a child's needs, would determine parenting. For example, Conservative Protestants subscribe to the belief that corporal punishment as a disciplinary practice is beneficial for young children's socialization (Ellison, Bartowski, & Segal,1996; Thompson & Miller, 1997). Stronger religiosity is related to lower convergence between the mothers' beliefs about the ideal mother and the profile of the highly sensitive mother (Emmen et al., 2012). With possible exceptions of extremists, parental religiosity is positively associated with more effective parenting, communication, closeness, support, monitoring, conflict, and peer acceptance and negatively associated with authoritarian parenting (Snider, Clements, & Vazsonyi, 2004). A meta-analysis of studies associating religion and families found that religion relates to important outcomes in marriage and parenting, including higher global marital satisfaction, family cohesion and authoritative parenting and lower rates of interparental conflict and divorce, with subsequent benefits in children's self-regulation (Mahoney, Pargament, Swank, & Tarakeshwar, 2001). DeMaris et al. (2011) assessed mothers' and fathers' reports regarding religion and parenting with infants; religious conservatism in mothers was related to higher levels of infant care, but lower levels in fathers. According to Ho (1994), Confucian ethics emphasize obligation to others rather than individual rights and provide a foundation for parent-child relationships through the notion of filial piety. Among such filial precepts are obeying, honoring, and providing for the material and mental well-being of one's parents; performing the ceremonial duties of ancestral worship; taking care to avoid harm to one's body; ensuring the continuity of the family line; and in general conducting oneself so as to bring honor and not disgrace to the family name. These underlying Confucian values are thought to be reflected in many Asian parents' goals for what it means to be a good parent and what constitutes a good or virtuous child.

Two common construals offer insights into how religion might affect parenting. *Sanctification* refers to the extent to which parents view God as evident in their relationships with other family members and so view their parenting as imbued with religious and spiritual meaning. Sanctification is nondenominational. Sanctification in parenting is one way religion is manifested in everyday interactions between parents and children (Mahoney et al., 1999). For example, sanctification is associated with constructive discipline practices and greater marital satisfaction and diminished discord and with decreased conflict with children (Mahoney et al., 1999; Volling et al., 2009). Murray-Swank, Mahoney, and Pargament (2006) evaluated mothers spanking in relation to their theological conservatism in interaction with their sanctification (how much they imbued their parent role with sacred and divine qualities and saw parenting as "God's work"). Mothers' conservatism and sanctification interacted in predicting spanking: Theologically conservative mothers who also viewed their parental role as sanctified, sacred, and holy were more likely (than other conservative mothers) to spank their children, whereas mothers who were theologically liberal and also viewed their role as sacred and holy were less likely (than other liberal mothers) to spank.

Religious coping describes the ways that individuals utilize religion to work through life challenges (Pargament, Smith, Koenig, & Perez, 1998). It concerns specific beliefs about God's role in times of distress and accounts for variance in health and well-being outcomes above and beyond the influences of nonreligious coping (Pargament, 1997). In addition, religious coping mediates the relation between general religious orientation and outcomes of life events. This functional aspect of religion might explain how sensitive and involved parents are with their children via-à-vis measures of attendance or global religiosity.

Research has rarely considered whether religion has unique associations with parenting after accounting for related constructs that also may influence parenting. For example, as indicated, individuals reporting greater religiosity also tend to report greater marital satisfaction (Mahoney et al., 2001) and greater warmth and affection toward children (Wilcox, 1998), all of which predict more sensitive and involved parenting. In an investigation to rule out third-variable explanations for associations between

religion and parenting, measures of civic engagement or conventional behavior (e.g., voting) were not found to diminish the association between church attendance and father involvement (Wilcox, 2002). Examining the roles of other potentially important constructs linked to parenting will be critical for understanding how religiousness and spirituality each specifically shapes parenting.

Ethnicity

Parenting is conditioned by ethnicity and varies in meaningful ways among people of various ethnicities (as already noted). For example, parenting values is an instance case. A national survey in the United States revealed that (69%) African Americans say it is especially important to teach children religious faith; by contrast, about half of European Americans (51%) and Latin Americans (54%) say teaching children religious faith is important. African Americans (70%) are also more likely than European Americans (57%) to place importance on teaching children to be obedient (Doherty et al., 2014). Parenting style is often assessed along two separate broad dimensions, warmth (responsiveness and child-centeredness) and control (demandingness), which combined produce four parenting types: authoritative, authoritarian, permissive, and disengaged (Baumrind 1967, 1978, 1991; Maccoby & Martin, 1983). These styles are hypothesized to contribute differentially to child identity formation and cognitive and moral development. An authoritative parenting style combines high levels of warmth with moderate to high levels of control. In middle-class European American families, it is associated with children's achievement of social competence and overall better adaptation. Parents who are supportive in this way are often identified with being emotionally and physically responsive to their children's autonomy and prepare children for a world they regard as validating, trusting, and accepting. Authoritarian parenting, by contrast, is composited of high levels of control and low levels of warmth, and among European Americans it is generally associated with poorer child developmental outcomes. However, different ethnic groups in the United States have different approaches to parenting and value different outcomes. Parental control is equated with loving concern and associated with perceptions of warmth in Asian and Latin, but not European, American families (Chao & Tseng, 2002; Harwood et al., 2002). In European American families, parental warmth protects against children developing externalizing problems, but in African American families, it is a risk factor (Lau et al., 2006; Lorber, O'Leary, & Smith Slep, 2011). African American parents hold different beliefs about the world because of racism, inequality, and residence in neighborhoods that are unsafe (Ogbu, 1981). Thus, supportive parenting and its effects may look very different in different ethnic communities (Brody & Flor, 1998; Ispa et al., 2004).

Tamis-LeMonda and Kahana-Kalman (2009) interviewed low-income, urban, African Americans as well as Mexican, Dominican, and Chinese immigrant mothers in maternity wards hours after the births of their babies. Mothers' views were assessed using open-ended questions, and their responses were coded as relevant to four main categories: child development, parenting, family, and resources. Mothers from the four ethnic groups varied in how much they spoke about child development, family, and resources. Relative to the other groups, Chinese immigrant mothers talked more about child development; African American and Dominican immigrant mothers talked more about resources; and Mexican immigrant mothers talked more about family. Latin American and African American mothers read to their children less frequently as compared to European American mothers (Yarosz & Barnett, 2001), and Spanish-speaking Latin American families have fewer children's books available in the home than their non–Latin American counterparts (Raikes et al., 2006). As discussed earlier, O'Brien et al. (2005) surveyed adults living in 13 different neighborhoods in Texas about their attitudes regarding child discipline. Neighborhood cohesion and collective efficacy were associated with decreased endorsement of yelling/threatening for African Americans and U.S.-born Latin Americans and decreased endorsement of time out and withdrawal of privileges for European Americans. Neighborhood physical disorder, social disorder, and fear were associated with increased endorsement of time out and withdrawal of privileges among European Americans but were not associated with endorsement of these strategies among ethnic minorities. Minority Latin and African American parents do not differ from one another in parenting knowledge but do differ from European American parents (García Coll & Pachter, 2002). Harwood, Miller, and Irizarry (1995) found that European American mothers underscore the importance of values such as independence, assertiveness, and creativity, when asked to describe their ideal child, whereas Latina American mothers underscore the importance of obedience and respect for theirs.

Ethnicity also plays a role in parental supervision. European American, Latin American, and African American parents all similarly encourage their adolescents to establish same-ethnicity friendships and caution their adolescents about the challenges of cross-ethnic romantic relationships (Dornbusch et al., 1987; Hamm, 2001). Latin

American and African American parents are consulted less by adolescents than are European American parents (Bornstein, Jager, & Steinberg, 2012). Asian American parents, as compared to European American parents, attribute the effort the child directs toward schoolwork as most important contributor to the child's academic success (Chao & Tseng, 2002).

Culture

Like social class, religion, and ethnicity, culture pervasively influences who parents (Leinaweaver, 2014) as well as how parents view parenting and how they parent (Bornstein & Lansford, 2010). Culture defies ready definition, but most scholars agree that culture embraces patterns of beliefs and behaviors, acquired through socialization, that distinguish social groups (Boyd & Richerson, 2005). The majority of research in parenting refers to a Western, educated, industrialized, rich, and democratic cultural database (Bornstein, 2010b; Henrich et al., 2010). Nonetheless, from extant comparative studies, we have learned that culture influences parenting (and child development) from very early in life in terms of when and how parents care for children, the extent to which parents permit children freedom to explore, how nurturant or restrictive parents are, which behaviors parents emphasize, and so forth (Benedict, 1938; Selin & Stone, 2009; Whiting, 1981). For example, in some cultures, children are reared in extended families where care is provided by many relatives; in others, children and their mothers are isolated from almost all social contexts. In some cultures, fathers are treated as irrelevant social objects ("honored guests"); in others, fathers assume complex and continuing responsibilities for children ("house husbands"). Japan and the United States maintain reasonably similar levels of modernity and living standards, and both are child-centered societies, but the two differ dramatically in terms of history as well as beliefs and behaviors with respect to parenting. Traditional Japanese mothers expect early mastery of emotional maturity, self-control, and social courtesy in their children, whereas American mothers expect early mastery of verbal competence and self-actualization in theirs. American mothers promote autonomy and organize social interactions with their children so as to foster physical and verbal assertiveness and independence, and they promote children's mastery of the external environment. Japanese mothers organize social interactions so as to consolidate and strengthen closeness and dependency within the mother-child dyad, and they tend to indulge young children (Bornstein, Cote, Haynes, Suwalsky, & Bakeman, 2012; Morelli & Rothbaum, 2007).

Parents in different cultures can differ radically in what they value. Consider play, for example: Parents in some cultures believe that play provides important development-promoting experiences; parents in others see play primarily to amuse; and parents in still others do not include play in their job description (Bornstein, 2007; Bornstein & Putnick, 2015). Tamis-LeMonda, Wang, Koutsouvanou, and Albright (2002) investigated child-rearing values in mothers of preschoolers from Greece, Taiwan, and the United States using open-ended probes and an ordering task. They identified four broad categories of values: decency (values emphasizing character), proper demeanor (values emphasizing appropriate relatedness and behaviors), self-maximization (values emphasizing the development of self potential and individuality), and sociability/lovingness (values emphasizing affective and social dimensions of relatedness). Cultural differences in all value categories emerged, echoing the unique cultural frameworks of the three societies. Likewise, expected developmental timetables in new mothers in Australia of Australian versus Lebanese heritage differ, showing that culture shapes mothers' expectations of their children much more than other seemingly more immediate factors, such as experiences observing their own children, comparing them to other children, and advice from friends and experts (Goodnow, Cashmore, Cotton, & Knight, 1984). Indeed, culturally defined beliefs are so powerful that parents sometimes act on them as much as or more than on what their senses tell them about their own children. Parents in Samoa, for example, reportedly think of young children as having an angry and willful character, and, independent of what children might actually say, parents consensually report that their children's first word is *tae*, Samoan for "shit" (Ochs, 1988).

Among European Americans, self-esteem is thought to be important to healthy development in children, but among Taiwanese, self-esteem is less important or even thought to create psychological vulnerabilities. When A. L. Miller et al. (2002) compared European American and Taiwanese mothers' beliefs about child rearing and self-esteem, unsurprisingly they found that nearly all European American mothers spontaneously invoked self-esteem and spoke about the importance of building children's self-esteem. In contrast, few Taiwanese mothers talked about "self respect–heart/mind" (a Chinese term that approximates self-esteem). Asian Indian child rearing emphasizes close family bonds with parents highly involved in their children's lives. Individuals of all ages are expected to sacrifice and to contribute to the honor and welfare of the family (Jambunathan & Counselman, 2002). Rites of

passage are associated with the onset of biological puberty, but there is no corresponding change in adolescents' status, responsibilities, or autonomy in decision making in Asian Indian families (Dasgupta, 1998), and even adult children are expected to remain at home until marriage and follow parental advice when dating or making career choices (Jambunathan & Counselman, 2002). By contrast, European American families tend to be nuclear, and children are generally viewed as transitional members who by adolescence are expected to individuate and pursue their own interests. Indeed, adolescence as it is conceptualized in Western society is a foreign concept in traditional Asian Indian society. Thus, Asian Indian parents hold negative views of their adolescents' independent and autonomous behaviors, behaviors that European American parents are trying to foster. Harwood et al. (1995) found that both working and middle-class Puerto Rican mothers valued respectfulness and proper demeanor in their children, but U.S. mothers wanted their children when grown up to possess the qualities of self-maximization. Parents in Sweden stress independence and assertiveness more than parents in India (Ekstrand & Ekstrand, 1987).

Even very basic parenting practices vary widely across cultures. Konner (1977) recorded variations in the frequencies of African Kalahari San, Guatemalan, and Bostonian caregivers' vocalization to infants; Caudill and Weinstein (1969; see also Ferguson, 1977) found that U.S. mothers talk more to their babies than do Japanese mothers; and Richman et al. (1988) reported that North American, Swedish, and Italian mothers vocalized at higher rates than Kenyan (Gusii) mothers. (Many observers have noted the relative dearth of speech among African caregivers, be they Gusii speakers in Kenya or native speakers of Sooninke or Pular from west Africa; Dixon, Tronick, Keefer, & Brazelton, 1981; Rabain-Jamin, 1994; Richman et al., 1988.) Furthermore, European American mothers in Lafayette, Indiana, speak in response to their infants' vocalizations more than mothers in Nagoya, Japan, do (Fogel, Toda, & Kawai, 1988); mothers in Boston, Massachusetts, are more verbally responsive to their infants than are Gusii mothers in west Kenya (Richman et al., 1992); and urban Berliner mothers show higher levels of contingent vocal responsiveness compared with Nso mothers in rural Cameroon (Keller, Kärtner, Borke, Yovski, & Kleis, 2005).

One dynamic attests to the influence of culture on parenting, and consequently the malleability of parenting. When parents reared in one culture migrate to another, they eventually adopt the parenting cognitions and practices of the new culture (Bornstein & Bohr, 2011; Bornstein & Cote, 2003, 2004a, 2004b, 2007; Cote & Bornstein, 2003, 2005; Cote et al., 2015). Notably, these rarely happen simultaneously, but practices seem to migrate sooner and more readily than cognitions.

Multicultural comparative studies of parenting beliefs and behaviors, and even more challenging longitudinal ones, are increasing in incidence and sophistication (see Bornstein et al., 2015a, b; Lansford et al., 2011, 2014; Putnick et al., 2012). For example, mothers from Argentina, Belgium, Israel, Italy, Japan, and the United States were asked about their attributions for parenting successes and failures—if being able to successfully comfort their child when the child cries was due to their parenting ability (e.g., "I am good at this"), effort (e.g., "I have tried hard"), mood (e.g., "I am in a good mood"), task difficulty (e.g., "This is easy to do"), or a child characteristic (e.g., "My child makes this easy to do"). Among many culturally differentiated patterns of findings that emerged, Japanese mothers were less likely than mothers from all other nations to attribute success to their own ability and more likely to indicate that, when they were successful, it was because of the child's behavior (Bornstein et al., 1992). Bornstein, Putnick, and Lansford (2011) evaluated similarities and differences in mean levels and relative agreement between mothers' and fathers' attributions and attitudes in parenting in nine countries: China, Colombia, Italy, Jordan, Kenya, the Philippines, Sweden, Thailand, and the United States. Mothers and fathers reported their perceptions of causes of successes and failures in caregiving and their progressive versus authoritarian child-rearing attitudes. Country differences emerged in all attributions and attitudes that were examined. In diverse domains of development, parenting practices relate differently to children's adjustment depending on the broader cultural context. A study of associations between parental corporal punishment and children's adjustment in China, India, Italy, Kenya, the Philippines, and Thailand disclosed that more frequent corporal punishment was linked to higher levels of child aggression and anxiety in all six countries, but the connection was weaker in countries where the use of corporal punishment was more culturally normative (Lansford et al., 2005).

Bornstein and his colleagues (2015) observed mothers and their infants in 11 societies world-wide under ecologically valid, natural, and unobtrusive conditions to study their usual routines in the familiar confines of their own homes. They videorecorded mother-baby dyads and then used mutually exclusive and exhaustive coding systems to comprehensively characterize frequency and duration of six maternal caregiving practice domains (nurture, physical, social, didactic, material, and language), and they then

asked about cultural similarities and differences in base rates of parenting in the six caregiving domains. Mothers in different cultures differed in every domain assessed. Moreover, mothers in no one culture surpassed mothers in all others in their base rates of parenting across domains.

Parents' goals for their own parenting and for their children arise, in part, out of their society's expectations of its adult members (LeVine, 2003; Rosenthal & Roer-Strier, 2001). For example, many Western societies encourage independence, self-reliance, and individual achievement among their children, whereas many Asian and Latin cultures encourage interdependence, cooperation, and collaboration among peers (Triandis, 1995). These general values are associated with differences in parenting goals (Harwood, 1992; Ogbu, 1981). Keller et al. (2004) analyzed culturally informed parenting styles during infancy, as related to the sociocultural orientations of independence and interdependence. Free-play situations between mothers and 3-month-old infants were videorecorded in five cultural communities (West Africa, India, Costa Rica, Greece, and Germany) that differ according to their sociocultural orientations. They analyzed videorecords using coding systems that focused on four parenting systems, including body contact, body stimulation, object stimulation, and face-to-face contact. Two styles of parenting (distal and proximal) emerged across cultures that could be related to the sociocultural orientations of independence and interdependence. Li, Fung, Bakeman, Rae, and Wei (2014) compared conversations between European American and Taiwanese mothers and children (6–10 years) about good and poor learning. European American mothers mentioned mental activities and positive affect more, whereas Taiwanese mothers mentioned learning virtues and negative affect more. Schulze, Harwood, and Schoelmerich (2001) found that mothers from European American and Puerto Rican backgrounds commonly valued independent socialization, but European American mothers emphasized emotional autonomy whereas Puerto Rican mothers focused on instrumental independence. Suizzo and Cheng (2007) analyzed mothers' socialization goals by parsing attributes of relatedness into family obligation and relational intimacy; relational intimacy was valued more highly by European American than Taiwanese mothers. By contrast, Taiwanese mothers were more likely than European American mothers to value agency-status goals concerning power and achievement.

Some children are relatively relaxed when confronted with an unfamiliar situation and display little distress, whereas other children react to novel objects and situations with anxiety, try to remain close to their mother, and do not easily interact with unfamiliar people. These latter actions indicate behavioral inhibition. X. Chen et al. (1998) unearthed cultural differences in mothers' attitudes toward behavioral inhibition in children. Chinese mothers, who traditionally value mutual interdependence, view behavioral inhibition in toddlers as a positive trait. Behavior inhibition is associated with maternal acceptance of the child and belief in encouraging the child's achievement. In contrast, for Canadian parents of European origin, who traditionally hold a more individualistic orientation, behavioral inhibition is negatively associated with maternal acceptance and encouragement of children's achievement. Among traditional Chinese families, children who display higher levels of behavioral inhibition have mothers who are less likely to believe that physical punishment is the best way to discipline and who are less likely to feel angry toward the child. However, maternal punishment orientation was positively correlated with behavioral inhibition in Canadian families; mothers whose children displayed higher levels of behavioral inhibition are more likely to believe that physical punishment is the best discipline strategy. In short, behavioral inhibition in children is associated with positive attitudes in Chinese mothers and negative attitudes in Canadian mothers.

In disciplining children, parents often escalate to corporal punishment. Today, 77% of American men and 65% of U.S. American women endorse the statement that sometimes a child needs a "good, hard spanking" (Child Trends, 2013), and almost 50% of American parents indicate that they had spanked their 2- to 5-year-old child in the last month (MacKenzie, Nicklas, Brooks-Gunn, & Waldfogel, 2011). Sanction of corporal punishment is widespread world-wide: A study of 30,470 families with 2- to 4-year-old children in 24 low- and middle-income countries revealed that 29% of parents reported believing that using corporal punishment is necessary to rear a child properly, and 63% of parents reported that their child had been corporally punished in the last month (Lansford & Deater-Deckard, 2012).

Parents across cultures engage in child socialization practices to cultivate values and behaviors that promote adaptation to the social, economic, and ecological conditions of their society (Quinn, 2005). However, there are cultural differences in which values are prioritized to define the optimal endpoint of child development (Greenfield, Keller, Fuligni & Maynard, 2003; LeVine, 2003). Parenting cultural knowledge is often conceptualized as naive theories about how children progress toward idealized social roles, what influences their development, how skills are

acquired, and the roles of different adults and environments in the developmental process (Keller et al., 2006; Rosenthal & Roer-Strier, 2001). Many argue that culturally distinct parenting beliefs provide parents with a framework for interpreting their children's behaviors, guiding parents' interactions with their children, and determining the activities and opportunities that parents are willing to supply for their children's development. Parenting is a response to, and is supported by cultural beliefs about, what parents should do to promote their children's development.

Distal Contexts

Distal contexts for parenting operate through proximal familial mechanisms and include, for example, ecology, time and history, and evolution. Here, I touch briefly on each.

Ecology

The ecological circumstances in which living organisms adapt and function are thought to bias them toward investing in either a relatively small number of "high-quality" offspring or a relatively large number of "low-quality" offspring. In humans, monogamy and biparental care are associated with allocation of resources toward few high-quality offspring: children who tend to have better health, survival, and developmental outcomes (Ellis, Figueredo, Brumbach, & Schlomer, 2009). Challenging, dangerous, and/or unpredictable environments favor low parental effort, and low parental effort is empirically associated with harsh, neglectful, rejecting, and insensitive parenting (Belsky et al., 1991). In an analysis of mostly preindustrial societies, Quinlan (2007) found that ecological stress, in terms of conditions of warfare, famine, and high pathogens, was associated with mothers decreasing parental care and terminating breastfeeding at earlier ages (De Baca, Figueredo, & Ellis, 2012). In reviews of maternal decision making under resource scarcity, Bateson (1994) and Hrdy (1999) concur.

Specific patterns of child rearing can be expected to adapt to specific settings and needs. Thus, geographic conditions can be expected to play a consequential role in many aspects of parenting (O. Davis, Haworth, Lewis, & Plomin, 2012). Different geographic regions have different climatic, vegetative, and living conditions, and these circumstances can be expected to contribute to parenting cognitions and practices (R. R. Dunn, Davies, Harris, & Gavin, 2010). Insofar as tropical areas are denser with pathogens that lead to infections and poor child growth and mortality, for example, parenting in those ecologies can be expected to cope with greater challenges with respect to children's health and illness. Along these same lines, father-present social systems, monogamous marriage, and wide birth spacing are all more likely among human hunter-gatherers inhabiting harsh ecologies where biparental care is substantial and important for offspring survival and reproductive success (O. Davis et al., 2012; Draper & Harpending, 1988; Geary, 2000; Marlowe, 2003). Even different adapted mazeways in proximate ecologies give rise to divergent parenting. For example, nomadic hunter-gatherer Aka are more likely to hold and feed young infants in close proximity than are settled Ngandu farmers who are more likely leave infants by themselves, even though these two traditional groups live close to one another in central Africa (Hewlett, Lamb, Shannon, Leyendecker, & Schoelmerich, 1998). Aka parents are thought to maintain closer proximity to infants because this nomadic group moves in search of food more frequently than do more sedentary farmer Ngandu.

Within small rural communities characterized by subsistence economy, face-to-face interactions in small stable social networks, and lower levels of formal education and technology, socialization favors rearing children to promote group solidarity to meet communal needs. The extent to which the severity of exposure to social risk is related to parenting in the first 2 years of life was studied in diverse samples of families in two rural poor regions of the United States. The geographic isolation of families moderated associations between risk and expressions of maternal sensitivity and warmth as well as language and learning activities (Burchinal, Vernons-Feagans, Cox, & Key Family Life Project Investigators, 2008). By contrast, in urban settings characterized by formal schooling and commercial economic conditions that yield more fleeting interactions with strangers, socialization favors independence and competition in educational and economic realms (Greenfield, 2009). When Bornstein and colleagues (2008, 2012) investigated mothers' emotional availability to their children in contrasting rural and urban ecologies in three countries, they found patterns of parenting intrusiveness consonant with this urban-rural distinction.

Time and History

The bioecological view of parenting encompasses multiple scales of time. Every parent realizes that the days are long but the years are short. As mentioned earlier, parents do not vary in themselves much from day to day—parenting cognitons and practices tend to be stable—and family values are especially conservative. For example, Bomhoff and Gu (2012) found that East Asians continue to endorse

traditional and conservative values despite their residence in economically developed nations, including Japan, South Korea, and Taiwan.

Time of day and time of year influence parenting. For example, parents are more likely to spank their children in the evening than other times of the day (Clifford, 1959; Holden, Coleman, & Schmidt, 1995), and parenting differs during summer and winter months, consistent with parents' work schedules (Crouter & McHale, 1993).

Over longer periods, parents also change on accounts of personal development, development in the child, and historical development. The ratio of adult-directed speech to child-directed speech increases across just the first postpartum year (Bornstein & Tamis-LeMonda, 1990), and parents of younger children spend much more time in child care than parents of older children (U.S. Bureau of Labor Statistics, 2013). "Parents who are highly effective at one stage in the child's life [are] not necessarily as effective at another. . . . Similar behaviors do not necessarily produce the same effects at successive stages in [a] child's life" (Baumrind, 1989, p. 189). Parenting, like children's behavior, develops to become more hierarchical, differentiated, and complex (Sroufe & Jacobvitz, 1989).

It is important to recognize that child-rearing cognitions and practices evolve and change with longer scales of time (Bronfenbrenner, 1958; French, 2002). In classical Rome, the *pater familias* dictated the literal life and death of children; later if any question arose about child care, mothers' rights prevailed; today in the postdivorce binuclear family, joint custody is fast becoming preferred law and the norm. The attitudes and actions of parents at any one time in any one generation may differ from those characteristic of parents in another. Change over time in the parent, the context, and the relation between the parent and context is expectable. Thus, parenting values change over time along with societal changes. In essence, child-rearing cognitions and practices depend on the current cultural context as well as contexts of past and future (Cole, 1996; Valsiner, 2000). Across cultures, there is a general drift toward greater individualism that emphasizes individual self-sufficiency. Unsurprisingly, in their self-representations young and middle-aged adults use more agency attributes, whereas older adults use communion attributes (Diel, Owen & Youngblade, 2004).

On account of high rates of child mortality, parents earlier in history may have cared for but resisted emotional investment in the very young (Dye & Smith, 1986), an orientation that appears to persist where especially dire circumstances reign (Scheper-Hughes, 1989). One historian theorized that parents have generally improved in their orientation to and treatment of children because parents have, through successive generations, improved in their ability to identify and empathize with the special qualities of early childhood (deMause, 1975).

Society at large is also witnessing the emergence of striking permutations in parenthood and in the constellation of the family structure that have plunged the family generally, and parenthood specifically, into an agitated state of question, flux, and redefinition (Ganong et al., 2015; Solomon, 2012). Peruse the panel of graphs in Figures 5.1 through 5.12. They evidence startling cultural shifts and social changes in central aspects of parenting even in so short a time as the second half of the twentieth century. In an analysis of parenting change from just 1989

to 2010, Park, Coello, and Lau (2014) noted that, relative to earlier-generation parents, later birth cohort parents in a number of Eastern and Western counties now endorse child independence, imagination, and determination and are less likely to value hard work, responsibility, obedience, thrift, and religious faith. Social change toward economic development may be associated with deemphasizing traditional mores, hierarchy, and work ethic while orienting parents to child-centered parenting. This pattern of change is consistent with emerging evidence concerning shifts toward materialism and individualism as economic fortunes increase at familial and national levels (Park, Twenge, & Greenfield, 2013). Research regarding birth cohort and social class suggests that economic development and schooling are especially influential in cultural change (Kashima et al., 2009; Inglehart & Baker, 2000; LeVine, 2003). Rapid cohort effects on child socialization have been documented in China, where social reticence formerly valued in traditionally collectivist Chinese contexts no longer appears adaptive in urban centers that favor selection of social initiative (X. Chen, Cen, Li, & He, 2005).

According to Greenfield (2009), worldwide social change associated with economic development is altering cultural values and socialization environments as parents

adapt to promote the success of their offspring in modernizing society. Greenfield reasoned that, as an environment shifts toward urbanization and economic development, individualist socialization waxes and collectivist socialization wanes. This line of thought echoes Inglehart's (1997) concept of transition from premodern to postmodern societal values. These kinds of studies reveal the imprint of historical time on parents' priorities in child socialization.

Evolution

This examination of determinants of parenting began with biological factors in the parent that are themselves presumptive of grander evolutionary origins. So we have come full circle and end where we began. Driven by evolutionary pressures related to survival and reproduction, parents feel compelled to care for their (biological) offspring (Dawkins, 1976). Evolutionary theory might therefore elucidate some causes of variation in parenting (De Baca et al., 2012). For example, genetic relatedness among family members is a strong predictor of parental quality and even grandparental investment (O'Connor, Dunn, Jenkins, & Rasbash, 2006). Consider too the next predictions based on evolutionary thinking.

First, as indicated, in an evolutionary perspective, a central principle governing parental effort is genetic relatedness. Parenting is selected to discriminatively favor biological offspring and to inhibit expending effort on the offspring of unrelated individuals. Research suggests that

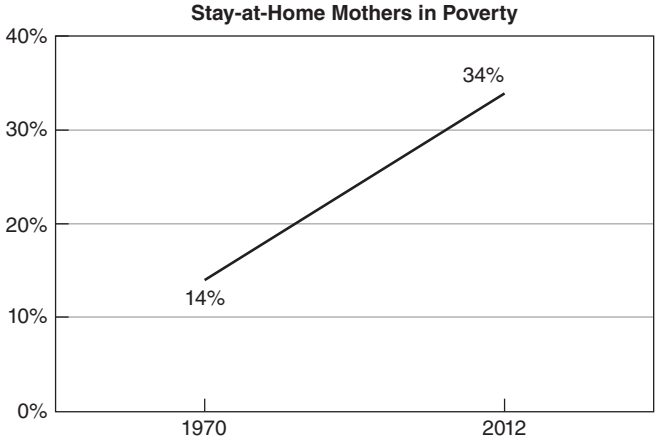

Figure 5.11 Stay-at-Home Mothers in Poverty. *Source:* D. Cohn & A. Caumont (2014) 7 key findings about stay-at-home moms. Pew Research Center. Retrieved from http://www.pewresearch.org/fact-tank/2014/04/08/7-key-findings-about-stay-at-home-moms

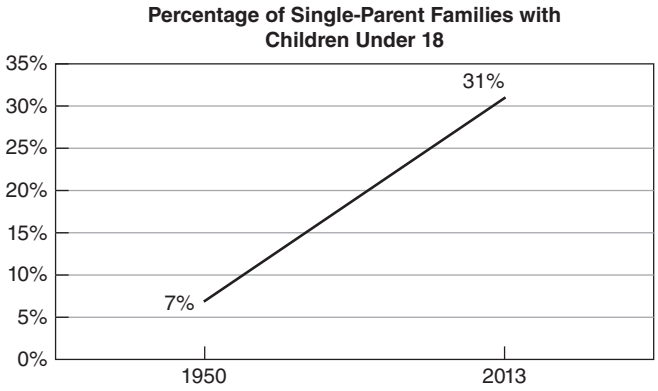

Figure 5.12 Percentage of Single-Parent Families with Children under 18.

parents tend be warmer and engage in more caregiving of their biological children compared to stepchildren (which anecdotal evidence from a host of fairy tales seems to confirm; Bettelheim, 1976). In a comprehensive study of adolescent family relationships in stepfamilies, Hetherington and colleagues (1999) learned that biological relatedness between parent and adolescent was a potent determinant of parenting. Low genetic relatedness between adults and children in a family is associated with a higher probability of neglect, abuse, and homicide of children. The child abuse literature is consistent that children in stepfamilies are at greater risk for neglect and abuse compared to families with two biological parents (Daly & Wilson, 1988).

Second, evolutionary-based research, using animal models and humans, has demonstrated that major biobehavioral reorganizations occur in the parents' physiology and behavior during periods of bond formation that lead to heightened sensitivity to infant cues, prepare parents for the challenging tasks of infant care, and give rise to expressions of the species-specific practices critical for child growth and adaptation to their ecocultural setting. Nurturance is a prerequisite for children's survival and well-being; seeing a child's survival to reproductive age enhances parents' probability of passing on their genes (Bjorklund et al., 2002).

According to life history theory, third, a fundamental trade-off faced by parents is between current and future reproduction. Effort put into reproducing now will use energy or resources that cannot be used or saved for future reproduction. Thus, the greater the parent's probability of breeding in the future, the more the parent can be expected to withhold resources from current reproduction (Ellis et al., 2009; Trivers, 1972). Because age is a determining factor limiting future reproduction in women, this evolutionary view predicts that older mothers will systematically invest more in their current offspring. Consistent with this expectation, young mothers are more likely to elect to abort fetuses (Finer & Henshaw, 2006) and to neglect, abuse, or even murder their young children (J. Brown, Cohen, Johnson, & Salzinger, 1998). Conversely, as mothers age, their levels of parental effort allocated toward offspring tend to increase. Older mothers tend to be more satisfied in their role as a parent and spend less time away from their children (Ragozin, Basham, Crnic, Greenberg, & Robinson, 1982). These effects are not explained by maternal education, parity, gestational age, or income. A common proximate explanation for the effects of parental age on parental effort presumes that compromised parenting represents dysfunction or immaturity in young parents (e.g., inadequate prefrontal development, poor judgment and planning, high impulsivity). An evolutionary explanation assumes that women of all ages adaptively calibrate their levels of parental effort in relation to future reproductive opportunities. This adaptive calibration may be instantiated at a proximate level through variation in such factors as maternal sentiments and interest in competing in nonparental activities.

Fourth, from an evolutionary perspective, the level of genetic relatedness between a man and his assumed children, including uncertainty about that relatedness, is a crucial factor in determining whether (and how much) fathers care for their children (Geary, 2000). The expenditure of limited resources in a genetically unrelated child entails large fitness costs, so natural selection can be expected to favor discrimination and differential parental solicitude by fathers (Daly & Wilson, 1988). Relevant cues to paternity uncertainty include past and current extra-pair

copulation rates, the mother's own sexual history, levels of trust and commitment in the father-mother relationship, and perceived similarities between the father and his putative children. Cues that indicate high paternity confidence support greater paternal investment and reduce the likelihood of paternal violence (Burch & Gallup, 2000). For example, across foraging groups in a representative data set of over 186 cultures around the world, monogamous societies are characterized by greater paternal investment (De Baca et al., 2012).

Articulating four types of general evolutionary questions (we can appropriate to understanding the determinants of cognitions and practices in parenting), Tinbergen (1963) contended that evolutionary explanations concern phylogeny (What is the evolutionary history of a cognition or practice, and how did it change across time and species?), adaptation (Why is the cognition or practice the way that it is, and what selective advantages does it confer, or did it confer, to the organism?), mechanism (What is the cognition or practice like, and how does it work?), and development (How did the cognition or practice come to be, and how does it change across the life span?). These "evolutionary" questions pose contemporary challenges to parenting science.

Summary

Parenting is conditioned by multiple spheres of influence in which the parent is embedded, including proximal, social group, and distal contexts. As this chapter has shown, researchers know a lot, but still not nearly enough, about the determinants of parenting. Some key questions that arise from the foregoing considerations concern the further specification of multiple processes by which parents' cognitions and practices come about and the multiple moderators that condition them (Bornstein, 2015; Bornstein, Bradley, Lutfey, Mortimer, & Pennar, 2011).

In addition, there is a host of arenas about whose effects on parenting we know embarrassingly little. Consider ideology. The public is politically polarized, and ideological disparities between liberals and conservatives presumably color the cognitions and practices parents feel are important vis-à-vis children. We know that among the never married, large majorities of women (70%) and men (62%) alike seek a potential mate who shares their ideas about rearing children and consider that characteristic as more important than finding a partner who shares their moral and religious beliefs, has similar educational accomplishments, or even comes from the same ethnic background (W. Wang & Parker, 2014). Doherty et al. (2014) conducted a nationally representative panel survey of randomly selected U.S. adults living in households that asked about the importance of teaching 12 different qualities to children that included responsibility, hard work, manners, persistence, tolerance, and faith. Respondents were also asked to choose the three traits that they felt are most important. Across ideologies, responsibility was viewed as important to teach children: 93% say teaching children to be responsible is "especially important," and 55% rate responsibility as very important. Large majorities in different ideological groups also think it is essential for children to learn independence, hard work, and good manners. However, 86% of consistent liberals say it is important to teach children empathy; far fewer consistent conservatives (55%) agree. Liberals also prioritize teaching children curiosity (82%) and creativity (85%), compared with 60% or so in other ideological groups. By contrast, consistent conservatives think it is especially important for children to be taught religious faith (81%), and 59% say it is one of the three most important of 12 top qualities, whereas among consistent liberals, just 26% rate the teaching of religious faith as especially important and only 11% regard it as among the most important child-rearing qualities.

TRANSLATIONAL IMPLICATIONS

Practically speaking, parenting has positives, such as intimacy, nurturance, and rewards, which we want to encourage, but parenting can also be encumbered with negatives, such as frustration, anger, and violence, which we want to avert. It is a sad fact of everyday life that parenting children does not always go well or right. Infanticide was practiced historically, and although it is rare today, it is not unknown (Hrdy, 1999). Short of infanticide, vulnerable young are too commonly the victims of parenting that is neglectful (parents forget children in locked cars on hot days, fail to immunize them, or abandon them to wither in orphanages) and abusive (parents bear drug-addicted children, discipline them harshly, or traffic them). Infant cries draw a parent's attention but also trigger shaken baby syndrome (C. Lee, Barr, Catherine, & Wicks, 2007) and assaults (Cavanagh, Dobash, & Dobash, 2007). Every year, child protection agencies in the United States alone receive 3 million referrals for child neglect and abuse involving an estimated 6 million children younger than 5. About 80% of the children in investigated neglect and abuse cases are not removed from the home, although about 80% of perpetrators are parents, the vast majority

biological parents. According to the National Research Council (2013), neglect and abuse amount to an estimated $80 billion per year in direct costs of hospitalization, law enforcement, and child welfare and indirect costs of special education, juvenile and adult criminal justice, adult homelessness, and lost work productivity. Many factors increase the risk of child abuse, but parental depression, parental substance abuse, and whether the parents were themselves neglected or abused as children rank high.

Although usually protected, children are still too often exposed to relatively hostile and emotionally negative climates in the home, and parents in the front seat of the car fail to recognize that children in the backseat overhear what they say. By the current standards of meta-analytic evidence, parents contribute to their children's internalizing and externalizing behavioral problems (Fearon, Bakermans-Kranenburg, van IJzendoorn, Lapsley, & Roisman, 2010; Groh, Roisman, van IJzendoorn, Bakermans-Kranenburg, & Fearon, 2012). Moreover, many parents resort to harsh verbal and physical treatment and even corporal punishment of children (Gershoff, 2002; Lansford et al., 2005; Mejia, Miewer, & Williams, 2006). From Finland and Denmark to Kenya, child-rearing violence predicts later child externalizing (Peltonen, Ellonen, Larsen, & Helwig-Larsen, 2010; A. T. Skinner, Oburu, Lansford, & Bacchini, 2014). The American Academy of Pediatrics (1998, p. 723) declared that "corporal punishment is of limited effectiveness and has potentially deleterious side effects," recommending alternative determinants in that "parents be encouraged and assisted in the development of methods other than spanking for managing undesired behavior." The American Academy of Pediatrics reaffirmed that pediatricians encourage parents to use alternate age-appropriate forms of nonaggressive discipline, such as distraction, time-outs, and offering explanations. The Convention on the Rights of the Child identifies violence toward children as a problem to be eliminated at an international level. The use of corporal punishment toward children has now been legally banned in all settings in 46 countries, and legislation is pending in several others (Global Initiative to End All Corporal Punishment of Children, 2013).

Strong secular and historical trends operating in modern society—industrialization, urbanization, poverty, increasing population growth and density, and especially widespread dual-parental employment—constitute centrifugal forces on parenting. Because these society-wide developments exert many unfortunately debilitative influences on parenthood, on parenting, and, consequently, on children and their development, a significant proportion of parents needs assistance to identify more effective strategies to optimize child care and to create more satisfying family relationships. Not surprisingly, a one-time U.S. commissioner of education preached that every child has a right to a "trained parent." Parents are usually the most invested, consistent, and caring people in the lives of their children, so providing parents with skills and supports will help them respond more positively and effectively to social and child-related challenges. Professionals are normally a positive source of information related to parenting knowledge.

As it is said, children do not come with a manual, and not all people naturally parent or know how to or can keep up with their constantly developing children. Parenting advice dates back at least to ancient Egypt, the Code of Hammurabi, and the pre-Socratics. In the *Laws*, Plato (ca. 355 BC) theorized about parenting. Many parents can use instruction. In 1914, the U.S. Children's Bureau published the first edition of the pamphlet "Infant Care," which advised, among other things, that "Sunshine is as necessary for the baby as for the plant" (M. West, 1914, p. 10). Only a fraction of parents who could benefit from parent services receive them, however. Thus, organizations at all levels of society increasingly feel a mandate to intercede in child rearing and right social ills through parenting preventions and interventions. As a result, contemporary parenting has witnessed an explosive growth in information and support programs. One implication of the increasingly sophisticated view of the origins and conduct of parenting is that many determinants of parenting cognitions and practices are modifiable; thus, what we learn about parenting holds the promise of far-reaching practical implications. Slep and O'Leary (1998) found that mothers who were led to believe that their children intentionally misbehaved responded to their children with greater negative affectivity and harsher discipline than mothers who were led to believe that their children accidentally misbehaved. As mentioned earlier, Stein et al. (2012) randomized mothers to a worry/rumination prime (WRP) or to a neutral prime (NP) and assessed mother-infant interactions before and after priming. Type of priming predicted maternal cognitions: The WRP resulted in more negative thoughts, higher thought recurrence, and more self-focus relative to the NP. Moreover, interaction effects between group and priming were significant: Compared with NP controls, the WRP inhibited maternal responsiveness and maternal vocal interactions. In the view of some critics, however, the trend to family professionalism also paradoxically leads away from a focus on parents as the proximal protectors, providers, and proponents of their

progeny and toward entrusting child rearing to experts and the state.

Nonetheless, contemporary parents from families along multiple risk continua might become more effective. Preventions and interventions designed to help parents come in a variety of venues (psychotherapy, classes, media), in a variety of settings (homes, schools, health clinics, houses of worship) and formats (individual, family, group), and with a variety of goals (from specific to universal). For example, some programs primarily target parents' cognitions and practices; others are focused on improving the quality of parent-child relationships.

Competencies are knowledge, skills, abilities, personal characteristics, and attitudes, and competencies to adequately perform a task, duty, or role are (usually) learned (Roe, 2002). Competent parenting, crucial to child development and well-being, can be learned. Profession-specific competencies provide motivation and direction for learning as well as a means to judge the adequacy of parenting programs (Epstein & Hundert, 2002). Many experimental trials and parenting intervention programs have been devised. A review of 46 randomized trials provides evidence of prevention of a wide range of problem outcomes from 1 to 20 years later. However, this literature offers a paucity of evidence concerning processes that account for program effects (Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011). Interventions to promote positive parenting have been touted to offer positive outcomes for children, but they often consume substantial resources and require rigorous appraisal. Biglan, Mrazek, Carnine, and Flay (2003) called for the integration of more science into societal parenting practices to prevent youth behavior problems and to promote "agreement on a set of consensus standards for selecting disseminable preventive interventions" (p. 438). A popular example is Triple P, the Positive Parenting Program, a multilevel behavioral family intervention (Prinz, Sanders, Shapiro, Whitaker, & Lutzker, 2009; Sanders & Kirby, 2010; Sanders, Markie-Dadds, & Turner, 2003). However, systematic reviews and meta-analyses comparing Triple P with wait-list or no-treatment comparison groups reveal only relatively small effect sizes on maternal and paternal outcomes (Wilson et al., 2012).

Some interventions on determinants to improve parenting succeed: for instance, targeted interventions to develop maternal mentalizing and sensitivity and parents' positive practices (Juffer, Bakermans-Kranenburg, & van IJzendoorn, 2007; Lunkenheimer et al., 2008; Sadler et al., 2013). Others focus on factors that facilitate provider attitudes and skills (buy-in, support), staff selection and professional development (training, coaching), intervention and delivery (fidelity, accessibility), individual- and family-level factors (expectations, benefits), incentive and retention strategies and those designed to overcome barriers in parent and program (costs, integration, caseload, competition). (See Axford, Lehtonen, Kaoukji, Tobin, & Berry, 2013; Damashek, Doughty, Ware, & Silovsky, 2011; Eisner & Meidert, 2011; Gottfredson et al., 2006; Korfmacher et al., 2008; Lees & Ronan, 2008; Mendez, Carpenter, LaForett, & Cohen, 2009; Mytton, Ingram, Manns, & Thomas, 2014; Shapiro, Prinz, & Sanders, 2012; Randolph, Fincham, & Radey, 2009; N. L. Weaver et al., 2008.)

Unhappily, however, most interventions fail and do so for a wide variety of reasons, as when parents short-shrift intervention "homework" assignments, or when program staff fail to help parents access needed services, or when measurement is biased, or when the control group is contaminated through unintended diffusion of the parenting intervention. Some individuals or groups avoid seeking support out of embarrassment, stigma, or norms (in many communities, parents do not want to be told how to rear their children). (See Bodenmann, Cina, Ledermann, & Sanders, 2008; Fixen, Naoom, Blasé, Friedman, & Wallace, 2005; Goodson, Layzer, St. Pierre, Bernstein, & Lopez, 2000; Hebbeler & Gerlach-Downie, 2002; Okagaki & Bingham, 2005; Pinquart & Teubert, 2010; S. G. West, 2009; see Kaminski, Valle, Filene, & Boyle, 2008, for a meta-analysis of training programs.)

To overcome these barriers and challenges, interventions need to adopt creative ways to market parenting and destigmatize the idea of parenting support (Chu, Farruggia, Sanders, & Ralph, 2012; Sanders, 2010). By deconstructing reasons for failures critically, it is possible to learn ways that future parenting interventions might succeed. Happily, Powell (2013) provides solid and timely guidance on central aspects of undertaking and evaluating parenting interventions, including preliminary work, sampling, research design, options for comparison conditions, measurement of implementation fidelity, and analysis of outcomes (Boutelle, Cafri, & Crow, 2011; DeGarmo & Forgatch, 2005; Flay et al., 2005; McCall & Green, 2004; Sandler et al., 2011; Shadish, Cook, & Campbell, 2002). To summarize some main points of that tutorial, parenting interventions should be based on theoretical and empirical models that specify the overarching goal of the intervention with regard to: anticipated improvements in specific parent outcomes; how change in malleable parenting variable(s) is targeted by the intervention; and how intervention components are expected to change focal parenting variable(s). Development of a coherent, measureable theory of

change and articulation of a precise logic model are critical to an intervention functioning as intended. Randomly assigning parents or larger units in which parents are based to intervention and comparison conditions provides robust evidence of intervention effectiveness, assuming the outcome study is also well implemented. Intervention evaluations should routinely determine whether intervention effects are sustained beyond the intervention period (Olds et al., 2002). It can be guaranteed that intervention fidelity—the degree to which a program has been implemented as planned—is less than 100% ensured (Durlak & DuPre, 2008; Korfmacher, O'Brien, Hiatt, & Olds, 1999); but fidelity to an intervention protocol predicts change in parents' practices (Forgatch et al., 2005). Finally, no single intervention fits all (Barrera, Castro, & Steiker, 2011). So, for example, as an Institute of Medicine report (O'Connell, Boat, & Warner, 2009) recommended, interventions that successfully adopt and integrate cultural mazeways will experience likelier successes with both consumers and community agents (see Takanishi & Bogard, 2007).

As this chapter shows, individual factors are important determinants of parenting, and they are frequent targets of intervention. Higher reflective functioning is associated with sensitive parenting (Pajulo et al., 2009). Core concepts of reflective functioning and mindful parenting include, in addition to understanding mental states and intentions, full presence, nonjudgmental stances, emotional awareness, self-regulation, and compassion (Duncan, Coatsworth, & Greenberg, 2009). Certain mindfulness tools can help to successfully address pressing parenting requirements (Barth & Liggett-Creel, 2014; Kaminski, Valle, Filene, & Boyle, 2008; Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011).

- Parents benefit from knowledge of how children develop. For example, of three cognitive measures, maternal education, IQ, and specific knowledge of child rearing and child development, knowledge uniquely explains age differences in mother-child emotional relationships (Bornstein, Putnick, et al., 2012). Therefore, the normative patterns and stages of children's physical, verbal, cognitive, emotional, and social development should be part of the knowledge base for parenthood.
- Parents need to know how to observe children and how to interpret and use what they learn. Informed child watching helps to clarify a child's level of development in relation to how parents want their children to behave and what parents want their children to learn and to accomplish. Observing also allows parents to identify potential trouble early and may help them respond to it more meaningfully.
- Parents need all manner of skills for managing children's behaviors. Knowledge of alternative methods of managing discipline and problem avoidance, for example, is basic.
- Parents need to understand the tremendous impact they have on their children's lives through the simplest things they do: their attention, expressed pleasure, listening, and interest.
- Parents need to know how to take advantage of everyday settings, routines, and activities to create learning and problem-solving opportunities that enhance childhood and parenthood.
- Parents need to be patient, flexible, and goal oriented—to call on their personal resources and extrapersonal sources of support—and they must command an ability to extract pleasure from their encounters with children.

The responsibility for determining the child's best interests rests first and foremost with parents. Few ethical or sentient parents want to abrogate their child-rearing responsibilities (Baumrind & Thompson, 2002). Insofar as children's parents can be enlisted and empowered to provide children with experiences and environments that optimize their development, society is positioned to obviate after-the-fact remediation. In the dedication of *Some Thoughts Concerning Education* to Edward Clarke, of Chipley, Esq., the seventeenth-century moral philosopher John Locke (1692) wrote: "The well educating of their children is so much the duty and concern of parents, and the welfare and prosperity of the nation so much depends on it, that I would have every one lay it seriously to heart." On these grounds, the doctrine of parental rights remains a fundamental premise to child rights. Parents sometimes do not know what to do, but they can find out; they sometimes do know what to do, but they still do not get into the trenches and do it.

CONCLUSIONS

Even the most vocal critics of parenting admit that "parents are the most important part of the child's environment and can determine, to a large extent, how the child turns out" (Harris, 1998, p. 15). We know a lot, but still not nearly enough, about what determines good or poor parenting. Parenting is multidimensional, modular, and specific and is also multilevel and multidetermined by parent, child, and contextual factors. This chapter has endeavored to overview the main determinants of parenting from that stance. To understand sources of variation in parenting,

information about multiple domains is required, including biological and psychological characteristics of all individuals in the family, parents' families of origin, relationships between parents and between parents and children, and key individuals or institutions outside the family (including friends, peers, work, child care, ethnicity, culture, and historical era). Nuanced and complex principles of parenting, such as specificity, interdependence, transaction, and indirect and direct effects, do not make the study of determinants easy. Parenting sits at the confluence of many rivulets of influence; some flow from within the individual, whereas others spring from sources external to the parent in the child and in the multiple contexts that situate caregivers in the landscape parenting. Within complex developmental systems, it is unlikely that any single factor accounts for substantial amounts of variation in a criterion, and more multivariate and nuanced conceptualizations will explain parenting better than simpler ones with fewer variables. Parenting has many determinants, which is fortunate in the sense that in this way parenting is protected and the species continues, but parenting's multicausality is also demanding in the sense that many determinants require attention and a parent's job is never done.

INTRODUCTION

Resilience science is quintessential developmental psychopathology because it focuses on variation among individuals in relation to their experiences as they adapt and develop. Research on resilience emerged around the same time and in many of the same contexts as the study of developmental psychopathology and this is not a coincidence (Cicchetti, 1990, 2006; Cicchetti & Garmezy, 1993; Masten, 1989, 2007, 2012). Leading scholars concerned with understanding the origins and course of psychopathology and interventions to prevent and treat problems in development began to recognize that adverse experiences played an important role in the lives of many young people who developed problems; however, they also observed that there were striking variations in the adaptive function and life course of children and youth who were believed to be at risk for psychopathology. Influential scholars studying risk for mental illness in human development realized that understanding this variation in adaptive behavior and outcomes was crucial to a full understanding of the origins, prevention, and treatment of problems and disorders (Anthony & Koupernick, 1974; Garmezy, 1985; Garmezy & Rutter, 1983; Rutter, 1979, 1987; Werner & Smith, 1982).

The investigators and clinicians who would become pioneers in resilience science recognized that it was vitally important to know why some children do well under very high-risk circumstances while others do poorly in the tasks of life or develop serious mental health problems. They realized, further, that this knowledge could have profound implications for promoting positive development when conditions were not optimal and also for intervening to prevent, ameliorate, or treat symptoms and disorders of psychopathology.

The study of resilience in development has had transformational effects on the science and practice of developmental psychopathology. The perspectives and data generated by this work have overturned deficit-oriented models of mental health and intervention, opened up new directions for research, and expanded the range of strategies considered in practices and policies intended to support health and well-being (Cicchetti, 2010, 2013; Masten, 2011, 2013, 2014a, 2014b; Panter-Brick & Leckman, 2013; Prince-Embury & Saklofske, 2013, 2014; Rutter, 2013).

The study of resilience has matured and changed over the past half-century of work, in part reflecting the normal progression in any maturing area of inquiry and in part reflecting the dramatic advances in developmental theory and the technologies and methods for research in related fields (Cicchetti, 2010, 2013; Luthar, 2006; Masten, 2014a, 2014c). Resilience science advanced from basic descriptive goals to studies of processes and experiments to test resilience theory by trying to promote positive adaptation in contexts of risk or adversity. Definitions of resilience became more dynamic and multilevel as developmental systems theory became the prevailing perspective in developmental theory and science more broadly considered (Cicchetti, 2010, 2013; Masten, 2011, 2014a, 2014b, 2014c). Advances in techniques for modeling complex data, observing the human brain in action, and studying how genes work and other biological processes provided traction for more sophisticated research on processes proposed in resilience theories or models. There also was growing interest in and efforts to study resilience in more diverse cultural contexts (Ungar, 2012; Ungar, Ghazinour, & Richter, 2013).

In this chapter, we highlight the core ideas, findings, and advances in resilience science, emphasizing contributions from the past decade of conceptual and empirical work. Two previous editions of *Developmental Psychopathology* have included sections on resilience in young people (Luthar, 2006; Masten & Coatsworth, 1995). Our goal in this edition is to provide a current update on the models and findings in resilience science, with a particular focus on the changing definitions and methods emerging from this research domain. Definitions of resilience have shifted over the decades toward a much more dynamic approach, influenced by developmental systems theory. Pathway models and methods have become more prominent. Research on the neurobiology of resilience and cultural processes in resilience are expanding rapidly.

This chapter opens with historical perspectives on resilience science, focusing on the goals driving this domain of study. Then we delineate the major concepts and models that define and organize the work in this area, followed by a summary of common methods in resilience research. Next we summarize findings on psychological processes implicated by the evidence on resilience and then we discuss the roles of key socioecological contexts in the resilience of young people, including families, peers, schools, culture, and community. In the following section, we describe the rapidly expanding science on the genetics and neurobiology of resilience. The subsequent section focuses on interventions based on resilience models and the translational implications of the accruing data on resilience for practice and policy, highlighting recent intervention studies designed to test resilience models. In the concluding sections of the chapter, we discuss enduring and new controversies in resilience science and we provide a closing summary of progress and future directions.

HISTORICAL PERSPECTIVES

Research on resilience in development has many roots. Many of those roots are intertwined with the history of developmental psychopathology and the study of competence in human development (Cicchetti, 1990, 2006, 2010; Masten, 1989, 2014b; Masten & Coatsworth, 1995). These roots include psychoanalytic theory about the protective roles of the ego and mechanisms of defense, the concepts of adaptation and competence in developmental theory, studies of coping and adaptation to stress in clinical psychology and psychiatry, and many other theoretical and empirical efforts to understand variation in the adaptation or development of individuals, particularly those faced with challenges. This history has been discussed in numerous reviews of competence, risk, and resilience over the years (e.g., Cicchetti, 2006, 2010; Cicchetti & Garmezy, 1993; Garmezy, 1981, 1982a, 1985; Luthar, 2006; Masten, 1989, 2012, 2013, 2014b; Masten & Coatsworth, 1995; Masten, Burt, & Coatsworth, 2006; Masten & Garmezy, 1985; Murphy, 1962; Sameroff & Chandler, 1975).

The systematic study of variation in adaptation dates to the nineteenth century, shaped particularly by Darwinian and Freudian theory (Masten & Coatsworth, 1995; Masten, Burt, et al., 2006). The "ego" in Freud's theory functioned to facilitate internal and external adaptation amid conflicting needs and goals to meet personal (often unconscious) desires and the expectations or goals of parents and society. How well the personality of an individual managed to balance these competing or conflicting goals would later be described in terms of two dimensions in the personality concepts of Jack and Jeanne Block (1980) as "ego resiliency" and "ego-control."

World War II had a profound influence on the course of psychology and psychiatry, in multiple ways pertinent to the emergence of resilience science (Masten, 2014a, 2014b). The global devastation wrought by the war, with millions of children injured, orphaned, starving, or traumatized by bombing, separations, loss, and many other exigencies of this global conflict, motivated an outpouring of humanitarian aid for children and many efforts to help children affected by the war. These efforts included early research on the effects of traumatic experiences on children as well as intervention to help child survivors of war. Examples of intervention include the establishment of treatment centers for children, such as the Hampstead Nurseries in Great Britain, where Anna Freud and her colleagues treated children affected by the war, and also the founding of the United Nations International Children's Emergency Fund (UNICEF; later broadened to become the UN Children's Fund) in 1946 (Masten, Narayan, Silverman, & Osofsky, 2015).

Individuals who would later become leaders in resilience science experienced this war as young people in distinctly different ways (Masten, 2014b). Norman Garmey was a young foot soldier in the European theater of war, fighting at the Battle of the Bulge. After the war, he studied clinical psychology and eventually began studies of risk and premorbid competence that would lead him to observe the variation in adaptive function among children at risk and then on to studies of resilience. Emmy Werner was a young girl in Germany who lived through the bombings, hunger, and destruction resulting from the war in Europe and also experienced the humanitarian aid to children after the war (Werner, 2000). She would go to graduate school in the United States and later lead a classic longitudinal study of resilience, following into adulthood a birth cohort of children born on the Hawaiian island of Kauai in 1955 (Werner & Smith, 1982). Michael Rutter, a third pioneer in resilience science, was one of the British children evacuated to escape the bombing during the Blitz, a "seavacuee" sent to safety in America for the duration of the war. Subsequently, he returned to Great Britain to study medicine, psychiatry, and epidemiology, conducting extensive research on risk, deprivation, and resilience and publishing many highly influential papers and books, including the most cited article to date on resilience in the psychological literature (Rutter, 1987).

Resilience Science Emerges from Studies of Children at Risk

After the war, there was a rapid expansion of research in psychology and psychiatry, some of which was focused on understanding the etiology of mental illness and risk factors in development. There were studies of infants and children at risk due to low birthweight, genetic anomalies, poverty, and other disadvantages (Kopp, 1983; Sameroff & Chandler, 1975) as well as studies of children at risk for mental illness, often because they were related to family members with a known disorder (e.g., Anthony & Koupernik, 1974; Garmezy, 1974; Gottesman & Shields, 1972, 1982; Kopp, 1983; Sameroff & Chandler, 1975; Watt, Anthony, Wynne, & Rolf, 1984). In addition, there were studies of children at risk due to specific adversities, such as death of a parent, divorce, abuse, disasters, and other traumatic experiences (Garmezy & Rutter, 1983).

Risk researchers studying children and families soon realized two fundamental facts about the lives of the individuals observed in their research. First, risks and stressors

tended to pile up in the lives of many children to the apparent detriment of their adjustment or development. Scores on measures that captured this cumulative risk, including simple tabulations of risk factors or negative life experiences, were associated with less adaptive outcomes. Second, although these risk gradients were often observed, suggesting cumulative effects of adversity, there also was great variation in the adaptive function or development of children with similar levels of risk, suggesting that more was involved than risk alone.

The risk researchers who would become pioneering resilience scientists were intrigued by the variation in outcomes among children in their risk studies and particularly by the clear evidence of good adaptation in the presence of high risk for psychopathology or developmental problems. They observed striking cases of individual children who manifested health and competence in the midst of risk and adversity or aftermath of disaster. Those observations and cases motivated the early science on resilience in development (Masten, 2014b).

Four Waves of Science on Resilience in Development

Four waves of resilience science ensued (Masten, 2007, 2011; Wright, Masten, & Narayan, 2013).The first wave of resilience science was largely descriptive, as investigators tried to measure the phenomenon of resilience and gain a basic understanding of the qualities of person, relationships, or environment that were associated with better adaptation in conditions of risk or adversity. As investigators gained confidence in the replicated correlates of resilience, they shifted their attention to understanding how protective processes work, and the key question changed from What makes a difference? to How? As hypothesized processes were studied and confidence grew about key processes, attention turned to identifying and targeting *malleable* resilience processes through intervention, both in applied clinical contexts and in experiments designed to test hypothesized protective processes, such as effective parenting, mentoring, or self-regulation, discussed later in this chapter. The essential question characterizing the third wave was this: Can resilience be promoted?

The fourth wave, now overtaking all the others, emerged from a series of advances in science and technology that revolutionized the study of resilience along with many other aspects of science on development and psychopathology (Cicchetti, 2010, 2013; Masten, 2007, 2014a, b; Wright et al., 2013). These advances included methods for studying the human genome, epigenetics, and the human brain in action as well as statistical strategies for analyzing complex multivariate data. Conceptually, developmental systems theory surged to become the central model of change in human development (Lerner, 2006; Lickliter, 2013; Overton, 2013; Sameroff, 2010; Zelazo, 2013). Concomitantly, dynamic systems theory became a unifying theme in diverse sciences concerned with threats to global well-being and socio-ecological systems, including climate change, disaster, war and terror, economic crises, and computer security, among other issues (Folke, et al., 2010; Gunderson, 2010; Longstaff, 2009; Masten, 2014a; Masten et al., 2015; Norris, Stevens, Pfefferbaum, Wyche, & Pfefferbaum, 2008).

In the next sections of this chapter, we highlight concepts and studies that reflect recent advances in resilience theory and methods, particularly those that represent the still-rising fourth wave in the science. Definitions and methods have shifted to emphasize dynamic systems models. A neurobiology of resilience, long anticipated, is finally emerging as methods for studying the role of genes, stress systems, and neuroscience involved in resilience processes improved and became practical. Similarly, there are major advances in research on cultural systems in resilience, also long anticipated. In many ways, the fourth wave engages multiple systems and disciplines in the enterprise of understanding and promoting resilience in human development.

CONCEPTS AND MODELS

Concepts central to the study of resilience in development have changed as the study of resilience emerged and matured. The definitions and central ideas in resilience have become more dynamic, and they have aligned with the prevailing models of developmental science more broadly defined. In this section, we examine the central ideas and concepts of resilience science as they have evolved, focusing on the past decade of conceptual advances.

Resilience in Developing Systems

Definitions and conceptual models of resilience, basic and applied, have shifted theoretically in concert with a broader shift in human developmental sciences and related fields toward a *relational developmental systems* framework (Overton, 2013; Zelazo, 2013). This broad perspective integrates theory and ideas from ecological theory (Bronfenbrenner, 1979; Bronfenbrenner & Morris, 1998); general systems theory (von Bertalanffy, 1968); developmental systems theory (Gottlieb, 2007; Lerner, 2006; Sameroff, 2010);

systems thinking in biology (Gottlieb, 2007; Lickliter, 2013); family systems theory (Goldenberg & Goldenberg, 2013; Masten & Monn, 2015); developmental psychopathology (Cicchetti, 2006, 2010, 2013; Gottesman, 1974; Gottesman & Hanson, 2005; Sroufe, Egeland, Carlson, & Collins, 2005); and resilience theory (Cicchetti, 2010, 2013; Masten, 2001, 2013, 2014b).

The central themes in a developmental systems perspective on resilience include these eight principles:

1. Human adaptation and development—in both low-and high-risk environments—arise from continuous interactions across levels of function within individuals and between individuals and their environments.
2. Many interacting systems shape the course of development and the processes involved in resilience.
3. The capacity for adaptation can be conceptualized at multiple levels.
4. The capacity for adaptation in challenging circumstances (resilience) depends on many interacting systems.
5. Manifested resilience emerges from many interacting systems and always reflects the current context as well as the history of the child (or system).
6. Living systems are self-organizing with emergent properties that can be surprising or unpredictable from lower levels of analysis.
7. Resilience is dynamic—always changing—because the systems involved in the capacity for adaptation are developing and changing.
8. Resilience—potential or manifested—should not be construed as a trait, although many traits could influence resilience.

Defining Resilience

Concomitant with the shift in theory about resilience, definitions have become more dynamic while at the same time becoming more scalable (Masten, 2014a, 2014b). Contemporary definitions emphasize the processes of adaptation and the distributed capacity for adaption rather than trait-like notions of inherent "hardiness" or the "ability" within a system to bounce back from difficulties.

Efforts to address mass-trauma events, such as natural disasters, war, terror, and epidemics, as well as concerns about global climate change, have spurred interest in diverse fields to consider resilience processes that involve multiple systems at different levels of analysis (e.g., Gunderson, 2010; Masten, 2014a, 2014b; Masten et al., 2015). Given goals of integrating theory and findings coming from different fields of inquiry, important for understanding and responding effectively to global challenges, interest grew in communicating findings across fields and integrating knowledge across levels of analysis. These goals motivated efforts to define resilience in ways that would work across levels and disciplines that typically may focus on one or two specific levels (e.g., resilience in neural systems, individuals, families, communities, ecologies, computer systems, etc.). Scalability of terminology can be very helpful for communication and integration.

A small group of investigators that included the first author worked on this issue of terminology and scalability in a network on resilience funded by the National Science Foundation (see Longstaff, 2009; Masten & Obradović, 2008). This group presented their ideas at Resilience 2008, the first of several ongoing international conferences on resilience sponsored by the Resilience Alliance, Swedish Academy of Sciences (the first meeting was held in Stockholm), and others. Subsequently, Masten (2011, 2014a, 2014b) adopted a systems-oriented definition of resilience that would be workable for other disciplines focused on diverse kinds and levels of systems.

Given the advantages of a scalable definition of resilience to describe the processes and capacity for adaptation of any dynamic complex system in the context of serious threats or adversities, we think it is useful to define resilience for scalability across levels of dynamic, developing systems. *Resilience* broadly refers to the potential or manifested capacity of a dynamic system to adapt successfully through multiple processes to disturbances that threaten the function, survival, or development of the system. This definition can be applied to many dynamic, developing systems, including an individual child, a family, a community, an emergency response system, an economy, or various ecological systems in the context of threats to the global climate. For the purposes of this chapter, which is focused on the resilience of human individuals, we define resilience in this way:

> *Resilience* is the potential or manifested capacity of an individual to adapt successfully through multiple processes to challenges that threaten the function, survival, or positive development.

Many systems are involved in the processes leading to successful adaptation in a child, family, or community. Moreover, systems that are interconnected across levels will influence the resilience of each other. In other words, the resilience of an individual child that is manifested and observable at the level of behavior depends on the

operation and interactions of many other systems, both within the child (immune system, stress response system, etc.), in relationships or family resilience, or in the larger sociocultural and ecological systems in which that child's life and development are embedded.

Two Judgments

Identifying resilience in the individual case or for the purposes of research requires two criteria, as noted for some time by resilience scholars (e.g., Garmezy, 1974; Garmezy, Masten, & Tellegen, 1984; Luthar, 1991; Luthar, Cicchetti, & Becker, 2000; Masten & Coatsworth, 1998). *Resilience* refers broadly to positive adaptation in a context of risk or adversity. Thus, two constructs must be considered in making inferences about resilience, whether one is simply thinking of an example of a single case of manifested resilience or one is operationalizing the core constructs in order to conduct a large-scale research project on resilience. The "risk/adversity" criteria and the "adaptation" criteria have been defined in multiple ways in the literature over the years, reflecting the complexity of the issues but making it difficult to synthesize the findings, particularly through empirical strategies such as meta-analysis. Many critiques of the resilience literature have noted this problem (Luthar, 2006; Masten, 1999, 2012, 2014b). Nonetheless, there is broad agreement that *resilience* refers to a subset of adaptive processes or outcomes when there is significant threat. In situations where there is little or no adversity experienced, we would describe children in terms of how well they are doing or developing rather than their resilience. The construct of resilience assumes that there is exposure or potential exposure to serious challenges or adversities to the function or development of the system under consideration. In the next section, we discuss the two major components for defining resilience in more detail.

The Challenge Criteria: What Are the Risks and Adversities?

Concepts and measures of risks or various threats to the well-being or development of a child have been considered for decades in the developmental sciences (Evans, Li, & Sepanski Whipple, 2013; Garmezy, 1974; Kopp, 1983; Obradović, Shaffer, & Masten, 2012; Sameroff & Seifer, 1983). As noted, the study of resilience emerged from the study of risk as investigators noted the variability in adaptive patterns among children considered to be at risk for psychopathology. A wide range of risk factors—predictors of specific problems or generally undesirable developmental outcomes—were identified, including premature birth, abusive parenting, exposure to trauma in war or disaster, and the disadvantages of poverty, among many others.

Risk researchers quickly realized that the factors associated with elevated probabilities of mental health symptoms, academic problems, health issues, and other undesirable outcomes rarely appeared in isolation and commonly piled up in the lives of the same children. This realization led the risk scholars to focus on *cumulative risk* and its effects on development (Masten, Best, & Garmezy, 1990; Rutter, 1979; Sameroff, Seifer, & Bartko, 1997). Many of the cumulative risk concepts and measures were modeled on the study of risk in medicine. Sameroff (2006) has described the history of composite risk scores dating back to the Framingham heart study, where it was observed that a cumulative total number of risk factors, rather than any one risk in particular, predicted heart problems.

Numerous studies of cumulative risk emerged, with many investigators observing *risk gradients*, where problem or symptom levels tended to risk as risk levels rose (Evans et al., 2013; Obradović et al., 2012). *SES gradients* linked health outcomes to cumulative risk scores based on socioeconomic disadvantage, with much higher mortality and morbidity rates found among those with low socioeconomic status (SES; Adler & Ostrove, 2006). In studies of war and disaster, these gradients were often termed *dose gradients* when it was found that trauma symptoms, for example, were often higher with greater exposure to danger, loss, destruction, and other indices of life-threatening intensity of adverse experiences (Masten & Narayan, 2012).

The risk researchers also recognized the complexity of the processes involved in stressful life experiences, such as divorce, death of a parent, homelessness, extreme poverty, and other adversities. Divorce, for example, was recognized as a process punctuated with many possible adverse experiences along with a number of potentially positive experiences (Hetherington, 1979; Kelly & Emery, 2003).

Two major types of measures of cumulative risk became prominent: tallying life events (weighted or unweighted by objective or subjective magnitude scales) and counting up established risk factors into a composite risk score. Rutter (1979) and Sameroff and colleagues (Sameroff, 2006; Sameroff, Seifer, Barocas, Zax, & Greenspan, 1987) were highly influential in modeling strategies for compositing risk factors.

The other main strategy utilized life event questionnaires or interviews to measure the level of adverse life

experiences that a person or family had experienced in a specified time window (e.g., past year, lifetime). The study and assessment of negative life events by questionnaire was pioneered by Holmes and Rahe (1967) and also Brown and Harris (1978), who developed a widely-used method of structured, contextual life interviews. These methods were adapted for studies of children by Coddington (1972a, 1972b), the Project Competence research group (Masten & Tellegen, 2012), and others that wanted to assess exposure to stressors in the form of heterogeneous life experiences (e.g., Compas, 1987; Goodyer, Kolvin, & Gatzanis, 1985). Hybrid methods also developed, combining methods to create more complex indices of cumulative adversity in a child's life, utilizing a combination of lifetime life event questionnaires, life history charts, and similar methods (e.g., Gest, Reed, & Masten, 1999).

A recent variation on the life event questionnaire method is the Adverse Childhood Experiences (ACEs) measures, typically a set of 10 or 11 items completed by adults about their childhood history. This approach was used initially to survey adults in California (Felitti et al., 1998); subsequently it has been used by various states in the United States to depict the rates of exposure to major risk factors in childhood (as recollected by teens or adults), such as child maltreatment or parental incarceration, and link this to adolescent or adult health and mental health indicators (e.g., Minnesota Department of Health, 2011). Research with ACEs indicates striking risk gradients where poor health outcomes are related to the number of ACEs.

ACEs and other clearly negative life experiences have negative effects when they occur but may have little or no effects on development when they do not occur. However, many of the "risk factors" associated with problems in adjustment are actually continuous variables that have a positive pole, such as good versus poor parenting. Resilience scholars have pointed out that these measures of risk are simultaneously measures of "assets" or resources because they reflect bipolar dimensions (Masten, 2001; Masten & Reed, 2002). The same measures can be flipped over to produce "asset gradients" where the probability of desirable outcomes rises as a function of cumulative assets. The Search Institute has capitalized on this reality to create a widely used measure of 40 "developmental assets" that can be used to gauge the support of communities for young people; this group recognized that it was powerful and motivating to show communities the positive side of the story—that youth with more of these assets were doing well (Lerner & Benson, 2002; Scales, Benson, Leffert, & Blyth, 2000; Scales, Benson, Roehikpartain, Sesma, & Van Dulmen, 2006; Sesma, Mannes, & Scales, 2013). Their approach underscored the importance of adding assets rather than reducing risks.

However, whether one focuses on risk gradients or asset gradients, many of the cumulative risk indices obscure the variation within a particular level of risk, high or low. Pioneers in the study of resilience brought attention to the off-gradient cases that were not well predicted by high cumulative risk scores (Masten, 2014b). Some individuals were doing much better than might be expected from their level of risk. Historically earlier diathesis–stress models of psychopathology had proposed in a similar way that some individuals were more vulnerable to adversity, doing worse than might be expected by the level of risk (Gottesman, 1974). Off-gradient cases in either direction (worse or better than expected) suggested that there might be moderating influences on risk or adversity that could not be captured by additive effects. These interaction effects became the focus of research on protective factors that might explain better-than-typical or expected outcomes as well as the diathesis studies of genetic vulnerability and other moderating influences that could lead to worse effects.

Cumulative risk scores also could mask the salient effect of particular experiences on well-being or function. These scores were designed to package risk because risk factors often co-occurred, and the number of risk factors often seemed to be more important than the nature of the particular risk exposures. However, there are situations where this may not be the case, particularly in situations of extreme trauma. In a meta-analysis of posttraumatic stress (PTS) studies, Furr, Comer, Edmunds, and Kendall (2010) were able to show that in disasters (mass-trauma events including natural disasters and terror attacks), greater PTS symptoms were found in disasters with greater loss of life and loss of loved one and friends. In a specific analysis to unpack risk in their study of Bosnian adolescents exposed to war and political conflicts, Layne and colleagues (2010) identified particular experiences as more potent risk factors, including exposure to life-threatening experiences and traumatic death. In their study of former child soldiers, Betancourt et al. (2010) described the "toxic" effects of rape and killing others on long-term well-being and adjustment.

Many of the cumulative risk models and gradients were conceptualized and tested using linear models. However, there also was consideration of nonlinear models, at least in theory (Garmezy et al., 1984; Masten et al., 1988). The "challenge" model was curvilinear, where the relation of adaptive function to stress or adversity was quadratic—with the best outcomes at mid-levels of stress

rather than very low or very high levels of challenge, akin to the familiar inverted "U" function of the Yerkes-Dodson law relating performance to arousal. The concept of possible steeling effects of some adversity exposure also was nonlinear (Rutter, 1987).

In recent years, nonlinear models of risk have become more prevalent as the statistical strategies and data collection needed for testing these effects became more widespread and feasible to execute. Intriguing data from studies of children in war and political conflict have suggested nonlinear dose effects (see Masten et al., 2015). For example, some research on child soldiers exposed to extraordinary trauma in captivity suggest that there may be asymptotic effects where the exposure is so high that everyone has passed the threshold for full expression of posttraumatic symptoms; at this level of risk, symptoms are less related to exposure dose of traumatic experiences and more related to the quality of the recovery environment (Klasen et al., 2010). Another study of youth engaged in political conflict, Palestinian youth in Gaza, by Qouta, Punamäki, and El Sarraj (2008) found nonlinear relations of engagement to conflict exposure. At lower to middle levels of exposure to the conflict, they observed a typical dose-response effect, with adaptive behavior declining as exposure levels rose. However, at extremely high levels of exposure to extreme political violence, youth appeared to rally for the cause.

Another important theme that became salient in recent studies of adversity, particularly in regard to mass-trauma adversities, was the role of media exposure in risk (Masten & Narayan, 2012; Masten et al., 2015). Evidence has accumulated that exposure to adversity through media coverage can have significant dose effects on children, and particularly young children. Moreover, studies that examine the potential risk of social media exposure are just getting under way.

The Adaptation Criteria: How Well Is the System Doing?

Resilience science focused on the processes that make it possible for some individuals to weather the storms of adversity. What are the criteria by which resistance, recovery, or posttraumatic growth are judged? Here, too, many criteria have been the focus of study, some broad and some narrow, some external and observable, others internal and subjective. To judge or study resilience, one must evaluate how well a system is doing by some kind of criteria.

In research on human resilience, positive adaptation, adjustment, or outcomes have been judged by different criteria at different levels of analysis (Cicchetti, 2010; Luthar, 2006; Luthar et al., 2000; Masten, 2007, 2014b; Masten, Burt, et al., 2006; Schoon, 2006). With the study of resilience emerging from research on children at risk for major mental disorders or antisocial behavior, sometimes the criteria were defined in negative ways, by avoiding psychopathology or manifesting few symptoms (e.g., avoiding substance abuse or conduct disorder). A study by Nigg and colleagues (2007) provides an example; they examined protective factors associated with avoiding the development of attention-deficit/hyperactivity disorder, oppositional defiant disorder, or conduct disorder in children at risk due to family adversity. However, some investigators focused on how well children were doing in the developmental tasks of childhood, adolescence, or early adulthood on multiple dimensions of competence, discussed further in the next paragraph (e.g., Masten & Tellegen, 2012). These measures of adaptation or adjustment were often behavioral (e.g., academic achievement, getting along with peers) and age-related, changing as children matured and entered new contexts. Some investigators focused on subjective well-being or happiness as key criteria for adapting well (e.g., Jordan & Graham, 2012). Studies of immigrant youth and acculturation stress often focus on both psychological well-being and adjustment in school (Motti-Stefanidi, 2014).

Developmental studies, particularly longitudinal studies, often measured adaptation by achievements in the tasks that are commonly expected for individuals to accomplish at different ages (McCormick, Kuo, & Masten, 2011). For example, success in age-salient developmental tasks were key criteria for the assessment of adaptation in three influential longitudinal studies of risk and resilience: the Children of Kauai (Werner & Smith, 1982, 1992, 2001), the Minnesota Longitudinal Study of Risk and Adaptation (Sroufe, Egeland, Carlson, & Collins, 2005), and the Project Competence Longitudinal Study (Masten & Tellegen, 2012). In early childhood, these developmental tasks include forming attachment bonds with caregivers, learning to walk and talk, and beginning to comply with rules. Older children are expected to go to school, learn to read and write and calculate with numbers; get along with peers and teachers; and follow the cultural rules and laws of their societies. Adolescents and young adults are often expected to form deeper friendships, develop romantic relationships, form their own families, and enter the workforce, higher education, or take on child-rearing responsibilities.

Although it was recognized long ago that adaptation criteria are grounded in cultural and historical context (Masten & Coatsworth, 1995, 1998), empirical attention

to cultural variations in the criteria for adaptive behavior or competence gained considerable traction in the past decade of resilience science (Masten, 2014a; Panter-Brick & Leckman, 2013; Ungar, Ghazinour, & Richter, 2013). Work of the Resilience Centre in Halifax, Nova Scotia, provides examples of the collaborative international efforts under way to study cultural similarities and differences in defining good adjustment, as well as protective processes, in resilience.

Developmental Cascades

Over the past decade, there also has been a surge of empirical studies focused on developmental cascades across domains and levels of adaptive function. *Developmental cascades* refer to progressive or spreading changes across systems, time, and even generations, resulting from multiple-level interactions in complex living systems, that have cumulative effects on the course of a system's development (Masten & Cicchetti, 2010c). These effects were noted long ago in research on the etiology and course of psychopathology and also in the literature on the development of competence (Burt, Coatsworth, & Masten, Chapter 9, this volume; Cicchetti & Cannon, 1999; Cicchetti & Tucker, 1994; Cole & Maxwell, 2003; Dodge, Greenberg, Malone, & the Conduct Problems Prevention Research Group, 2008; Hanson & Gottesman, 2007; Hinshaw, 1992; Hinshaw & Anderson, 1996; Kagan, 2005; Kohlberg, LaCrosse, & Ricks, 1972; Masten & Coatsworth, 1998; Masten et al., 2005; Patterson, Reid, & Dishion, 1992; Rutter, 1999; Rutter, Kim-Cohen, & Maughan, 2006; Rutter & Sroufe, 2000). These effects have been called snowball effects, amplification effects, positive chain reactions, and spillover effects among other terms for similar concepts. Basically, cascades describe the cumulative consequences of the interactions among systems that shape the course of development, recognizing that changes spread in dynamic, interdependent systems. Developmental systems theory forecasted and empirical findings supported the systems idea that problems or successes in one domain or level or part of interacting systems (e.g., within a person and a family or a peer group) could spread to affect other domains, levels, or people (see Masten & Cicchetti, 2010a, 2010b).

Research on resilience highlighted the cascade effects pertinent to positive adaptation, as well as promotive and protective processes. One central theme focused on the theory and findings that *competence begets competence* as children develop. Achievements in core developmental tasks in one period of development set the stage for future competence. This idea has been championed not only by developmental psychologists (Masten & Coatsworth, 1998; Sroufe, Egeland, Carlson, & Collins, 2005), but also by economists and prevention scientists concerned with benefit-to-cost analysis (Heckman, 2006; Temple & Reynolds, 2007). Investing in competence early in development was recognized as a highly cost-effective strategy for both promoting later competence and preventing psychopathology, because of cascading consequences in development.

A second central theme focused on interrupting negative cascades or intervening to prevent negative cascades from unfolding through strategic prevention or intervention efforts (Burt et al., Chapter 9, this volume; Masten & Cicchetti, 2010c). Interventions can be designed to target mediating processes in anticipated developmental cascades sequences, timed and targeted to prevent negative and promote positive consequences of system interactions. Basic research on naturally occurring resilience highlighted the potential for cascading consequences of deliberate efforts to reduce dose and mitigate negative consequences of adversity and stress on development. Examples of interventions to interrupt or generate cascades are discussed further in subsequent sections.

Adaptation through Time: Pathways of Resilience and Maladaptation

Resilience theory also highlighted *positive pathways of adaptation through time*. Pathway models of adaptive function have a long history, dating back to the work of early embryologists describing development. Examples of early pathway models include the epigenetic landscape of Waddington (1957/2014) and pathways delineated by Gottesman and his collaborators (Gottesman, 1974; Gottesman & Shields, 1982) portraying the combined effects of epigenetic processes in shaping the life course toward and away from schizophrenia. In resilience science, theoretical pathway models represented efforts to capture the course of adaptive function over time, in the relation to changes in adversity and other circumstances.

In the literature on resilience in children, Masten and Reed (2002) delineated a number of pathways that had been described in both theory and individual case histories of resilience. These included pathways of *stress resistance, breakdown and recovery, and normalization*. Later, Masten and colleagues would differentiate pathways for acute challenges, such as those observed in disasters, terrorist attacks, and accidents, from those commonly observed in chronic adversity exposures, such as family dysfunction

with domestic violence or substance abuse, entrenched poverty, and child neglect or abuse in the family (e.g., Masten, 2013; Masten, Monn, & Supkoff, 2011; Masten & Obradović, 2008). For example, Masten and Narayan (2012) illustrated a number of theoretical pathways often described in the literature on children in war and disaster. Bonanno (Bonanno, 2004; Bonanno & Diminich, 2013) have delineated similar pathway models in the literature focused on adult resilience.

A sample of pathway models are illustrated in Figures 6.1 and 6.2 showing patterns of different pathways in the context of acute trauma or a period of chronic adversity followed by a period with *improved* context (due to natural changes in adversity or interventions to reduce adversity). In the aftermath of acute trauma, these manifested resilience patterns have been observed and theoretically proposed*: stress-resistance*, where functioning remains about the same despite the challenges; *breakdown and recovery*, where there is initial decline in function followed by return to more or less the original level of function; and *posttraumatic growth*, where function improves in the aftermath of a severe challenge, sometimes following an initial decline, as if the individual's functioning is galvanized by the demands of responding to the challenge and/or the processes of recovery. During the period of severe, chronic trauma, children do poorly or decline in function, as illustrated during the first period of time in Figure 6.2. Then, when conditions improve for child function or development, as capacity for resilience builds or replenishes, resilience pathways in the form of recovery or normalization become evident.

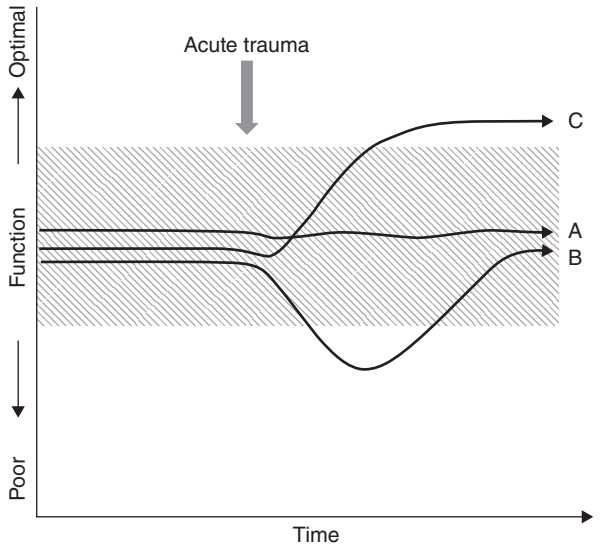

Figure 6.1 Resilience Pathways After Acute Trauma. Model of resilience pathways after acute trauma. The gray zone represents normal or typical adaptive function. Path A represents stress resistance. Path B illustrates breakdown and recovery. Path C represents posttraumatic growth. *Source:* © Ann S. Masten. Reprinted with permission.

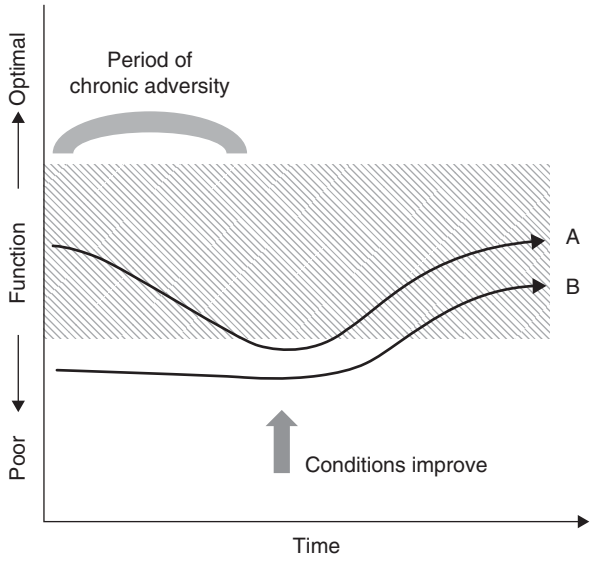

Figure 6.2 Resilience Pathways after Chronic Adversity. Model of resilience pathways showing a period of chronic exposure to severe adversity followed by a period when conditions improve. Path A shows declining adaptive function during chronic adversity followed by recovery when conditions improve. Path B shows a normalization pattern when conditions improve. *Source:* © Ann S. Masten. Reprinted with permission.

With the advent of advanced statistical modeling and more longitudinal studies using repeated measures, it has become feasible to examine and test such models empirically. Readily available methods of growth mixture modeling or group-based trajectory modeling developed by Nagin, Muthén, and their colleagues have made it possible to identify pathways followed by groups of individuals within a longitudinal sample (Jung & Wickrama, 2008; Muthén & Muthén, 2000; Nagin, 1999, 2005; Nagin & Odgers, 2010; Nagin & Tremblay, 1999). Although some of the resulting studies emphasized pathways of symptoms or problems rather than competence or positive adaptation (see Nagin & Odgers, 2010, for examples), these analyses frequently identified relatively healthy or positive trajectories too (paths with stable low levels of symptoms or trajectories with declining symptoms). In fact, studies of symptom pathways following disasters reveal that the majority of children or youth show improving or stable good functioning following acute disasters (e.g., La Greca, Lai, Joormann, Auslander, & Short, 2013). Betancourt and colleagues also observed that in a majority of cases, trajectory analyses indicated resilience in war-exposed

youth followed over time from Sierra Leone, many of them former child soldiers with extremely high and chronic exposure to trauma (Betancourt, McBain, Newnham, & Brennan, 2013). Their results for internalizing symptoms indicated four trajectories, with 41% of young people showing stable, low symptom levels and an additional 48% showing an improving trajectory over time. Only 5% showed stable, high-level symptoms, and 6% showed deteriorating patterns.

Although the advent of mixture/trajectory modeling has facilitated empirical studies of resilience pathways, it is interesting to note that there appear to be more examples modeling symptoms than positive criteria of adjustment. There are very few examples of mixture modeling to identify resilience trajectories based on positive criteria (e.g., Obradović, Burt, & Masten, 2006) even though there have been some attempts to identify trajectories of academic achievement in normative samples. Davis-Kean and Jager (2014), for example, used growth mixture modeling to analyze data from the Early Childhood Longitudinal Study-Kindergarten Cohort, a nationally representative sample. They examined achievement trajectories within racial groups, which revealed achievement gaps and interesting "catch-up" trajectories within racial categories.

Steeling Effects and Posttraumatic Growth

One of the most intriguing pathways reported anecdotally in resilience case studies is posttraumatic growth, when adaptive function appears to *improve* following exposure to adversity (particularly acute catastrophes). Some have suggested that there is an initial breakdown of function followed by a reorganization or strengthening process (Calhoun & Tedeschi, 2006). Some families report better function after dealing with a crisis or a child's illness. Colville and Cream (2009), for example, found that many parents of children who were in a pediatric intensive care unit reported posttraumatic growth after the children left the hospital. On closer inspection, they also noted that this effect was curvilinear—it was more commonly reported by parents with moderate levels of PTS than those with higher or lower perceived stress levels.

The idea that some exposure to adverse experiences and challenges is better than none or too much exposure for longer-term adaptive function also is a concept with a long history in resilience science (Masten, 2012). Rutter (1987) described the steeling effects of exposure long ago in his classic article on resilience, and he continues to garner the evidence on these nonlinear effects (Rutter, 2012). The vaccination model of prevention is built on an exposure model (to a weaker or less-threatening form of the threat; Masten, 2014b). Adaptive systems often require calibration or experience to "learn" to work properly or tune to the expected environment; this is true of the immune system and our muscles, and may well be true of behavioral adaptation. Such findings have led to a flurry of articles on the sometimes-controversial theme that Nietzsche (2013) so succinctly described in 1888: "What does not kill me makes me stronger." The controversy comes with the idea that trauma is "good for you," which is very problematic in situations of child maltreatment and other devastating adversities. Practice with adaptation may be helpful but only in modest amounts that do no harm. Surviving Ebola may provide immunity, but the risk of dying and cost to health and well-being are astronomically high.

That said, the possibility that adapting to adversity can alter the organism in positive ways for future adaptation is fundamental to preventive interventions, including stress-inoculation training as well as immunizations against childhood diseases. An overprotected child may not end up with the adaptive capacity for responding successfully to the vicissitudes of life that will inevitably come.

Nonlinear effects of early life adversities also have been studied in animal models and particularly in primates (Lyons & Parker, 2007; Parker & Maestripieri, 2011). Here too evidence has accumulated that the relation of adversity experiences to later adaptive function is quadratic rather than linear. Loss, abuse, or deprivation of caregiving can have calamitous effects on the development of primates, similar to human infants. However, some experience with brief separations in infant macaques and other primates apparently can result in better regulated stress-responses systems that yield greater resilience later in life. This effect in squirrel monkeys has been described as a stress-inoculation effect (reviewed by Parker & Maestripieri, 2011). Some experience with manageable separations, in other words, can be better for long-term adaptation than no experience with separations.

Promotive and Protective Processes

The search for factors that could account for the variation in short-or long-term outcomes among children exposed to adversity resulted in the identification of variables or conditions that seemed to make a difference. However, one of the first issues that came up in this search was distinguishing generally good predictors of positive outcomes (in various domains of function or development) regardless of risk from predictors that appeared to play a particularly important role when risk or adversity was high. Eventually these

two kinds of effects came to be called "promotive" factors (a term popularized by Sameroff, 2000) and "protective" factors.

In essence, this distinction differentiated effects observed at most or all levels of risk from those effects observed in conditions of challenge. Moreover, it was not the factors that truly mattered, but instead their *function* in varying conditions, because it was quickly observed that the same factor could function both ways. Parenting quality and good cognitive skills have been extensively implicated as both correlates/predictors of achievement in developmental tasks and also as moderators of risk or adversity (Masten, 2014b; Masten & Coatsworth, 1998).

Pioneering investigators often commented on this issue. Garmezy et al. (1984), among others, pointed out that this distinction from an analytical perspective reflected "main effects" in contrast to "interaction effects." Rutter (1987) was an early champion of keeping these functional roles distinct, and he has continued to argue (Rutter, 2012) that studies of resilience and protective processes related to resilience should be focused on what happens when adversity is high.

Promotive factors (which also can be called promoters, assets, and resources) are positive correlates and predictors of desirable outcomes. Some of these may be purely positive, but in many cases, the correlates of positive development or adjustment are actually dimensional attributes (e.g., good versus poor parenting) that could easily be "reversed" to become a risk measure, as already noted in the discussion of risk.

Similarly, moderators of risk or adversity that predict variations in adaptive behavior or other outcomes in the context of threats to adaptive function could be described as "protective" or "vulnerability" indicators in terms of their function. But in the situation of high challenge or threat to adaptive function, the "expected" norm references help to define the presumed nature of the factor's role or function. Thus, for example, if the expected typical response to increasing adversity or threat is a decline in function, and the moderating action appears to be at the high end of the purposed moderator, the variable will be described as a protective factor. If one is low on the moderator and the outcome is worse than generally expected or observed, and the action is concentrated at the other end of the dimension, that effect will be described as a vulnerability effect. And both effects could be observed. The normative levels of the moderator and adversity/threat in the general population also influence the interpretation of a moderator as a protective factor or a vulnerability. If average levels of parenting warmth or structure appear to protect children from the effects of high adversity exposure, then parenting effects will be viewed as protective. Poor parenting, in contrast, could exacerbate the consequences of even modest exposure to adversity, often interpreted as a vulnerability effect.

The essential idea in defining these effects is not the factor is protective or promotive per se but instead that it *functions in a particular way in a given context or situation with respect to a particular criterion of outcome*. This idea was emphasized in early reviews (e.g., Masten, Best, & Garmezy, 1990; Rutter, 1987), but it has been underscored by recent theory and evidence on differential sensitivity to experience, discussed further in the section on "Differential Sensitivity or Susceptibility to Experience and the Environment." In a negative environment, rife with adversity, "sensitivity" could be viewed as a vulnerability, whereas in an enriched and safe environment, or in the context of an intervention, it could be enhancing to development. The functional significance of "sensitivity" varies in different conditions.

Biological Models and Processes

Early resilience investigators were strongly influenced by the biological models prevailing at the time, particularly in medicine and public health, including psychiatry and epidemiology (Masten, 2014b). These models included numerous concepts and models already discussed, such as cumulative risk, diathesis-stressor models of disease, and vaccination, that all explained how multiple influences might account for the development of problems or illnesses and, concomitantly, how to think about prevention.

The ideas of stress-inoculation and steeling effects drew on models of vaccination, where exposure to a weaker or safer form of a dangerous biological agent could stimulate the immune system to make antibodies that subsequently would protect the organism from the worst ravages of dangerous diseases like smallpox or polio. Similarly, challenging the muscles by exertion would initially break down function but, with recovery, lead to strengthening of those muscles in the future. In these models, clearly it is not "no exposure" that is best but rather some kind of manageable exposure to a challenge that is followed by recovery and yields a more adaptive organism.

Modern examples include the hygiene hypothesis for asthma, where lower exposure to pathogens or microorganisms in development can lead to higher risk for asthma in the future. Explanations for the hygiene effect are complex (see Figueiredo et al., 2013), but the general idea is that modern lives may be "too clean" to tune or program

the individual's immune system effectively. Growing up on a farm with exposure to a range of microorganisms can be viewed as protective for some kinds of allergies (Guerra & Martinez, 2008; Okada, Kuhn, Feillet, & Bach, 2010; von Mutius & Radon, 2008). In these models, developmental timing is important because protection is conferred by early exposure that helps to calibrate the immune system whereas later exposure to the same environmental exposures can result in allergic reactions. There also is a growing body of evidence based on animal models that repeated exposures to moderately stressful experiences can have positive effects on how young animals handle future stressors (Parker & Maestripieri, 2011).

Contemporary variations of these biologically-based challenge models include child-rearing or educational ideas where parents or teachers aim to build psychological strength by exposing children to manageable challenges. Another example can be found in interventions based on stress-inoculation training that are designed to prepare children for potentially traumatic experiences, such as hospitalization or terror attacks. In Israel, for example, school children have been trained to handle attacks related to political conflict and terror, with natural experiments showing that such training can be effective for reducing the risk of PTS (e.g., Wolmer, Hamiel, & Laor, 2011).

It is noteworthy that the models and empirical evidence on the effects of challenging experiences, whether biological or psychological, suggest that it is modest levels of challenge, with adequate resources and supports for recovery, that may help to prepare a child or a primate for future challenges. There is little evidence that overwhelming trauma and adversity make children stronger.

Another early biological model was provided by sickle-cell anemia, where having two alleles for this genetic disorder caused a life-threatening illness yet having one allele could confer some protection from malaria in certain regions where the disease was endemic. One of the resilience pioneers, Michael Rutter (1987), noted this model in a classic article on resilience. This biological model indicated the importance of context for interpreting risk and protective effects, both the genetic context and the rearing environment. This example illustrated the phenomenon of a balanced polymorphism, where the heterozygous individual has a survival advantage but only under some conditions.

Over the past decade, advances in the development of increasingly accurate and practical tools to measure genes and epigenetic processes have revolutionized the science in multiple fields, including medicine and the study of adaptive function and development more broadly defined. These advances have influenced research in developmental psychopathology (Grigorenko & Cicchetti, 2012) and resilience (Kim-Cohen & Gold, 2009; Kim-Cohen & Turkewitz, 2012). Consequently, new models of resilience and resilience-based intervention have emerged.

GxE: Genetic and Epigenetic Models and Processes in Resilience

Gene–environment interaction (GxE), one of several distinct forms of gene–environment interplay (Rutter, Moffit, & Caspi, 2006), refers to observable variations in individual functions or development that are attributable to the interdependence between a specific identified variation in the DNA sequence of a gene and a well-defined and carefully measured experience or feature of the environment, often a pathogen (Caspi, Hariri, Holmes, Uher, & Moffitt, 2010; Moffit, Caspi, & Rutter, 2006). In GxE, environmental experiences moderate genetic effects (or vice-versa) on adaptive function and development, including normal, pathological, or optimal outcomes (Cicchetti & Rogosch, 2012; Rutter, 2006). For example, genetic effects on outcomes may be observed only in certain environmental contexts or in conjunction with different histories of experience; conversely, experience may relate only to outcomes among individuals with specific genetic characteristics. Risk-exposed individuals who carry the "protective" version (or allele) of a gene with respect to that risk condition develop significantly lower levels of psychopathology compared to comparably risk-exposed individuals with the "vulnerable" allele (Kim-Cohen & Gold, 2009).

Although there has been an abundance of research conducted on GxE interactions and evidence for GxE interactions in the etiological pathways of psychopathology and manifested resilience (Caspi et al., 2010; Karg et al., 2011), it is important to note that a number of criticisms have been levied against GxE research (see, e.g., Duncan & Keller, 2011; Duncan, Pollastri, & Smoller, 2014; Keller, 2014). These include small sample sizes that can yield low statistical power, failure to control for all potential confounders in all models and failure to compute all relevant interaction terms in the same model, and a paucity of replication studies (Duncan & Keller, 2011; Keller, 2014).

Advances in molecular biology have helped to usher in a renascence of interest in the contribution that studies on GxE can make to unraveling the complex pathways of adaptive and maladaptive development, including resilience processes (Cicchetti & Blender, 2006; Grigorenko & Cicchetti, 2012a, 2012b; Rutter, 2006). These advances

include the completion of the DNA sequencing of the human genome (Collins, Morgan, & Patrinos, 2003; Cowan, Kopnisky, & Hyman, 2002) and the publication of the map of human haplotypes that provides valuable information about individual genetic variation and a powerful tool for identifying both vulnerability and protective genes (D. C. Crawford & Nickerson, 2005; Insel & Quiron, 2005). As Rutter et al. (2006) articulated, an understanding of the complexities involved in comprehending normal, abnormal, and resilient patterns of development may prove useful in avoiding misleading types of stigma and biological reductionism (see also Curtis & Cicchetti, 2003; Hinshaw & Cicchetti, 2000). Moreover, comprehending the complex variation in dynamic multilevel pathways emphasizes the importance of genes in all developmental trajectories involving risk and protection.

The empirical contributions of a molecular genetic approach enable us to discover genetic elements that contribute to developmental processes of normality, psychopathology, and resilience without requiring foreknowledge of the underlying biochemical abnormalities (Ciaranello et al., 1995). These contributions make the search for the intermediate developmental mechanisms in the gene-environment-brain-behavior interconnections more accessible than ever before (Gottesman & Gould, 2003; Gottesman & Hanson, 2005; Hanson & Gottesman, 2007; Lenzenweger, 2013; Moffit et al., 2006). Moreover, progress in molecular genetics also raises hope of developing interventions to prevent and remediate mental disorder and to promote resilience (Belsky & van IJZendoorn, 2015; Cicchetti & Blender, 2006; Cicchetti & Curtis, 2006; Grigorenko & Cicchetti, 2012a, 2012b; Howe, Beach, & Brody, 2010; Masten, 2014b).

Differential Sensitivity or Susceptibility to Experience and the Environment

One of the most influential set of ideas in GxE theory over the past decade with implications for resilience science stems from the concepts of differential susceptibility (Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; Belsky & Pluess, 2009) and biological sensitivity to context (Boyce & Ellis, 2005; Obradović & Boyce, 2009). According to the evolutionary-derived hypothesis of differential susceptibility to the environment, individuals vary in their developmental plasticity or malleability to negative or positive experiences (Belsky & Pluess, 2009). Genes that confer risk in harsh environments are thought to confer benefits in normal or nurturing environments (Belsky et al., 2007; Belsky & Pluess, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011). In other words, the characteristics of individuals (including their gentoypes) that render them disproportionately more vulnerable to effects of experiencing adversity may also make them disproportionately more likely to benefit from supportive contexts (Belsky et al., 2007; Boyce & Ellis, 2005; Ellis et al., 2011).

Differential susceptibility in the view of Belsky and colleagues (2007) can be distinguished from related ideas, including diathesis-stressor theory (Gottesman & Shields, 1972), by evidence on effects in negative and positive environments. If susceptibility is evident only in negative environments, but not in positive environmental contexts, then "diathesis" is indicated. In contrast, differential susceptibility theory is supported by a cross-over interaction such that susceptible individuals are disproportionately affected "for better and for worse" by both positive and negative experiences (Belsky et al., 2007).

Because a simple phenotype cannot be adapted to all potential conditions, the creation of variability within families increases the probability that at least some offspring will be successful in every generation (Belsky & Pluess, 2009). Therefore, differential susceptibility to the environment presumes that individuals vary in their susceptibility to context as a result of genetic differences.

Differential susceptibility to the environment also provides a possible explanation for individual variability in responsiveness to intervention (Ellis et al., 2011). This variation is particularly important because most treatment outcome studies, even those yielding statistically significant effects and having medium to large effect sizes, include many individuals who do not benefit from the intervention (Belsky & van IJzendoorn, 2015). Thus, identifying differential susceptibility markers is a key to tailoring treatments to uniquely fit individual differences. As such markers are identified, they may be examined as potential moderators of resilience or of intervention outcomes.

Theoretically, while there may be "sensitive" children who are responsive to both bad and good environments, there also could be traits or other endogenous factors in a child that yield receptivity only to positive environments. This possibility led to a further differentiation of individual differences to describe the sensitivity to positive environments or advantaged conditions, described as "vantage sensitivity" by Pluess and Belsky (2013), along with Manuck (2011). Substantially less research has been directed toward investigating endogenous factors that are associated with variation in response to positive influences. Vantage sensitivity could be viewed as the bright side of differential susceptibility theory (Pluess & Belsky, 2013).

Vantage sensitivity is used to describe the notion that some persons are more sensitive and positively responsive to the environmental advantages to which they are exposed (Pluess & Belsky, 2013). Vantage sensitivity also can be differentiated from a general sensitivity to good or bad environments. Some individual differences in developmental responsiveness to environmental experience may emerge *only* under positive or supportive conditions. In these instances, vantage sensitivity, not differential susceptibility—which is characterized by disproportionate sensitivity to both positive and negative exposures and experiences—would be indicated (Pluess & Belsky, 2013).

Biological Models of Protective Parenting

Many other models of resilience could be drawn from the biological literature, including animal models. A complete treatment of this topic is beyond the scope of this chapter. Just one additional model example will be highlighted, which is the rat model of parenting developed by Michael Meaney and colleagues that dramatically illustrates the power of environments to moderate genetic risk through epigenetic pathways (Karatsoreos & McEwen, 2013; Meaney, 2010). Animal models have played a key role in understanding how both risk and protective influences may work. Meany and colleagues demonstrated through a series of elegant experiments that maternal behavior in rat mothers, even foster mothers, can alter gene expression, with lasting effects on the adaptive behavior and vulnerability to stressors among the pups. Additional studies in animals and humans support the idea that qualities of parenting can alter the effective genotype and thereby influence later vulnerability or resilience in the face of adversity (Karatosreos & McEwen, 2013). Here again, developmental timing matters. The high-versus low-licking behavior of rat mothers has its greatest impact during a sensitive period early in pup development.

A General Framework for Action

As resilience models and corresponding research strategies developed, a parallel resilience framework for action also emerged, because children in urgent situations cannot wait for a complete science to guide translation of knowledge into practice (Masten, 2011, 2014b). Action often may be required before the evidence we ideally would want to have is in place. In these situations, action can be guided by general principles based on the science to date.

Resilience perspectives on programs and policies usually emphasize these principles:

- Set positive goals.
- Include positive influences and outcomes in models of change as well as risks.
- Monitor and measure positive achievements and progress as well as problems.
- Increase promotive influences and mobilize adaptive systems while also reducing harmful exposure to risk or adversity.
- Consider multiple levels and systems for leveraging change.
- Intervene strategically during windows of opportunity for promoting positive cascades and interrupting negative cascades.

These principles do not ignore or neglect risk, recognizing that preventing adversity or toxic risk exposures often yields a high return on investment, both financially and socially. Additionally, these principles underscore the importance of timing, for preventing risk as well as for promoting positive processes: interventions are more effective when they are well-timed in terms of developmental plasticity or contextual transitions during periods when developing and interacting systems may be more amenable to change (Masten, 2014b).

METHODS

Resilience research required methods to explore and test hypotheses about adaptation in the context of risk or adversity. These methods included strategies for assessing the primary components of resilience models—including risk, adaptation, and potential mediators or moderators discussed in the section on models—but also methods for studying patterns and processes in the lives of people who did or may manifest resilience. In this section, we discuss two major traditions for studying resilience in children, person-focused and variable-focused in approach, as well as recent hybrid methods that combine features of both and intervention studies as a method for studying resilience.

Person-Focused Approaches

Single cases of manifested resilience have played a prominent role in the history of resilience science and continue to play key roles in inspiring new lines of work and in

communication of research findings. Scientists often report that their interest in resilience was spurred by case examples of individuals in their own or other studies, particularly the pioneers in psychology and psychiatry who propagated the first wave of research (Masten, 2014b). These pioneers set out to study the origins of psychopathology among children at risk for various reasons but often were struck by the compelling individual examples they observed of young people who were doing well despite high-risk status or exposure to severe adversity. Garmezy (1982b) wrote an article titled "The Case for the Single Case" in which he described the heuristic value of individual case examples for providing insights, inspiration, and clues for future research. He often described individual cases when he taught, spoke, and wrote about resilience, including famous examples (e.g., Queen Elizabeth I) and anonymous examples from newspaper accounts or his studies.

There are published case studies of resilience, although they are far fewer than the biographical accounts available in books, films, and other media. One example is the case of "Sara" (Masten & O'Connor, 1989), an account of a high-risk child (of a mentally ill mother) who experienced traumatic family losses around 1 year of age followed by an inadequate foster case placement with strangers. Growth failure and developmental decline in multiple areas of function followed until she was hospitalized for a full evaluation at the age of 30 months. On recommendation of the treatment team, Sara was referred for adoption and the "treatment" of an experienced, stable, loving family. Sara was followed over time, and she responded to her permanent placement with a dramatic developmental rebound, returning to a normative developmental trajectory in physical, cognitive, and social development. A blind-to-history follow-up assessment when Sara was 6 years showed a continued course of positive development.

In their book on the High Valley Resilience Study, Hauser, Allen, and Golden (2006) tell the stories of nine individuals from a longitudinal study of 67 young people hospitalized for emotional and behavioral problems during adolescence who managed to "get out of the woods" as they grew up. The authors focused more deeply in this narrative on four of these resilient youth and how they overcame a troubled adolescence, identifying three major protective factors often observed in larger studies of resilience: positive relationships, agency, and reflective self-control. By moving beyond the single case and comparing a subgroup of cases that showed resilience by their criteria, Hauser et al. illustrate the aggregated case method, which has a number of advantages over the single-case approach.

The key drawback to the single case study is generalizability. It is not clear to what degree a single life represents unique processes versus broad, generalizable findings. Although a single case can be highly compelling and heuristic, investigators are motivated to turn to the power of numbers to make a more convincing case about their hypotheses. Nonetheless, even in large studies of resilience, scientists often single out single case examples to illustrate and communicate their findings.

Aggregated case studies focus on the whole person, as do single case studies, but aim to identify larger samples of persons who show resilience as defined for the particular study. One classic approach begins with identification of a high-risk group known from past evidence to have a higher-than-normal probability of some undesirable outcome due to a well-established risk factor, high cumulative risk, or adversity exposure. Then a subgroup of individuals who are doing well is identified within the high-risk group. The High Valley Resilience Study followed this approach. Some of best-known data from the influential resilience study of a birth cohort born on Kauai by Werner and Smith (1982) also followed this approach. The investigators identified a high-risk subgroup based on biological and environmental risk factors present before the children were 2 years old (e.g., poverty, family discord, perinatal stress, mental or physical illness in a parent). Then they examined how well members of the high-risk group were doing in subsequent follow-ups on multiple criteria of adjustment. These criteria at ages 10 and 18, for example, included indicators of conduct, achievement, and social competence. Werner and Smith identified a "resilient" subgroup of 72 youth who were then compared to less successful peers from the high-risk category at different points in development in order to identify individual and family differences associated with resilience.

Focusing only on high-risk youth has some limitations. Without low-risk comparison groups, for example, it is not possible to distinguish promotive and protective factors. A difference may be found on cognitive skills, personality, or parenting quality, but it will not be clear if the effect of the factor is any different than it would be among a low-risk sample. Factors that show similar roles under low and high risk—promotive factors—have "main effects" from a statistical point of view, showing the same relation to the adaptive criterion of interest at any level of risk. In contrast, protective effects suggest a more important role when risk is high. In other words, the two groups may differ on an individual or family variable of interest in exactly the same way for a high-risk sample as they would in a

low-risk sample, which suggests a correlate of adjustment but does not suggest a special role when risk is high.

The extended classic approach adds one or more low-risk comparison groups, so that promotive and protective effects can be differentiated. The Project Competence Longitudinal Study (Masten & Tellegen, 2012) utilized this approach in some person-oriented analyses, cross-classifying participants into groups by multiple criteria of competence as well as cumulative levels of adversity. Either cluster analysis or cut-scores can be used to identify the groups. This strategy led to interesting findings on similarities and differences among the different subgroups as well as a nearly "empty cell" suggesting that there were few young people in a school-based sample with a history of low risk who were maladaptive. Results indicated many similarities in the two groups showing positive adjustment around age 20, low-risk and high-risk, and many differences between these two groups of adaptive youth and their high-risk/maladaptive peers.

In some situations, there is no comparable "low-risk" group; virtually everyone has been exposed to the risk or adversity, although there may be subgroups with lower exposure. This can happen when a population is exposed to mass-trauma events, such as hurricanes, terror, war, or disease pandemic. Studies of survivors of the Khmer Rouge genocide in Cambodia encountered this problem (Masten, 2014b). Sometimes the low-risk comparison group differs in so many ways from the high-risk group that it is difficult to control for all the ways the two groups differ other than the key difference of interest. An example might be comparing children who grow up in foster care, who often have a long and complex history of risk, to children raised in stable family situations who have lower risk but also may differ in many aspects of sociodemographic status.

A contemporary twist on these classic person-focused strategies is trajectory analysis. These strategies, discussed later in this section, are designed to extract subgroups from longitudinal patterns of adaptation among high-risk populations based on intraindividual change over time in a variable of interest, and thus they share features of person-focused and variable-focused methods (Muthén & Muthén, 2000).

Variable-Focused Approaches

Person-focused methods consider the lives and attributes of individual people as a whole organism, often comparing similarities and differences in people identified on the basis of history and current function as showing resilience. Variable-focused methods are designed to study patterns of variance and different ways that variables are linked, drawing on the power of statistical methods to identify potential clues to processes that might explain resilience. Variable-focused methods often provide more nuanced clues to key processes involved in resilience.

Common models of variable effects often investigated in resilience studies are shown in Figures 6.3 to 6.7. Figures 6.3 and 6.4 illustrate several ways of showing the roles of multiple risks (negative) or assets/promotive factors (positive) or bipolar variables in predicting a desirable or positive outcome. From a statistics perspective, both figures represent "main effects" models.

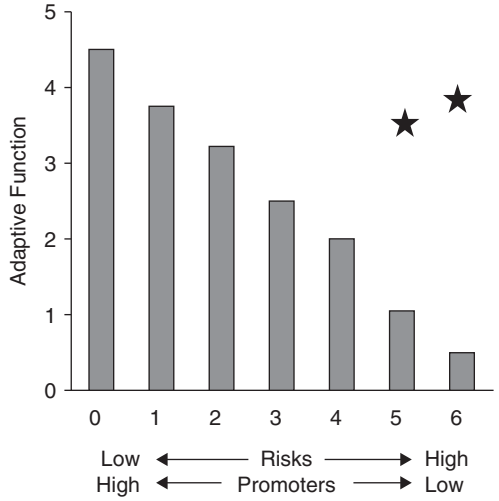

Figure 6.3 Risk or Promoter Gradient. A cumulative risk or promoter gradient illustrating how adaptive function falls as accumulating risk factors rise or promotive factors fall. Stars represent individuals who are functioning well even though their risk levels are high. *Source:* © Ann S. Masten. Reprinted with permission.

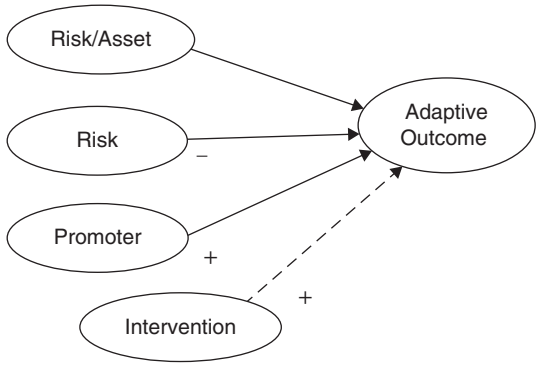

Figure 6.4 Risk and Promoter Model. Basic "main effects" model of risk and promotive factors that influence an adaptive outcome of interest. This model includes an intervention with a promoter effect. *Source:* © Ann S. Masten. Reprinted with permission.

Figure 6.3 represents a typical risk or dose gradient where adaptation is better at lower levels of risk and/or higher levels of promoters (assets or resources). In Figure 6.3, at the high-risk end of the *x*-axis (which may also indicate low levels of promotive factors or assets), adaptation is typically poor (symptoms are high or achievement is low or both). However, the stars represent two cases where an individual is doing much better than might be expected for the person's level of risk. These stars specify off-gradient cases that may signify resilience. Individuals may adapt at levels better than expected due to moderators operating to mitigate risk or unmeasured promotive influences that are in play, discussed further later.

Another way to depict these additive models with risks, bipolar predictors, or promoters is shown in Figure 6.4. This simple model includes one bipolar variable (risk/asset), one risk factor, one naturally occurring promotive factor, and an intervention intended to act as a promoter that was added to a child's life (represented by the dashed line), such as providing a tutor.

Mediating effects are illustrated in Figure 6.5. Here the effect of a risk factor (e.g., economic stress or maltreatment) on the adaptive outcome (e.g., child function or achievements; child competence) is mediated by an intervening variable, such as parenting quality or executive function skills. Mediating models set forth a hypothesis of *how* risks (or interventions to mitigate risk effects) work. An intervention (shown as a dashed line) has targeted the mediator as a strategy for changing the consequences of adversity or risk on child outcome. This intervention strategy illustrates a potential moderator effect (discussed later) on a key mediator of risk. For example, interventions have targeted parenting quality in families or executive function skills in children in an effort to mitigate the effects of disadvantage on school success or psychopathology (e.g., Zelazo & Carlson, 2012; Masten et al, 2014; Patterson et al., 2010). These types of interventions can focus on mitigating risk effects on the mediator or boosting support for the mediator.

Moderator models are shown in Figure 6.6. There are two primary forms of moderators: independent moderators of risk, such as personality factors (e.g., emotional reactivity) that enhance or reduce sensitivity to a particular kind of risk or stressor, and risk-dependent moderators, where the risk or stressor triggers or activates the moderator. The independent moderator might include individual differences in personality or biology that influence how an individual usually responds to stress (e.g., stress-reactive or calm). The risk-activated moderator is analogous to an airbag in a motor vehicle or the immune response to an infection. Emergency services for children and families are examples of risk-activated protective factors, intended to mitigate harm to children or families by providing emergency services or supports. Interventions in this model take the form of boosting the risk-independent protective influences and adding or mobilizing more or better "emergency services." Parents and teachers, for example, can learn to respond more effectively to emergencies and threats of various kinds that threaten children in their care. Stress-inoculation strategies of prevention seek to prepare children, families, or schools for what to do in emergencies in an effort to boost risk-activated protective processes.

Figure 6.7 illustrates two additional variations on moderating influences stemming from the theories on differential susceptibility or biological sensitivity to context already discussed. Differential sensitivity moderates both positive

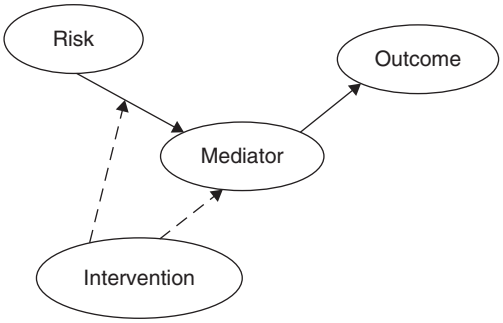

Figure 6.5 Mediated Risk Model with Intervention. Risk affects an intermediate variable that in turn changes adaptive outcome. This model includes an intervention intended to indirectly improve the outcome by mitigating risk effects on the mediator or by supporting the mediator. *Source:* © Ann S. Masten. Figure 6.6 Moderated Risk Model. Moderated risk model showing one independent moderator that mitigates or enhances the effects of the risk (adversity) variable and one risk-activated moderator that is triggered by risk or adversity and then buffers or exacerbates the effects of the risk/adversity. *Source:* Adapted from "Ordinary Magic: Resilience processes in development," by Ann S. Masten, 2001, *American Psychologist, 56,* pp. 227-238.

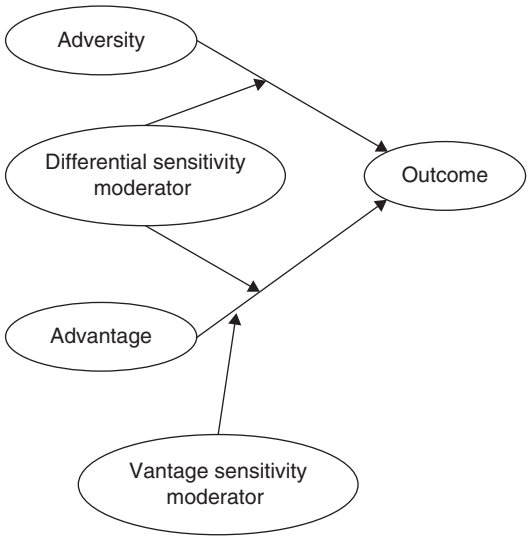

Figure 6.7 Differential Sensitivity Model. Moderator model of differential sensitivity to experience showing one "differential sensitivity" moderator that enhances or attenuates the impact of both bad (adversity) or good (advantage) experiences and a second "vantage sensitivity" moderator that moderates the impact only of good (advantage) experiences. Vulnerability (a moderator of adverse experiences) is not shown. *Source:* © Ann S. Masten. Reprinted with permission.

and negative experiences, enhancing their effects, which is good in a favorable environment and bad in an unfavorable environment. Vantage sensitivity moderates only favorable (advantaged) environments. Not shown in this figure is the third kind of moderator that enhances only negative experiences, which would be described as vulnerability.

Combined Approaches

There are two approaches to analyses of resilience that combine features of person-centered and variable-centered analyses. Some investigators conduct multiple sets of analyses to examine the data from different perspectives. In the Project Competence Longitudinal Study, for example, investigators combined methods focused on variables, including structural equation modeling and regression analyses, with classification of people into groups of high or low risk and adaptation, a classic person-focused approach (Masten, 2014b; Masten & Tellegen, 2012). This group also has presented case material from the study, carefully disguising the identity of the participants (Masten, Morison, Pellegrini, & Tellegen, 1990). In the Kauai study, Werner and Smith (1992, 2001) also reported multiple methods, some focused on person and others focused on variables. Approaching longitudinal data sets from multiple methodological perspectives can be illuminating.

A different strategy that combines both approaches is methods that examine distinct trajectory patterns of intraindividual growth and change, using the advanced statistical techniques already described, often called group-based trajectory modeling (Nagin, 1999, 2005) or growth mixture modeling (Muthén & Muthén, 2000). These methods are used to identify distinct groups of people who follow a similar trajectory or pathway of functioning on a variable of interest over time. Using techniques pioneered by Nagin, Muthén, and others (see Jung & Wickrama, 2008; Nagin & Odgers, 2010), groups of children or youth showing different patterns of function over time can be extracted from longitudinal data with repeated measures. These groups can then be compared on other variables that might explain the different patterns of adjustment. As noted in the discussion of pathway models, these mixed-model approaches have been used to identify subgroups of children and adolescents who show different recovery patterns after trauma experiences, including hurricanes (La Greca et al., 2013) and prolonged trauma as child soldiers (Betancourt, McBain, Newnham, & Brennan, 2013). In both these examples, the majority of individuals showed improving or good function over time, consistent with theoretical models of resilience pathways.

Mixed models also can be used to demonstrate treatment effects in interventions studies and to identify subgroups responding better (or worse) to treatment (Nagin & Odgers, 2010). Through propensity score matching, comparison groups can be studied of people on the same trajectory, some of whom were randomly assigned to receive an intervention. These tools are valuable for research to develop and test interventions based on resilience theory.

Intervention as Resilience Theory-Testing

One of the most powerful methods for testing theories and hypotheses about resilience is experiments with random assignment to treatment, testing a well-delineated model of change. Randomized controlled trials are the gold standard of evidence on what works to promote change and also for establishing causal evidence. Children cannot be assigned to random adversity or risk exposure, of course, but ideas about promotive and protective processes can be tested by intervention designs where the goal is to promote resilience in children or youth.

Numerous intervention studies have attempted to promote better outcomes in young people at risk by mitigating risk, boosting resources, or improving protection in order to foster resilience (Masten, 2014b). Targets of these efforts include: the reduction of premature birth and all its

consequences by prenatal care (Alexander & Kotelchuck, 2001); the reduction of insecure and disorganized attachment in maltreated youngsters through improving the quality of parent-child attachment or interaction (e.g., Cicchetti, Rogosch, & Toth, 2006; Dozier, Peloso, Lewis, Laurenceau, & Levine, 2008;); promoting school engagement (Anderson, Christenson, Sinclair, & Lehr, 2004; Hawkins, Kosterman, Catalano, Hill, & Abbott, 2005); providing after-school programming (Durlak, Weissberg, & Pachan, 2010; Lauer et al., 2006; Mahoney, Larson, & Eccles, 2005); building self-regulation skills (Diamond & Lee, 2011; Raver, 2012); and improving parenting (Patterson, Forgatch, & DeGarmo, 2010; Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011). There are numerous other examples, both of interventions designed to test resilience theory and of interventions designed with other goals in mind that provide compelling evidence that it is possible to promote resilience.

In addition, resilience theory and models suggest that change can be initiated at different system levels or multiple levels simultaneously (Masten, 2014b). Change cascades across systems, so that an intervention targeting the parent can spread throughout the family or an intervention targeting child behavior change also changes the parents, siblings, or family as a whole (Masten & Monn, 2015). Changes at a biochemical level in the brain, perhaps from medication or experience-induced epigenetic changes, can cascade upward into behavior, thereby alleviating depressed mood and leading to changes in parent behavior toward children or broader family changes (see Masten & Cicchetti, 2010).

The challenge for inducing change based on resilience science is knowing enough to optimally target the who, what, and when of leverage and opportunity for change: who to target, at what system level, and when, in terms of developmental timing or a cascade progression. Although prevention science is beginning to address this challenge, evidence to date is sparse but growing.

PSYCHOLOGICAL PROMOTIVE AND PROTECTIVE PROCESSES

Five decades of research on resilience consistently implicate a set of promotive and protective factors across wide-ranging situations and cultures, suggesting that there are fundamental adaptive systems that promote and/or protect human development and function under challenging circumstances (Masten, 2001, 2007, 2014b). Very early reviews and books (e.g., Garmezy, 1985; Garmezy & Rutter, 1983; Rutter, 1979, 1987) as well as more recent reviews and volumes on the empirical literature (e.g., Goldstein & Brooks, 2013; Luthar, 2006; Masten, 2014b; Rutter, 2013) have identified these commonly observed correlates or predictors of good adaptation among children at risk due to various adversities or risk. From a developmental systems perspective, the processes involved in these correlates and predictors of resilience would be multiple level and complex, spanning interactions from the cellular and genetic to the socioecological level. In this section we review these key adaptive systems at the level of psychosocial function, the level of focus when they were initially studied. The neurobiological processes of resilience related to these adaptive systems, which is a focus of intense interest in contemporary research, are discussed subsequently in the chapter.

Love and Emotional Security

All reviews on what matters for human resilience have pointed to the importance of relationships across the life span (Luthar, 2006; Masten, 2014b; Rowe & Kahn, 1998). The nature of the relationships varies across development, with the quality of caregiving and the attachment bonds with caregivers very salient in early development. As children grow older, relationships with other adults and friends or romantic partners become important for resilience. With respect to resilience, the theorized and observed functions of any of these relationships are multifaceted and multidimensional.

In developmental theory, attachment theorists have proposed that beginning early in development, humans (as well as other social mammals) evolved to form powerful and special bonds with their caregivers and other individuals involved in their lives (Ainsworth, 1989; Bretherton & Munholland, 1999; Cassidy & Shaver, 2008; Sroufe, 1979; Sroufe et al., 1999; Thompson, 2000). These relationships were naturally selected because of their survival and reproductive value. The human attachment system with primary and other important caregivers organizes in the latter part of the first year of life, providing emotional security, safety, and also motivation for learning. Between caregiver and the young child, attachment is bidirectional. In the event of a threat perceived by either party, the attached individual will seek proximity or other means to connect and ensure felt security. A frightened child will crawl, walk, and eventually run to the caregiver; a frightened parent, fearful for a child's safety, will also take action to ensure the child is safe or soothe the child. In the disaster literature, the physical proximity of attachment figures reduces stress

and trauma symptoms (Masten & Narayan, 2012; Masten et al., 2015).

The attachment system functions as a nurturing and safety system, but it also is strongly related to learning and exploration. A young child who feels secure is more likely to explore, play, and learn and often takes observable joy in sharing accomplishments and interacting with the attachment figure. The attachment system is linked with the mastery motivation system, discussed in the next section.

Responsive and sensitive caregiving predicts secure attachment relationships that are then carried forward into relationships with teachers, friends, or romantic partners that play helpful roles later in a person's life (Sroufe et al., 2005; Thompson, 2000). At the same time, high-quality parenting of this kind serves the immediate function of co-regulation so that children who do not yet have independent self-regulation skills to modulate arousal, emotion, or behavior have an "external" regulator at hand. Thus, good parenting also would be expected to relate to the development of self-regulation, another adaptive system implicated in research on resilience.

Parents and other caregivers serve many other functions as promoters and protectors of development (Masten 2014b; Sroufe et al., 2005). Parents function as teachers of language, life skills, and culture, and they also protect children from immediate and anticipated dangers, seek medical attention for them, and soothe their anxieties, among many other functions. Given these many roles for development in normative and dangerous situations, a capable parent/caregiver is central to healthy development and resilience. Not surprisingly, the greatest threats to the early well-being and development of a child occur when the primary caregiver is lost, disabled, or unable to serve these roles, such as when a parent is killed or neglectful. In disasters or war, when children lose or are separated from caregivers, restoring contact or functions of this system is viewed as an emergency (Masten & Narayan, 2012).

Even worse is the situation when the caregiver her- or himself poses threats to the child, when a parent is the source of maltreatment or danger. This situation can pose double jeopardy to a child who faces adversity without the protection of a fundamental adaptive system in the form of an attached and capable caregiver. Nonetheless, even in the context of maltreatment, at least one good relationship with a caregiver shows protective effects on child function and development (Alink, Cicchetti, Kim, & Rogosch, 2009; Collishaw et al., 2007; Egeland, Carlson, & Sroufe, 1993; McGloin & Widom, 2001).

Given the salience of secure attachment relationships and the effective parenting that often accompanies these relationships, it is not surprising to find that interventions for high-risk children focused on restoring, improving, or otherwise bolstering the functions and quality of parenting have been successful. Interventions to improve parenting and foster care, for example, have shown efficacy in controlled experiments for promoting better outcomes in children at risk for behavior and emotional problems (e.g., Patterson et al., 2010; Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011; Toth & Manley, 2011).

Mastery Motivation and Self-Efficacy

A powerful reward system for adaptation and learning, often described as "mastery motivation," has been linked to both competence and resilience in development (Masten, 2014b; Masten et al., 1995). People get feelings of satisfaction and pleasure from perceptions of their own agency and accomplishments, evident from an early age. Toddlers newly able to walk or to run take great delight in what they can do. Robert White described this motivation for agency as "effectance" and experience of satisfaction that accompanied perceived effectiveness in the environment as "efficacy." White (1959) argued in a classic paper on this powerful biological system was naturally selected because of its value for adapting successfully. Other psychologists and developmental scientists have studied the apparent motivation for learning and adapting in psychological concepts of "self-efficacy" (Bandura, 1997) or "intrinsic motivation" (Ryan & Deci, 2000).

Individual children and adults who score high on mastery motivation measures or self-efficacy tend to respond to challenges or failures by persisting or trying again rather than giving up (Bandura, 1997). Hauser, Allen, and Golden (2006), in their book on teens who succeeded in the years following psychiatric hospitalization, noted the importance of "agency and the quest for mastery" in the youth showing a resilient pathway. Laub and Sampson (2003) similarly were struck in their follow-up research by the role of agency and satisfaction in the lives of the men from the famous longitudinal study of delinquency by Sheldon and Eleanor Glueck (1950) who were able to desist from a life of crime.

Parents and teachers often reinforce this system by providing opportunities for children to experience pleasure in their own accomplishments (Masten, 2014b). They break down learning and other challenges into manageable steps and encourage children to try on their own so that children get a sense of accomplishment and develop a can-do attitude toward challenges.

This system has been relatively neglected compared to some of the other prominent adaptive systems associated with resilience, yet it seems likely that many of the intervention programs that promote competence in parents or children are engaging this system and aligning with the natural reinforcement and pleasure that humans gain from attempting and succeeding in something challenging but doable.

Intelligence and Problem-Solving Capabilities

Since the earliest research on resilience, the capacity for problem-solving by children (or adults) also has been identified as a key promotive and protective factor for adaptive function and development, in both low- and high-risk situations (Luthar, 2006; Masten, Burt, et al., 2006). Intelligence tests were developed to predict adaptive success, particularly in a school context, so this finding also was not surprising (Masten, 2014b). Classic studies of resilience over the years have found that cognitive skills or assessed intellectual abilities forecast better adaptation among children from high-risk backgrounds, particularly in regard to better grades and fewer behavior problems (e.g., Loësel & Farrington, 2012; Masten & Tellegen, 2012; Werner & Smith, 1992, 2001). Good intellectual function appears to afford protection for children at risk for conduct problems, possibly through multiple pathways, including school success or engagement, better planning or self-regulation skills, and greater likelihood of affiliating with prosocial rather than deviant peers. Additional pathways arise from correlated promotive or protective factors that often accompany good cognitive functioning, including competent parents and socioeconomic advantages; children with good cognitive skills are more likely to have competent families, live in resource rich and safer neighborhoods, and attend better schools.

Highly aversive environments for child development may impair cognitive development through multiple pathways, beginning prenatally. What some investigators describe as "toxic stress" can undermine brain development and the potential of a child for resilience (Shonkoff, 2011). Better cognitive skills may well reflect better nutrition, health care, parenting, and opportunities to learn, all potentially mediated by healthier brain development and the development of specific cognitive and learning skills, including various aspects of memory and cognitive control. Good cognitive function and development in a context of very high risk may be an indication that multiple aspects of child development have been protected despite adverse childhood experiences.

Recent research on cognitive development and its role in resilience has focused particularly on executive function and other self-regulation skills, discussed in the next section, as well as the role of parent-child interaction and quality of early childhood education for the development of good cognitive and self-regulation skills and school readiness (Masten, 2014b). Interventions to promote competence and resilience in young children have targeted executive functions and early literacy or numeracy (Blair & Raver, 2012; Diamond & Lee, 2011; Zelazo & Carlson, 2012).

Self-Regulation

Resilience studies often report that more adaptive children and youth from high-risk or adverse backgrounds have better self-regulation skills compared to less successful peers (Zelazo & Carlson, 2012; Masten, 2014b). Self-regulation of attention, emotion, cognition, and action is associated both with current and future competence in achieving developmental tasks and also in responding effectively to adversity (S. M. Carlson, Zelazo, & Faja, 2013; Duckworth, 2011; Masten & Coatsworth, 1998; Rothbart, 2011). Research on self-regulation is burgeoning, although the ideas linking self-control to adaptive behavior date back more than a century to concepts of the ego in psychoanalytic theory (Masten, 2014b). The multifaceted job of the ego in this theory was to regulate internal experiences of anxiety and pleasure while ensuring that external adaptation to the environment (including the rule for social conduct) was appropriate.

Over the past decade, research on executive function (EF) skills has expanded rapidly, including basic investigations and intervention research (Zelazo & Carlson, 2012). What were originally developed as laboratory tests and methods to assess or boost EF skills have moved into classrooms, homes, and even emergency shelters for homeless families in research aimed at understanding nature and roles of these skills in high-risk populations (Masten et al., 2014; Zelazo & Carlson, 2012). Interventions to promote EF skills through teacher, parent, or child training show promise as strategies for promoting resilience among high-risk children.

Meaning-Making

Human capacity for imbuing life with meaning has been implicated in autobiographies on resilience and also in empirical studies. *Man's Search for Meaning,* Viktor Frankl's (1959/2006) account of survival in a concentration

camp during World War II, provides one of the most compelling accounts of human capacity for finding beauty and meaning in the midst of great suffering. Generations of readers, including school children the world over, have been moved by Anne Frank's diary, another classic example of human ability to construct meaning in a context of great adversity and the comfort that such beliefs can hold. The act of "telling the story" or constructing a narrative may be an important form of meaning-making in action for survivors of extraordinary trauma. A recent example is provided by Elizabeth Smart's 2013 book about her life in captivity after she was kidnapped, where she tells her story of anguish, faith, and survival (Smart & Stewart, 2013). In the book, Smart described how her faith in her family's love and her religion sustained her hope in the face of ongoing imprisonment, rape, and hunger.

Religions, and associated spiritual faith of individuals following a religious system, reflect shared systems of beliefs about the meaning of life, among many other protective practices and beliefs offered by cultural systems handed down across generations (E. Crawford, Wright, & Masten, 2006). Older youth and adults in resilience studies report that their spiritual faith and beliefs that life has purpose sustained them during period of great adversity or that a religious conversion marked a turning point in their lives (e.g., Elder & Conger, 2000; Werner & Smith, 1992, 2001).

Although religious beliefs and practices can apparently serve a protective role, religion also can lead to extremism and participation in violence (E. Crawford et al., 2006). Similarly, gang leaders and war leaders in political conflicts can provide meaning for life and may recruit young people, particularly adolescents, by exploiting the need for meaning in a context of despair and conflict (Masten, 2014b). Meaning-making, like other fundamental human adaptive processes, can be directed toward goals that other people would not view as evidence of resilience but rather as destructive or immoral. Findings in research on voluntary youth participation in political violence (see Barber, 2009, 2013) indicate that marginalized young people, otherwise hopeless or oppressed, may find a sense of purpose and feelings of mastery through their active participation in political conflicts, including acts of violence. One of the most provocative issues in contemporary resilience science, as well as for societies in search of peace, is the co-option of such adaptive systems for antisocial or violent purposes.

The concept of meaning making is complex, and the empirical literature on processes that may be involved lags behind the conceptual literature (Park, 2010). Moreover, little data on young people is available. In the theoretical literature focused on adults, a person's beliefs, goals, subjective sense of purpose, and motivation have been conceptualized as key elements of a global sense of meaning (Park, 2010). Even in the adult literature, it is not clear whether preexisting meaning, searching for meaning, or finding meaning in relation to a traumatic experience is important and how (Bonanno, Westphal, & Mancini, 2011).

One of the rare domains of research focused on meaning making in youth has investigated meaning in relation to identity development. McLean and Pratt (2006), for example, studied identity development and turning points in the transition years from adolescence into early adulthood. Their study spanned ages 17 to 23, including measures of identity status and optimism along with writing a narrative about important transitions or changes in life, called a "turning point narrative." These narratives were analyzed for meaning making through a qualitative coding strategy, with the authors concluding that their results corroborated other evidence that "the redemptive story sequence is associated with meaning. . . . The management of difficult life events by using meaning-making processes to find the good within the bad is important to the development of a healthy narrative identity" (p. 721). Redemptive meaning refers to finding meaning in suffering or adversity. McLean and Pratt also found that general optimism was associated with more mature narratives on meaning.

Narrative identity is a research domain focused on the processes and adaptive significance of observations that people construct narratives or stories about their lives that provide a sense of coherence and identity (McAdams & McLean, 2013). A salient theme in these narratives is what McAdams, McLean, and their colleagues refer to as "redemptive sequences," where a negative experience leads to some kind of positive outcome. Investigators of narrative identity often code constructs such as agency and meaning making in their qualitative analysis of narratives that have played a salient role in accounts and research on resilience. McAdams and McLean (2013) also noted the influence of culture on the personal narratives of young people.

Positive mood or subjective well-being has been linked to perceived meaning in life in the studies of narrative identity in youth (McAdams & McLean, 2013) as well as in adult research on meaning in life (King, Hicks, Krull, & Del Gaiso, 2006). The direction of the causal influence is not clear yet. In numerous accounts of resilience, beliefs that life has meaning are strongly associated with positive perspectives on the self and future.

Research on narratives about the self includes studies of neural processes that may be involved in constructing these narratives and also intervention studies. In a paper

on brains creating stories of selves, D'Argembeau and colleagues (2014) used functional magnetic resonance imaging (fMRI) to study neural processes during tasks of autobiographical remembering. Their results are consistent with the idea that there are individual differences in which aspects of neural function are engaged during personal narratives, with differences in self-reflectiveness playing a role. Their findings suggest possible neural processes linked to meaning making in the context of autobiographical memory.

Finally, it is interesting to note that some evidence-based interventions for youth who have experienced trauma combine a sharing of narrative with desensitization techniques. Narrative exposure therapy (NET) and the child version of this method (KIDNET) involve symbolic and narrative accounts of the life story combined with exposure techniques of desensitization. For example, using a rope to represent the life course, rocks (bad experiences) and flowers (good experiences) are laid out and gradually discussed. Narrative exposure therapy has been effective in controlled trials with recovering child soldiers (Ertl, Pfeiffer, Schauer, Elbert, & Neuner, 2011) and child survivors of disaster (Catani et al., 2009). This approach appears to involve "remaking" of personal narrative. It is conceivable that telling one's life story in a book, art, or film about a traumatic experience may have similar effects on trauma symptoms and/or well-being.

Positive Perspectives on the Self and the Future

Survivors of adversity and better-adapting subgroups in studies of resilience frequently report a positive outlook on self, life, and/or the future. These accounts often are retrospective, so it is difficult to know whether overcoming adversity or surviving led to positive feelings and beliefs or whether optimism and hope played a causal role in adaptation or recovery. Longitudinal studies of resilience also suggest that optimism and positive outlooks on life and the future at least accompany resilience, if they do not directly contribute to it (e.g., Werner & Smith, 1992, 2001).

Valerie Maholmes published a book in 2014 on fostering resilience in children and families in poverty subtitled: *Why Hope Still Matters*. In the book, she argues that hope is the "essential mindset" that makes it possible for individuals to show resilience in the face of the adversities associated with poverty. Hope, in Maholmes's view, motivates efforts to overcome adversity and strive for a better future.

In the view of Snyder and colleagues (1997), hope is a complex construct combining cognitive and motivational aspects. They created the Children's Hope Scale to measure this construct. In their view, hope is grounded in goals and agency, such that young people with higher hope scores would be expected to have conscious goals, perceive multiple ways to reach to their goals, and be motivated to work and persist in achieving these goals. To date there is very little longitudinal data directly testing the idea that hope or optimism functions directly as a moderator or promotive factor in resilience. However, in a longitudinal study of students age 10 to 18 by Valle, Huebner, and Suildo (2006), hope scores on the Snyder measure showed moderate stability over time and predicted life satisfaction and internalizing symptoms (controlling for starting levels of life satisfaction and symptoms). There also was an interaction of hope with stressful life events. These findings are consistent with the possibility that hope has promotive and protective roles in the context of negative life experiences, although there is a clear need for additional research with more independent assessment of hope, symptoms, life satisfaction, and life events, moving beyond self-reports.

Positive ideas and beliefs about self and future are often linked to competence, as noted in many reviews of both competence and resilience (e.g., Kirschman, Johnson, Bender, & Roberts, 2009; Luthar, 2006; Masten & Coatsworth, 1998). More research is needed on the processes that may underlie these associations. Additionally, it is interesting to note that positive affect, subjective well-being, and feelings of mastery or achievement are associated with resilience, given that several of the major adaptive systems purported to play a role in adaptive function and development have been linked to positive emotions and related neural reward systems. These systems include attachment, mastery motivation, and meaning-making. Reward systems are discussed further in the section on neurobiological processes.

CHILD-IN-CONTEXT RESILIENCE PROCESSES

In relational developmental systems theory, many aspects of the social context play crucial roles in the interactions that shape development. Resilience science long has emphasized the role of multiple interconnected systems in shaping adaptive capacity. However, during the past decade, research on social systems in resilience has surged, particularly in regard to family and cultural processes. In this section, we highlight advances in research on resilience focused on social contexts, with a particular emphasis on family, school, and cultural systems, where research has been growing.

Family Systems

Although resilience has been studied at the level of the family for decades, theory and research on family resilience has not been well integrated with the literature on individual child resilience (Masten & Monn, 2015). This state of affairs is somewhat surprising, given that the study of individual and family resilience share many roots, including general systems theory (von Bertalanffy, 1968). One explanation may be that, until recently, work in family resilience focused more on family therapy and practice; family resilience theory has distinct roots in family systems theory and therapy (Goldenberg & Goldenberg, 2013; Nichols, 2013; Small & Memmo, 2004; Walsh, 2006).

In research on individual child resilience, the family always was viewed as a key promoter and protector of development. In the field of family resilience, the focus is shifted to the adaptation of the family as a unit, with challenges that threaten family functions and protective processes that sustain family resilience or facilitate family recovery to full adaptive function (Masten & Monn, 2015; Walsh, 2011). Analogous to the two components for defining resilience in an individual, family resilience can be defined on the basis of family adaptation quality or success and stress or challenges to the family (Patterson, 2002). Proponents of family resilience as a concept highlighted family strengths and protective processes in their theories and practice to help families address or recover from major family stressors, including loss, marital conflict, maltreatment, economic crisis, and divorce (Nichols, 2013; Walsh, 2006, 2011).

Families also develop over time; face changing developmental tasks as they form, change, or dissolve; and follow varying pathways of adaptive function (Hawley & DeHaan, 1996; Masten & Monn, 2015). How well a family is doing in the developmental tasks defined at a family level can have profound consequences for children growing up in that family. The resilience of children often depends on the physical and emotional nurturance of their families as well socialization from the family; if the whole family system is stressed, then the adaptive capacity for a child in that family may well be affected.

From a child perspective, families serve as promoters and protectors of development. Families provide emotional security and a sense of belonging, which in turn support learning, exploration, self-efficacy, and social development in many different ways, according to both developmental theory (Bandura, 1997; Bowlby, 1969/1982; Cassidy & Shaver, 2008) and family theory (Goldenberg & Goldenberg, 2013; Walsh, 2006, 2011). Families nurture brain development, language and other cognitive skills, self-regulation skills, and also teach their children about their culture, all of which play key roles in the growing resilience of children throughout the course of childhood (Masten, 2014b).

Many of the most dangerous hazards faced by children arise in the family, when a parent is abusive or neglectful, or unfold when the family is unable to protect their children due to death, injury, health problems, separation, or extreme poverty (Cicchetti, 2013; Dubowitz & Poole, 2012; Masten et al., 2015). Family function in crucial family roles mediates many kinds of threats and also moderates (exacerbates or buffers) child experiences in adversity. The Family Stress Model developed by Conger and colleagues (Conger & Elder, 1994; Conger, Reuter, & Conger, 2000) and supported by their empirical work described how economic recessions affect family processes, cascading to influence how children or adolescents fare. Parenting effectiveness can be undermined by depression or by catastrophes affecting the family, such as job loss or a natural disaster that destroys the home or war that leads to forced migration (Masten, 2014b; Masten & Monn, 2015). Recent research also suggests that allostatic load in families can spread to other members of the family, as chronic stress takes a toll both on individuals and on the function of the family as a whole (Repetti, Robles, & Reynolds, 2011).

Nonetheless, evidence continues to accumulate that, in times of crisis, an effective parent can mitigate the impact of family illness or economic and other disasters on child function and development (Masten & Monn, 2015; Walsh, 2013). Intervention research that aims to support parents or families in their family roles provides strong evidence that good parenting matters and also that intervention effects can spread to affect other family members (e.g., Fisher, Gunnar, Dozier, Bruce, & Pears, 2006; Patterson et al., 2010; Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011).

One of the ways that families work to mitigate stress is by maintaining family routines and regulatory roles, even in times of turbulence or after disaster (Fiese, 2006; Masten & Monn, 2015; Walsh, 2006). Family routines of everyday life, such as family meals or bedtime rituals, can be reassuring or calming to children. In contrast, chaotic family organization with little or no routine is viewed as a marker of family dysfunction that is highly stressful for children (Evans & Wachs, 2009).

In multiple respects, families can function as an external regulatory system until children develop their own self-regulatory capacity for handling challenges (Masten & Monn, 2015). Beeghly and Tronick (2011; Tronick &

Beeghly, 2011) described how coregulation processes of interaction in infancy shape the development of child self-regulation. There is growing interest in capturing these coregulation processes in research on the family processes associated with the development of competence and resilience in adversity (Herbers, Cutuli, Supkoff, Narayan, & Masten, 2014).

Families also transmit cultural practices and traditions that can promote competence and resilience in their children in multiple ways (Harkness & Super, 2012; Masten & Monn, 2015; Ungar, 2012; Ungar, Ghazinour, & Richter, 2013). These are discussed further in the subsequent section on cultural systems.

As the role of families in child resilience grows, there is increasing appreciation of the idea that communities and societies can support family resilience in order to promote or protect the well-being of children at risk of harm. Families can be supported in their role as nurturers of child resilience and moderators of child stress. In the disaster field, for example, there is widespread recognition that family resilience and child resilience are linked, and disaster preparedness and response have changed as a result of this perspective (Masten et al., 2015). Efforts by communities or societies to support child resilience through family-or community-based efforts also underscore the importance of resilience in larger social systems for both family and child resilience (Becvar, 2013; Conger & Elder, 1994; Masten & Narayan, 2012; Norris, Stevens, Pefefferbaum, Wyche, & Pfefferbaum, 2008; Walsh, 2006).

The Special Roles of Schools in Child Resilience

In most societies of the world, education systems play an enormous role in child development. School is the most organized system outside the family where children spend large amounts of their time (Eccles & Roeser, 2012). It is not surprising, therefore, that the school context holds great interest in resilience science.

Schools have multiple roles in nurturing resilience (Masten, 2014b). Schools are charged with the development of competence as defined by the community and society supporting the school. Through formal education, children learn and hone many of the psychological skills that will foster resilience later in development, including self-control and problem-solving skills. They acquire knowledge of information and values important for life in their community or culture, along with reading and mathematical skills. Schools can provide positive adult role models, routines, food, health care, opportunities to develop a talent, and other important resources or interactions missing from the lives of some children.

Effective schools, classrooms, and teachers have qualities similar to effective parents or families. These include a positive and supportive atmosphere, rules and structure, high expectations, and strong leadership (Bandura, 1997; Cohen, 2013; Doll, 2013; Doll, LeClair, & Kurien, 2009; National Research Council and Institute of Medicine, 2004; Rutter & Maughan, 2002). Schools also provide opportunities for children to experience mastery through guided and scaffolded steps as well as opportunities for relationships with competent adults outside the family.

Children spend so much time in school that numerous intervention programs have been designed for implementation in a school context or through after-school programs. One example is the Life Skills Training program developed by Botvin and colleagues (Botvin & Griffin, 2004; Botvin & Tortu, 1988), a universal school-based intervention designed to prevent substance abuse, with a strong emphasis on building social competence along with specific skills and attitudes for resisting drug use. The Seattle Social Development Project is another school-based intervention with good evidence of efficacy for promoting achievement and reducing risks of antisocial behaviors, based on fostering positive processes of school engagement and relationships (e.g., Hawkins, Kosterman, Catalano, Hill, & Abbott, 2005). Similarly, "Check and Connect," another efficacious program developed by Christenson and colleagues (Anderson, Christenson, Sinclair, & Lehr, 2004; Christenson et al., 2008) successfully has reduced truancy and school dropout by building school engagement through positive relationships. Recent meta-analyses also suggest that after-school and summer programs are effective, particularly for high-risk children (Durlak et al., 2010; Lauer et al., 2006).

There also is considerable research focused on preparing children to be more effective in school through preschool education and prevention programs. Head Start REDI (research based and developmentally informed) was designed to boost the effectiveness of Head Start programs by enhancing the curriculum, teacher training, and materials for families. Results indicate that this program is effective in promoting better social and emotional function as well as academic skills in high-risk preschoolers (Bierman, Domitrovich, et al., 2008; Bierman, Nix Greenberg, Blair, & Domitrovich, 2008). The Chicago School Readiness Project developed by Raver and colleagues (2011) for Head Start classrooms also showed efficacy in a randomized controlled trial, with a specific focus on targeting self-regulation skills as a strategy for improving

school readiness. This intervention is a successful example of recent efforts to promote resilience by improving self-regulation skills, particularly during developmental windows of opportunity, including the preschool years (Diamond & Lee, 2011; Zelazo & Carlson, 2012). The preschool years appear to be a developmental window when there is considerable brain plasticity for acquiring and improving self-regulation capabilities that provide a foundation for learning in school.

Schools routinely function to nurture human capital and provide resilience-building resources and opportunities for children from typical and disadvantaged backgrounds. However, schools also serve as a powerful symbol of recovery in the aftermath of disasters (American Psychological Association, 2010; Masten & Narayan, 2012; Masten et al., 2015). Reestablishing the routine of school for children is now widely recommended as a crucial restorative step after disasters, symbolizing that recovery is under way.

Finally, it should be noted that schools are a major "crossroads" where many important systems of child development intersect and interact, including society, community, culture, family, peers, and individuals. In addition to multiple forms of learning and socialization, many processes of acculturation also occur in the school context. Thus, schools can influence the processes that contribute to peace or conflict among cultures and peoples (Leckman, Panter-Brick, & Salah, 2014) as well as the future economic viability of a society (Lundberg & Wuemrli, 2012). Such macro-level processes in turn can alter the future resilience of children and families.

Social Networks and Peers

Play, social interaction, and friendships with peers are universal contexts of child development, and social competence with peers is widely recognized as a fundamental developmental task domain beginning in childhood (Hartup, 1996; Hartup & Stevens, 1997; Ladd, 2005; Masten & Coatsworth, 1998). Positive relationships of children with their parents forecast better peer relationships. Once children go to school, their relationships with teachers also are associated with more positive peer relations (Bierman, 2011; Hart, 2012). Interventions at school have successfully targeted peer ecology and interactions, for example, to enhance social-emotional skills (e.g., Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011) or reduce intergroup conflict (Beelmann & Heinemann, 2014).

Despite the salience of the peer context in development, there has not been much focus on the potential protective influence of peer relationships in the resilience literature. One exception can be found in the literature on antisocial behavior, where studies show a positive role of peers among high-risk children and youth with respect to delinquent behavior and violence. Having a nondeviant good friend or peer group has shown protective effects (Lösel & Farrington, 2012). Similarly, there is some evidence that high-risk adolescents who report positive peer support have better academic achievement. Gutman, Sameroff, and Eccles (2002) found that peer support moderated risk for math achievement among African-American seventh-grade students, with a significant interaction effect suggesting that peer social and academic support had a protective role at high levels of cumulative risk.

Peers also play an important role in the lives of immigrant youth in the classroom. Motti-Stefanidi (2014) and her colleagues have studied changes in peer acceptance in Greek classrooms with immigrant youth, observing that intergroup contact appears to improve peer acceptance, consistent with bidirectional acculturation effects.

Nonetheless, there continues to be a paucity of research on peer roles in resilience, which is surprising, given the large literature on peer relations in developmental science. Peers appear to be studied more often as risk factors or accelerators of risky behaviors than they are studied as protective influences (Dishion & Tipsord, 2011; Steinberg, 2008). Yet, as Dishion and Tipsord (2011) noted, there is no reason to expect that "peer contagion" or similar processes by which peers influence development would only be negative. Although there is evidence of positive roles of peers in the context of risk or adversity, the role of peer systems in resilience, either at a dyadic or larger group level, needs further study.

Cultural Systems

Over the past decade, research on resilience grounded in cultural context expanded rapidly, after decades of relative neglect (Masten, 2014a, 2014b; Ungar, 2012; Ungar et al., 2013; Wachs & Rahmann, 2013). There was more research on resilience in diverse cultures as well as efforts to understand the roles of cultural processes in resilience. The Resilience Research Centre in Halifax, Nova Scotia (see resilienceresearch.org), led two major programs to foster cultural perspectives on resilience in multiple countries and cultural contexts. A multinational team developed a new measure of youth resilience and initiated a study of about 1,500 youth across five continents, using a combination of quantitative and qualitative methods (Ungar, 2008; Ungar, 2012; Ungar & Liebenberg, 2005). This body of work has indicated common and unique promotive/protective

processes in different cultures. Common protective influences reported in many cultures include relationships (good parenting, mentoring), cultural belonging (grounded in cultural traditions), and individual characteristics, such as problem-solving or self-efficacy. As part of the Resilience Pathways Project, Theron, Theron, and Malindi (2013) contributed qualitative descriptions of resilience in Basotho youth in South Africa; their work illustrates the importance of *Botho* in this culture, a philosophy of life akin to *Ubunto* in other African cultures, where raising children is a collective enterprise and great value is placed on human interdependence, harmony, spirituality, and humanitarian practices. Youth identified as showing resilience by adults in the Basotho community were described as flexible, determined, skilled as communicators, connected to the community, respectful of community values, and accepting of things they could not control, among other qualities.

Books and articles focused on risk and resilience in low-and middle-income countries have proliferated over the past decade. These included a volume on early childhood development sponsored by UNICEF in collaboration with the Society for Research in Child Development (Britto, Engle, & Super, 2013) and another focused on risk and resilience in the face of the international economic crisis that was sponsored by the World Bank (Lundberg & Wuermli, 2012).

Research on immigrant youth and processes of acculturation also expanded rapidly at the same time. Many books and articles on immigrant youth have focused on resilience, perhaps because this is an issue of global significance for many receiving nations, with many societies depending on the well-being and success of immigrants (e.g., Masten, Liebkind, & Hernandez, 2012; Motti-Stefanidi, 2014). *Realizing the Potential of Immigrant Youth* (Masten et al., 2012) is an edited volume summarizing recent research in this area.

Multicultural societies have a vested interest in preventive and protective interventions to reduce the impact of discrimination on young people and its corrosive collective effect on society itself. There is growing research on strategies for parents, schools, and communities that reduce cultural and intergroup conflicts and foster resilience of young people in the context of discrimination (Evans et al., 2012; Fisher, Busch-Rossnagel, Jopp, & Brown, 2012; Hughes et al., 2006; Masten et al., 2012; Serafica & Vargas, 2006; Ungar et al., 2013; Ungar et al., 2013). Sirin and Gupta (2012) described the resilience of Muslim-American youth in the aftermath of 9/11, a challenging time for multicultural youth of Muslim heritage to navigate, documenting the success of young people who manage to reside happily "on the hyphen." Motti-Stefanidi and her colleagues, as noted, have studied risk and resilience among immigrant youth in Greece, which has received large numbers of immigrants from the former Soviet Union and neighboring Albania. Using hierarchical linear modeling of longitudinal data, their studies have illustrated changes in self-perceptions and peer interactions over time and the complex ways that classroom context, culture, and individual differences may influence change over time as development and acculturation proceed in concert (Motti-Stefanidi, 2014).

Research on resilience in diverse cultures can be a highly challenging endeavor. Panter-Brick, Eggerman, and colleagues (Eggerman & Panter-Brick, 2010; Panter-Brick, Goodman, Tol, & Eggerman, 2011) have studied resilience in the Afghan people as they suffered through years of political conflict. Despite considerable danger and instability, this team was able to carry out a large study of adolescents and their families, following subgroups over time to gain quantitative data along with rich ethnographic information. Their work emphasized the importance of Afghan values for their resilience, including faith, family unity, service, effort, morals, and honor.

Similarly challenging studies of resilience in wars and disasters have been undertaken around the world over the past decade (Masten, 2014a; Masten et al., 2015). These include studies of recovering child soldiers from Sierra Leone (Betancourt et al., 2010, 2013), Palestinian youth engaged in the Intifada (Barber, 2008), and disaster survivors after the 2004 tsunami in the Indian Ocean (e.g., Catani et al., 2009), Hurricane Katrina and the subsequent Gulf oil spill (Osofsky& Ososfky, 2013), the Sichuan earthquake in China (e.g., Luo et al., 2012), and studies under way of the triple disaster in Japan in 2011 (earthquake, tsunami, Fukushima meltdown (Latif, Yeatermeyer, Horne, & Beriwal, in press).

Religions are one form of cultural tradition that appears to engage many of the same adaptive systems identified as protective influences in studies of individual resilience (E. Crawford et al., 2006; Masten, 2014b). These systems include relationships, with both spiritual figures and religious leaders and with counselors, rituals to ease the pain of loss and other suffering, belief systems that give people a sense of higher purpose and meaning, and customs of social and material support for members of the religious community and the less fortunate. Religions also codify rules for living and rearing children, passing on values that their members believe will result in good behavior and success in life as defined by the religion.

Yet, like other adaptive systems, cultural systems, including religious ideas and practices, can be harmful or

dangerous to children and child development, leading to self-destruction or violence, for example. One of the great global challenges facing the world today is addressing the violence to and by children under the banner of radical religious factions or tribal affiliations. Global concerns about the numbers of children affected by war and conflict are giving rise to a growing literature on peace and peacebuilding in childhood (see Leckman et al., 2014).

Other Macro-Level Systems and Resilience

Other macrosystems implicated in threatening or supporting child resilience include communities and societal policies as well as mass media and social media (Masten, 2014b). Communities, societies, and media appear to influence resilience in multiple ways, although these processes have received less attention. For example, there is convincing research on the positive effects of economic policies, such as the Earned Income Tax Credit in the United States, showing that tax policies can have measureable benefits for child development (Duncan, 2012). The roles of community preparedness and media have been extensively considered in research and evaluation studies on the impact and recovery of children and families in disasters and war (Masten et al., 2015). Resilience of immigrant youth living in countries that vary in supports and cultural acceptance of immigrants also has been studied (Fuligni & Telzer, 2012; Masten et al., 2012).

Discussion of this expanding and diverse literature is beyond the scope of this chapter. However, it is clear that there is growing interest in research pertinent to resilience that extends across system levels and increasing appreciation of the interconnectedness of resilience among interacting systems. Child resilience depends on family resilience and many other systems that support the development and protect the function of children and families at macro-levels of the socioeconomic and physical ecology. New technologies, including social media, are changing many of these systems in ways that are difficult to study. New horizons of research for resilience science continue to appear.

NEUROBIOLOGICAL PROMOTIVE AND PROTECTIVE PROCESSES

Over the past decade, research on the neurobiology of resilience, long called for and anticipated, finally began in earnest (Cicchetti, 2010, 2013; Charney, 2004; Curtis & Cicchetti, 2003; Kim-Cohen & Gold, 2009; Feder, Nestler, & Charney, 2009; Masten, 2014a, 2014b; Southwick, Litz, Charney, & Friedman, 2011). This surge, which played a central role in propagating the "fourth wave" of resilience science, resulted in large part from major advances in the tools for research at genetic and neurobiological levels of analysis, including such breakthroughs as imaging the brain in action, measuring genes and their functional status, practical measures of stress hormones and other neurobiological variables, and the statistical means to analyze enormous quantities of complex data.

Work is proceeding on multiple fronts relevant to resilience. Only a few can be highlighted here. In this section, we describe selected research on the neurobiological processes related to the psychosocial adaptive systems strongly associated with resilience (discussed earlier in this chapter), examples of genetic studies opening new horizons for resilience science, and other promising directions for multiple-levels research on resilience that incorporates biological processes.

Neurobiological Research on Adaptive Systems Implicated in Resilience

Major psychological adaptive systems associated with resilience include attachment and caregiving, problem-solving, self-regulation, and mastery motivation. Research at the neurobiological level is beginning to illuminate how these processes develop and protect human function and development.

Meaney's groundbreaking work on the biological and behavioral effects of parenting by rat mothers on their pups was already mentioned (Meaney, 2010). Similar research on the role of caregiving in the development of stress, gene expression, and resilience or vulnerability to adversity has been conducted with primates (Stevens, Leckman, Coplan, & Suomi, 2009; Suomi, 2006, 2011). Powerful cross-fostering designs in both animal models (rodents and primates) have shown the effects of parenting and attachment bonds on individual function and development and gene expression as well as the interplay of individual differences.

There is a substantial body of work on social buffering of stress in relation to the hypothalamic-pituitary-adrenocortical (HPA) axis, based on both animal and human studies (Hostinar, Sullivan, & Gunnar, 2014). In addition, research on the "biochemistry of love" by other investigators has shown how oxytocin and vasopressin contribute to processes of social affiliation and attachment behavior in animal models and in humans (Adolphs, 2009; Carter & Porges, 2013, 2014; Porges, 2011). Carter and

Porges (2013) have posited that oxytocin plays many roles in adaptation, not only including its well-known roles in birth and lactation, but also in attachment behaviors and neurogenesis. Their ideas have been explicitly tested in prairie voles, animals that show strong attachment bonds.

There also have been many advances in understanding how chronic stress affects neurocognitive development, with investigators highlighting the "toxic" effects of severe and prolonged adversity in early development (pre-and postnatal; Gunnar & Herrare, 2013; Shonkoff, 2011). Concomitantly, neurobiological research is emerging on the protective effects of interventions on brain development, theoretically mediated by altering various processes that mitigate negative effects of stress on brain development. Experimental studies of preventive interventions to provide support higher-quality caregiving, nutrition, stimulation, and other key elements of nurturing environments have shown protective effects on brain function and corresponding cognitive skills among high-risk children (e.g., Fisher, Van Ryzin, & Gunnar, 2011; Fox, Almas, Degnan, Nelson, & Zeanah, 2011; Fox, Nelson, & Zeanah, 2014; Nelson et al., 2007; Rutter, Sonuga-Barke, & Castel, 2010). Baker, Salinas, and Eslinger (2012) suggest that school is increasingly viewed as a "neurocognitive-developmental institution."

Research on the neurobiology of self-regulation processes often implicated in resilience also is burgeoning. Examples of hot areas include work on executive function and mindfulness (S. M. Carlson et al., 2013; Zelazo & Carlson, 2012; Zelazo & Lyons, 2011) and stress regulation involving processes linked to the HPA system (Feder et al., 2011; Gunnar & Herrare, 2013; Karatsoreos & McEwen, 2011, 2013; McEwen & Gianaros, 2011).

Research on reward systems linked to resilience processes such as mastery motivation also is expanding, although these systems are highly complex. Activation of the dopaminergic reward system, for example, has been linked to positive emotions and motivation associated with resilience as well as to exploratory behavior and learning (Feder, Charney, & Collins, 2011; DeYoung et al., 2011). However, reward systems also play important roles in negative adaptive behaviors, such as maladaptive drug use (Volkow et al., 2011).

Molecular Genetic and Neurobiological Processes

Empirical investigations of resilience over the past four decades have examined a wide range of psychosocial correlates and contributors to resilient functioning. In recent years, a number of scientists have urged researchers studying the determinants of resilience to incorporate molecular genetic and neurobiological measures into their investigations of the developmental pathways to resilient functioning (Charney, 2004; Cicchetti, 2010, 2013; Cicchetti and Blender, 2006; Curtis & Cicchetti, 2003; Feder, Nestler, & Charney, 2009; Masten, 2007, 2014; Sapienza & Masten, 2011).

Since the onset of the millennium, increasing research has been conducted to discover the contributions that genetics and neurobiology might make to promoting resilience in individuals experiencing severe adversity (Curtis & Cicchetti, 2003; Kim-Cohen & Gold, 2009; Masten & Obradović, 2006). This shift in research from predominantly psychosocial models to those including biological aspects of resilience was spurred by the groundbreaking research on GxE interactions conducted by Avashalom Caspi, Temi Moffitt, and their colleagues (e.g., Caspi et al., 2002, 2003).

A high percentage of GxE interaction research conducted to date has demonstrated that child maltreatment is a strong candidate environmental pathogen (Caspi, Hariri, Homes, Uher, & Moffitt, 2010; Karg, Burnmeister, Shedden, & Sen, 2011). Maltreatment is an objectively measured, well-defined stressor, and meta-analyses have shown that robust findings in GxE investigations are more likely to occur when a specific stressor is identified (Karg et al., 2011). Much of the GxE research in the past decade relevant to resilience has focused on how genes may serve as protective factors against developing psychopathology in individuals who have experienced maltreatment.

In a longitudinal investigation, Caspi et al. (2002) first documented that the association between child maltreatment and later antisocial behavior was moderated by a functional polymorphism in the promoter region of the gene encoding the monoamine oxidase A (MAOA) enzyme. Specifically, they discovered that maltreated children whose genotype conferred low levels of MAOA expression had significantly higher levels of antisocial behavior in adolescence and adulthood compared to similar-aged maltreated individuals who carried the high-activity version of the MAOA gene.

In a subsequent longitudinal study, Caspi et al. (2003) found another GxE interaction involving a functional polymorphism in the promoter region of the serotonin transporter (5-HTT) gene. Individuals who had high stressful life events and/or child maltreatment and who had one or two copies of the 5-HTTLPR "short" allele (S or SS) had more depressive symptomology, higher rates of diagnosable depression, and more suicidality than similarly stressed individuals with two copies of the 5-HTTLPR

"long allele" (LL). In both of the Caspi et al. studies (2002, 2003), genetic variation had little or no relation to the mental health outcomes in individuals who had not experienced adversity.

Since the publication of Caspi et al.'s (2002, 2003) seminal investigations, there have been numerous GxE studies indicating that genetic variants in a number of genes, including MAOA, 5-HTTLPR, corticotropin-releasing hormone receptor gene (CRHR1), the oxytocin receptor gene (OXTR), and the dopamine receptor D 4 (DRD4) gene, may confer protection against various forms of psychopathology in individuals who have experienced maltreatment or early adversity, such as institutionalization (see, e.g., Bakermans-Kranenburg & van IJzendoorn, 2008; Bradley et al., 2011; Cicchetti, Rogosch, & Oshri, 2011; Dackis, Rogosch, Oshri & Cicchetti, 2012; DeYoung, Cicchetti, & Rogosch, 2011; Gunnar et al., 2012; Hostinar, Cicchetti, & Rogosch, 2014; Kaufman et al., 2004, 2006; Polanczyk et al., 2009). However, it is important to recognize that the absence of psychopathology is conceptually distinct from competent functioning. Consequently, in order to increase the relevance of GxE research for discovering the determinants of resilience, such investigations must go beyond relying solely on the absence of psychopathology. These studies also should include measures of competence that are likely to be influenced by genotypic variation.

GxE studies have focused predominately on how genotypic variants may moderate the effects of environmental pathogens. However, genes also may moderate positive health-promoting environments (Kim-Cohen & Gold, 2009). As such, it is important to conduct GxE research in these environmental contexts. Furthermore, the effects of the interaction of genetic and environmental factors may vary depending on the stage of development (Sroufe, 2013).

One of the first published GxE studies that explicitly investigated the relationship between genetic variants and resilience was conducted by Cicchetti and Rogosch (2012). These investigators' research examined whether experiences of child maltreatment in interaction with gene variants of specified candidate genes were related to adaptive functioning. A multicomponent index of adaptive functioning was identified in the sample of maltreated and nonmaltreated school-age children from disadvantaged backgrounds. The genetic variants of HTTLPR, CRHR1, DRD4 -521 C/T,and OXTR were investigated. These candidate genes were specifically selected for their link to behaviors associated with resilience.

An adverse main effect on adaptive functioning was consistently observed for maltreatment. Although a main effect was not shown for any of the gene variants investigated, this study identified GxE interaction effects. Nonmaltreated children with the SS genotype variant of 5-HTTLPR were significantly more likely to have higher adaptive functioning while maltreated children with the same genetic variant had significantly less adaptive functioning. Analysis of the CRHR1 genotypes presented similar findings in the comparisons between children with zero, one, or two copies of the TAT haplotype. A crossover interaction presented a differential susceptibility to environmental influences interpretation (Belsky, & Pluess, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011) for those children with zero copies of the TAT haplotype in that they exhibited better adaptation in the context of nonmaltreatment and worse adaptation with maltreatment. Analysis of the OXTR gene variants contrasting the GG with the AA or AG genotypes produced similar results, but they were only marginally significant.

Analyses of the DRD4 -521C/T single nucleotide polymorphism (SNP) revealed a different pattern. The interaction (contrasting the TT genotype group with CC or CT genotypes) suggested that for this candidate gene, variations in genotype were more important for *nonmaltreated* children. Nonmaltreated children with the TT genotype were more likely to exhibit the highest level of adaptive function. In the context of maltreatment, which had a main effect on adaptive function, genotype variation did not appear to matter.

In further analyses, Cicchetti and Rogosch (2012) examined the relation between number of maltreatment subtypes as well as specific subtypes of maltreatment in relation to DRD4 -512C/T genotype in predicting adaptive function. Maltreated children who had experienced three or four subtypes fared dramatically worse with the TT genotype, whereas nonmaltreated children with this genotype fared the best. These results are congruent with a differential susceptibility role of the TT genotype of DRD4 -521C/T in relation to environmental variations in maltreatment.

Cicchetti and Rogosch (2012) identified different gene variants as differentially important through contrasting maltreated and nonmaltreated children in relation to adaptive function. Genotype was not generally related to adaptive function unless context was taken into account. Maltreatment, in contrast, appeared to have powerful negative main effects for adaptive function.

It is important to note that despite the multidomain assessment of adaptive functioning and the large, well-defined sample of maltreated and nonmaltreated

children, a limitation of this study was its cross-sectional nature. Given that resilience is a dynamic developmental construct that is not immutable, future investigations of gene–environment interaction and resilience should have a prospective, longitudinal, and developmentally sensitive design (Luthar, 2006; Luthar et al., 2000).

It also is important to acknowledge that other biological systems are negatively impacted by abuse and neglect (Cicchetti & Toth, 2015; DeBellis, 2001, 2005). Differences in brain structure and function (Hart & Rubia, 2012; McCrory et al., 2010), stress neurobiology, (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Doom & Gunnar, 2013; Heim et al., 2008; Trickett et al., 2008) and immunological processes (Danese et al., 2008; Miller et al., 2011) are not innate features of children but rather are consequences of child maltreatment.

Maltreatment experiences also may influence other developmental processes, including epigenetic processes involving the extent to which genes are expressed (Tyrka, Price, Marsit, Walters, & Carpenter, 2012); however, these effects are not examined when focusing exclusively on GxE interaction. Future investigations of molecular genetic contributions to resilience also should pay more attention to the process of development (D). These GxE, GxD, and DxExD studies could discover how a particular genotype may operate differently depending on developmental period or environmental period or environmental context (see Sroufe, 2007). Moreover, genotypic variation for genes other than those utilized in the Cicchetti and Rogosch (2012) investigation may be related to higher resilient functioning in maltreated children. Thus, broader approaches to genetic influences associated with resilience in maltreated children must occur.

Epigenetic Studies of Resilience

Epigenetic research pertinent to resilience is rapidly expanding, although it likely will take some time for this knowledge base to mature. The field of epigenetics has demonstrated that DNA is not the static entity it was once thought to be (Mill, 2011). Epigenetics is the study of heritable changes in gene function that do not alter the DNA sequence but instead provide an extra layer of transcriptional control that regulates gene activity and plays an important role in the acute regulation of genes in response to environmental changes. Research on epigenetic processes hold high promise both for basic research investigations and translational intervention research on the determinants of resilience, providing a potential mechanism by which environmental experiences (natural or in the form of intervention) may exert their impact on gene expressions that can last throughout the life span or even across generations (Lenroot & Giedd, 2008).

Epigenetic mechanisms may be a realistic target for intervention due to their reversibility (Ramchandahl, Bhattacharya, Cervoni, & Szyf, 1999). However, some epigenetic changes are long lasting across the course of development. Moreover, some of these methylation changes can be transmitted across generations (Roth, 2013). Research on early adversity, such as child abuse and neglect and living in impoverished environments, has demonstrated that there are individual differences in DNA methylation patterns. Methylation assays can be conducted genome-wide or at site-specific regions of candidate genes whose functional properties are known. For example, several investigations have used a candidate gene approach to examine the effects of child maltreatment on methylation. Epigenetic regulation is a viable candidate mechanism through which caregiving behavior, including child maltreatment, may exert long-term effects on HPA axis activity and neuronal function (Szyf & Bick, 2013). Candidate genes utilized in this regard include the serotonin transporter gene (5-HTT), the glucocorticoid receptor gene (NR3C1), and the binding protein 5 gene (FKBP5). These studies have found that child maltreatment was associated with increased methylation in both the serotonin transporter and the glucocorticoid receptor genes (see Yang et al., 2013). Increased methylation (hypermethylation) is commonly associated with decreases in gene expression. Decreased methylation (hypomethylation) is associated with increases in gene expression—often of genes that should *not* be expressing.

Epigenetic mechanisms may help to elucidate pathways of risk and resilience and illuminate how interventions work. The dynamic nature of epigenetic processes demonstrates that genetic influences on behavior are responsive to experience and the environmental surround. Protective factors in the environment may bring about alterations in gene expression and thereby set in motion a cascade of positive adaptation to stress that is promotive of resilience (Bowes & Jaffee, 2013; Masten & Cicchetti, 2010c).

Multiple-Levels in Developmental Reorganization and Plasticity

As emphasized throughout this chapter, several cogent and extensive summaries of resilience theory and research have been published that have explicated the need to examine the processes leading to resilience from multiple levels of analysis, in particular from the level of brain and neurobiological functioning (Cicchetti, 2010, 2013; Cicchetti &

Blender, 2006; Feder, Nestler, & Charney, 2009; Luthar, Cicchetti, & Becker, 2000; Masten, 2001, 2007, 2014b). Advocates of a self-organizing systems theory viewpoint of neurobiological and psychological development contend that individuals actively participate in the creation of meaning by structuring and restructuring experience through self-regulated mental activity (Cicchetti & Tucker, 1994; Mascolo, Pollack, and Fischer, 1997). Early experience and prior levels of adaptation neither doom the individual to continued maladaptive functioning nor inoculate the individual from future problems in functioning. Change takes place in a system as new needs and environmental challenges destabilize the existing organizations, necessitating the emergence of new organizations that may prove to be more adaptive than the preexisting ones in the current context. The reorganizations that occur both within and between developmental domains (e.g., between emotion and cognition) provide critical opportunities for changes in capacity for adaption, thus influencing prospects for resilience (Cicchetti & Tucker, 1994).

The reorganization that takes place is often dramatic, with observable changes in the neural substrate that are translated into changes observable at the behavioral level (Cicchetti, 2002; Curtis & Nelson, 2003). The brain can change in a number of ways, including: (a) endogenous changes that take place in the organization of the remaining intact circuits in the brain; (b) the generation of new neural circuitry; (c) dendritic outgrowth and the formation of synapses; (d) the strengthening and weakening of some neural circuits through the processes of synaptogenesis and synaptic removal, respectively; (e) the sprouting of new axons, regenerating old ones, or elaborating their dendritic surfaces; and (f) the generation of new neurons and glia to replace at least some lost neurons (Cicchetti, 2015; Kolb & Gibb, 2001). Such central nervous system changes that are the hallmarks of plasticity can occur on one or more levels of analysis, including molecular, cellular, neurochemical, and anatomical and at the level of brain systems (van Praag, Kempermann, & Gage, 2000; Nelson, 1999). Plasticity also plays a prominent role in neurodevelopmental processes (Cicchetti & Cannon, 1999; Cicchetti & Walker, 2003; Cowell, Cicchetti, Rogosch, & Toth, 2015).

Biological factors influence psychological processes; however, social and psychological experiences also exert actions on the brain by feeding back upon it to modify gene expression and brain structure, function, and organization (Cicchetti & Tucker, 1994; Eisenberg, 1995; Kandel, 1998; Kolb & Wishaw, 1998). It has also been discovered that alterations in gene expression induced by learning and through social and psychological experiences produce changes in patterns of neuronal and synaptic connections and thereby in the functioning of nerve cells (Kandel, 1998). Such neuronal and synaptic modifications not only exert a prominent role in initiating and maintaining the behavioral changes that are provoked by experience but also contribute to the biological bases of individuality, as well as to individuals being differentially affected by similar experiences, regardless of their positive or negative/adverse valence (Kandel, 1998). Because the brain is only diffusely structured by gene-driven processes and the eventual differentiation of the brain is very reactive to the individual's active coping in a particular environment, the normal, abnormal, and resilient outcomes of this developmental process should encompass a diverse range of neural, synaptic, and associative networks that are the physiological determinants of many possible individual psychological organizations (Cicchetti, 2007; Kandel, 1998).

Diversity in process and outcome are hallmarks of the developmental psychopathology perspective (Cicchetti, 1990; Cicchetti & Rogosch, 1996; Sroufe, 1989). The application of equifinality to resilience requires that researchers must understand that the maintenance or improvement in a system's function, just as is true with its breakdown, can occur in many ways, even in the face of significant adversity. In particular, because the organizational model of development that undergirds much research in developmental psychopathology and resilience takes into account environment-organism interactions and transactions, it becomes quickly apparent that a variety of developmental progressions may eventuate in maladaptive or adaptive outcomes (Luthar et al., 2000). Clearly, biological and psychosocial factors both can play a role in the pathways to diverse outcomes. Furthermore, the relative contributions of biological and psychosocial contributions to these diverging pathways will vary among individuals.

Likewise, the concept of multifinality alerts resilience researchers to the fact that individuals may begin on the same major developmental trajectory and, as a function of their subsequent "choices" or experiences, exhibit very different patterns of maladaptation or adaptation (Cicchetti & Rogosch, 1996; Sroufe, 1989; Sroufe, Egeland, & Kruetzer, 1990). Pathways of psychopathology or resilience are influenced by a complex matrix of the individual's level of biological and psychological organization, current experience, social context, timing of the adverse event(s) and experiences, and developmental history.

As the developmental process proceeds, neural plasticity appears to be guided by events that provide information to be encoded in the nervous system (Greenough, Black, &

Wallace, 1987). These experience-dependent processes involve the adaptation of the brain to information that is unique to the individual. An important central mechanism for experience-dependent development is the formation of new neural connections. Because all individuals encounter distinctive environments, each brain is modified in a singular fashion. This variability in experience-dependent plasticity is likely to emanate from existing differences between neural subsystems in rates of maturation, the extent and timing of redundant connectivity, and the presence of the neuromodulators and receptors that are critical for neural modifiability. Unlike the case with experience-expectant processes, experience-dependent processes do not take place within a stringent temporal interval because the timing or nature of experience that the individual engages or chooses cannot be entirely and dependably envisioned (Black, et al., 1998; Cicchetti, 2002).

Given that experience-dependent processes can occur throughout the life span, social interactions, behavioral interventions, and pharmacotherapy, in conjunction with individuals' self-righting tendencies, have the capacity to repair brains that are afflicted with disorders (Black et al., 1998; Cicchetti, 2002). There is growing evidence that successful intervention modifies not only maladaptive behavior but also the cellular and physiological correlates of behavior (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011; Dozier et al., 2008; Fisher, Stoolmiller, Gunnar, & Burraston, 2007; Kandel, 1998). Such interventions are critical to implement because abnormal perturbations at a particular stage of brain development may lead to the development of aberrant neural circuitry and often compound themselves into relatively enduring forms of psychopathology (Arnold, 1999; Nowakowski & Hayes, 1999).

In self-organizing brain development, some regions of the brain serve to stabilize and organize information for other areas, whereas other regions utilize experience to fine-tune their anatomy for optimal function (Singer, 1995). In this manner, individuals can benefit from the interaction of genetic constraints and environmental information to self-organize their highly complex neural systems. Thus, children manifesting resilience, who develop in a positive and adaptive ways even though they have experienced adversity, may be likely to function adaptively in a wide array of environments. Children play an active role in seeking and receiving the experiences that are developmentally appropriate for them. Through experience-dependent processes, children who function adaptively are likely to seek out experiences that serve to modify and/or protect their brain development in ways that foster future adaptive developmental outcomes and generate resilience. In effect, the individual is helping to create his or her capacity for adaptive development. At one level, different functional units of the brain may attempt to compensate for dysfunctions in another functional aspect, and at another level, the organism may seek out new experience in areas where it has strength (Black et al., 1998). Because experience-dependent plasticity is a central feature of the mammalian brain, neither early brain anomalies nor aberrant experiences should be viewed as determining the ultimate fate of the organism (Cicchetti & Tucker, 1994).

Normative Biological Processes in Resilience

The biological processes implicated in resilience and discussed briefly in this chapter are in fact normative processes. Neural plasticity, for example, is an inherent property of the central nervous system. This observation represents an interesting parallel to Masten's (2001) suggestion that resilience is common and typically emerges through the operation of ordinary human adaptational systems. Likewise, at the biological level of analysis, normative processes may mediate most pathways of resilience, as long as these systems are functioning within normal parameters. This viewpoint underscores the importance of the interaction of normative systems at all levels of analysis in the promotion of resilience.

Empirical Studies on the Biological Contributors to Resilience

In 2004, Charney proposed an integrative model of vulnerability and resilience that encompassed the neurochemical response patterns to acute stress and the neural mechanisms mediating reward, fear conditioning and extinction, and social behavior. Charney identified 11 potential neurochemical, neuropeptide, and hormonal mediators of the psychological response to extreme stress. He concluded that the neural mechanisms of reward and motivation (e.g., hedonic capacity, optimisim, and learned helpfulness), fear responsiveness (e.g., engaging in effective behaviors despite fear), and altruism were relevant to the personality/character traits associated with resilient functioning. It will be important to conduct empirical research relating the neurobiology of these systems to a multidomain assessment of resilient functioning (Masten, 2014b).

In the context of normative conditions, the connections of the medial prefrontal cortex with the amygdala are immature during childhood and become more mature during adolescence. Gee et al. (2013) found that children who

were previously institutionalized, thereby experiencing early maternal deprivation, exhibited an early emergence of mature medial prefrontal cortex connectivity and resembled the adolescent/adultlike phenotype. This pattern of connectivity, which was mediated by the cortisol hormone, may confer some degree of enhanced emotion regulation because maternally deprived children with adolescent/adultlike phenotypes manifest less anxiety than their counterparts with immature phenotypes. Gee et al. conjectured that the accelerated amygdala-prefrontal development may serve as an ontogenetic adaptation in individuals in response to early adversity.

Peterson et al. (2014) used fMRI to compare brain function during the performance of an attentional, self-regulatory task. They studied a large community sample of multigenerational families enrolled specifically to be at either high or low risk for developing major depressive disorder (MDD). The sample was comprised of individuals who were at higher or lower risk for developing MDD based on being a biological offspring of persons with MDD or a control sample of persons drawn from the community who had no discernible lifetime illness. Peterson and colleagues discovered a risk endophenotype that included greater activation of cortical attention circuits and a protective endophenotype that included a greater activation of the dorsal anterior cingulate cortex. Thus, neural systems were identified that increased the risk for depression, protected individuals from the illness, and that endured following illness onset.

Few multilevel, multidomain empirical studies of the predictors of resilient functioning have been conducted. Curtis and Cicchetti (2007) investigated whether the positive emotionality and increased emotion regulatory ability associated with resilient functioning would be related to greater left frontal electroencephalogram (EEG) activity. Hemispheric asymmetries in EEG activation index a neural system that has emotion-specific influences such that the two hemispheres of the cerebral cortex are differentially involved in emotions (Davidson, 2000). The left hemisphere has been shown to be associated with positive emotions/approach behavior, and the right hemisphere has been linked to negative emotions/withdrawal behavior. Positive emotion and good emotion regulatory abilities have consistently been associated with resilience (Bonanno et al., 2007; Masten, 1986). Thus, the potential connection of hemispheric EEG asymmetry with resilience lies in its common linkage with emotion and emotion regulation. The investigation of a neural-level phenomenon such as hemispheric EEG asymmetry in the context of resilience underscores the point that no one single characteristic will be ascendant in resilience processes of adaptation over the course of development.

EEG asymmetry across central cortical regions distinguished between children with high and low resilience manifested in adaptive functioning, such that left-hemisphere activity characterized those maltreated children who were adapting well based on a multilevel, multidomain competence composite index (e.g., effective peer relations, adapting successfully to school, low levels of depressive symptomatology, low externalizing and internalizing psychopathology). In addition, a behavioral measure of emotion regulation, based on 35 hours of observation of the children, also independently contributed to the prediction of resilience in maltreated and nonmaltreated children.

In a multilevel investigation of another sample of low-income maltreated and nonmaltreated children, resilient functioning in relation to the regulation of two stress-responsive adrenal steroid hormones, cortisol and dehydroepiandosterone (DHEA), as well as the personality constructs of ego resiliency and ego control, was examined. A composite measure of adaptive success was utilized in this study of resilience that included multidomain, multimethod, multi-informant assessments of competent peer relations, school success, and low levels of internalizing and externalizing symptomatology. Cicchetti and Rogosch (2007) found that the personality characteristics of ego resiliency and moderate ego overcontrol, and the adrenal steroid hormones associated with stress (i.e., cortisol and DHEA) made independent and noninteractive contributions to resilience. Although operating at different levels of analysis, behavioral/psychological and biological factors each made unique contributions to resilience.

Cicchetti and Rogosch (2007) also discovered that higher morning levels of cortisol were related to lower levels of resilience evident in the functioning for the nonmaltreated children. High basal cortisol may indicate that nonmaltreated children are experiencing greater stress exposure and consequently are constrained in their ability to adapt competently. Physically abused children with high morning cortisol had significantly better functioning than physically abused children with lower levels of morning cortisol. The positive role of increased cortisol for physically abused children is divergent from the more general pattern of higher cortisol being related to lower competence in functioning that was discovered in the nonmaltreated and sexually abused children in this investigation.

Prior research on neuroendrocrine regulation has indicated that physically abused children generally exhibit

lower levels of morning cortisol secretion (Cicchetti & Rogosch, 2001a), especially those children who experience physical abuse early in life (Cicchetti, Rogosch, Gunnar, & Toth, 2010; Cicchetti, Rogosch, & Oshri, 2011). It may be that the subgroup of physically abused children who had elevated cortisol to cope with stressful vicissitudes in their lives were demonstrating a greater capacity for positive adaptation that signifies resilience in progress. In contrast, the larger subgroup of physically abused children with lower levels of morning cortisol may have developed hypocortisolism over time in response to chronic stress exposure. As a result, these children may have a diminished capacity to mobilize the HPA axis to promote positive adaptation under conditions of ongoing stress. Finally, maltreated children with good adaptive functioning exhibited a unique atypical pattern of a relative DHEA diurnal increase. Maltreated children who have evinced elevated DHEA over the course of the day may be better equipped to cope with the demands of high chronic exposure to stress and to adapt competently. In contrast, the nonmaltreated children who functioned well did not exhibit the pattern of diurnal DHEA increase; instead, they displayed the lowest levels of DHEA across the day. DHEA has been shown to generate effects that are associated with resilience. For example, DHEA counteracts the harmful effects of hypercortisolism, thereby potentially conferring neuroprotection to the brain (Charney, 2004).

The experience of childhood maltreatment has been shown to be related to changes in the structure of the brain (Hart & Rubia, 2012; McCrory et al., 2010; Teicher, Tomoda, & Andersen, 2006). Little is known about the neurobiological contributors that protect against the negative sequelae that commonly occur with child maltreatment (Cicchett & Toth, 2015). Van der Werff et al. (2013) obtained resting-state fMRI scans in a sample of 33 adults. Twenty-two of these individuals had been maltreated, and the remaining 11 served as controls. Eleven of the previously maltreated adults formed the resilient group, whereas the other maltreated individuals form the vulnerable group. Van der Werff and colleagues sought to identify resting-state functional connectivity patterns specific for resilience to the effects of child maltreatment. Resting-state functional connectivity patterns were discovered that were specific for individuals in the resilient groups. The regions of interest that were implicated were related functionally to declarative memory and the processing of emotional stimuli.

Sheinkopf et al. (2007) examined the predictors of better outcomes in children with prenatal cocaine exposure (CE). A 15-item risk index of prenatal and postnatal experiences was developed for children with and without CE. Preschool cognitive outcomes, problem behaviors, and adaptive behaviors were assessed. Vagal tone (VT) was assessed on two occasions—at an infant exam at 1 month and toy exploration at 36 months. Children were classified as having consistently high, consistently low, or fluctuating VT. Moreover, children were also classified as high versus low risk. High-risk children were found to have lower IQ scores, more problem behaviors, and lower adaptive behavior ratings than low-risk children. The investigators also conducted a risk-by-VT stability interaction that indicated that the high-risk children who had stable low VT had higher ratings of adaptive behaviors at 36 months. These results were viewed as consistent with theory that links reduced VT during tasks to adaptive regulation and suggest that such regulatory function may serve as a protective factor for children with prenatal CE.

Nigg and colleagues (2007) classified children as showing resilience if they avoided developing attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder (ODD), or conduct disorder (CD) in the face of family adversity. Neuropsychological response inhibition and a composite catecholamine genotype risk score were chosen to be potential protective factors because of their potential relevance to prefrontal brain development. Resilient children showed more effective response inhibition. Moreover, the high-risk genotype index that was comprised of allelic variants of three genes chosen that express in the prefrontal cortex (i.e., dopamine transporter, dopamine D4 receptor, and noradrenergic alpha-2 receptor) was a reliable indicator of resilience with respect to the development of ADHD and CD but not ODD in the face of significant psychosocial adversity. Thus, neurobiological and genetic factors related to prefrontal cortex development may serve as protection by enabling children to avoid developing ADHD and CD in the context of significant adversity.

Avoiding Biological Reductionism

Future research on the determinants of resilience should increasingly contain both biological and psychological measures. We want to stress, however, that our viewpoint does not reduce resilience to biology, let alone to a unitary biological variable. A multiple levels of analysis perspective on resilience should not be misinterpreted as equating resilience with biology. The incorporation of a biological perspective into research on resilience still requires adherence to a dynamic, transactional view that acknowledges and respects the importance of context and the interplay through interactions across multiple levels of

function. Biological and psychological domains are both essential to include in basic research on resilience and in resilience-promoting interventions. If we are to grasp the true complexity of the concept of resilience, then we must investigate it with a commensurate level of complexity.

TRANSLATIONAL RESEARCH AND IMPLICATIONS

Resilience science has had transformative effects on interventions and practice aiming to promote better outcomes or function among children at risk for many different reasons. The initial stage of transformation occurred at a conceptual level as many applied fields shifted toward strength-based models and away from deficit-oriented disease models and then rapidly infused more positive models, measures, and goals into their practices (Masten, 2011). This shift can be observed in: school psychology and school counseling (Akos & Galassi, 2008; Masten et al., 2008); family therapy (Goldenberg & Goldenberg, 2013; Walsh, 2006, 2011); disaster preparedness (Masten et al., 2015); training and services for military families (Cozza & Lerner, 2013; Masten, 2013; Park, 2011); positive youth development and out-of-school programming (Lerner, 2009); child welfare reform (Flynn et al., 2006, Masten, 2006); social work (Anthony, Alter & Jenson, 2009); medicine (Szanton & Gill, 2010; Southwick et al., 2011); and the practices of humanitarian agencies (Ager, 2013; Lundberg & Wuermli, 2012; Masten, 2014a).

Luthar and Cicchetti (2000) observed that research on resilience has substantial potential to guide the development and implementation of interventions for facilitating the promotion of adaptive function and development in diverse high-risk populations that have experienced significant adversity. Prevention scientists have contended that it makes far more sense to promote the development of adaptive functioning as early as possible in the course of development than it does to implement treatment strategies designed to repair existing disorders among high-risk individuals.

From its inception as an integrative science, developmental psychopathology spurred investigators to discover the most effective means of preventing and ameliorating maladaptive and pathological outcomes (Cicchetti, 1984; Rutter & Garmezy, 1983; Sroufe & Rutter, 1984). An early stated goal of developmental psychopathology was to help reduce the schism between empirical research and its application to the treatment of individuals struggling with adversity and mental disorders (Cicchetti, 1990). In reflecting on the past achievements and future promises of developmental psychopathology, Cicchetti and Toth (2009) stated that "one of developmental psychopathology's potential contributions lies in the heuristic power it holds for translating facts into knowledge, understanding, and practical application" (p. 17). Knowledge of developmental norms, appreciation of how developmental level may vary within same age groups, sensitivity to changing meaning that problems have at different developmental levels, attention to the effects of developmental transitions and reorganizations, and understanding of the factors that are essential features to incorporate into the design and implementation of preventive interventions all may serve to enhance the potential for optimal intervention efficacy and the promotion of resilience. The principles of developmental psychopathology (Cicchetti, 1993; Cicchetti & Toth, 2009) lend themselves to fostering translational research that has implications for society and for policymakers. The very subject matter of developmental psychopathology necessitates thinking clearly about the implications of the work and devising intervention strategies that will promote competent functioning and positive developmental pathways in challenging contexts (Masten, 2014b).

In this vein, efforts to prevent the emergence of psychopathology or to ameliorate its effects also can be informative for understanding processes involved in the development of resilience and adaptive functioning (Cicchetti & Blender, 2006; Masten, 2014b). For example, if the developmental course is altered as a result of a preventive intervention and the risk for negative outcomes is reduced, then prevention research helps to specify processes that are involved in the development of psychopathology or other outcomes. As such, prevention research can be conceptualized as true experiments in altering the course of development, thereby providing insight into the etiology and pathogenesis of disordered outcomes and to the promotion of resilience (Cicchetti & Hinshaw, 2002; Howe, Reiss, & Yuh, 2002).

The experimental nature of randomized clinical trials (RCTs) provides an unparalleled opportunity to make causal inferences in resilience research. Independent variables manipulated in RCTs may be several steps removed from underlying etiologic factors because such trials are primarily concerned with alleviating suffering and promoting competence. Nonetheless, careful research design and assiduous measurement of ancillary process variables through which intervention effects may occur can shed light on the theory-driven mechanisms underlying pathways of pathological and positive adaptation (Cicchetti & Hinshaw, 2002).

Intervention Research Based on Resilience Models

Reviewing even the past decade of intervention research based on resilience models is beyond the scope of this chapter. However, selected examples can highlight major trends in resilience-focused intervention science.

Throughout this chapter we have noted examples of interventions that target promotive or protective processes in order to foster positive development or recovery in children exposed to adversity. Examples of resilience-based interventions include carefully controlled experiments to test programs designed to: promote parenting skills among parents with children or youth at risk for antisocial and other high-risk behavior (e.g., Brody et al., 2004; Patterson et al., 2010); improve parenting in families at risk for child maltreatment (e.g., Toth & Gravener, 2012) or in foster parents (e.g., Dozier et al., 2008; Fisher et al., 2006); implement foster care or adoption as an alternative to institutional care (Nelson et al., 2007; Rutter, Sonuga-Barke, & Castle, 2010): and improve executive function skills among disadvantaged preschoolers (e.g., Raver et al., 2011).

The best of these studies provide a theory of change that delineates the process targeted for change. Executive functions were the mediator targeted by Raver et al. (2011) in their intervention for high-risk preschool children. Their intervention improved school readiness, and their study further indicated that this change was mediated, as hypothesized, by improvements in cognitive self-control skills. Similarly, experiments to promote resilience in families with children at risk for maltreatment from the parent have targeted the quality of parent-child interaction and the attachment relationship, showing better outcomes in children. Illustrative randomized control trials are highlighted in the next section.

Interventions that showed cascade effects were particularly noteworthy over the past decade. In their intervention to promote better outcomes in foster children, discussed further later, Fisher et al. (2006) intervened at the parenting level and measured the outcome in the biological stress system of the child, finding that the intervention had a normalizing effect on the child's HPA system. The Strong African American Families Program (Brody et al., 2004; 2006) intervened with families to alter the risky behaviors of their adolescents. The Oregon Social Learning Center group, led by Patterson, Forgatch, and DeGarmo (2010), showed spreading effects of their Oregon model of parent management training (PMTO) on multiple members of the family over multiple domains over time.

Intervention studies also are beginning to test genetic moderating effects of response to intervention. In their intervention with African-American families, Brody et al. (2009, 2013) tested gene by intervention effects of intervention in their randomized controlled trial. They found evidence of genetic moderating effects, some of which are congruent with a differential susceptibility hypothesis (Brody et al., 2013). Such research on genetically (or epigenetically) moderated treatment effects in resilience science are in the early stages but are likely to be an important area of growth in the coming decade.

Randomized Controlled Trials Targeting Parent-Child Relationships

Interventions successfully targeting the quality of caregiver-child relationships in RCT designs with high-risk families offer powerful evidence of promotive or protective roles of this relationship in child resilience. Groundbreaking RCT experiments have been conducted with children and their caregivers at risk due to maternal depression, maltreatment, and foster care.

In a study of families at risk due to maternal depression, Cicchetti, Toth, and Rogosch (1999) conducted an RCT with families of 20-month-old toddlers. The mothers suffered from Major Depressive Disorder (MDD), which poses serious risks to child development (Cicchetti & Toth, 1995). Half of these youngsters and their mothers with MDD were randomly assigned either to toddler-parent psychotherapy (TPP; Lieberman, 1992) or to an enhanced community standard control group. A third group was comprised of demographically comparable toddlers whose mothers had no past or present MDD or other psychopathology (normative controls; NC). The intervention lasted 16 months. At baseline, there were no differences found in attachment security between the two groups with mothers who had MDD; both groups of MDD offspring had significantly more insecurity than the toddler offspring of well mothers. At the conclusion, Cicchetti et al. (1999) found that the TPP intervention increased attachment security in the MDD group receiving this intervention to a percentage comparable to that seen in the toddler offspring of well mothers. The MDD group with the community standard of care did not show improvement in attachment security. The results of this investigation are noteworthy; they were one of the first to suggest that attachment security is malleable and can be modified through the provision of an intervention informed by attachment-theory.

In a later and larger RCT investigation of mothers with MDD and their toddlers by Toth, Rogosch, Manly, and Cicchetti (2006), attachment security was assessed in the Strange Situation (Ainsworth, Blehar, Waters, & Wall,

1978) rather than with the Attachment Q-Sort (ASQ) that had been used in the 1999 study by Cicchetti and colleagues. The Strange Situation is the gold standard measure of attachment security in the field. Moreover, security of attachment as assessed in the Strange Situation has been shown to relate to a number of later positive outcomes (e.g., autonomous self-development, effective peer relations, ego-resiliency, fewer behavior problems, etc.; Cicchetti & Roisman, 2011; Sroufe, Egeland, Carlson, & Collins, 2005).

To further elucidate the impact of TPP on attachment organization, Toth et al. (2006) conducted an RCT with mothers who had MDD and their toddlers. The toddler offspring of MDD mothers were randomly assigned to either TPP or to a community standard intervention control. A third group of mothers who had never experienced psychopathology and did not differ from the two groups with MDD (intervention and control) demographically served as a normative comparison group (NC). The TPP intervention lasted approximately 18 months. At baseline, toddlers in the two groups with mothers who had MDD were significantly more likely to be insecurely attached to their mother than were toddlers in the NC group. The percentages of Type D disorganized attachment at baseline were 45%, 37%, and 20% for the MDD control, the MDD TPP intervention group, and the NC groups, respectively. At postintervention, statistically significant differences were obtained in security of attachment between the mothers with MDD who received TPP intervention (67%) compared with the community standard control (17%) group. Furthermore, the TPP intervention group had significantly more attachment security than the NC group (48%). The percentages of Type D disorganized/disoriented attachment at postintervention were 11%, 41%, and 21% on the TPP, community standard, and NC groups, respectively.

The results of the TPP intervention for toddlers of mothers with MDD provide compelling support for the potential malleability of attachment insecurity. The TPP intervention was effective not only at modifying attachment insecurity but also in maintain existing security in the toddler offspring of depressed mothers. Conversely, offspring of mothers with MDD not receiving the TPP intervention were less likely than intervention offspring to maintain secure attachments at the postintervention assessment. Thus, even if offspring of mothers with MDD are securely attached, the parenting milieu and the emotional climate of the home that accompany maternal depression, even once an active episode has remitted, may mitigate against the continuance of their secure attachment.

The malleability of insecure and disorganized attachment among infants from maltreating families also was investigated through an RCT (Cicchetti, Rogosch, & Toth, 2006). Findings from research on the effects of maltreatment on infant attachment were incorporated into the design and evaluation of the intervention (V. Carlson, Cicchetti, Barnett, & Braunwald, 1989; Cicchetti & Barnett, 1991; Cyr, Euser, Bakermans-Kranenburg, & van IJzendoorn, 2010). One-year-old infants from maltreating families and their mothers were randomly assigned to one of three intervention conditions: (a) child-parent psychotherapy (CPP), (b) psychoeducational parenting intervention (PPI), and (c) community standard (CS) controls. A fourth group of infants from nonmaltreating families and their mothers served as an additional low-income normative comparison (NC) group. At baseline, mothers in the maltreatment group, relative to the nonmaltreatment group mothers, reported greater abuse and neglect in their own childhoods, more insecure relationships with their own mothers, more maladaptive parenting attitudes, more parenting stress, and lower family support, and they were observed to evince lower maternal sensitivity. Infants in the maltreatment groups had significantly higher rates of disorganized attachment than infants in the NC group. At postintervention follow-up at age 26 months, children in the CPP and PPI groups demonstrated substantial increases in secure attachment, whereas increases in secure attachment were not found for the CS and NC groups. Moreover, disorganized attachment continued to predominate in the CS group.

Following the tenets of an organizational perspective, it is expected that these maltreated youngsters, now that they are traversing a more positive developmental trajectory, will be more likely to continue on an adaptive pathway and successfully resolve future salient developmental tasks (Sroufe, 1983). The preventive interventions have demonstrated that behavioral plasticity is possible, at least in the early years of life.

The parenting education intervention and the CPP intervention were both found to be equally efficacious in fostering secure attachment and in reducing disorganized attachment in infants from maltreating families. However, when examining the sustained efficacy of these intervention models, only CPP was found to be efficacious in promoting quality of attachment over time (Pickreign Stronach, Toth, Rogosch, & Cicchetti, 2013). These results suggest that, in cases of extremely maladaptive parenting such as child maltreatment, more intensive models of intervention that go beyond parent skills training may be necessary as increasing developmental complexity unfolds over time.

The extremely high stability of attachment insecurity in the group receiving the community standard of care is especially alarming. These results portend that the maltreated infants in this group are at exceedingly high risk of maladaptive outcomes on subsequent stage-salient issues of development. The typical intervention services provided to maltreated infants are not sufficient to remediate their early developmental difficulties. Without the receipt of theoretically derived, intensive interventions, maltreated infants are likely to embark on a negative developmental trajectory. Clearly, case management focused on monitoring the physical safety of maltreated children is inadequate to foster positive socioemotional development. Moreover, these results underscore the critical importance of providing evidence-based services to maltreating families to interrupt this negative cascade.

The results of this randomized prevention trial are both heartening and sobering. The fact that plasticity is possible during infancy and that even the most disorganized form of attachment is modifiable in extremely dysfunctional mother-child dyads offers significant hope for thousands of young children and their families. By fostering secure attachment, costlier interventions, such as foster care placement, special education services, residential treatment, and incarceration, can be averted. Unfortunately, these results also shed light on the harsh reality of ineffective services currently being provided in communities throughout the nation. It is critical that professionals, government officials, social policy advocates, and mental health insurers recognize the necessity of investing in the delivery of theoretically informed, evidence-based interventions. Although this may appear to be a costly endeavor in the short term, the long-term benefits with respect to enhancing positive child development, preventing the dissolution of families, and decreasing the burden of mental illness in society cannot be overstated.

Randomized Control Trials Targeting Caregiving with Neurobiological-Level Evaluation

RCTs to promote child resilience by targeting the quality of caregiving also can measure effectiveness at biological levels of function in children. Research on the impact of early caregiving adversity in humans has revealed that the HPA axis is highly likely to exhibit evidence of dysregulation and that this dysregulation may entail both hyper-and hypofunctioning (Cicchetti & Rogosch, 2001b; Cicchetti, Rogosch, Gunnar, & Toth, 2010; Gunnar & Vazquez, 2001; Heim et al., 2008). Levels of cortisol, the final hormonal product of the neuroendocrine system, that are chronically elevated during development when neural circuits are still in the process of maturing exert an impact on brain development by affecting neurotropic factors and regulating gene transcription, thereby influencing the manner in which neural circuits perceive and interpret environmental threat and the magnitude and duration of future stress responses (Tarullo & Gunnar, 2006). In addition, chronically low levels of basal cortisol also can eventuate in harmful effects on the brain as well as on physical and mental health and behavior (Juster, McEwen, & Lupien, 2009; Juster et al., 2011; Lupien et al., 2006). Both hyper- and hypocortisolism can reflect allostatic load, typically defined as the result of chronic exposure to fluctuating or heightened neural or neuroendocrine responses that emerge in response to chronic environmental challenges that are perceived as especially stressful (McEwen & Stellar, 1993). Stressful experiences in early life are vital in the determination of the capacity for flexible/resilient adaptation or the lack thereof (McEwen, Gray, & Nasca, 2015).

The plethora of studies documenting the neuroendocrine disturbances following child maltreatment, in concert with the likely harmful developmental sequelae of these HPA axis disturbances and the accompanying sustained allostatic load, have underscored the potential importance of RCTs to try to modify and reorganize alterations in HPA axis functioning (Cicchetti & Gunnar, 2008). In the human literature, evidence is beginning to accrue suggesting that efficacious interventions with children in foster care may modify not only maladaptive behavior but also the neuroendocrine correlates of behavior (Dozier et al., 2008; Fisher, Gunnar, Dozier, Bruce, & Pears, 2006; Fisher, Stoolmiller, Gunnar, & Burraston, 2007). Methodologically rigorous RCTs that incorporate a multilevel measurement battery have begun to provide a unique lens through which the processes responsible for the development, maintenance, and modification of both typical and atypical functional neuroendocrine outcomes can be discerned (Gunnar, Fisher, & the Early Experience, Stress, and Prevention Network, 2006).

In an innovative illustration of the capability of psychosocial interventions to modify diurnal cortisol activity, noted briefly earlier, Fisher et al. (2007) conducted a 6- to 9-month RCT of a family-based foster care therapeutic intervention for preschool children. The therapeutic intervention was compared to a regular foster care condition and a demographically comparable group of same-aged, nonmaltreated preschool children from low-SES families. Fisher et al. (2007) collected and assayed early-morning and evening cortisol levels from the preschool children

(mean age = 4.4 years) on a monthly basis from the baseline until the end of the interventions. One common disturbed cortisol pattern that emanates from disruptions in caregiving is a low early-morning cortisol that displays minimal change across the day. Fisher and colleagues found that the foster children who received the family-based therapeutic intervention exhibited cortisol activity that became comparable to the nonmaltreated comparison children over the course of the intervention. In contrast, children who received routine services in state foster care (e.g., weekly individual psychotherapy; developmental screening for delays with the subsequent provision of special education services, if needed) displayed an increasingly flattened pattern of early-morning to evening cortisol activity throughout the course of the RCT. The results of this psychosocial intervention demonstrate that improvements in caregiving following the experiences of early adversity have the potential to reverse or prevent disturbances in the HPA system (Fisher et al., 2007).

The study of child maltreatment as a "natural experiment" provides a valuable lens into the relations between sensitive caregiving and stress regulation and reveals insights for translation of basic empirical findings into RCTs aimed at reorganizing and normalizing these relations. Moreover, the conduct of RCTs, such as that already described, yields important knowledge regarding the malleability of developmental processes. Psychosocial randomized preventive interventions with previously maltreated children placed in foster care provide important opportunities for children who have transitioned into a changed environment to manifest competence in biological and behavioral functioning. For children in foster care, there may be variability with respect to the presence of continued stressful experiences. For example, the move to foster care may be traumatic for some children even in they have been placed in a better setting than their previous home or foster care experience.

Longitudinal effects of child maltreatment on cortisol regulation in infants from 1 to 3 years were investigated in the context of an RCT (Cicchetti, Rogosch, Toth, & Sturge-Apple, 2011). Thirteen-month-old infants and their mothers were randomly assigned to one of three intervention conditions: child-parent psychotherapy (CPP), psychoeducational parenting intervention (PPI), and a control group involving standard community services (CS). A fourth group of infants from nonmaltreating families and their mothers comprised a nonmaltreated comparison (NC) group. The two active interventions were combined into one maltreated intervention (MI) group for statistical analyses. Saliva samples were obtained from children at 10:00 a.m. before beginning a laboratory observation session with their mothers when the children were 13 months of age (preintervention), 19 months (midintervention), 26 months (postintervention), and 38 months (1-year postintervention follow-up). At the initial assessment, no significant differences among groups in morning cortisol were observed. Latent growth curve analyses examined trajectories of cortisol regulation over time. Beginning at midintervention, divergence was found among the groups. Whereas the MI group remained indistinguishable from the NC group across time, the CS group progressively evinced lower levels of morning cortisol, statistically differing from the MI and NC groups. These results are consistent with those of Fisher et al. (2007) and Dozier et al. (2008) and highlight the value of psychosocial interventions for early child maltreatment in normalizing biological regulatory processes.

Random assignment to adversity or trauma is not possible, but random assignment to intervention is. If biological systems recover in response to an RCT intervention, then this provides support for arguments that the systems under study are sensitive to environmental input during development. Furthermore, if randomized interventions alter neurobiological systems associated with disorders, and it can be shown that they mediate positive changes in psychosocial functioning, then these intervention studies can foster a better understanding of the neurobiological contributors to resilience.

The Bucharest Early Intervention Project (BEIP) is a landmark multilevel RCT preventive intervention informed by developmental theory (Nelson, Fox, & Zeanah, 2014). The project has three major goals: (1) to document the impact of institutionalization on child development across a number of salient domains; (2) to ascertain the extent to which children in foster care can recover from experiencing early adversity; and (3) to assist the Romanian government in building alternative means to institutionalization of caring for children experiencing adversity.

BEIP is a foster care intervention for children who had been abandoned at or shortly after their birth and placed in an institution for young children in Bucharest, Romania (Fox et al., 2011; Nelson et al., 2007; Zeanah et al., 2003). Half of a group of 136 children residing in an institution in Bucharest were randomly assigned either to high-quality foster care designed specifically for the BEIP, and the other half were randomly assigned to remain in institutional care (care as usual group). A group of never-institutionalized children serves as community controls. Over time, the purity of this experiment was affected by naturally occurring changes in child status. However, it

remains an extraordinarily rare effort to test the effects of foster care in comparison to institutional and typical family care.

On average, children in the high-quality foster care group entered into foster care at 22 months and were assessed longitudinally at stage-salient developmental periods at 30, 42, 54, and 96 months. A follow-up assessment at age 12 years is under way, focused on early adolescence, which represents another critical developmental transition. A variety of psychological and biological domains were assessed at various developmental periods, with each transitional turning point thought to provide both opportunities and challenges for the developing child.

Among the major findings of BEIP, it was demonstrated that children who were placed into foster care early in life showed improved cognitive, emotional, and behavioral functioning. In contrast, children randomly assigned to remain in institutionalized care showed ongoing developmental deficits across all domains assessed. Thus, early placement into foster care resulted in the most optimal outcomes for the formerly institutionalized children. Interestingly, children who were randomly placed in foster care demonstrated increases in cognitive functioning (IQ) and in brain development, whereas children who remained in institutions displayed lower levels of electrical activity across all brain regions (Vanderwert, Marshall, Nelson, Zeanah, & Fox, 2010).

The inclusion of a normative community control group was an important addition to the BEIP design. It provided a more stringent test for evaluating the efficacy of the foster care interventions than would a foster care versus care as usual comparison. On several of the domains assessed in the BEIP, children randomly assigned to foster care performed similarly to children in the never-institutionalized group; however, for other domains, children in foster care were functioning in between the institutionalized (care as usual group) and never-institutionalized groups (e.g., on measures of IQ, emotional responsiveness and reactivity, attachment security, and anxiety disorders).

Miller, Brody, Yu, and Chen (2014) investigated whether a psychosocial intervention, focused on improving parenting, strengthening family relationships, and building youth competencies could reduce inflammation in low-SES, African American families residing in poverty. Families were randomly assigned to a 7-week psychosocial intervention or to a control condition. When youth reached age 19, peripheral blood was collected to quantify six cytokines that orchestrate inflammation, the dysregulation of which contributes to many of the health problems known to pattern by SES. Youth who participated in the intervention had significantly less inflammation on all six indicators relative to controls. Inflammation was lowest among youth who received more nuturant-involved parenting and less harsh-inconsistent parenting as a consequence of the intervention. These findings have theoretical implications for research on resilience to adversity and the early origins of disease. If substantiated, they may also highlight a strategy for practitioners and policymakers to use in ameliorating social and racial health disparities.

Moving toward RCTs in Multiple-Levels-of-Analysis Research on Resilience

Developmental psychopathologists have advocated a multiple-levels-of-analysis approach to the investigation of maladaptation, psychopathology, and resilience (Cicchetti & Blender, 2006; Cicchetti & Curtis, 2006, 2007; Cicchetti & Dawson, 2002; Masten, 2007, 2014). Thus, the examination of multiple biological and psychological systems, domains, and levels of the ecology on each individual participant in an RCT preventive intervention should eventuate in a more complete understanding of individual patterns of maladaptation, psychopathology, and resilience. We think it is essential that this multiple-levels-of-analysis approach is adopted by prevention scientists who are conducting RCTs. For example, the inclusion of molecular genetic methods (e.g., sequencing DNA and utilizing functional polymorphisms to examine genetic and epigenetic methylation and moderation of intervention), neuroimaging techniques (e.g., to investigate brain structure, function, and connectivity, pre-and post-intervention), and stress-reactivity paradigms (e.g., to ascertain whether neurobiological stress systems are modifiable as a result of intervention), in conjunction with the incorporation of psychological/behavioral outcomes, will enhance the understanding of interventions on brain-behavior relations (Cicchetti & Blender, 2006; Fishbein, 2000; Zeanah et al., 2003). Similarly, the inclusion of biological measures into the research armamentaria of researchers investigating pathways to adaptive functioning in the presence of significant adversity, as well as the translation of this integrative research into resilience-promoting interventions that assess biological and psychological measures concurrently, will contribute to reducing the schisms that exist between the study of normal and abnormal development and between research and practice (Beauchaine, Nehaus, Brenner, & Gatzke-Kopp, 2008; Cicchetti & Toth, 2006; Masten, 2014b).

The utilization of a neurobiological framework and the incorporation of genetically sensitive designs into

interventions seeking to promote resilience or to repair positive adaptations gone awry may contribute to the ability to design individualized interventions that are based on knowledge gleaned from biological and psychological levels of analysis. If assessments of biological systems are routinely incorporated into the psychological measurement batteries employed in resilience-promoting interventions, then researchers will be in a position to discover whether the nervous system and psychological processes have been modified by experience. A challenge that will need to be surmounted involves the determination of the mechanisms whereby different levels of analysis interact and transact across developmental time. Furthermore, researchers conducting their work at each level will need to develop theories that are consistent or coherent with respect to other key levels of analysis. Although investigations that focus solely on the behavioral level of resilience remain valuable, it is now important that researchers who examine the determinants of resilience integrate empirical work conducted on the behavioral level with the genetic and biological levels, study their coactions, and investigate the relations among these mutually influencing systems.

Determining the multiple levels at which change is engendered through RCT prevention trials will provide more insights into the mechanisms of change, the extent to which neural plasticity may be promoted, and the interrelations between biological and psychological processes in maladaptation, psychopathology, and resilience (Cicchetti & Curtis, 2006). Moreover, preventive interventions with the most in-depth empirical support, based on integrative multilevel theories of normality, psychopathology, and resilience, can be implemented in effectiveness trials in community or real-world settings to reach the broadest number of people and prevent, alleviate, and ultimately cure suffering from mental disorders. Furthermore, the inclusion of biological assessments in evaluations of interventions designed to foster resilience will enable scientists to discover whether the various components of multifaceted interventions each exert a differential impact on separate brain systems. It is thus possible to conceptualize successful resilience-promoting interventions as examples of experience-dependent neural plasticity.

Finally, although resilience is a dynamic developmental construct that, theoretically, is changing throughout the life course, it nonetheless is important to ascertain whether and, if so, when there are optimal timing windows for efforts to promote resilience. Specifically, it will be extremely important to know which resilience-promoting interventions are more effective when implemented in the early years of life and which interventions need to be timed later for optimal effect. Likewise, are such interventions more likely to achieve their goal of promoting resilience if they are instituted as closely as possible to the identification of the adverse event(s) or experience?

Genetic and Epigenetic Moderation of Intervention

Despite rapid, promising advances, our understanding of genetic moderation of intervention outcome remains in its early stages. Most interventions have aimed to change the environment with little to no consideration for genetic involvement. Thus, interventions that consider both genes *and* environment are in a nascent state. In a meta-analysis of 22 RCTs, van IJzendoorn and Bakermans-Kranenburg (2015) found clear-cut experimental support for genetic differential susceptibility. A recent Special Section of the journal *Development and Psychopathology*, edited by Belsky and van IJzendoorn (2015), was devoted to examining genetic moderation of intervention efficacy. The focus of the Special Section was to test differential susceptibility by examining the RCTs conducted to date on genetically moderated RCT interventions. To provide an example, Cicchetti, Toth, and Handley (2015) examined the genetic moderation of interpersonal psychotherapy (IPT) efficacy for economically disadvantaged women with MDD. Specifically, Cicchetti et al. examined whether genotypic variation in the corticotropin-releasing hormone receptor 1 gene (CRHR1) and the serotonin transporter gene (5-HTT) moderated effects of IPT on depressive symptoms over time. Cicchetti et al. also tested genotype moderation of IPT mechanisms social adjustment and perceived stress. A diverse sample of nontreatment-seeking urban women at or below the poverty level with infants was recruited from the community and randomized to individual IPT or enhanced community standard. Results revealed that changes in depressive symptoms over time depended on both intervention group and genotypes (5-HTTLPR and CRHR1). Moreover, multiple-group path analysis indicated that IPT improved depressive symptoms, increased social adjustment and decreased perceived stress at posttreatment among women with zero copies of the CRHR1 TAT haplotype only. Finally, improved social adjustment at postintervention significantly mediated the effect of IPT on reduced depressive symptoms at 8 months postintervention only for women with zero copies of the TAT haplotype. Post-hoc analyses of 5-HTTLPR were indicative of differential susceptibility, albeit among African American women only.

Prevention scientists have recently begun to consider epigenetic mechanisms within the context of understanding the efficacy of intervention on developmental outcomes and resilient functioning. As noted earlier, epigenetic mechanisms may be a realistic target for intervention because of their reversibility. Epigenetically informed RCT preventive interventions can include methylation assays in their measurement batteries to evaluate the effects of the interventions on these mechanisms and to refine theory.

Nothing can be done to prevent the DNA sequence variations that eventuate in the emergence of risky phenotypes. Yet DNA methylation changes in response to experiences such as child abuse and neglect could help to bring about the design, implementation, and multilevel prevention and intervention strategies that change expression of risky genes through reversal or demethylation and thereby promote healthy physical and mental health development. Szyf and Bick (2013) concluded that DNA methylation adaptations early in life are system-wide and that they involve multiple gene circuits. Methylation assays also can be conducted at the level of site-specific regions of candidate genes with known functional properties, such as the glucocorticoid receptor gene (Bick et al., 2012). Thus, because responses to social adversity such as child maltreatment are not limited to the brain and also likely affect peripheral tissues, it is also possible to assess the efficacy of an intervention in peripheral cells.

Prevention and intervention strive to alter the environment in order to bring about positive outcomes. Research on epigenetics suggests that prevention and intervention also may change the epigenome and that this could result in improved outcomes. If researchers are to understand the processes thorough which early adverse experiences such as child maltreatment and institutionalization impact maladaptation, psychopathology, or resilience, then it is critical that genetic variation (functional polymorphisms) and epigenetic modifications are examined.

Research on GxE and on epigenetics needs to incorporate, as well as to emphasize, a developmental perspective (GxExD; Sroufe, 2013). Genes may influence how environmental experience affects development, and this moderating role may operate differently at various developmental periods. Moreover, the effects of genes and experience at a particular period may be influenced by the effects of prior development. Environments may affect the timing of genetic effects and gene expression. In addition, there are experience effects on the epigenome, and these effects also would operate differently across the course of development.

Genetic effects on intervention efficacy can occur in a number of ways. Are some individuals, based on genetic variation, more susceptible to the positive effects of intervention? Are different interventions more effective with different individuals based on genetic differences (i.e., matching intervention to genotype group)? Does intervention affect DNA methylation, resulting in changes in gene expression? DNA methylation changes in response to experience could lead to the design of both prevention and intervention strategies that change the expression of genes to promote healthy physical and mental health outcomes. Given that the demethylated epigenome would be transmitted to the next generation, it will be important to determine if decreased child maltreatment risk through efficacious intervention alters the epigenome, which in turn results in a "less risky" epigenome being transmitted to offspring. The design and conduct of longitudinal multilevel RCTs that incorporate baseline pre-intervention, postintervention, and postintervention follow-up assessments of psychosocial, neurobiological, and epigenetic processes through the collection of DNA and RNA over developmental time represent an exciting direction for future intervention studies.

Implications of Resilience Science for Policy

Resilience science has many implications for policymakers at many levels of governmental and nongovernmental organizations, and there is growing evidence that policymakers are taking notice, with surging popularity of the concept in initiatives and products of humanitarian and governmental agencies at local, state/provincial, national, and international levels (Ager, 2013). UNICEF (2011), for example, published the *Humanitarian Action for Children: Building Resilience* (2011) report. The World Bank published an edited volume on *Children and Youth in Crisis: Protecting and Promoting Human Development in Times of Economic Shocks*, with a strong emphasis on concepts and findings from a resilience perspective for mitigating the effects of economic shocks on child development (Lundberg & Wuermli, 2012). Educational policies and practices have adopted positive more models of practice, often drawing directly on resilience science (e.g., Cohen, 2013; Doll, 2013).

The impact of a resilience perspective on child welfare reform was well documented in a conference and subsequent publication, *Promoting Resilience in Child Welfare* (Flynn, Dudding, & Barber, 2006). The global movement to shift child welfare toward a positive, strength-focused, and developmental approach was highlighted in the

conference and book, which also underscored the appeal of this approach to the stakeholders involved, including young people as well as social workers and funders.

Disaster preparedness and response approaches have also begun to incorporate resilience perspectives at multiple levels, underscoring the interconnectedness of resilience at the child, family, and community levels, with important effects on policies (Institute of Medicine, 2014; Masten et al., 2015). Data from studies of resilience in children following disaster consistently indicated the importance (for minimizing harm and facilitating recovery) of keeping families together, restoring child care and school, and providing opportunities for children to play and return to other childhood and family activities, and these have become guiding priorities in disaster preparation and response policies.

As noted, prevention science has incorporated many of the models and findings from resilience science, expanding the focus from preventing problems and interrupting negative progressions to promoting positive development, building assets, and facilitating competence cascades (Cicchetti, 2013; Gest & Davidson, 2011; Luthar & Cicchetti, 2000; Masten, 2014b; Zimmerman et al., 2013). Universal prevention programs, as well as targeted programs for high-risk families or children, now often emphasize building resources in the family, school, or community (or all three) and competence skills in individual children, parents, or teachers (National Research Council and Institute of Medicine, 2009; Winslow, Sandler, Wolchik, & Carr, 2013).

There appears to be a broad consensus among many stakeholders involved in policy that resilience approaches are valuable. The evidence base grows stronger for efficacy of interventions in many domains of adaptive development and for different situations that can be harmful to children. In addition, parents and policymakers alike find models appealing that focus on promoting positive development and achieving success (Ager, 2013; National Research Council and Institute of Medicine, 2009; Sandler et al., 2011). At the same time, evidence is building that well-timed and targeted intervention can have high long-term returns on public investments, benefiting the individual children or families as well as society (e.g., Cunha & Heckman, 2011; Heckman, 2006; Reynolds, Temple, White, Ou, & Robertson, 2011).

As resilience science moved toward dynamic models of interacting systems, the implications for policy have concomitantly shifted to encompass more systems and the idea of integrated interventions that address more than one system at a time in order to generate synergy (Masten, 2011, 2014b, 2014c). Policymakers often must choose where and when to invest most strategically to promote the well-being of their constituents in the near and distant future. Research on the economics of human capital investment, naturally occurring resilience, and prevention science is aligning in helpful ways for applications in policy, although it still remains crucial to communicate the evidence and its implications effectively (Winslow et al., 2013).

At the level of global intervention and investment in children, momentum is growing to raise the bar of humanitarian aid beyond child survival to children with the capacity to thrive, even in a world still plagued by war, epidemics, and extreme poverty (Masten, 2014a). Early in 2014, the U.S. National Academies launched a new international forum, "Investing in Young Children Globally," to assemble evidence about best practices worldwide for strategic investments in children to promote lifelong health and well-being in individuals and societies (see their website at http://iom.edu/Activities/Children/InvestingYoungChildrenGlobally.aspx). This international network of scientists, clinicians, policymakers, and other professionals convenes workshops and other meetings around the world to evaluate, integrate, and disseminate promising data and strategies for governments and nongovernmental organizations to invest effectively in young children in order to promote the healthy development of children and their societies. This effort produces workshop reports, infographics, and other products for widespread distribution to policymakers and funders worldwide.

Also in 2014, a consortium of partners from multiple countries initiated a new set of three initiatives as part of the ongoing global "Grand Challenges" effort launched originally a decade earlier by the Bill and Melinda Gates Foundation, the Canadian government, and others. "All Children Thriving" is one of the new Grand Challenges initiatives with the goal of helping mothers and children thrive in the developing world.

CONTROVERSIES OLD AND NEW

Beginning with the first generation of resilience science, controversies emerged (Masten, 2012, 2014b; Rutter, 1987). Some of these controversies have waned as the science matured, some have returned in new forms, and some new issues have surfaced. All these trends are expectable in a maturing science and actually may reflect real progress. Here we highlight several of the enduring controversies and issues for research on resilience in human development.

Theoretical Issues

From early in the study of child resilience, there were debates about how to define the concept, and these issues continue to be the subject of debate (Masten, 2014b; Panter-Brick & Leckman, 2013; Southwick, Bonanno, Masten, Panter-Brick, & Yehuda, 2014). Although there is general agreement that resilience science is focused on understanding adaptation in contexts of challenge or adversity, definitions of resilience vary, which leads to issues in operationalizing the concept in research (Luthar, 2006; Masten 2014b). Some definitions continue to focus on a traitlike concept of resilience (see later discussion) while others focus on capacities for, processes of, or outcomes of positive adaptation in the wake of adversity or contexts or risk. Even for those who accept a systems definition, where resilience refers to capacity or processes of a system engaged in adapting in response to a significant challenge, there are issues about focusing on internal function of the system or its adaptation to the environment. These issues reflect the nature of adaptation in living systems, which are always functioning as a unit embedded and interacting with other systems. Methodologically, this situation leads some investigators to focus on psychological well-being or internal indicators of function, such as allostatic load, while others focus on competence in the environment (e.g., social and academic competence) and still others include both kinds of adjustment indicators.

Striking consistencies in findings have emerged in the resilience literature despite the variations in concepts and methods (Masten, 2014b). It is nonetheless problematic that the variations in conceptual approaches make it difficult to integrate theory and findings on resilience. Greater effort to harmonize research concepts, designs, and measures would greatly facilitate gains in knowledge in resilience science.

Empirical Issues

Numerous methodological issues flow from the conceptual variations in resilience science and also from the inherent complexity of research on dynamic living systems. Any competent and reflective researcher engaged in studies of resilience must confront these issues and make choices about concepts, models, measures, and methods.

One of the major issues confronting resilience researchers is how to define and measure the core criteria of "risk" and "adaptation" delineated in the theoretical section of this chapter. Some investigators study a single risk marker, such as "homeless" or "premature" or "maltreated," fully cognizant that these indicators represent a cumulative index of risks and resources. Other investigators deliberately assess cumulative risk or adversity indicators, and they must make choices about how to aggregate them for purposes of analysis (Evans et al., 2013; Obradović et al., 2012). These may include counts or other kinds of composite scores on sociodemographic indicators, perceived stress, or adverse experiences. Similarly, choosing what to assess on the adaptation side of the equation also is challenging. Some investigators focus on success in age-salient developmental tasks while others focus on symptoms of mental illness or psychological distress.

Investigators are more aware now of the cultural influences on these choices, which often were ignored in early studies (Masten, 2014b; Panter-Brick & Leckman, 2013; Ungar et al., 2013). In international research, much more attention is given now to the issue of defining and measuring resilience in culturally meaningful ways.

Many choices are made by investigators when they define resilience and choose measures of risk/adversity, adaptive function or outcome, and potential promotive or moderating influences. These choices have yielded an incredibly diverse and wide-ranging set of findings and also posed challenges for empirical methods of compiling the findings, such as meta-analysis. Again, coordinated studies could be extremely valuable in future resilience research.

Is Resilience a Trait?

One of the most tenacious and wrong-headed issues in resilience science is the idea that resilience is a trait (Masten, 2012, 2014b; Panter-Brick & Leckman, 2013; Rutter, 1979). This enduring idea may stem from the origins of the word *resilience* itself, in that it often refers to a property of a thing or substance—the resiliency of a spring or a rubber band for instance. Early concepts of "hardiness" (Kobasa, 1979) and "ego resiliency" (Block & Block, 1980) in personality theory also contributed to this notion.

While traits have been implicated in the observed capacity of human individuals to withstand or recover from major blows or challenges, there is no single trait that could be construed as "resilience." The idea that resilience is a trait ignores overwhelming evidence that the adaptation of individuals to adversity depends on relationships and many other systems external to the individual. Moreover, this is a dangerous idea because it implies that children or adults who struggle to adapt or have not yet recovered from traumatic experiences are somehow lacking the "right stuff," in effect blaming the victim when the causes of stress or breakdown have much more to do with overwhelming

adversity exposure and lack of socioecological supports or protections.

Furthermore, there is ever-growing evidence that the same trait that functions in one set of conditions as a protective influence on function or development can function as a vulnerability in another context or at another point of time in development. Early examples identified by resilience investigators included individual differences in temperament as well as the biological example of sickle-cell trait (Rutter, 1987; Masten, 2012, 2014b). Recent research on differential susceptibility or biological sensitivity to context described previously in this chapter underscore the point that a trait may have different roles in different contexts.

Do Genes Determine Resilience?

The trait debate has returned in a new guise with the research on genotypes as singular promotive or protective factors. This deterministic view is completely unreasonable and simplistic, given that *all* human function and development is influenced by many interactions of genes with context and many forms of experience. The capacity of any individual for adaptation is highly complex, develops over time as a result of many interactions of the individual with the environment, and at any given time is distributed across multiple systems, including social systems external to the person.

Is Adversity Good for Children?

The idea that challenges can promote growth or, to paraphrase the famous words of Nietzsche quoted earlier that "whatever does not kill you makes you stronger," is another concept that keeps returning as an issue in resilience science. As discussed in the section on steeling effects and posttraumatic growth, there is some evidence suggesting that modest challenges and the recovery that follows can strengthen capabilities involved in resilience. This idea was captured by the challenge model of resilience early in the science (Garmezy et al., 1984) as well as in the notion of steeling effects (Rutter, 1987). Contemporary data on adaptive systems (e.g., the immune or stress-reactivity systems) are congruent with the idea that some challenge is helpful for adaptive systems to organize and calibrate themselves effectively for the expected environment. However, we want to emphasize again that there is no evidence that severe adversity and trauma is good for development. As in the situation of surviving Ebola as a method for achieving immunity, the risks and costs of severe threats to development, exemplified by child abuse and other forms of child exploitation or suffering, far exceed any conceivable benefit. When severe adversity does occurs, though, certainly it is the case that support and recovery are better for development than continued adversity or neglect.

Is There a Cost to Resilience?

A final example of enduring issues in resilience science is raised by the intriguing question of whether there is a price to pay for resilience (Masten, 2014b, Masten & Coatsworth, 1998). A number of influential studies raised the possibility that the stress or strain of overcoming adversity could cause current distress or later health issues (Luthar, 1991; Luthar, Doernberger, & Zigler, 1993; Werner & Smith, 2001). Some of these "costs" may be attributable to the adversity itself, akin to scars from battle, whereas others may result from the strains of setting high goals and related adaptive efforts. Recovering child soldiers and survivors of severe maltreatment, for example, would not be expected to come away from terrible experiences with no residual effects, but these effects may be better described as the costs of chronic trauma rather than resilience.

This question has resurfaced in recent work on allostatic load. In a provocatively titled article ("Is Resilience Only Skin Deep?"), Brody and colleagues (2013) reported that some of the most successful young people in their study of high-risk African American youth were showing signs of high allostatic load despite their positive psychosocial adaptation. They raised the possibility that overcoming the risks of economic strains and racism may take a toll on the body in the form of chronic wear and tear, indexed by high blood pressure or body mass index. As they follow these young people, it will be important to track their adaptation at multiple levels of analysis to see if success at one level continues to have costs at another level.

PROGRESS AND FUTURE DIRECTIONS

Progress and transformation in resilience science over the past decade is marked in many ways by implementation of a dynamic, multiple-levels perspective in conceptual, methodological, and empirical gains. This is the hallmark of the fourth wave, and it has set the stage for the coming decade.

Advances in Models and Methods

In conceptual models, the shift toward dynamic, transactional theory transformed resilience science to reflect the

growing prevalence of relational developmental systems theory as the core perspective in developmental science (e.g., Overton, 2013, Zelazo, 2013). Definitions of resilience, although still sometimes criticized and controversial, dramatically tilted toward systems-based definitions that are compatible with related concepts in other sciences that focus on other system-levels, including family resilience, community resilience, and ecological resilience. With this shift, the idea of resilience as a trait lost support, and interest grew in the processes linking multiple systems to influence development.

Among the most prominent conceptual drivers of theory and research on resilience in the past decade were GxE concepts and particularly the roles of epigenetic processes in adaptation that could influence resilience (Cicchetti & Rogosch, 2012; Karatsoreos & McEwen, 2013; Kim-Cohen & Gold, 2009; Kim-Cohen & Turkewitz, 2012). Conceptually, these ideas renewed theoretical and empirical interest in the programming of adaptive systems important for resilience (as well as vulnerabilities) and also sparked new thinking about intervention.

The concept of individual differences in the openness of an individual to environmental influence, combined with recognition of developmental windows of greater or lesser plasticity and sensitive periods for adaptive tuning of the individual to the expected environment, is transforming theory and research on the roles of both genes and experience in resilience (Del Giudice et al., 2011; Ellis et al., 2011; Masten, 2014b). These ideas and the empirical studies they inspire remain a key frontier for resilience research in the coming decade, particularly for intervention experiments designed to promote resilience through strategic timing and targeting or to program/reprogram adaptive systems to increase resilience.

The concept of developmental cascades, where function at one system level can spread to affect other levels through intersystem interactions, attracted considerable interest, including two special issues of the journal *Development and Psychopathology* (Masten & Cicchetti, 2010a, 2010b). These cascades can be bidirectional with neurobiological changes influencing psychosocial processes or vice versa. In addition, there was growing interest in delineating and testing models of how resilience in contextual systems of a child's life, such as a family or school, spreads to boost the resilience of individual children within the family or school. These resilience cascades can be naturally occurring or result from deliberate efforts to induce a cross-system cascade, as in interventions to foster better parenting as a means to normalize the biological stress regulation system (e.g., Fisher et al., 2007). Empirically, we would expect research on these intersystem, multiple-level cascades to expand.

Methodological advances also reflect improved capabilities in the science to measure and analyze multilevel and multivariate models (Masten, 2014b). For example, testing for developmental cascade effects requires repeated measures over time and statistical approaches that can account for inevitably missing data and multiconcept, transactional models. In addition, practical advances in structural equation techniques and software for analyzing interindividual growth and linking such growth to other variables or growth parameters at other levels also became feasible.

Tools for assessing neurobiological function and change also spurred research on processes that might account for resilience (Masten, 2014b). Perhaps most dramatic was the rapid increase in genetic tools for assaying DNA and epigenetic change at a more reasonable cost. Additionally, new tools for assays of cortisol in hair as well as saliva were helpful in research on stress and adaptation, and strategies for safely and meaningfully imaging brain function in very young children also advanced. We expect these tools to be put to even more use in resilience science going forward.

Advances in the Knowledge Base

Research on resilience has expanded dramatically at the biological level of focus, as noted. After many calls for greater attention to the neurobiology of resilience, numerous studies were undertaken with many more doubtless in progress. Psychosocial findings on resilience are now being studied at multiple levels to shed light on how change occurs, through both biological and social processes and intersystem interactions, and we expect the knowledge base to expand.

At the same time, there also has been remarkable progress in conceptual and empirical work on resilience in sociocultural context, in two major ways. First, there is simply more research in more diverse cultures focused on resilience, ranging from studies of resilience in child soldiers of Africa to survivors of disasters in regions all around the world, from China to Chile and Finland to South Africa. There is particularly more research on resilience in children of low-and middle-income countries, long neglected heretofore.

Second, there is more research focused on cultural similarities and differences in resilience processes. Specific areas of expanding science on resilience in cultural contexts include multinational studies, research on immigrant youth, research on investing in children globally,

and studies of children in ongoing political conflicts and war, including refugees (Masten, 2014a, 2014b). Research from diverse cultures supports to a surprising degree many of the major findings from earlier generations of resilience studies limited to a few cultures or economically developed countries. However, culturally focused research also highlights cultural differences in resilience and the culturally-grounded practices of communities designed to promote resilience (Ungar et al., 2013; Ungar, 2012).

This decade witnessed many additional and higher-quality intervention experiments pertinent to resilience, often in the form of gold standard RCTs (Cicchetti et al., 2006; Cicchetti et al., 2015; Masten, 2014b; Masten et al., 2015). Examples have provided throughout this chapter of intervention trials, including examples that illustrate how RCTs are beginning to include multiple levels of assessment that make it possible to study GxE and GxI effects and multiple-level cascades. We expect these directions of research, with their triple benefits—to theory, practice, and policy—to continue and expand in the coming decade.

More broadly, there is a surge of resilience-oriented research focused on investing in children and particularly children at risk globally, in both developing and developed nations (Lundberg & Wuermli, 2012; Masten, 2014a). Investment models for international organizations like UNICEF and the World Bank increasingly appear to reflect a focus on promoting competence and resilience, moving beyond survival. Additionally, international aid organizations are seeking evidence-based practices that build human capital and integrate resources across system levels to promote positive child development in very disadvantaged populations.

The past decade also is characterized by increasing attention to resilience in policies aimed at the well-being of children and adults at the local, national, and international level (Ager, 2013; Masten, 2014a; Panter-Brick & Leckman, 2013). We also see this translational application of resilience science continuing and also hope that it will be guided by the best possible research.

Future Directions

Given the progress and transformations we have documented in this chapter, we anticipate a fruitful decade of resilience science to come. We expect a continuing focus on multiple-level processes in models and methods that will fill in the many blanks in our understanding of how resilience works within and across levels, from the molecular level to the levels of individuals, families, schools, communities, cultures, media, and global policy.

As knowledge and tools continue to improve on the human genome and epigenetic processes, we expect a surge in theory-building and studies of resilience processes, particularly those that explain how naturally- and experimentally-induced adaptation influence resilience. We also expect more research on effective timing and targeting of interventions with respect to individual and cultural differences, biological programming, developmental cascades, and recovery pathways. We anticipate that there will be growing attention to the synergistic effects of integrated interventions that address multiple processes simultaneously to change the odds in favor of resilience and positive development.

In the coming decade, we also hope to see evidence that adaptive systems that developed in less optimal ways due to high adversity and inadequate protections can be recalibrated by new experiences. It will be exciting to see interventions that build resilience in the lives of children whose development may be compromised by residual effects of adversity or lack of protection.

Finally, we expect that the developmental study of resilience over the life span will become more integrated. A number of longitudinal studies are following cohorts later into adulthood, and the research on resilience in late life is expanding. Long-term studies of resilience have the potential to illuminate the benefits and costs of both adversity and resilience for future health and well-being.

The future of resilience science at this juncture appears to be bright with promise. No doubt critical evaluations of the theory and evidence will continue, as expected in a mature science. Challenges and effective responses to such challenges can build a stronger science. Thus far, resilience science appears to be robust in the face of challenges and contributing in meaningful ways to practice and policy that benefits children and societies, just as the pioneers envisioned.

CHAPTER 7

Vulnerability and Resiliency of African American Youth: Revelations and Challenges to Theory and Research

MARGARET BEALE SPENCER and DENA PHILLIPS SWANSON

Until lions have their own historians, tales of the hunt shall always glorify the hunters who tell it.
—Ewe-mina (Benin, Ghana, and Togo) Proverb

Everybody is a genius. But if you judge a fish by its ability to climb a tree, it will live its whole life believing that it is stupid.
—Albert Einstein

REFERENCES 373

For the nation's citizens of color, 150 years following President Abraham Lincoln's signing of the Emancipation Proclamation and notwithstanding Barack Obama's election during the interim as the first African American and forty-fourth President of the United States of America, unequal access to supports and opportunities persists. The relationship between the presence of accessible supports and the level of challenge confronted (i.e., given myriad risks), considered together, potentially makes the fact of individuals' unavoidable human vulnerability status both more complex and potentially critical for pursuing (traditional) human development tasks (see Havighurst, 1953). The specific level and character of vulnerability is necessarily fluid, context linked and, thus, demonstrates plasticity. Although this fact is uncomfortable for some to acknowledge, and infrequently evidenced in the design of research and in its interpretations, at any given time irrespective of gender, race, ethnicity, skin color, and place of birth, all humans' daily experiences represent some level of vulnerability.

HISTORICAL AND CONTEXTUAL FRAMING OF VULNERABILITY AND RESILIENCY

Individuals' lives represent ever-changing exposure to assets and resources as well as experiences of risks and challenges (see Spencer 1995, 2006; Spencer, Harpalani, Cassidy, et al., 2006). For America's minorities, the insufficiency and uncontrollability of assets and the challenges confronted have much to do with their identifiability as "the other" and persistent situations of high risk.

Multiple studies explicitly express the role of resiliency among African American youth and also acknowledge

the need for them to cross "cultural boundaries" and to use achievement as a way of coping with stress linked with socially constructed conditions (Phelan, Davidson, & Cao, 1991; Pollard, 1989; Siddle-Walker, 1996). From the program of research conducted by Pollard (1989), the character of findings resulted in recommendations targeted to educators which suggested that they encourage students to have high expectations and reward youth for their achievement efforts. During the same time, Werner's (1989) study reported longitudinal findings on the developmental trajectory of children that had experienced high-risk pre- and perinatal births. By the mid-1990s, several studies were examining resiliency for African American youth. Since that time, these studies have evolved with increasing attention to theoretical orientations, considerations of environmental influences inclusive of, but beyond that of the family, and nuanced methodological and statistical approaches for analyzing complex phenomena. Despite these advances and recommendations, for many African American youth, outcomes have declined in education, in physical health, in mental health, and in more general well-being. To address these contradictory trends, this chapter provides a sociohistorical framing in reviewing research that has informed the field, with specific attention on African American youth vulnerability and resilience.

Contextual Background: America's Race Salience Dilemma

Obtaining achieved good outcomes while facing significant obstacles is generally viewed as demonstrations of resiliency (see Spencer & Swanson, 2013). Accordingly, human vulnerability and resiliency are inherently intertwined; the former represent our human experience of normative and nonnormative challenges and supports, and the latter indicate successful outcomes albeit achieved under conditions of significant risk. Of course, efforts to achieve resiliency for self and others is not without dire consequences, as Sherman James and colleagues argued (e.g., see James, Keenan, Strogatz, Browning, & Garrett, 1992). Their patterned findings as epidemiological reports suggested an inverse relationship between socioeconomic status (SES) and hypertension. This paradoxical relationship between effort and health-challenging outcomes is associated with prolonged exposure to stress and is called John Henryism; their characterization follows.

> John Henryism is a strong behavioral disposition to cope in an active, effortful manner with the psychosocial stressors of everyday life. The latter include financial pressures, job demands, parenting, and managing interpersonal conflict, among other things. Persons manifesting the John Henryism coping style believe that daily stressors of this kind can be effectively managed (and high levels of psychological stress thus avoided) if they work hard and are determined to succeed. (p. 15)

Implicit in the James et al. (1992) analysis is that adult daily stressors may compromise the adequate provision of supports needed for carrying out developmental tasks due to racial gap differences for hypertension, diabetes, and oft-deadly stroke outcomes. Thus, adults' efforts to successfully meet developmental tasks relevant for themselves, their children, and others for whom they have responsibility are complex (see Havighurst, 1953). Life course efforts and goals designed to meet developmental tasks are not independent of the noted effort described by James et al.

Also relevant is the widely disseminated perspective by Swedish economist sociologist Gunnar Myrdal (1944), who posited a particular European perspective. In fact, virtually 50 years before the James et al. (1992) theory, Myrdal framed racial gap differences as an American dilemma and linked it to group membership. With a focus parallel to that of James et al., Myrdal also noted the significant physiologically adaptive costs for minority-status individuals. The analysis of African American historian Ralph Ellison (1944), a contemporary of Myrdal, posited that the process of living in a democracy and adhering to inherent democratic ethos represents the actual dilemma; thus, with a focus on the historical context, Ellison posited that the considerable physical and psychological costs hypothesized are related to the American Creed, which promises success with hard work. Our synthesis of the points of view salient for African American youth resilience and vulnerability implies that the extreme stress-creating dilemmas experienced by socializing adults and youth cannot be isolated from their efforts to tackle normative, stage-specific traditional lifelong developmental requirements. Tasks relevant to the life course call for a variety of supports and accessible assets (i.e., physical, social, economic, and historical)—both for youth and for socializing adults.

Research shows that African American parents embrace both American and African-based values and endeavor to instill both value systems in their children (Spencer, 1990b). Parents' values and history of sociocultural experiences with discrimination affect the socialization strategies instituted (D. Hughes & Johnson, 2001; McHale et al., 2006). Parents value honesty, academic success, and family responsibility and teach these values to their children. In addition, adults are likely to embrace culturally distinct values, which include among others kin networks, respect for the elderly, and mutual cooperation and sharing

(S. A. Hill, 2001; Murry, Berkel, Brody, Miller, & Chen, 2009). An underreported perspective is that parenting adults emphasize humanistic values over more ethnic specific parenting practices and values (Marshall, 1995). African American parents want to raise children with values and expectations common with all parents. At the same time, however, they recognize that although they raise their children to treat others with respect, they will not always encounter respect from others or have access to the same resources and supports as others. Accordingly, adults of color and particularly African American socializing agents have the additional and unique task of communicating to youth that the American Creed may not apply to their experiences. Relative to John Henryism (see James et al., 1992), also critically important to socialization effort and character is the reality that minority adults are required to communicate the socialization-relevant message noted without jeopardizing youth motivation, effort, and hope.

Relatedly, education has historical value linked to the belief that knowledge represents power and serves as a mechanism for obtaining economic stability. Parental experience with controlled access and lack of receptivity in schools has strained their own efforts for engaged involvement (Hanlon, Simon, O'Grady, Carswell, & Callaman, 2009). Given the wealth of research supporting the impact of parental involvement on positive academic outcomes for students, Black parents' perceived lack of involvement, as inferred by school personnel and defined largely as responding to calls from school and appearing for teacher conferences, is characterized as disinterest in the education of their children (Deslander & Bertrand, 2005; Gutman & McLloyd, 2000). The distancing of parents from the school also compromises the parents' access to information and informal factors relevant to resources. D'Agostino, Hedges, and Borman (2001) suggest that schools, specifically Title I schools designated as schools with a high enrollment of low-income students, create comprehensive procedures to engage parents who may also be confronting a myriad of unacknowledged circumstances critical to the socialization and support of students of color. Such procedures continue to be minimally implemented, creating limited accessibility for supportive educational opportunities for students and their families.

Patterns of asset accessibility (or not) may be connected with group membership and assumptions concerning social status that suggest inherent group value (e.g., given race, faith group, immigration status, national origin, skin color, and ethnicity). Unfortunately, the historically linked and broadly diverse challenges confronted by individuals and communities of color remain largely invisible, unacknowledged, and, in fact, minimally addressed by the social science and policy communities. Silencing discussions of disparity etiologies from a human vulnerability perspective, in fact, actually communicates the salience and dilemma of the persistent uneven resource distribution between groups of North Americans residing in the 50 states. In many ways, the situation is well illustrated by the African proverb cited at the beginning of this chapter. Specifically, the silencing of devalued points of view, particularly evident when pertaining to race/ethnicity comparisons and suggested shortcomings, matters; the situation determines whose "voice" is used for framing the experiences associated with one's racial group and thus the character of policies intended to be supportive. The situation contributes to the American dilemma as described by Myrdal (1944). Ellison's (1944) review of the work, however, noted that the continuing social ambiguity of the nation specifically concerning Blacks had more to do with the nation's Whites experiencing a clash between the American creed and what were actually everyday anti-American practices.

The lack of resolution of the conundrum described is not unexpected and influences the interpretation and framing of reports of patterned "gap" findings. The patterns of broadly disseminated between-group racial differences and outcomes, in fact, are merely further stereotypes of already maligned groups. Specifically, and as a case in point, the problematic descriptions and general pathologizing of African American males' life course experiences demonstrate the conceptual dilemma described.

The highly negative reporting and limited historical conceptualizing of the lives of African American males is evident as early as the preschool years and persists across the life course. For minority-status individuals more generally, the framing of gap findings frequently adds to active "problematizing" of lives rather than seeking and achieving insights as to contributing forces and persistent social conditions; thus, the dilemma suggests intergenerational significance. The work by Gibbs (1988) on Black males as an endangered species was designed to shock the nation into recognizing the impact negative and persistent societal conditions were having on their life trajectory. The emphasis was designed not to problematize but to create urgency for mitigating action. Rather than the latter, further stigmatizing occurred, creating heightened stress for caring adults who wished to protect youth from experiences that undermine their opportunities. Irrespective of the success level achieved, the stress associated with the experience of group stereotyping, oppressive situations, socially limiting conditions, and adverse health consequences of adults as a

function of the proffered efforts required, in fact, persistent and subsequently remain problematic.

For example, the literacy rates for Black boys at third grade are framed and disseminated broadly as the critical statistic used for determining the number of prisons requiring construction (see Neal & Rick, 2014). Similarly, the frequently disseminated statistical descriptions that note the existence of more Black males in prison than in college could be framed differently. That is, given that prenatal experiences and neonatal status of Black boys are not unlike those of other groups, literacy rate differences by third grade could be framed in ways which (a) question disparate and persistent contextual experiences, (b) consider accessible supports, and (c) evaluate opportunities had (or not) within the first 8 years of life. For example, a curious and consistent finding is that the status of Black boys is frequently linked to family SES. What is it about a low-resource socialization context that increases the high vulnerability of Black boys over that of girls (e.g., see Swanson, Cunningham, & Spencer 2003)? Given James et al.'s (1992) speculations concerning the dilemma of John Henryism and the racial differences in mortality and morbidity rates, it can be inferred that the social and contextual character of the life course suggests a dire prognosis for males of African descent. Accordingly, questions might inquire about: (a) the extraordinarily untoward social, emotional, and achievement-relevant experiences of Black boys in the first 8 years of life (e.g., achievement gaps, "special needs" labeling patterns, too few fathering figures, and context-linked coping responses to environmental experiences that label them as dangerous); (b) the character of and supportive capacities available in low-resourced communities (e.g., disproportionate contact with police for male adults and youth); and (c) compromised adult health status and socialization capacity to meet developmental task requirements. As indicated, the prenatal developmental status and perinatal experiences had by Black boys do not suggest anticipated gaps in cognitive, affective, or physiological differences by third grade. However, the compromising economic and stress relevant experiences had in the first 8 to 10 years appear impactful and significant in enough character for offsetting inferred developmental advantages evident at birth (i.e., given the absence of early gaps). Reports indicate neither physiological nor cognitive statuses of Black boys at birth that would indicate untoward middle childhood and early adulthood disparate outcomes (e.g., disproportionate Individualized Education Program assignment in school, contact with the criminal justice system, and more adult "prison time" convictions than college attendance when compared proportionally with similarly situated White youth). As suggested by the epigraph by Albert Einstein, erroneous criteria or descriptors may be used for assessing youth of color and particularly Black boys.

Frequently, undifferentiating explanatory labeling used for describing gap differences, such as "structural factor" effects, is, in fact, not helpful as it impedes serious proactive discussions. Alternatively, the unhelpful "explanatory devices," may actually limit consideration of serious and substantive queries having to do with (a) the nature of vulnerability, (b) the role of context and its persistency of compromising conditions, (c) the salience of culture as adaptive traditions, (d) the nature of assets required for resiliency, and (e) the myriad consequences of inadequate supports. Given James et al. (1992) theorizing, the lack of supports, in fact, may suggest a large and underacknowledged impact of John Henryism and influences due to the nature of microsystem experiences of youth. Additionally needed are insights about the salience of long-term challenges that represent persistent conditions of high risk in contexts which assume the same supportive impact of the American Creed for everyday experiences of all citizens.

The varieties of conceptual dilemma concerning the American Creed and the lack of equal access noted diminishes the production and availability of authentic information required concerning the specific character of resources actually needed and adequate for African American youth resiliency. Also affected and minimally understood is the impact of misinformation on youth performance. The situation impedes the design and delivery of adequate supports. Strangely, the shortcomings suggested are not represented in research strategies, overall project conceptualizations, or methodological techniques implemented. Nor are the challenges described evident and considered in questions asked by social scientists for determining their contributions to the broadly disseminated disparity findings that impact funding decisions. The dilemma is particularly salient for the developmentally relevant, conceptually unavoidable, and cognition-linked perceptions inferred by study participants themselves.

Although the impact of accrued individual insights might vary according to the group's status, all the factors are critical for youth, irrespective of race/ethnicity and SES. In addition and quite recently, social bias denial (e.g., given the election of the nation's first African American president) provides yet an additional source of social stress requiring coping and adaptations to alleviate psychological, physiological, and social impact. Failing to acknowledge social and racial stigma linked to group membership remains problematic, especially in the absence

of critical supports. The situation contributes to traditional "culture blaming" social science research explanations (see Small, Harding, & Lamont, 2010). Additionally, another postelection perspective suggests that the United States became "postracial" virtually overnight—that is, the American Creed is similarly experienced by all. At the least, the widely and rapidly disseminated assumption of a postracial America may have served to exacerbate the previously noted conceptual challenges.

The broadly aired, continuing, and social media–assisted conceptual strategy of framing the United States of America as a postracial nation attempts to reverse the U.S. identity as a race-conscious society wherein the American Creed and everyday race linked practices are at odds. The long-term program of research demonstrating race consciousness beginning in early child development was highlighted by Kenneth and Mamie Clark (1939, 1940) and Horowitz (1939). Research replications and extensions (e.g., Spencer, 1976, 1985; Spencer & Horowitz, 1973;), racial identity theorizing (e.g., Cross, 1991, 2003), and synthesis theoretical statements continued over the next several decades; see work by Spencer (1985, 1990a) and associates: Spencer and Dornbusch (1990); Spencer and Markstrom-Adams (1990); and Swanson, Cunningham, Youngblood, and Spencer, 2009. The focus has continued into the current period, although the research is plagued by problematic methodological strategies (see Brown & Bigler, 2005) and Kinzler and colleagues (Kinzler & Dautel, 2012; Kinzler & Shutts, 2008; Kinzler, Shutts, & Correll, 2010).

There is no question that even very young children are unavoidably aware of differences in values about and treatment by race. Changes in cognitive growth and development include the learning of stereotypes and objective concepts, given opportunities for learning the alphabet, colors, gender role expectations (representing similarities and differences), number recognition, as well as the treatment, values, and labels associated with racial/ethnic group membership; concurrently, the learning of "color-blind" attitudes by White children (e.g., see Brown & Bigler, 2005) might, in fact, belie their exposure to models and the learned expectations of White privilege (which is infrequently acknowledged or assessed in developmental science). With progressive increases in cognitive maturation during middle childhood and continuing into adolescence, progressively sophisticated analyses are evident and unavoidable, particularly with regard to color-associated evaluative judgments and attitudes and beliefs concerning group membership (e.g., see Fegley, Spencer, Goss, Harpalani, & Charles, 2008; McGee & Spencer, 2013; Spencer, 1990b; Swanson, Cunningham, Youngblood, & Spencer, 2009; Way et al., 2008). At the same time, there continues to be a penchant to ignore the significance of racial consciousness findings, maturation-associated patterns, contributions of such patterns to stereotyping and stigma, and myriad historical events leading up to the perspective of the twenty-first-century postracial America as the context for human development more generally.

Perspective and Significance

Lincoln's signing of the Emancipation Proclamation in 1863 was an important legal achievement. Nonetheless, regarding its everyday manifestation and influence on contemporary American life, the decree fails to provide the implied equity and fairness-valuing beliefs, attitudes, and practiced character traits assumed as the achieved outcome formally called the American Creed. Shortcomings include slight awareness of and concern about the psychological impact and challenges encountered over the life course on individual and group-level social experiences and policy-relevant consequences moving forward. The fact of the conundrum and its stability over time aids in explaining the high-risk contextual experiences had for some and a status of "invisible privileges" for others. For the most part, and as another contributing factor to this conundrum, the state of affairs is not acknowledged in formal social studies curriculum and disparate race-relevant academic experiences. Nor is the fact evident in the varied systems purported to afford myriad supports. In fact, social situations described as unequal conditions communicate a peculiar North American history.

Generally understated is another critical context-relevant development pressure on youth: the historical fact and persistence of inequality influencing the conduct of science. The shortcomings impact the research questions posed, the character of the theoretical and conceptual framing of the work posited, and interpretations of findings (as well as the conceptual framing of the scientific enterprise itself) (see Fisher et al., 1993, 2002; Graham, 1992; Guthrie, 1976). All these problems significantly undermine potential supportive impact (or not) of social policy and opportunities for fair practices intended to shore up equalizing conditions for all youth and, for the most part, their support-intending families. Consistent with the African proverb cited, a highly critical element of the persistent American inequality includes the limited conceptual framing of human development research and theorizing for those considered "other" (see

Harris, 1995). For example, the design of significant numbers of studies on American youth of African descent is frequently troubling. As an example of one major research flaw, methodological strategies too frequently compare low-income minorities with middle-income Whites. One result has been a conceptual pattern for minority status to be viewed as synonymous with lower income status, no matter families' actual social class status. The consistency of this pattern reveals the American Creed fallacy; in fact, housing restrictions, employment discrimination, loan procurement traditions by banks, and "redlining" (housing) practices continue to control the neighborhood opportunities, including quality-of-life concerns (e.g., healthy food options and services), available to working-class and middle-income families of color independent of their actual earning capacity and income bracket. Accordingly, the attendance of nonpoor minority children in schools characterized by percent of participation in free lunch programs is never disaggregated from school-level labels (i.e., level of participation in free lunch programming). Among other disadvantages, the practice contributes to the assumption of homogeneity among residents within the Black community, an assumption that ultimately fuels stereotyping and synonymous (low) expectations. As suggested, notwithstanding long-term critiques of comparative practices in research (i.e., along with other similar methodological oversights), the undifferentiating and stereotypical conceptual associations made about minority life—and particularly the development of African American children—continue as routine and troubling traditions (e.g., see Fisher et al., 1993, 2002; S. Graham, 1992; Guthrie, 1976; Spencer, 1990a; Spencer, Brookins, & Allen, 1985). The conceptual orientation and patterned research tradition encourages a level of superficiality of knowledge garnered about the context of human development processes for varied individuals of color as well as many diverse generational immigrant groups. These underacknowledged practices compromise perspectives about the risks and challenges confronted by children of color and thus normative levels of high vulnerability. Additionally, the frequent and a priori "strengths- or asset-free" character of such research minimizes contributions to non–problem-focused questions about life experiences of minority children and adolescents.

Our approach posits that all humans are unavoidably vulnerable (i.e., are confronted by challenges and risks) but have access to myriad supports and unique protective factors (see Spencer, 1995, 2006, 2008a; Spencer et al., 2006; Spencer, Swanson, & Harpalani, 2015). Thus, given the balance between accessible supports versus challenges and risks, appropriate ways of describing situations include statuses of high versus low vulnerability. Resilient individuals are those burdened by high risks and challenges but are able to take advantage of high (and often unique) supports. Privileged individuals may have challenges and risks but simultaneously benefit from superordinate levels of accessible and numerous supports and protective factors. The history of the social sciences has generally associated minority status with high vulnerability conceptualized narrowly as high risk level; Whites and favored minority-status (i.e., particular subgroups of Asian Americans) individuals have been associated with "normalcy." The privileged American status of the latter groups is generally unacknowledged. The former situation is an added source of social risk and conceptual challenge for research and policy on African Americans; the latter circumstance is viewed as an additional component of an individual's knapsack of privilege, as described by Peggy McIntosh (1989) and other critical race theorists. Historical critiques of research traditions on minorities have been explicit although generally insignificant impacts on the conduct of social science (e.g., see Guthrie, 1976). As indicated, contemporary methodological and conceptual dilemmas linked with the framing and implementing of research on minorities of color continue to represent a "flat learning curve" (e.g., Fisher et al., 1993, 2002; S. Graham, 1992; Spencer, Brookins, & Allen, 1985; Spencer & Spencer, 2015; Swanson, Spencer, Harpalani, Noll, Seaton, & Ginzberg, 2003).

In fact, the dilemma is clearly illustrated by a recent large-scale, positive youth development (PYD) study (see Lerner et al., 2011). Representing an impressive scope, the long-term, large, and much-needed undertaking included virtually 7,000 participants, living across 42 states, and represented at least eight repeated sequential points of data collection; in fact, given the sensitivities and sensibilities of the collaborators, the multiyear national data collection project included a variety of minority participants. However, the implementation of even this carefully conceptualized study, which suggested a critical consciousness concerning minority representation, still failed to include adequate numbers of minority youth to successfully accomplish within- and between-group analyses.

As indicated by the *Commentary* on the recent publication of project outcomes (see Spencer & Spencer, 2015) and particularly given the PYD emphasis, what could be conceived as a research implementation failure represented much more than a missed opportunity. If analyzed from an ecological perspective (see Bronfenbrenner, 1992), which acknowledges the contributions of the chronosystem and thus historical forces on the character of ecologies navigated by young people, missed opportunities were

numerous. These missed opportunities were particularly salient for African American male youth, given that preexisting circumstances require close attention to understand contemporary everyday inequalities and long-term representational inequities in the conduct of science. In fact, across the life course, living as a Black male is fraught with myriad and unique challenges (e.g., see Barbarin, 2013a, 2013b; Barbarin et al., 2013; Boykin, 1986; Cunningham, Swanson, Spencer, & Dupree, 2003; Lewis, Butler, Bonner, & Joubert, 2010). The perspective described and methodological inadequacies noted (e.g., sampling flaws) are consistent, as well, with the Einstein epigraph. Accordingly, if vulnerability is defined as a universal human characteristic wherein everyone has both protective factors or assets and risk characteristics or challenges, having available assets or accessibility to resources matters. That is, protective factors must be present and prominent to offset the dilemma and extraordinarily high-risk situations.

When it comes to racial group membership in the United States, and as described by Cooley (1902) over a century ago, the context character for one's evolving sense of self matters. In fact, Cooley noted, "The thing that moves us to pride or shame is not the mere mechanical reflection of ourselves, but an imputed sentiment, the imagined effect of this reflection upon another's mind" (p. 152). Although represented as varying realities consistent with the individual's stage of development, mechanisms associated with biologically determined maturation experienced in multiple layers of social context are unavoidably unique, influential, and heighten awareness of self-relevant perceptions. For example, the egocentrism of young children associated with normal maturation protects the self from troubling race/ethnicity associated feedback of the type described by Cooley (i.e., particularly during the sensorimotor and preoperational periods of cognitive development) (see Spencer, 1976, 1982a, 1982b). However, as children move into middle childhood and adolescence, changes in inference-making capacities occur. Appropriate, expected, and diminished cognitive egocentrism takes place. Progressive cognitive shifts change the character of manifested egocentrism (see Elkind, 1966, 1967). This, in turn, reverses the ego-protecting function of children's developmentally appropriate level of cognitive development (see Spencer, 1985, 1990a). Thus, when linked with Cooley's perspective, Einstein's quote demonstrates overlapping and synergistic links between maturation-based cognition, socio-emotional functioning, and unavoidable human biological processes of youth; children's intellectual (cognitive) processes are associated with their emotional life, which are collectively connected recursively to biology and thus are unavoidable aspects of human development and functioning.

Given the context of development and recursive experiences had with others—and as suggested by the Cooley (1902) quote—identifiability with and/or membership in a particular racial group or ethnicity still matters in twenty-first-century America. Accordingly, when considered long-term from a chronological perspective (the chronolevel of the ecology), the history and treatment of minority groups must be factored into analyses for achieving authentic insights and understanding of group members' contemporary life experiences. Thus, history provides insights about the problem of persistent inequality—as context—and individuals' daily experiences. Appreciating the character and expressions of human vulnerability and resiliency of North American children and adolescents of African descent must be framed from a historical standpoint, which provides interpretive framing for contemplating needed supports, policies, and enveloping practices. That said, and as an opportunity to situate and emphasize the fact, race/ethnicity (i.e., identifiability with group membership) represents a source of significant risk for some (thus, increasingly high vulnerability) and, at the same time, corresponds with unacknowledged privilege for others (thus, lowered vulnerability).

The next major segment of the chapter highlights the concepts of vulnerability and resiliency, providing a necessary perspective inclusive of all humans. In particular, it provides broadened perspectives and interpretations of development for youth of color. The section includes a discussion of the residual problem of slavery and its enduring character, which determines the context for human development while also serving as an influence on implemented policies and practices (i.e., the "what" and "how" of policies and practices intended to support and assist). The historical perspective also considers the persistency of privilege as Whiteness and African Americans' treatment as property associated with protected legal rights (see Harris, 2002) and describes contemporary colorism themes as well. The chapter discusses an ecological systems human development theory (i.e., phenomenological variant of ecological systems theory, PVEST). As an identity-focused cultural ecological perspective, PVEST is a unique life-course human development theory. Its context and culturally inclusive character accommodates the experiences of diverse humans (i.e., both minority and majority group members) as each navigates unique and traditional tasks associated with specific periods of the life course. The distinctiveness of the dynamic and recursive systems perspective lies in its ability to represent, address,

and explain the mechanisms of human development (i.e., both as processes and as outcomes) of minority as well as majority group individuals; thus, it explains development of humans (i.e., not only individuals of color). Accordingly, as an identity-focused cultural ecological perspective, PVEST encompasses the minority life-course experience and majority group meaning-making processes, thus affording a strategy for examining the vulnerability status and resiliency patterns of African American children and youth while, at the same time, acknowledging the role of the American Creed and historical contributions that reified "Whiteness."

HUMAN VULNERABILITY AND RESILIENCY

Before providing as background the role of history in the everyday contemporary lives of African American youth, a discussion of vulnerability and resiliency is critical. Consistent with all stages of the life course and as suggested elsewhere (Anthony, 1974; Spencer, 2006; Spencer, Harpalani, Cassidy, Jacobs, et al., 2006; Spencer & Swanson, 2013; Spencer et al., 2015), adolescence unfolds in contexts influenced by the particular historical moment, physical space, sociocultural traditions, and distinct interactions among them. As part of their efforts to achieve adulthood status, adolescents strive to attain progressively abstract academic and career-linked competencies as well as socioemotional-relevant relational skills. Their efforts may occur in generally underacknowledged conditions of stress and risk as well as with broad arrays and levels of support. Nonetheless, expectations for youth stage-specific outcomes and adulthood-supporting competencies are broadly disseminated by the media, which also aid in their reinforcement and maintenance. Thus, the socially constructed and historically linked variations in levels of support are frequently overlooked or not recognized in media portrayals of the many within- and between-group gap findings. Group membership as social identifiers, including gender, race, immigration status, skin color, ethnicity, and socioeconomic position, influences the availability and accessibility of resiliency supports. The American Creed frequently prevents candid discussion of social differences in group-associated treatment. The absence of authentic ways of acknowledging the salience of identifiability and stigma is problematic. Accordingly, also missing are options to discuss the impact of the shortcomings and unavoidable implications—to name a few—such as the training of professionals (e.g., teachers, health professionals, criminal justice personnel), the conduct of research (e.g., the nature of the sampling technique), the design of programming (e.g., social and health delivery services), and the framing and ultimate implementation of policies. The exemplar categorical associations noted impact statuses of privilege and, at the same time given one's particular categorical position(s), support insufficiency. These associations are both alarming and informing. The possible impact of supports and challenges for groups of individuals have the potential to widen gaps by further privileging situations for some while simultaneously and potentially adding to the challenging conditions endured by others.

The theoretical stance taken emphasizes the shared human experience of vulnerability. The level of vulnerability indicates the balance (or imbalance) between protective factors accessible versus risk level present; both vary, and thus human vulnerability shows significant plasticity. The fact of human plasticity reinforces the importance of accessible supports and the impact of risk conditions (i.e., both perceived and in fact).

Accordingly, our view posits that as a life-course fact, all humans experience a variety of risks as well as secure benefits from protective factors of one sort or another as each individual navigates the world (see Spencer, 2006, 2008a; Spencer & Swanson, 2013; Spencer et al., 2015; Spencer & Tinsley, 2008). The framing suggests that human vulnerability does not reflect most traditional research perspectives but instead, consciously or unconsciously, situates privilege (including generally unacknowledged benefits) as the status of all citizens. The assumption implied is one of equal accessibility to supports, thus implicitly reifying the genuineness of the American Creed for all. More specifically, equity as fair competition and equal opportunities for advancements are seen as uniformly attainable. Given actual lack of credibility and legitimacy of this view for the everyday lives of particular citizens (i.e., especially those of color and/or highly impoverished individuals), the assumption demonstrates shortcomings. The inference of equal access promotes the conclusion that disproportionality or failure for some, and the patterned successes for others, are legitimate and "earned" achievements or group status outcomes. That is, some of a society's citizens, as success stories or assumed earners of superior performance, are portrayed as the norm. Individuals' disproportionate access to protective factors and supports (i.e., those enjoyed without full acknowledgment of them) is seldom noted. Given the inequalities that characterize experiences by group membership, theorizing for those having experienced such sensitivities has been helpful.

An Inclusive Perspective: Phenomenological Variant Of Ecological Systems Theory

Providing new conceptual strategies of salience to all humans, phenomenological variant of ecological systems theory (acronym pronounced: P-VEST) is a human development framework that acknowledges the critical role provided by individuals' own perceptions (Spencer, 1995, 2006, 2008a; Spencer, Harpalani, Cassidy, & Jacobs et al., 2006; Spencer, Swanson, Harpalani, 2015). It focuses on identity formation while considering structural factors, cultural influences, and individual perceptions of self, significant others, life experiences, and the environments in which one lives and copes; the processes unfold for individuals or groups while they navigate across myriad social and physical contexts. As such, the system's framework is conceptualized as an identity-focused cultural ecological perspective, which represents significant and unavoidable plasticity. Identity formation takes place across the life course and is especially relevant for adolescents, given their heightened self-consciousness during that period of development. PVEST combines its emphasis on individual perceptions with Bronfenbrenner's ecological systems theory (1979), thus linking context and perception. While Bronfenbrenner's model provides a means for describing the ways in which multiple levels of context can influence individual development, PVEST illustrates life-course development within and between contexts and group membership. In doing so, it emphasizes the individual's meaning-making processes that underlie identity development and responsive behavioral processes and outcomes (Spencer, 1995, 2006, 2008a); both are linked with the developmental tasks and maturational themes salient for the particular developmental period. As typical and atypical risks and challenges are confronted, the character and level of accessible supports play critical roles.

Supports and challenges matter particularly for youth development. The theoretical perspective of PVEST helps situate work by McIntosh on privilege and the concept of John Henryism detailed earlier. McIntosh (1989) designated the frequent (but unarticulated) association of support with high status. Characterizing the advantages as having to do with "Whiteness," she described the association of Whiteness with privilege and indicated an individual possessing or having access to (or not) a knapsack of privilege. McIntosh suggested that benefiting from a "knapsack of assets and privileges" makes a difference; appropriating greater success with less effort, developmental tasks are handled with greater ease. However, the lack of easy access and "assumed privileges" and greater exposure to attendant tension (i.e., given minority-group status and social stigma) is infrequently acknowledged or considered in programs of research or the evaluation of research. Importantly, patterns associated with persistently high-risk status and hurdles related to multiple contexts matter as well. Additionally, the dilemma associated with high risk status, in fact, multiplies the problem of patterned adversity, given that significant challenges are perceived as "ordinary" life-course experiences. The dilemma virtually explains the physiological adversity described by James et al. (1992) as "John Henryism." More troubling, assumptions concerning legitimate outcomes of meritocracy accompanied by assumed parallel individual-level investments of labor, hard work, and intrinsic motivation (believed expended) reinforce stigma; they compound the state of privilege as "norm level" and reaffirm assumptions concerning effort expended for particular—and, in fact—privileged individuals. For some, widening outcome gaps reinforce stereotypes of laziness, lack of motivation, and intellectual deficits assumed to represent native capacities for the particular undervalued referent group.

In contrast to these views, a conceptual commitment to the universality of human vulnerability and its dual contributors as protective factors and risks allows for greater exploration of the "how" of outcomes and not just the "what" as a development-specific product. The suggested alternative conceptual frame connects risks as pitted against individuals' diverse strengths and protective factors. The PVEST framing allows for consideration and analysis of particular levels (and character) of supports and protection. The framework affords a nuanced analysis that makes explicit both culturally specific and shared protective factors, strengths, and supports (e.g., intergenerationally based resources, religious beliefs, social connectedness, spirituality, faith traditions, cultural socialization practices, social connectedness, etc.). Also critical and a conceptual benefit of the framework is that a group's high vulnerability due to significant social risks (and neglect) are acknowledged (e.g., reversed policy impact, low school resources, significant levels of stigma and stereotyping, inadequate health resources); the emphasis is different from that of traditional social sciences and specifically developmental stances, which ignore their salience (see Spencer & Tinsley, 2008).

In fact, Spencer & Tinsley (2008) indicate that there are at least two strategies for interpreting standards upon which programs of research are implemented and findings are evaluated and interpreted. One considers primarily protective factors for certain youth and groups; in parallel fashion, strengths of other youth are viewed as basically

inferior or invisible in regard to salience. The latter group of young people, in fact, are represented in the literature as possessing primarily and narrowly defined risk factors; their availability of protective factors is not acknowledged (e.g., both as familial and group traditions and shared strengths). Accordingly, this shortsighted perspective is associated with assumptions of meritocracy for some and presumptions that high-risk-status individuals are devoid of strengths and supports. The clear bonus of the PVEST conceptual strategy is its inclusiveness of experiences representing culturally diverse communities and making explicit how the traditions are protected or challenged by specific opportunities or burdens. Accordingly, these research values or perspectives contribute quite different insights into the policy, research, and practice (e.g., as pedagogy) traditions which are present at any historical point in time, impacting life course outcomes. The conceptual strategy and framing of PVEST not only explore and acknowledge significant imbalances in human life experiences but potentially introduce significant dissonance when one reflects on the conduct of social science research, theorizing, and everyday policy-relevant practice.

Challenges to Youth Development

Irrespective of supportive conditions, biological, cognitive, and affective changes still have the potential to enhance youth vulnerability, thus contributing to findings that suggest typical or atypical patterns of outcomes. As described, this fact also suggests that human vulnerability includes the relationship between frequently unacknowledged risks and frequently ignored privileges as protective factors. Supports matter, given the obligation to confront the requirements of developmental tasks (see Havighurst, 1953) and the psychosocial needs to support them (see Swanson, 2010). There are few points in life beyond adolescence (as well as the neonatal period) when the invisible or unacknowledged fact and character of vulnerability have more dire implications. Erik Erikson (1950) described human development across the entire life course and emphasized the need to focus on ego identity development as the defining characteristic of adolescence (e.g., see Muuss, Porton, & Velder, 1996).

Erikson (1950) explained that "psychosocial development proceeds by critical steps—'critical' being a characteristic of turning points, moments of decision between progress and regression, integration and retardation" (pp. 270–271) and proposed eight distinct stages of development. Police officers may perceive Black males' extended good-byes with friends or with group of youth as threats, no matter how they are intended. Being experienced as a threat is associated with Black males understanding of how they are perceived by the world around them, thus shaping turning points relevant in their development (Stevenson, 1997). For Erikson, each stage is characterized by a conflict between two opposing forces; the primary goal of development is the acquisition of ego identity. Stage 5, which occurs during adolescence, is defined by a conflict between identity and role confusion. Strategies by which adolescents resolve the identity conflict impacts their development through the final stages from early to late adulthood. With the onset of puberty, adolescents are "primarily concerned with what they appear to be in the eyes of others compared with what they feel they are, and with the question of how to connect the roles and skills cultivated earlier with the occupational prototypes of the day" (p. 260). Given the problem of unequal access to opportunities for minority youth (African Americans particularly), stage 5 experiences for African American youth might provide quite different identity resolution opportunities.
