Without question, an accrued sense of ego identity is accomplished when "inner sameness and continuity prepared in the past are matched by sameness and continuity of one's meaning for others" (Erikson, 1950, p. 261). The danger of stage 5 is role confusion, a state in which individuals temporarily overidentify with peers held in high regard and, in doing so, seem to lose their own sense of identity. As a defense against role confusion, adolescents tend to be "clannish, and cruel in their exclusion of all those who are 'different,' in skin color" (p. 262) and other arbitrary characteristics. The differences in accessible supports matter. At the same time, inordinately high levels of challenge and stress variation make the identity processes (i.e., given coping supports) quite different for youth even if they appear to share "similar contexts." For example and relative to identification processes, the election of White presidents has not represented the same challenges and assumptions about "Whiteness" for European American youth as it has for people of color, given the nation's election of its first president of African descent (e.g., broad media-disseminated assumptions of the achievement of a postracial status hours following the election of Barack Obama).

To further illuminate the complex processes experienced during Erikson's fifth stage, James Marcia (1966, 1980) described and empirically validated four distinct modes in which adolescents react to the identity crisis. The four modes differ along two variables—whether the subjects have undergone a crisis and whether they have committed to a particular occupational, political, or religious

ideology. Identity achieved individuals have experienced a crisis or exploration period in which they were forced to reevaluate their beliefs and have emerged from the crisis with a commitment to a particular identity. Exposure to myriad privileges would be expected to impact the process. Foreclosure individuals have also committed to particular ideologies or occupations but have not experienced the crisis period. These individuals tend to exhibit identities that mirror those of their parents or other socializing adults; these identifications are potentially dissonance producing for youth of color, given the extra stress and strain on parents and a potential John Henryism level of effort required for carrying out societal roles (see James et al., 1992). Thus, the greater challenges associated with minority status (including relational processes with parents) makes the identification processes of minority youth more nuanced (at best). McIntosh's (1989) knapsack analogy suggests that high-privileged parents may experience adult developmental tasks differently, given their access to unacknowledged privileges linked to Whiteness. Obviously such experiences are quite different from the support insufficiency situation described by James et al.

Moratorium individuals are actively engaged in the adolescent crisis period; that is, they explore different paths and question belief systems. From moratorium experiences, individuals may reach a point of commitment and identity achievement or may disengage from the crisis without making a commitment, thus entering the next stage, identity diffusion. Of course, the extrarelational challenges associated with minority status indicate that the comfortableness of engaging primarily in experimentation may not be an option for youth of color. Identity-diffusion individuals are characterized by their lack of interest in committing to a professional, political, or religious path. For youth whose participation may be associated with membership in a stigmatized group or living under support insufficiency conditions, their options may be more limited; thus, diffusion may well be more constrained or show unexpected variations for youth of color. Not surprising, atypical trajectories may be observed more often, and researchers who perform uncritical analysis may infer simplistic conclusions that further promulgate stereotypes.

According to Marcia's (1966, 1980) identity status framework, identity achievement is a dynamic process, which means that an identity-achieved individual can regress to a state of moratorium many times over the life course. When the environment changes and individuals are faced with dissonant value systems (e.g., questionable and dissonant feedback about the self and beliefs about what is possible), they may return to a state of moratorium. At any point, the moratorium individual has the potential to become either identity achieved or identity diffused. These shifting processes require psychic energy and supportive environments for productive resolution. Of the four modes of Marcia's framework, identity achievement is associated with the highest self-esteem and greatest resilience in the face of negative feedback. It is important to avoid value judgments when comparing foreclosure and moratorium. Each may be adaptive, depending on social context and individual differences. However, the level of misinterpretation of the achievement gap fomented by Fordham and Ogbu's (1986) "acting White" characterization provides a case in point. Alternative interpretations have posited identity-focused but culturally and ecological-sensitive perspectives relevant to meaning-making processes of youth. The more general historical events reportedly experienced immediately following the end of slavery suggest a perspective not consistent with the Fordham and Ogbu perspective (see Spencer, Cross, Harpalani, & Goss, 2003). As described by Cross (2003) and by Siddle-Walker (1996), historical documents as contextually relevant evidence suggest an overall valuing of education by Black educators and communities. Cited historical data and research reported by Cross and by Siddle-Walker reveal a general activist orientation by Black educators in support of the development of competence formation among youth. The observations are generally not included in the design of research for implementation, which emphasizes the role of teachers (i.e., attitudes, beliefs, social and emotional connectedness, and values) and may aid in explaining the findings of the atypical late-twentieth- and early-twenty-first-century achievement gap.

Another strategy that links contextual factors with typical and atypical findings for Black youth is Boykin's (1986, 2000) analysis, which makes clear the potential impact of the context on tensions experienced in learning environments. His approach describes the source of and reason for heavy psychic energy misuse as the "triple quandary." Boykin's characterization is consistent with PVEST (Spencer, 1995, 2006, 2008a); he reaffirms the role of cognitive mechanisms, coping processes, and identity pursuits. Boykin describes the three elements of the achievement triple quandary identity dilemma as the need of youth to balance identities; the three identities include a "mainstream White experience," the minority [status] experience, and the specific (and frequently highly devalued) Black culture experience (see Boykin, 1986, 2000). Boykin's analysis, which is focused on identity and coping, suggests that the issue may not be youths' association of school-linked competencies with "acting

White" identifications. From a PVEST perspective, the efforts of African American students indicate ego resiliency attempts to protect the self, given cultural values and the lack of contextual experiences that provide for a seamless inclusion, for example, in their school.

According to Spencer and Harpalani (2008), Fordham and Ogbu (1986) were not the first to characterize the minority achievement gap as "acting White." That perspective had been argued over a dozen years earlier by McArdle and Young (1970). Counter to the perspective emphasized by Ogbu and Fordham, Spencer and Harpalani suggest that "gap findings," in fact, represent a virtual "youthful pushback" from values designed to demean, devalue, and disgrace. Youth of color, frequently in environments of stigma and stereotyping, push back from accepting school-linked preferences and values. More specifically, youth consider the oft-dominating values as focused efforts to denigrate Black culture, values, and beliefs (Spencer & Harpalani, 2008). Spencer and Harpalani concluded that youth need to resolve the counteridentifications noted (i.e., consistent with the triple quandary analysis proffered by Boykin) while simultaneously coping with school-relevant competencies.

In regard to the acting White perspective, it appears fair to speculate that at any given time, youth have a finite amount of psychic energy for responding to school-relevant developmental tasks. The emotional combating of self-relevant (mis)labeling by youth represents a significant misuse of psychic energy. Efforts by African American youth to protect their "cultural heritage" and race-relevant "selves" is energy consuming. The process may leave less psychic energy available for satisfying or resolving the tasks at hand (i.e., an academic learning orientation, productive school record, and achievement outcomes). Further, and as implicated by Marcia's (1966) identity status perspective, identity processes for stigmatized group members require more adaptive processes (i.e., both reactive and stable coping) and, accordingly, would be expected to be significantly and behaviorally nuanced. And as a function of unavoidable plasticity, adaptive processes suggest many more opportunities for producing atypical outcomes relevant to ego identity.

Commensurate with the reactive and stable adaptive coping processes required when framed by a PVEST perspective, achievement outcomes for Blacks are often "explained" by "event labeling" (e.g., acting White or stereotype threat). Event-specific labels fail to acknowledge the complexity of the process and the contributions of supportive cultural traditions (e.g., religious identity [Brittian & Spencer, 2012]), the designation and importance of "referent others" (e.g., an elderly, culturally affirming next-door neighbor) who represent important sources of cultural identification and allegiance (see McGee & Spencer, 2013).

In addition to informing convictions regarding careers, religion, and politics as normative tasks toward productive citizenship, racial and ethnic minority youth must also adopt an identity congruent with their group membership that offers the foundation of group strengths in contrast to the stereotyped societal messages promulgated in the media. Various models exist for explaining and assessing the relationship of these identity processes on youth outcomes (Cross, 1991; Sellers, Smith, Shelton, Rowley, & Chavous, 1998). Although there are between-group influences and differences in how identity formation develops, nonetheless, there is consistency regarding the impact on viewing the world from a Eurocentric lens versus a secure racial and ethnic identity. The former situates youth for internalizing stereotypic messages, while the latter may contribute diverse perspectives without youth risking their own identity. Luthar and Lattendresse (2002), in contrast, describe maladaptive coping of privileged youngsters who lack adaptive coping practice opportunities. However, from a developmental science perspective, few studies examine privilege, "fear of differences," and commensurate identity processes in the case of White, middle-income youth.

Thus, the contributions of historical circumstances, particularly the institution of slavery, assist the current conceptual task by linking the history of North American slavery to contemporary and frequently highly challenging experiences of youth and the impacts of Whites' perceptions of their own privilege as it functions and represents the context for others' human development. Another interesting revelation is the infrequent acknowledgment of the significant and positive impact, historically, that the Black community had on its residents and their children (see Siddle-Walker, 1996). In contrast to the historical role of the Black community and Black schools as described by Cross (1991) and Siddle-Walker (1996), the lack of an ego-supporting environment for Black youth in contemporary school and neighborhood settings is described by Stevenson (1997) as resulting in youth feeling "missed, dissed and pissed." That is, no matter the historical relationships of Black youth in their schools and neighborhoods (see Cross, 2003; Siddle-Walker, 1996), legitimate inferences and unavoidable meaning- making processes of contemporary youth in hostile environments are important (e.g., see Chestang, 1970). Such cognition-, psychosocially-, and biology-dependent processes matter for oft-reported findings of achievement gaps. The situation serves to

compound school-associated relational and identity challenges for both students and families.

Historical Placement

It is important to acknowledge that the 2015 publication of the third edition of the *Developmental Psychopathology* handbook also marks the 150-year anniversary of the passing of the Thirteenth Amendment to the Constitution, which marked the December 1865 abolishment of American slavery. The maintenance of the institution of slavery contributed to significant levels of dissonance.

Historical Relevance of Slavery for Contemporary Cultural and Social Traditions

The institution of slavery was viewed by Thomas Jefferson, one of the nation's Founding Fathers, as a necessary evil. The views held about African slaves and their economic benefit, particularly to the South, resulted in the establishment of the Confederacy and the waging of the Civil War. There is no doubt that slavery was seen as an economic benefit but also represented frequent concerns about potential social consequences of freed slaves, given the less-than-human labeling assigned to them. It is critical to acknowledge that the passing of the Thirteenth Amendment to the United States Constitution in 1865 was an enactment of policy. It did absolutely nothing to contain or change the broadly held assumptions, values, assessments, and beliefs concerning people of color as fellow humans residing as equal citizens of the nation. As suggested by the Chestang (1970) analysis, the inhumane labeling solidified the socialization task for parents of Black children to engage in supportive parenting and positive youth development efforts, albeit under multilayered hostile ecologies and practices regarding home, school, and neighborhood experiences. Situations and strategies to change thought processes concerning color-associated "difference" were neither acknowledged as fundamentally needed nor formally enacted. In sum, policies were fomented and filed as the law of the land, which—of course—was no small feat. However, continuing attitudes, beliefs, and feelings about the price paid for the freedom of "unlike others" were left virtually unaddressed for over 140 years. More specifically, during the recent half dozen plus years (and following the passage of the Thirteenth Amendment in 1865), several reconciliation-relevant resolutions were passed. In 2007, the State of Virginia Assembly was the first state to pass the House Joint Resolution (Number 728) acknowledging "with profound regret the involuntary servitude of Africans and the exploitation of Native Americans, and call for reconciliation among all Virginians." On July 30, 2008, the United States House of Representatives passed a resolution apologizing for American slavery and called for reconciliation for the subsequent discriminatory laws. The United States Senate followed suit on June 18, 2009, also apologizing for the "fundamental injustice, cruelty, brutality and inhumanity of slavery." However, assuming no real damage or long-term harm, the latter statement also noted that the resolution passed could not be used for requesting restitution. It is important to concede that before the Virginia resolution in 2007, 142 years passed when absolutely no responsibility was taken for the nation's institution of slavery and treatment of Blacks during the interim. Further, one might infer that the general opinion continues to be that the sustained beliefs and traditions about people of color during the interim were not salient in the design of supports, or contemporary race relationships, requiring redress of any kind.

Unlike the end to the institution of American slavery, at the end of apartheid in South Africa, truth and reconciliation public hearings provided opportunities for psychological processing of its long-term and heinous character as an unjust and brutal social and political system. The tribunals at Nuremberg at the end of World War II served a similar purpose. In fact, contemporary efforts continue to support the efforts of kin to obtain valuables confiscated from ancestors brutally killed in Europe.

As noted, however, and for over 140 years following the end of slavery and passage of the Thirteenth Amendment, responsibility was never assigned nor guilt acknowledged moreover than political resolutions generated and filed. The amendment provided rights but without accountability for protecting individuals' rights against exclusionary practices. Accordingly, one perspective about the persistent adverse attitudes and identity construal of Black Americans is that unaddressed and residual attitudes, assumptions, and beliefs continue to contribution to contemporary contextual and psychological conditions. The unacknowledged circumstance results in the enjoyment of privileges for some and enduring threat as sources of significant everyday risk and challenge for others (i.e., leading to multilevel support insufficiency). The conundrum has implications for practices and traditions across the life course and at all levels of social ecologies, including implications for conducting research, implementing practice, and shaping policies. For the nation's youth, the lack of attention has added to the complexity of experiences evident both within and between groups' everyday developmental experiences (i.e., particularly youth of color). Identifiable resources and access to them matters; thus,

protective factors such as Whiteness for Caucasians and skin tone differences for African Americans (as well as cultural socialization experiences needed for coping with persistent and nuanced discrimination) have implications for the character of treatment, risk level confronted, and accessible or experienced supports. Color and race still matter for African American youth.

Historical Framing of Challenge and Opportunity from a Critical Race Perspective

Critical race theory affords a late-twentieth-century and early-twenty-first-century lens for framing the design and interpretation of research on African American youth (i.e., particular patterns of findings for typical and atypical outcomes). For our purposes, it also provides a strategy for utilizing historical events for interpreting twenty-first-century findings about developmental outcomes for minority youth (i.e., both expected outcomes and more atypical ones). The use of historical sources supports the centrality of particular opportunities and challenges regularly confronted by youth of color. At the same time, the historical backdrop provided and critical race perspective, collectively considered, afford explanations for the particular types of opportunities and challenges confronted by Black youth. Additionally and of relevance to resiliency findings, critical race considerations provide useful ways of thinking about salient constructs for consideration in programs of research but too frequently remain conspicuously absent. The conceptual deficiency disguises and complicates authentic comparisons between the daily reality of minority group youth versus those of nonminority youth, who customarily enjoy or benefit from what has been referred to as "Whiteness as property" (Harris, 1995). In this case, the term *property* suggests experiences including opportunities that are governed by social rules; relatedly, the North American brand of slavery had unusually horrific social rules. In fact, and consistent with this perspective, D. B. Davis (1966) described the continuity of slavery as a concept as well as a social and legal category. Operational Whiteness traditions separated Blacks and Whites relative to slavery. However, Whiteness itself became associated with sets of social rules and traditions in the mode of property, as described by Harris (1995); from this lens, Blacks became objects of property (i.e., Whiteness). Davis suggested that slavery in the modern Americas was remarkably dissimilar from other forms of slavery; its uniqueness had to do with its importance as an economic commodity in the plantation economies. Thus, that importance was a key reason for its distinctness. Perhaps its uniqueness and continuation into the twenty-first century is due to its continuing economic impact. More specifically, failing to confront the view of Whiteness as property suggests that the dire outcomes for Blacks functions as an economic system (i.e., job creation, which sustains the contemporary form of an earlier tradition). Careers can be devoted to "fixing others" or the design and implementation of policies and practices misconceived and inadequate as supports for guaranteeing opportunities for self-determination among Blacks.

The social rules that were altered with Lincoln's signing of the Emancipation Proclamation represented a change in a legal tradition. However, it might be argued that the social rules governing everyday access to power and the control of power over nonmaterial resources (e.g., access and opportunity) did not change; the persistency may explain the current design of research, the queries posed, and the interpretation of everyday experiences had and required of youth of Black families and communities. Further, given the lack of change regarding perceptions of and representations of Whiteness as property, James et al.'s (1992) epidemiological relevant observation of "John Henryism" is not unexpected. That is, the Whiteness-as-property social dilemma, in fact, would make the resources and supports actually required for offsetting the level of effort expended virtually unobtainable in accomplishing "ordinary developmental tasks" as described by Havighurst (1953). Considered collectively, the critical race perspective (e.g., see Harris, 1995) evoked and the continuing residual problem of (social and psychological) slavery as described by D. B. Davis (1966) afford new insights concerning human vulnerability and resiliency when applied to the experiences of contemporary African American youth.

As suggested and from a developmental science perspective, there continues to be a tradition to ignore the normative knapsack of White privilege (McIntosh, 1989) and general salience of the Whiteness-as-property thesis (Harris, 1995), a tradition that communicates a litany of intergenerational privileges. The socially constructed supports and rules—unacknowledged but operational—automatically provide White youth and families with unacknowledged social and personal supports; they virtually guarantee positive "typical" outcomes; further, their utility operates to decrease the obvious sources of high vulnerability (i.e., especially economic sensitive indicators). From a critical race perspective, a legally supported Whiteness-as-property tradition has dire consequences for minority resiliency, self-determination, and beliefs about the American Creed. This "silent" although

operational tradition contributes to persistently low human vulnerability for nonminority citizens independent of social class.

As cited by Harris (1995) and specifically analyzed by Roediger (1991), there are wages (such as having consistent benefits and unacknowledged assets) associated with Whiteness. Importantly, and given the obvious consequences and benefits of *not* acknowledging the benefits of Whiteness, bringing attention to the different contributors to and consequences of it for human vulnerability matters. Roediger's perspective also assists in explaining the differences among poor White, Black, and Brown individuals; that is, poor Whites may persist no matter their situation since being White still "pays wages."

In similar terms as Roediger and as McIntosh, Harris suggests that economic challenges may be experienced differently by poor Whites even during conditions of economic downturns. Harris noted that "Whiteness retains its value as a 'consolation prize': it does not mean that all whites will win, but simply that they will not lose, if losing is defined as being on the bottom of the social and economic hierarchy—the position to which Blacks have been consigned" (p. 286). Long-term and consistent stereotypes are associated with the position and have important significance for performance (see Aronson, Lustina, Good, Keough, Steele, & Brown, 1999; Aronson, Fried, & Good, 2002). No matter the effort expended, unless having and opting for the "opportunity" of "passing," the Black vulnerability level is never made less severe by such reassurances as described by Harris—that is, of never being at the bottom. That fact, in and of itself—and independent of one's point in the life course—promotes a very different level of stress and risk and approach to everyday challenge.

Maturation-based social cognition makes the awareness of dominant race-as-caste messages evident beginning in the early years. Such messages have been recorded as young children's race awareness, racial attitudes, and racial preference literatures (e.g., see Spencer, 1985; Spencer & Dornbusch, 1990; Spencer & Markstom-Adams, 1990). Identity-relevant accommodations by middle childhood and adaptations at adolescence and young adulthood have also been reported (e.g., see Harpalani & Spencer, 2009; Harpalani et al., 2013; McGee & Spencer, 2013; Swanson & Spencer, 1999; Swanson, Spencer, Dell'Angelo, Harpalani, & Spencer, 2002; Swanson, Spencer, & Petersen, 1998). The cognition-based awareness of African American youth of Whiteness-as-property themes require that they cope with extra-challenging—albeit generally "invisible"—identity-relevant developmental tasks. Although frequently understated in the literature, youth and families of color require more complex cognitive and emotional adaptations and context-relevant accommodations and supports (e.g., home, school) (e.g., see Brittian & Spencer 2012; Cross, 1991, 2003; McGee & Spencer, 2013; McGee, Hall, & Spencer, 2015; O'Connor, Hill, & Robinson, 2009; Spencer, 1990b). The knowledge base and resource needs for parents who must serve as effective socializing agents are different from those of parents who enjoy the social privilege of Whiteness as property. As described by Harris (1995), a fundamental and core valued aspect of privilege is "its exclusivity; but exclusivity is predicated not on any intrinsic characteristic, but on the existence of the symbolic Other" (p. 290). Harris explained that this symbolic character also communicates an "illusion of unity" among Whites. Identity accommodations are not required by White youth as adolescents (i.e., coping with stereotypes about group membership); that is, in general, White youth can pursue traditional developmental tasks of salience used for assessing stage-specific competencies and general resiliency outcomes (see Havighurst, 1953). The experiential differences between Whites and Blacks—based solely on skin color—matter for coping as well as adaptations required, including identity formation processes, which have implications for level of vulnerability.

Consistent with the opening quote by Einstein, at the least, the findings of too many studies about minority children and families create highly troubling literatures. More specifically, as contributed to by "experts" in the disciplines and fields of sociology, psychology, education, public health, social welfare, criminality, and criminal justice, a tax dollar–funded "research industry" is frequently overly simplistic and represents decontextualized approaches. Considered collectively, the shortcomings create or contribute to a virtual "culture of poverty" literature. It provides problematic interpretations of developmental processes and outcomes for children of color as well as entire communities. The lack of understanding into developmental mechanisms and their linkages with long-term context considerations and historical traditions result in the dilemma implied by the Einstein quote, which has obvious implications for competency assessments and stereotypes about them (see Aronson et al., 2002; Steele, 1997). In fact, as suggested from a critical race perspective, such conceptual shortcomings reify and illustrate "the valorization of Whiteness as treasured property in a society structured on racial caste" (Harris, 1995, p. 277). One may infer that not knowing about or failing to acknowledge the character and heterogeneity linked to the unique

racial caste system of diverse groups and their children's everyday experiences introduces a pattern of conceptual shortsightedness, at best.

The situation influences ultimate questions posed that impact the nature and delivery of social policy, everyday cultural practices delivered in schools and similar settings (e.g., see Lee, Spencer, & Harpalani, 2003), and while navigating neighborhoods "protected" by individuals purporting to "protect and serve" but in fact frequently suggest historically different interactions with particular socializing agents (see Cross, 2003). Considered together, the implicit messages of the two quotes are consistent with the culture of poverty critique and analysis described by Small et al. (2010).

The depression-like economic conditions of the last several years have impacted the United States and the globe. Accordingly, given the extreme competition for limited resources, the unacknowledged problem of unequal access serves to make worse the problem of inequality, thus increasing high levels of human vulnerability. That is, people of color who lack the property commodity benefits of "Whiteness," as posited by critical race theorists, experience the economic situation differently from their privileged counterparts. For African Americans, in fact, it may be less clear whether further adverse economic impact is due to continuing biases that contribute to greater inequality or whether the "national recovery" lacks levels of support actually needed for communities of color (and its child development outcomes) to experience actual economic supports for offsetting resource or asset insufficiency. These themes potentially impact and compromise youth resiliency, levels of human vulnerability, and interpretation of both. But they are not alone. In fact, particularly given the historical framing provided, the role and impact of race, ethnicity, skin color, identifiability, and ego processes are critical constructs. They represent a level of atypicality and conceptual uncomfortableness in the traditional approaches taken to social science research involving youth of color and particularly African Americans.

The opening quotes suggest particular coping needs required by individuals and communities, given unavoidable inferred messages about group membership, particularly for minorities of African descent. The conceptual strategy is necessary both for establishing and maintaining a healthy "sense of self" and for determining and supporting—as effective policies and practices—positive adaptations to typical and atypical human development needs and issues. Bronfenbrenner's (1992) framework and the historical framing provided explains the problem of unnecessary coping requirements as a function of status difference associated with skin color variations. The situation indicates a normative state of lack of fit or unacknowledged privileges experienced as children prepare for, navigate across, and interact with determinative environments. The character of the interactions has consequences for challenges and/or opportunity. The research questions pursued and methodologies considered in the conduct of twenty-first-century programs of research, evaluation, practices, and subsequent policies must represent youth placement and subsequent experiences.

The next two sections highlight and review some of the research on youth of color, given the themes noted, and present for analysis methodological issues of importance for research that aims to be salient for the developmental tasks, and interpretation of experiences and outcomes for African Americans. By integrating and framing the historical and privilege-acknowledging perspectives presented, the final section concludes with a discussion of methodological concerns necessary to frame future research and theorizing about African American children.

Salient Perspectives Required to Appreciate Challenges to Resiliency

Given universal developmental needs and tasks, one quandary created by ignoring historical circumstances and treatment is not acknowledging that everyone has sets of developmental tasks to master. These tasks are associated with the individual's stage of development (Havighurst,1953) and are influenced by the chrono-level of the ecology; accordingly, the character of the social challenges faced by a society at a particular psychological moment in history has implications for outcomes achieved (e.g., the recent and—virtually—globally experienced economic anguish). Although citizens overall confront economic challenges, the nature of the experience for some may be decidedly different and thus exacerbating of risk level in many cases. Moreover, the fact of differential experience by race, ethnicity, and class (and interactions among factors including gender considerations for Hispanics and African Americans) is infrequently acknowledged and factored into the conduct of science and its interpretation and utilization as policy and practice in the design of culturally authentic supports. These are, in contrast, considered as control variables in studies that negate the breadth of challenges experienced as a function of the interaction among the noted attributes. While appropriate as control variables in research designs exploring outcomes believed related to these factors, nonetheless, there remains less

attention to the experiences that contribute to specified outcomes.

The introduction suggested that different historical relationships between groups and untoward experiences borne by particular individuals have unexpected (and typical) effects on the character of the life course experienced. A basic feature such as the maturation status of cognitive and social development may, in fact, represent a significant dynamic and serve as a protective factor (e.g., the cognitive egocentrism of preschoolers) (see Elkind, 1966; Spencer 1982a, 1982b, 1985, 2008b; Spencer & Markstrom-Adams, 1990); however, during adolescence, maturational status of the noted domains may exacerbate relational experiences and may impact well-being of youth (see Elkind, 1967; Spencer, 2006, 2008b; Spencer, Harpalani, Cassidy, et al., 2006). That is, on one hand, young children's developmentally appropriate self-centered thought processes limit the internalization of risk and threat due to negative group membership stigma and general stereotyping. However, the interpretations and inferences made are more complex during middle childhood (e.g., Spencer, Cole, Dupree, Glymph, & Pierre, 1993) and adolescence (e.g., see Fegley et al., 2008; Spencer, 2006, 2008b; Spencer, Harpalani, Cassidy, et al., 2006; Spencer, Dupree, Cunningham, Harpalani, & Munoz-Milleret al., 2003; Stevenson, 1997). As noted in several papers, socialization strategies, beliefs, and assumptions matter as a protective factor as well (Spencer, 1982b, 1985). These themes, occurring at all levels of the ecology, have special salience across the life course (even within a lower-income caste [e.g., see MacLeod, 1995]) for African Americans and other frequently stereotyped individuals of color.

We suggest that on a daily basis and in light of the historical and long-term conditions described, persistently occurring and uniquely patterned challenges characterize the everyday experiences of America's communities of color and should be included as part of the context for everyday functioning (see Szalacha et al., 2003). The challenges need not be necessarily framed as deficits and deficiencies but acknowledged as part of the context of everyday life. At the same time, for nonminority group members, representative constructs acknowledging privilege also requires recognition and inclusion in the conduct of research, particularly when between group comparisons are part of the methodological strategy.

The dilemma of "invisibility" of contextual differences between groups matters. There are consequences for the conduct of and interpretation of findings; moreover, the research enterprise omits the recognition that the psychological and physical contextual differences have profound implications for individuals' basic meaning making, coping processes, and level of vulnerability; and, of course, there are varied experiences among ethnicities (see Szalacha et al., 2003). For example, the honorary White status accorded some Asian American ethnicities is generally not protested but is accepted as an underacknowledged protective factor (myriad privileges); of course, the situation introduces other types of within- and between-group tensions (e.g., see Diemer, Kauffman, Koenig, Trahan, & Hsieh et al., 2006). Consistent with global colonial historical traditions and practices, contemporary citizenship claims as well as immigration apprehensions—particularly in regard to individuals of color—introduce group-level sources of stress, entitlement beliefs, and protective factors that remain ambiguous, anonymous, and, more generally—with a few exceptions—virtually absent from rigorous scholarly efforts in the social sciences. In fact, perhaps reflecting the nearly century and a half of silenced and unremorseful practices following the signing of the Emancipation Proclamation and the passing of the Thirteenth Amendment to the Constitution, traditions and beliefs became solidified (as well as "silenced" from consideration). Accordingly, robust behavioral and social science careers may represent successful constructions due too frequently to practices designed for reaffirming a priori assumptions of group inferiority (i.e., a pattern of scholarship that affords a virtual colonialist representation of others' lives). The possibility of intergenerationally transmitted attitudes and assumptions is important, given an articulated social science "objectivity goal" and training criteria that assume values-free strategies. However, practiced objectivity is less possible and requires more coping, given unacknowledged and unchallenged views about others' identities and placement within American culture, views that include long-term practices and particularly "colored and coded" definitions of humanity.

This situation is exemplified and generally viewed as "typical" as structured approaches to topics such as student discipline problems in school contexts: that is, where punishment is viewed as a way to restore justice and deter future offenses (Wenzel, Okimoto, Feather, & Platow, 2008).The historically retributive approach strives to maintain objectivity and consistency but is unsuccessful in deterring undesired behavior. More relevant, however, to the issue of vulnerability is that the approach holds youth accountable for responding to socially constructed and underacknowledged contextual conditions. The character of outcomes is framed as implying incompetence and undesirability when, in fact, youth efforts and supports

could never be an even match or represent a formula for success.

Restorative practices are frequently used in educational contexts and are interpreted and examined as an alternative to systems of retributive justice (Amstutz & Mullet, 2005). As a prevention and intervention approach, the practices are based on the principles of restorative justice that involve accountability for all members of a relational community (Morrison & Vaandering, 2012; Parsons, 2005; Swain & Noblit, 2011). Schools' codes of conduct often require that students who break rules be subjected to punishments that often have little to do with their inappropriate behaviors or with those whom they have harmed by their actions (Kohn, 2006). Restorative principles are based on the premise that harming others damages interpersonal and communal relationships and that justice is best achieved by seeking to repair relationships through restitution, resolution, and reconciliation (Braithwaite, 2002; Morrison & Vaandering, 2012). Instead of delegating the resolution of rule violations to an impartial third party (i.e., a court, judge or jury, or in the case of a school, a dean or an assistant principal), offenders, victims, and the communities that have been affected (i.e., friends of the offender and victim, and community members) come together in an attempt to understand what happened, how it has affected everyone, and what can be done to ensure a supportive outcome (Braithwaite, 2002; McCluskey, Stead, Kane, Riddell, & Weedon, 2008; Morrison & Vaandering, 2012; Popa, 2012). Instead of expelling a student from the community (or suspending from school), the community seeks to reintegrate the student in a manner that also holds members of the community accountable for supporting the student. This strategy is more consistent with the perspective proffered; atypically, the approach requires adults to examine conjectures regarding their personal assumptions and systemic practices to which youth utilize specific coping efforts to respond.

Differences in the character of coping efforts needed as adaptations to everyday life course developmental tasks required for achieving competence and sustaining health and well-being for members of the human species are significant contributors to vulnerability level. Acknowledgment of the differences may serve as a national embarrassment and thus source of conceptual resistance for some individuals; however, at the same time, it represents an ever-present inconvenient hurdle for others. The fact is especially cogent for America's diverse citizenry, given the nation's reluctance to acknowledge the continuing salience of slavery, Jim Crow practices, and skin color salience in twenty-first-century life despite how long it has been since Lincoln signed the Emancipation Proclamation. As indicated, we suggest that the dissimilarity of experience and actual effort required has to do primarily with epidermal melanin level variation (skin color hue). Einstein's view of "human genius status" as the norm, in fact, is an enacted value of relevance primarily ascribed to Caucasian Americans. Although generally the bias is inadequately acknowledged in the social sciences, more often than not, it represents a consistent theoretical dilemma and frequent conceptual orientation of research efforts. The fact contributes to the character of social policy, educational pedagogy, and a "backpack of life course experiences" wherein Whiteness functions differently for groups and their members (i.e., as a burden, given its absence as representative sets of unacknowledged privileges is the dilemma); how to represent the problem of Whiteness as a knapsack of privilege as inequality in rigorous research continues to be the unaddressed task. Highlighting its determinative influence contributing to structural conditions, Whiteness status conveys high status and support for some citizens; and, at the same time, for those of a darker hue, the unacknowledged power of Whiteness solidifies nothing less than an institutionalizing of risk and challenge. Across the life course both for children and those intending to protect, support, socialize and train, an individual's particular Whiteness status makes a difference. It serves either to contribute to psychological consonance (i.e., affording a best-fit status between individual and context experiences) or facilitates the experience of dissonance, which requires extra consciousness, responsive energy, and time for obtaining resiliency. It also supports the achievement of positive youth outcomes in the face of significant and persistent challenge. The typical research approach is to assume that social address variables (e.g., social class and race categorization) adequately differentiate the complex experiences suggested.

Accordingly, as conceptualized by Anthony (1987) and other scholars, vulnerability is a shared human condition. It communicates a level of balance or imbalance between individuals' degree of risk versus the level of protective factors either present or accessible. Accordingly, all humans represent a level of vulnerability, although the character and level of risks and protective factors may vary by type and level of significance. In fact and as suggested, a characteristic such as Whiteness may function as a source of privilege and support for some individuals (e.g., Caucasian Americans) and as a source of significant risk and challenge for others. However, as suggested, in the case of within-species melanin variation and societal experiences, the fact of difference as daily practices

experienced represents a set of atypical and unique events that parallel those alluded to in the Einstein quote. Further, particularly for the North American experience, the fact has always been responded to at the national level as a dilemma of everyday traditions and unexpected social policy outcomes, but never one of social justice. As historically evidenced, the failure as a nation to acknowledge and to accept responsibility for long-standing, intergenerationally impactful forces—both personal and group—at the individual and collective levels, chronic injury has consequences. Supports can come from sources infrequently acknowledged as constructs in research (e.g., see Brittian & Spencer, 2013; Dupree, Spencer, & Spencer, 2015; McGee et al., 2015; McGee & Spencer, 2013; Spencer & Swanson, 2015). Of course, like the failure of individuals to acknowledge the fact of the Holocaust or that the nation's first Black president is an American citizen—albeit with the name Barack Obama—as both a historic and contemporary fact, there have always been pockets of individuals comfortable with distorting history as a way of accepting dehumanizing practices for overall economic and individual-level gains. Everyday behavior, collective practices, and stigma-linked determinative policies based on flawed perspectives concerning individual responsibility continue to enjoy contemporary manifestations in research studies as constructs assessed and questions posed.

The predicament described communicates and demonstrates the continuing advantages enjoyed by non-Brown individuals (i.e., described by Roediger as the "wages of Whiteness" [1991]). The conundrum significantly adds to the persistent situation of unacknowledged privilege and, accordingly, a significant source of psychological support for those of a lighter hue, which is evident both within-group and between-group experiences and social practices. Specifically, curriculum based social studies lessons are taught from the perspective of "the victor"; as such, privileged students occupy a position of never having to explain or having dissonance about: (a) a group's enslavement (and often mortal destruction during the Middle Voyage) and the implications for perceptions about "the self" and one's community; (b) individual and group-level inhumane treatment, including the separation of families, raping of women, rulings against indigenous language use, and proscriptions concerning the teaching of literacy skills; (c) the creation and use of policies and practices determined by the dominant majority solely on the basis of either being of African descent or having one drop of Black blood; and, additionally, (d) as formally or informally communicated, White status situating a privileged self to never having to concede personal culpability in the heinous enslavement of a group, destruction of family systems of identification and support, murder, and—collectively as a nation—never having to confront or bear individual-level responsibility for the heinous institution of slavery itself. To reiterate, in many ways, the "free pass" set of conditions described and framed in American textbooks as historical representations of the nation's past represents what Roediger refers to the unquestioned "wages of Whiteness."

Considered overall, these themes are not included in the formulation of publicly and privately funded social science research. An excellent illustration is provided in the recent "thriving literature."

New Concepts and "Traditional" Assumptions: Thriving and Development

Thriving originally appeared in the literature as a set of positive "vital signs" (Benson, 1990). Subsequent research has aimed at identifying these signs and developing measures as indicators of thriving in adolescence, most notably the 5C's (Competence, Confidence, Connection, Character, and Caring). All of this work attempts to draw a distinction between thriving and happiness (Scales, Benson, & Roehlkepartain, 2011). However, for the most part, it does not acknowledge the themes concerning Whiteness status and privilege nor minority group membership—given the unique histories of each—in the construct's conceptualization.

In fact, some scholars conceptualize thriving as the high point on a curve overtaking resilience, surviving, and succumbing (Carver, 1998; O'Leary & Ickovics, 1995). These writers connect adversity to the positive benefits that can come after a negative experience. Of course, the long-term and unacknowledged impact of slavery and unresolved between-group status issues do not represent the level of adversity considered. The work distinguishes between threats and challenges with the former producing harm and the latter often leading to improvements. Under this model, resilience represents a return to the status quo following the particular experience whereas thriving refers to the improved state that follows. These scholars address specific forms of thriving, including desensitization to the stressor, enhanced recovery potential from the situation, and heightened level of functioning. Although infrequently addressed under the rubric of unequal accessibility to supports that sustain recovery, as a recent construct, the perspective assumes an equally experienced American Creed and equity in individuals' access to and exposure to resources and supports.

The ability to measure these abstract changes, however, is challenging, although some objective developments can be assessed. Concrete benefits, more easily measured, can include improved or newly acquired skills, greater confidence, and strengthened personal relations (Carver, 1998); all imply accessible assets and supports. Research has shown that the higher the number of positive developmental factors that a young person is exposed to, the more likely he or she will be to also report thriving outcomes (Scales et al., 2000). Generally and as suggested earlier, thriving may be applied to all youth, although accessibility is decidedly different by race, ethnicity, historical circumstance, and unacknowledged privilege.

Lerner, Lerner, von Eye, Bowers, & Lewin-Bizan (2011) discuss the adaptive developmental regulations and bidirectionality of the individual and context that, if fostered properly, can contribute to an adolescent's thriving, something the authors define as manifesting "healthy, positive developmental changes" (p. 1107). What is not considered and included in the various analyses are the historical and contemporary experiences linked with group membership. In fact, the literature on thriving has been framed as the successor to the at-risk and pathologically focused studies of the past (Scales et al., 2011) with renewed attention on personal strengths and resiliency. However, the challenges and continuing risk factors are underexamined by race, ethnicity, and national origin. Historical contributions to the stability of inequality and sustainability of privileging status for Whites are never considered.

Those affiliated with the Search Institute link thriving to "sparks," which they characterize as passions or interests that provide direction to one's life (Benson & Scales, 2009; Scales et al., 2011); however, in general, it is not mentioned that "sparks" may be conceptualized as opportunities that are unequally accessible. Fifteen indicators of thriving have been identified that assess qualities such as school success, social life, and emotional outlook. This work expanded on previous work that was connected to status-related indicators (Scales, Benson, Leffert, & Blyth, 2000; Theokas et al., 2005).

Overall, these perspectives seem to indicate the importance of moving forward (Carver, 1998) through time as a critical factor in conceptions of thriving. Much of the literature suggests that thriving is less a state of being or trait but rather a process of change (Theokas et al., 2005) reflecting an active individual functioning across time and place who is able to exert flexibility and adapt to changing contexts. One difficulty, of course, is the difference between conceptualizing thriving as a process but measuring it at a moment in time (Benson & Scales, 2009). As suggested, unaddressed are the traditions and behavioral residuals of a nation with significant unresolved issues having to do with a history of slavery and a continuing contemporary condition of structured inequality and variously masked privilege associated with skin color.

Growth is also implied in this framework, which poses a conceptual challenge in that it remains uncertain to what extent thriving can be distinguished from other forms of development (Carver, 1998). Carver (1998) concluded that thriving represents an "extreme" form of growth that operates similarly to other forms of growth, such as physical exercise, with the exception that the growth that drives from threats is unexpected.

As presented in the literature, individual variables linked to thriving include those coming from both personal and social psychology. Specifically, this research is related to whether an individual can actually thrive in the face of any given adversity; however, as suggested by the chapter epigraphs, the conceptual orientation does not consider the persistency of beliefs, attitudes, and long-term unequal conditions that paint a very different picture of adversity as experienced by youth of color and African American youth (and males) specifically. Individual factors can include optimism/pessimism, hope/hopelessness, and self-mastery and efficacy. Contextual factors can include the availability/lack of social supports and the extent to which an environment encourages self-determination (Carver, 1998).

Criticism of the thriving literature has focused on the inability for many scholars to come to an agreement about what constitutes a developmental asset and what contributes to and indicates thriving. Central to this dilemma has been the context and domain-specific nature of thriving (Benson & Scales, 2009). Without question, a conundrum is why investigators lack interest in collaborating in order to obtain the perspectives of individuals themselves. Of course, whether thriving should be treated globally inevitably depends on the nature of the indicators utilized; some (i.e., assuming leadership roles) clearly are culturally specific. Some have challenged the limitations of this literature on thriving and instead have sought to incorporate a racial, gender, and socioeconomic component into their work (Blankenship, 1998). Responses to this criticism have emphasized the importance of how many developmental strengths (i.e., sparks, relational opportunities, and empowerment) youth are exposed to and how these are far better predictors of thriving outcomes than gender, race, and socioeconomic status (Scales et al., 2011). Scales and colleagues (2011) showed that adolescents who have sparks and supportive

individuals in their lives are more likely to have other commitments and values that connect them to their communities. From a national sample of 1,817 (56% White, 17% Black, 17% Hispanic, 0.5% Asian) 15-year-olds, they found this was the case across demographic variables. However and unfortunately, the final study (Spencer & Spencer, 2015) could not explore the questions either between or within groups because of the inadequate number of minority participants. Similarly, self processes have been studied for at least 75 years, there are few conceptual and methodological constructs more misconstrued in the case of African American youth (for reviews, see Hare, 1985; Spencer, 1985, 2008a; Spencer, Harpalani, Cassidy, et al., 2006; Spencer & Horowitz, 1973; Spencer & Markstrom-Adams, 1990).

Black Identity and Self-Esteem

Research into the association between racial/ethnic identity and self-esteem has tended to produce mixed results (Rowley, Sellers, Chavous, & Smith, 1998). Variations in ethnicity, geography, and age contributed to differences in these findings. Within the realm of Black identity, results have been more consistent with racial identity affirmation positively predicting levels of self-esteem in African American adolescents and college students (Resnicow, Soler, Braithwaite, Selassie, & Smith, 1999; Rowley et al., 1998; Toomey & Umana-Taylor, 2012). This has been particularly true in recent years as models have become increasingly more nuanced in assessing the degree and quality of racial identity (Rowley et al., 1998).

In the first decades following school integration, research on self-esteem and race showed that in contrast to some widely held conceptions, Black children generally displayed higher levels of self-esteem than White children and that they did not suffer from the presumed self-esteem deficit (Hare, 1985; Simmons, Brown, Bush, & Blyth, 1978). Observations obtained by Simmons et al. (1978) drew from the results of multiple-choice tests administered to 798 students in the sixth and seventh grade across 18 schools in a large midwestern city. Subsequent work continues to support these findings (M. Hughes & Demo, 1989; Porter & Washington, 1989). Absent from this research, however, was how racial identity might predict or influence self-esteem levels in African American adolescents.

Toomey and Umana-Taylor (2012) conceptualized two different ways in which racial/ethnic identity is linked to self-esteem. They drew on a risk and resilience framework in which racial identity can either promote self-esteem via pride in one's self/collective or protect by minimizing the negative effects of stressors via racial discrimination (Rutter, 1987).

Phinney, Cantu, and Kurtz (1997) conducted a survey of 669 American high school students in order to assess the predictive functions of ethnic identity, defined as "a broad construct including sense of belonging, positive attitudes, commitment, and involvement with one's own group" (p. 170), on minority self-esteem. A series of regression analyses found that neither gender nor socioeconomic status were a strong predicator of self-esteem in African American youth but that ethnic identity was a significant predictor of self-esteem across racial groups.

Within the "protective" model, Yasui, Dorham, and Dishion (2004) found that self-esteem was associated with adolescent adjustment for both White and Black youth. They examined 77 White and 82 Black adolescents (67 male and 92 female) who had an average age of 12.2. They focused on students who were considered both successful and at risk and employed the Multigroup Ethnic Identity Measure (MEIM) to assess the strength of ethnic identity, and the Children's Depression Inventory (CDI), and the Child Behavior Checklist (CBCL) to assess adjustment. Conversely, lower levels of ethnic identity predicted lower levels of social and emotional adjustment.

Employing the Adolescent Discrimination Distress Index (ADDI), Racial Socialization Scale (RSS), and the Rosenberg Self-Esteem Scale (RSES), Harris-Britt, Valrie, Kurtz-Costes, and Rowley (2007) examined how racial socialization messages can protect African American adolescents from perceived racial discrimination. In their study of 128 African American eighth-grade students (68 girls and 60 boys) from two public schools in the southeastern United States, they found that although racial pride did not predict self-esteem, other forms of racial socialization (i.e., understanding of cultural history, expectations of possible bias/discrimination) could positively predict higher levels of self-esteem.

One area of recent interest is the mediating/moderating influences of racial identity on self-esteem. Eccles, Wong, and Peck (2006) examined how ethnic identity could mediate the effects of racial discrimination in African American adolescents. They drew their results from the 1990s-era Maryland Adolescent Development in Context Study (MADICS), which examined a middle-class community with 51% African American and 43% European American households that have relatively equal income/political influence in the community. They focused on 1,480 middle-school-age adolescents over a 2-year period (seventh and eighth grade). The researchers measured the self-reported experiences of discrimination at

school as well as students' future expectations of discrimination and how these experiences influenced their views of and performance in school. Also measured were the students' self-reported feelings of "positive connections with their ethnic group" (their way of assessing ethnic identity). Regression analysis revealed that a positive connection to ethnic group predicted grade point average during the eighth-grade year. Indeed, the measured effect was approximately equal to the negative effect of experiencing racial discrimination, suggesting that a positive relationship to ethnic identity can counter, protect, or minimize the effects of perceived racial discrimination on academic motivation and achievement in African American adolescents.

Gaylord-Harden, Ragsdale, Mandara, Richards, and Petersen (2007) explored how ethnic identity and self-esteem function as mediators between social support and internalizing symptoms such as anxiety and depression. A sample of 277 (85 males, 142 females) African American middle-school students from high-crime rate neighborhoods in Chicago was used. The researchers utilized the MEIM, Survey of Children's Social Support (SOCSS), Experience Sampling Method, and the State-Trait Anxiety Inventory for Children (STAIC) to gather results about the sample's ethnic identity, perceived social support, self-esteem, and anxiety. They found that the strongest predictor of depressive symptoms and anxiety was perceived social support. Ethnic identity and self-esteem seemed to account for males' perceived support and females' self-esteem respectively. The gender finding is important and should suggest research questions that further differentiate the experiences of Black boys and girls.

Oney, Cole, and Sellers (2011) explored how racial identity and gender moderated self-esteem and body image for African American men and women. They drew on a sample of 425 college students (109 male and 316 female) from three regions of the country (East Coast, Southeast, Midwest). Utilizing several subsets of the Multidimensional Inventory of Black Identity (MIBI), they found that for those whose race was less central to their identities, body dissatisfaction was related to lower self-esteem. For those subjects who had high private regard (of their identities) and low body dissatisfaction tended to have higher self-esteem. Those who had low public regard and high body dissatisfaction displayed lower levels of self-esteem. The researchers also looked at assimilation ideology (i.e., emphasis on similarities between African Americans and Western society) on self-esteem; however, no significant relationship was found. Not unexpectedly, the connection between body image and self-esteem was higher for females than for males. The researchers also looked at assimilation ideology (i.e., emphasis on similarities between African Americans and Western society) on self-esteem; however, no significant relationship was found. Not surprisingly, given the higher salience of body image particularly for females, the connection between body image and self-esteem was higher for females than for males.

Some research has shown that the differences in self-esteem among Whites and Blacks can be attributed to the design of self-esteem reporting methods (Bachman & O'Malley, 1984). Bachman and O'Malley (1984) showed that Black adolescents were more likely to report more extreme levels of self-esteem than Whites when using incremental-based (1–5) methods. When these differences were accounted for, the gap between levels of self-esteem were not as acute. Some have explored the relationship between parental influence and social/personal self-esteem in Black adolescents (Constantine & Blackmon, 2002). The work illustrates the more complex parental tasks required of Black socializing agents and contributes an understanding of the John Henryism well-being challenge referenced previously. In fact, Constantine and Blackmon (2002) found that parental messages that reinforced pride and value in African American culture were positively associated with self-esteem among Blacks and their peers. However, those who emphasized the preference of White/majority institutions and culture were negatively associated with school self-esteem in Black adolescents. Research has shown that for U.S. high school students, self-esteem is comparatively high, with Blacks scoring the highest, followed by Whites, Hispanics, and then Asians (Bachman, O'Malley, Freedman-Doan, Trzesniewski, & Donnellan, 2011). Slightly higher levels of self-esteem were reported by males compared to females.

Tynes, Umaña-Taylor, Rose, Lin, & Anderson (2012) explored the moderating influences of racial identity and self-esteem on the negative effects of online racial discrimination (i.e., depression and anxiety). They surveyed 125 African Americans ages 14 to 19 (55% female) from three urban high schools in the Midwest and compiled composite scores measuring online racial discrimination, ethnic identity, depressive symptoms, anxiety, and self-esteem. The researchers found that the negative effects were significantly minimized for those who reported higher levels of racial identification and self-esteem and observed that males experienced significantly less discrimination than females.

Researchers operating within a PYD perspective have tended to criticize the approaches of the risk and

resiliency models, given their emphasis on assets mediating/protecting at-risk youth from negative outcomes rather than an emphasis on the importance of positive assets (Evans et al., 2012). They point toward work that better measures the association between racial socialization messages such as preparation for bias with positive racial identity. They believe that this approach is more conducive to PYD concepts such as confidence, competence, and connection (Murry et al., 2009).

Lusk, Taylor, Nanney, and Austin (2010) explored the relationship between racial identity and self-esteem for Black/White biracial individuals. The average age of the sample in this study was higher than the age in other works cited in this review (23.62 years), but this study has been included to provide a wider perspective and because of the dearth of work on biracial identity and self-esteem in adolescents. Lusk et al. focused on 74 self-identified biracial individuals drawn from online multicultural websites as well as university campuses, which clearly limits the generalizability of their findings to more affluent/privileged populations. They utilized Rockquemore and Brunsma's racial self-identity measure (2002), MEIM and RSES and the Center for Epidemiological Studies Depression Scale (CES-D) to determine levels of emotional well-being. They found that the individuals in their study self-identified first as biracial ("border identity") and then a singular one (i.e., White/Black). This was in keeping with Rockquemore and Brunsma's (2002) original work on biracial identity. Lusk et al. did note, however, that more participants identify differently depending on context/circumstance. The overall results of the study confirmed previous findings regarding the positive relationship between racial identity and self-esteem as well as the negative correlation between identity and depression. Additionally, they found that those who identified with border identities exhibited higher levels of self-esteem than those who identified with singular or "transcendent" options.

The literature seems to point toward a generally positive association between racial identity and self-esteem, at least in regard to African American youth. Disagreements between researchers focus on conceptual differences relating to how to measure racial identity (i.e., pride of the group or affirmation of self) and whether this identity promotes/protects minority youth from stressors or whether that identity serves as a positive asset in and of itself. However, certainly the problem of colorism plays a very important role in the lives of youth of color. The research suggests that group membership is salient and, is particularly evident, when associated with contextual experiences. Given historical, underacknowledged, and generally ignored historical events and evolved social traditions, color matters.

Research Acknowledging Colorism

To address the recent literature surrounding the phenomenon known as colorism, a definition of the term is critical. Burke (2008) describes it as "the allocation of privilege and disadvantage according to the lightness or darkness of one's skin" (p. 17). The literature on colorism is vast, beginning with the classic Clark Doll Studies (Clark & Clark, 1940), which showed that Black and White children demonstrated a consistent preference for a White doll over a Black one (reviews are available that include at least 50 years; see Cross, 1991, 2003; Spencer, 1982a, 1976; Spencer & Markstrom-Adams, 1990). For a good overview of some of the principal contributions from the expansive literature on doll studies, see Fegley, Spencer, Goss, Harpalani, and Charles (2008).

More recent treatments have expanded, revised, and altered aspects of Clark's original work with some exploring how such preference (i.e., given skin color) might be altered through incentives (Jordan & Hernandez-Reif, 2009). Researchers explored this bias for other racial groups with Hispanic children also demonstrating a bias toward lighter skin (Kaufman & Wiese, 2012), although some have been skeptical of the reliability of traditional doll studies (Stokes-Guinan, 2011). Studies have also shown that Black children are more likely to remember narratives that depict darker-skinned African Americans in a negative or stereotypical light (Averhart & Bigler, 1997). Overall, these studies have tended to reinforce the original results of the Clark study with incentives and technological changes having limited impact on changing child and adolescent attitudes toward skin color (Fegley et al., 2008).

Despite these challenges, research into the effects of colorism on children and adolescents continues to be a dominant area of inquiry with particular emphasis on the negative impact of privilege on their development and life experiences. Scholars often depict colorism as a social ideology bound up with the institutions of public life, such as school and the workplace. The family, it would seem, serves as a place of refuge from which its members might contest dominant racial narratives. Some research has shown, however, that Black families often reinforce colorism by privileging lighter-skinned members (McDonald, 2006; Russell, Wilson, & Hall, 1993; Wilder & Cain, 2011). Russell et al. (1993) suggested that a family's preoccupation with skin color begins at the time of the child's birth.

McDonald (2006) explored a case study where a woman born with darker skin than her mother and siblings was abused and neglected as a result of her mother believing that she had "lowered" the family's status. Wilder and Cain (2011) showed that among Black women, maternal figures often play a central role in shaping Black children's attitudes about skin tone. Many of these women claim that they learned at a young age to associate darker skin with ugliness and lighter skin with beauty.

One area of research that remains particularly voluminous is in the impact of colorism on the social mobility of African Americans in United States. Many investigators examined the relationship between skin color and educational attainment and economic success in both contemporary and historical contexts (Bodenhorn, 2006; Bodenhorn & Ruebeck, 2005; Goldsmith, Hamilton, & Darity, 2006; Hannon, DeFina, & Bruch, 2013; M. Hughes & Hertel, 1990; Keith & Herring, 1991; Ryabov, 2013). These studies have found that even when accounting for parental variables, lighter-skinned Blacks are more likely to obtain higher levels of education and pursue more prestigious and lucrative professions than those who have darker skin.

In addition to professional and education success, some researchers have focused on more subjective evaluations, such as personal attractiveness (M. Hill, 2002; Wade & Bielitz, 2005). Drawing from the National Survey of Black Americans, Hill found that skin color had a greater impact on the perceived attractiveness of women than on men with lighter skin being seen as a more attractive quality. Wade and Bielitz (2005) examined perceptions across gender and race and found that African American women with lighter skin were rated higher than lighter-skinned African American men on intelligence and parenting. Women generally rated dark-skinned individuals higher than men did on intelligence. Self-esteem and self-efficacy have been important topics within the literature of colorism with some exploration of the differences affecting male and females (M. Hill, 2002; Thompson & Keith, 2001). Thompson and Keith (2001) demonstrated that skin color remains an important indicator for self-esteem in women but not in men and for self-efficacy in men but not in women. They also maintained that, for women, the power of colorism was strongly associated with the individual's social class with working-class darker-skinned women having lower self-esteem than dark-skinned women in higher social classes. Elmore (2009) explored the relationship between self-perceptions of skin tone and the processes of identity formation in adolescents. Other scholars have shown that young women who embrace an African American standard of beauty (reflecting a higher level of self-esteem) exhibit lower levels of substance use than those who embrace White standards of beauty (Wallace, Townsend, Glasgow, & Ojie, 2011).

As suggested previously, in light of Barack Obama's election as the first African American President of the United States, some scholars have examined the impact of colorism on political behavior (Weaver, 2012). Weaver (2012) demonstrated the limitations of traditional discussions of race and politics and argued that skin tone and hue play a far more pivotal, however subtle, role in shaping electoral outcomes in the United States.

The implications of colorism for immigrants and workplace discrimination are examined in Hersch (2011). In accounting for length of residency, English-language competency, and education, Hersch found that lighter-skinned immigrants earn 16% to 23% more on average than darker-skinned persons. The findings are important, given the role of socioeconomic status as a source of support and protection for families and children.

This phenomena is not unique to the United States. There have been a number of efforts to explore the implications of colorism around the world. (For Japan, see Wagatsuma, 1968; for India, see Beteille, 1968; for dark-skinned Puerto Ricans, see Hall & Julian Samora Research Institute, 1987; for Latin America, see Russell, Wilson, & Hall, 1993.) Ferguson and Cramer (2007) showed that rural Jamaican children who self-identify and idealize skin type as White exhibited higher levels of self-esteem. Some scholars have taken up the idea of "economies of color" in examining the pigmentocracy underlying racial liberalism globally (Glenn, 2009). Charles (2011) studied how Jamaicans have historically practiced skin bleaching in order to enhance sexual attractiveness. In a survey of self-reported health and racial categories in selected Canadian cities, Veenstra (2011) found that darker-skinned Blacks were more likely than lighter-skinned ones to report poorer health outcomes.

The findings of this research point toward a tendency to demonstrate preference for lighter-skinned and White phenotypes. However, some research has shown a more complex dynamic where Whiteness alone is not treated as a privileged category (Quiros & Dawson, 2013). Quiros and Dawson (2013) demonstrated how among Latino populations, although lighter skin is seen as being a more positive feature, being perceived as White does not carry the same level of prestige. The complexities of colorism therefore do not appear to be as uniformly internalized as previously believed. Other examples of research within this "revisionist" camp have shown that skin color does

not necessarily exacerbate racial discrimination outside of the family but that there is a correlation between skin tone and family dynamics (Landor et al., 2013). This research maintains that parents will demonstrate preferential treatment to their children based on skin tone. Specific gender variations were noted, with dark-skinned males and light-skinned females receiving "higher-quality parenting" and "racial socialization" within the family.

Colorism and Achievement

Dupree, Spencer, and Fegley (2007) tackled stereotypical assumptions about (relatively) low intellectual ability among African Americans and Hispanics. They reported research findings which suggest that many high-achieving male and female adolescents of color have self-schema that include positive racial identities. At the same time there are also high-achieving adolescents of color who do not. Their study investigated skin color preference of high-achieving Asian, Black, and Hispanic adolescents and was framed to indicate cognitive coping outcomes in response to skin color stereotypes and Eurocentric standards of beauty. In addition, relationships among different dimensions of youth self-schema (i.e., skin color preference, academic and social self-esteem, and body esteem) were explored. Place of origin and race-ethnicity were used as proxies for the different culturally based skin color connotations to which youth are exposed. Results suggest that, in interaction with race-ethnicity or place of origin, preference for lighter skin predicts academic and social self-esteem for high-achieving adolescent females; however, this was not the finding for high-achieving adolescent males. In interaction with place of origin, preference for lighter skin was a predictor of body esteem for both high-achieving males and females. These gender differences suggest gender-specific self-schema for high-achieving youth of color.

Skin Color and Well-Being

High academically performing adolescents of color negotiate multiple identities (e.g., gender, race, ethnicity, academic, etc.) (Bonner, Lewis, Bowman-Perrott, Hill-Jackson, & James, 2009; A. Graham & Anderson, 2008). The very idea that youth "negotiate" multiple identities suggests that there can be a variety of combinations of identity outcomes. These processes can differ in how central gender, race, ethnicity, and academics are to their identities. Research targeting high-achieving African American students provides many examples of such youth who are both high achieving and maintain positive racial identities (Bonner et al., 2009; D. J. Carter, 2007; Carter Andrews, 2009; A. Graham & Anderson, 2008; Harper, 2006; Spencer, Noll, Stoltzfus, & Harpalani, 2001). Some of these same studies demonstrate that these high-achieving youth not only hold race central to their identities but (a) they also have a critical understanding of the structural or systemic forces that work against the positive development and achievement of racial and ethnic minorities, and (b) they seek to actively resist these forces (Bonner et al., 2009; D. J. Carter, 2007; Carter Andrews, 2009; A. Graham & Anderson, 2008). Salient about the findings is that *youth are not resisting or opposing a culture of achievement. They are resisting stereotypical conceptions of their racial or ethnic group*. Specifically, they resist assumptions that they are underachievers and assumptions about the superiority of members of the majority culture. *Yet,* also critical to acknowledge is that *these data do not preclude the possibility that there are high-achieving youth who do have negative racial identities*.

It is more likely that there are many different identity profiles that reflect individual responses to proximal experiences of race and ethnicity. In the United States, a critical aspect of our individual experiences of race is visibility (i.e., what we look like, who we appear to be). Skin color influences visibility as it is one critical characteristic used to determine race, along with facial features, hair texture, and body type (e.g., Stepanova & Strube, 2009). Carter Andrews (2009) focuses on the skin color dissonance of high-achieving youth of color as one indication of how these youth are negotiating their racial identities. It represents another step forward by operationalizing racial identity in terms of actual physical status—the consonance-dissonance between one's actual skin color and one's preferred skin color. The study also explores how the skin color dissonance of high-achieving youth of color—as representative of cognitive coping outcomes in response to skin color stereotypes and Eurocentric standards of beauty—relate to other dimensions of their self-schema (i.e., academic and social self-esteem and body esteem).

Culturally Based Color Connotations and Skin Color Consonance-Dissonance

In many places, there exist skin color connotations that are qualitatively different from those in the mainland United States (Benson, 2006). Group differences may exist but not necessarily along the lines of White versus non-White. For instance, in the commonwealth of Puerto Rico, ethnic identity takes precedence over racial identity, and the caste system is a function of the culturally determined meanings given to SES, facial features, and hair texture in addition to skin color (Alarcon, Szalacha, Erkut, Fields, &

García Coll, 2000; Benson, 2006; López, 2008; Montalvo, 2004). Under such conditions, culture may have qualitatively different influences on skin color preference. Yet cross-cultural experiences, such as immigration from one country to another or regular travel between one country and another, can make the symbolic, culturally determined role of skin color much more explicit. That is, if one recognizes that the same skin color is perceived and responded to differently depending on the cultural context in which one resides, it becomes much more obvious that skin color connotations are culturally determined and not necessarily the norm for all.

However, as it relates to skin color, many places share culturally based color connotations that are similar to those of the mainland United States. There are places where—as in the United States—lighter or White skin is more valued (R. Frank, Akresh, & Lu, 2010; Uhlmann, Dasgupta, Elgueta, Greenwald, & Swanson, 2002; Ullrich, 2010). Accordingly, there would not necessarily be dissonance-creating immigration experiences that would raise awareness of the arbitrary and symbolic character of skin color connotations.

Individual experiences of skin color can raise awareness of the complex relationships among race, culture, and class for immigrants to the United States when, based on skin color, immigrants can be mistaken for nonimmigrants. For instance, in the United States, darker-skinned Hispanics with relatively coarse hair or Caribbeans of African descent may be treated like African Americans based solely on their physical appearance. Although they may originate from different cultural backgrounds, their mutual experiences of prejudice and discrimination in the United States work to acculturate these immigrants to the disfavored or stigmatized minority status of U.S.-born African Americans (Benson, 2006; R. Frank et al., 2010). Immigrant status can complicate self-perceptions based on skin color. Telzer and Vazquez-Garcia (2009) found that, in their study, U.S.-born Latinas with darker skin did not want to change their skin color, did not feel less attractive, and did not have low self-esteem. In contrast, the immigrant Latinas in their study wanted their skin color to be lighter, felt less attractive, and had lower self-esteem. These findings suggest that place of origin must be taken into account when conducting research examining skin color.

As it relates to European standards of beauty (e.g., a preference for lighter or White skin), research by Sahay and Piran (1997) suggested that the farther away from the European ideal individuals are (e.g., darker-complexioned South Asian Canadian females), the less likely they are to endorse a European ideal (i.e., less likely to prefer lighter skin). Likewise, the closer individuals are to the European ideal (e.g., lighter- or medium-complexioned South Asian Canadian females), the more likely they are to be influenced by this ideal (i.e., more likely to prefer lighter skin). In fact, Fegley, Spencer, Goss, Harpalani, and Charles (2008) reported, in their study of adolescents of color in the northeastern United States, that light-skinned adolescents were just as likely to prefer their own skin color as they were to prefer another skin color. In contrast, medium-complexioned adolescents were more likely than their light- and dark-skinned peers to prefer a skin color other than their own. Likewise, dark-skinned adolescents were more likely than their light- and medium-complexioned peers to prefer their own skin color (Fegley et al., 2008).

Skin Color as a Signifier of Attractiveness: The Complex Relationships between Skin Color and Body Esteem

Greater satisfaction with one's skin color in later stages of development (i.e., adolescence and young adulthood) is associated with higher self-esteem and body esteem (Falconer & Neville, 2000; Telzer & Vazquez-Garcia, 2009). In her study of ethnicity and body image, Altabe (1998) found that, in general, Asian Americans and African Americans held similar perceptions of the cultural ideal for skin color (i.e., lighter skin color is believed to be desired by other men and women). Relatively speaking, Asian Americans had the highest desire for lighter skin followed by African Americans. Hispanic Americans had the least dissatisfaction with skin color and valued darker skin or wanted darker skin color. However, Hispanic Americans showed more body dissatisfaction than Asians or African Americans. Interestingly, African Americans had higher self-ratings of attractiveness than Hispanic Americans. Likewise, Hispanics had higher self-ratings of attractiveness than both Caucasian Americans and Asian Americans. But, when asked to rate the importance of appearance to their self-esteem, all groups scored higher than the Asian Americans. In a study based in Canada, Sahay and Piran (1997) found that South Asian Canadians showed the least skin color satisfaction compared to European Canadian females and that light- and medium-complexioned South Asian Canadian females reported the lowest body satisfaction. Thus, a desire for lighter skin color likely reflects a devaluing of one's own skin color and a desire to identify with individuals who have lighter skin color. These findings reflect the complexity of identity negotiations even as they relate to physical appearance and perceived attractiveness.

Adolescents' Negotiation of Skin Color Consonance-Dissonance as a Coping Response

Given the topic's long-term silencing in the social science literature except for inferred assumptions about its psychopathological character for Blacks (for a review, see Guthrie, 1976), attentiveness to the proactive coping of youth with dissonance-producing contexts has been ignored. It might be that in the United States, wanting their skin to be lighter or darker is psychologically important for adolescents of color. Specifically, in race-based societies like the United States, such cognitions can represent attempts to adapt to the perceived cultural standards. The cognitions represent coping responses. As suggested by the theoretical grounding provided by the phenomenological variant of ecological systems theory (PVEST), identity processes are coping processes (Spencer, 2006; Spencer, Fegley, & Harpalani, 2003). More specifically, identity outcomes emerge from consistent coping behaviors (i.e., particularly patterned responses). Consequently, resulting *identities serve an organizing function as they influence one's thoughts and behaviors* (i.e., determining which *thoughts and behaviors that do* and *do not fit with my identity*). Spencer (2006) made a distinction between reactive coping and stable coping. Whereas reactive coping represents responses to specific and immediate challenges, stable coping represents general responsive strategies that are engaged consistently without significant regard for the specific character or nature of challenges encountered (e.g., having health consciousness as a significant aspect of one's identity, the automatic response to "pass" on the offer of a cigarette does not require conscious consideration). Particular challenges may be encountered quite regularly; accordingly, as a response, specific coping strategies are responsively and consistently employed (i.e., thus representing stable coping strategies); the patterned response contributes to and aids in maintaining an emergent identity status. The resulting identity serves as a filter for day-to-day (potentially and ideally healthy) functioning. There will be certain thoughts and behaviors that are in keeping with one's identity and, at the same time, other thoughts and behaviors that are not. A PVEST interpretation would suggest that skin color preference represents (a) a coping response to pervasive and consistent exposure to culture-specific color connotations and racial or ethnic stereotypes and (b) an identity outcome to the extent that it suggests the degree of acceptance of one's own skin color. For instance, when an individual does not fit the skin color ideal within a particular cultural context, skin color preference signifies his or her racial ideology (i.e., one's acceptance or rejection of a culture's overarching color connotations). A preference for lighter skin reflects a desire to be perceived as more similar to the other individuals who have light or White skin and to benefit from all the advantages and privileges afforded to those with light or White skin (i.e., perceived and treated as more attractive, smarter, morally upright, etc). For instance, research supports the notion that people who are perceived as more attractive (based on skin color or otherwise) are also perceived as smarter and more likely to be successful. In some instances, lighter skin is associated with more successful life outcomes, while darker skin is associated with less successful life outcomes (i.e., personal earnings) (R. Frank et al., 2010; Harrison & Thomas, 2009; Hunter, 2002; Kiang & Takeuchi, 2009; Townsend, Thomas, Neilands, & Jackson, 2010).

Gendered Differences in How High-Achieving Adolescents Negotiate Multiple Identities

As suggested by data, there are gender differences in the relationships between skin color and other dimensions of self-schema. For instance, as skin tone relates to self-perceptions, Thompson and Keith (2001) found that, for both men and women, the lighter the skin tone, the higher the sense of self-efficacy. However, the effect was more pronounced for men in the study. (Of course, these findings may be somewhat different for youth, given the study's focus on adult participants. Other research suggests that females are more likely to desire lighter skin color than males (e.g., Fegley et al., 2008; M. Hill, 2002; Wade & Bielitz, 2005). In relation to perceptions by others, Wade and Bielitz (2005) found that light-skinned African American females are perceived as higher in intelligence, a relationship that does not necessarily hold for light-skinned African American men. Together, these findings suggest that gendered experiences may influence the role of skin color for the identities of adolescents of color. Specifically, gender differences in their experiences may lead male and female African American adolescents to think about skin color—as a signifier of race—very differently. Overall, findings from African American youth suggest complex relationship and individual differences—including gender patterns—that index complex relationships among self, context, and identity as coping processes. In particular, the skin color findings suggest very interesting, nuanced, and overall complex color-associated patterns. More informed, theory-based, and rigorous research is needed for testing and integrating (1) the historical analyses by D. B. Davis (1966); (2) the critical perspective by Harris (1995), which hypothesizes the representation of "Whiteness as property"; (3) critical race viewpoints of Roediger (1991) alluding

to the "wages of Whiteness" (i.e., as affirming and supporting myriad benefits); and (4) the knapsack of supports and privileges suggested by McIntosh (1989). Along with others viewpoints, these are not typically woven into the constructs considered in social science research or reflected in the research methodologies and designs embraced. Most important, for African American youth, their self-identity formation generally does not represent developmental processes linked with their identifiability—skin color—in light of their progressively complex meaning-making capacity (i.e., given cognitive maturation irrespective of its expression in achievement-assessing contexts).

The final sections of this chapter describe in more detail both the methodological challenges and the opportunities possible. They also consider the conclusions and inferences possible from a social science perspective that acknowledges the impact of a 150-year historical backdrop in which color continues to matter.

METHODOLOGICAL CONSIDERATIONS

In theorizing about individuals' ability to resist and overcome risks, Prilleltensky (2008) asserted that power is always reflected in political processes which create conditions impacting psychological processes. We have framed the historical influences and research on vulnerability and resilience within this orientation. These factors provide not only the context in which development occurs but also the one in which research is conducted. The sociopolitical nature of most scholarship on African Americans requires significant consideration of issues involved in conducting research. "Central to a discussion of procedural issues in minority research is the awareness that research on minority issues often has perpetuated stereotypes, reflected prevailing biases, and assumed that personal characteristics of research participants reflect causal connections to specific outcomes" (Schwartz et al., 2014, p. 62). With that assertion, the next review presents conceptual and procedural issues related to research on resilience among African American youth.

Conceptual Issues

The study of resilience, with a focus on processes through which it develops, requires conceptual framing that offers criteria for defining and examining the processes. The framing defines the scope of risk in understanding intrapersonal, interpersonal, and contextual factors contributing to unexpected trajectories, given the magnitude of vulnerability. Risks are generally well defined, given their explicit associations with adverse outcomes, which include issues that are *school related* (i.e., academic failure and school dropout), health related (i.e., obesity and sexual behaviors), *justice system related* (i.e., various forms of delinquency), and *mental health focused* (i.e., anxiety, depression). Understanding mechanisms by which protective factors mitigate these risks has been a primary focus of resilience research.

The Scope of Risk

Resilience research evolved from examining trajectories associated with youth experiencing positive outcomes despite numerous compromising risks. This shift expanded historical research from a pathologizing orientation to including considerations for strength-based studies (Zimmerman et al., 2013). Over the past two decades, complex research designs have examined varying forms of vulnerability and risk in exploring differences in developmental trajectories and levels of need to be mitigated (Jung & Wickrama, 2008; Sohoni & Soporito, 2009). Consistent with the methodological and conceptual challenges associated with late twentieth-century and early twenty-first-century social science research traditions alluded to, importantly and unfortunately, *few focus on African American youth*.

Arrington and Wilson (2000) have suggested differentiating "risk" from "vulnerability." They asserted that the latter represents individual factors, in contrast to the former reflecting group experiences. Resilience theorizing, however, continues to broadly conceptualize risks as contributing to significant vulnerability for youth individually and collectively. Resilience, in essence, represents the individual experience of risk and the individual impact of vulnerability. Arrington and Wilson, however, introduced a consideration for explicitly acknowledging group vulnerabilities as a condition of individual risks.

Based on the dual-axis model of vulnerability (Spencer, 2006; Spencer, Harpalani, Cassidy, et al., 2006), all youth experience varying risks and levels of support. Many studies explore factors associated with the most vulnerable youth: high risk, low supports. The scope of risk frequently considers poverty as a contextual condition indicative of restricted resource accessibility, but poverty is also recognized as an inaccurate assessment for determining youth success. As a protective or support mechanism in mitigating risks associated with poverty, numerous studies confirm the impact of a trusting and caring adult as a significant, contributing factor toward youth resilience (see Zimmerman et al., 2013). The consistency of this

finding became the basis for mentoring programs and a central component of youth-focused intervention projects more generally (DuBois & Karcher, 2005; Herrera, Grossman, Kauh, Feldman, & McMaken, 2007). This body of research highlights the effects of caring adults throughout adolescence and into emerging adulthood, where many colleges and universities have incorporated mentoring urban youth into components of their service learning offerings. To understand attributes of particularly effective relationships, some studies have examined the individual histories and experiences of significant adults to capture their moderating impact on youth outcomes. These include discrimination experiences, racial socialization, earlier school experiences, substance abuse, and personal traumatic experiences. Acknowledging the direct and indirect impact of significant adults' histories is comparable to accounting for the impact of cultural trauma or sociohistorical influences (discussed later) in creating conditions of risk for contemporary youth.

Collaboration among families, schools, and community-based organizations are critical to building supports for the future trajectory of youth (Broussard, Mosely-Howard, & Roychoudhury, 2006). The greater the social support, the more competent and motivated students are in their educational abilities. As such, the guidance and care demonstrated through mentorship heightens willingness for school engagement as a basis for academic achievement and in deterring decisions to leave school (Darensbourg & Blake, 2013). Although research documents the positive impact of mentoring relationships, little research has been done on the nature of these relationships and the youth targeted to receive mentorship. For example, Monroe (2013) found that colorism impacts both youth opportunities for educational opportunities and also *selection as a mentee in nonschool programs*. Although there is a clear trend favoring lighter youth (and females over males), research regarding criteria for selecting youth participants remain unclear.

These approaches on interpersonal dynamics also draw from research on the impact of close peer relationships associated with resilience during adolescence (Masten et al., 1999; Morrissey & Werner-Wilson, 2005). Youth without trusting and stable relationships can experience difficulties navigating contextual risks that strain their limited coping abilities. There may, however, be critical or sensitive periods during which experiences influence the subsequent interpretation and response to future events of youth (see Swanson, 2010). A youth's history of unstable relationships, for example, has implications for social and emotional development and identity formation throughout the life course (e.g., ability to get along and work well with peers in school).

Phenomenological research has shown the value of accounting for the youth perspective in designing empirical studies but also for interpreting findings within a developmental orientation. This is particularly relevant given the shift in cognitive abilities experienced during adolescence related to self-appraisals and the abstract processing related to the assessment of risks and supports perceived as available. Work acknowledging the impact of poverty, for example, consistently indicates the limited opportunities available for exploration that support competence formation, self-appraisals, and identity development. It is misleading, however, to suggest that youth interpret their impoverished conditions as a risk or limitation (i.e., reports of low aspirations, or a narrow perspective of the future, by youth living in poverty is not indicative of them interpreting their future based on their family's income status). Similarly, it is misleading to suggest that mentoring relationships are supportive without also acknowledging the relevance of the relationship to the youth. The scope of risk is subsequently related to a clear conceptualization regarding the form of risk and also the historical nature of supports (i.e., stability) relevant to interpretation of experiences and supports by youth.

Attributes of Resilience

Other factors associated with resilience include individual attributes: an area of emerging or demonstrated competence, a positive reference group–oriented identity, and a future orientation (Masten et al., 1999; Mello & Swanson, 2007). As noted in the introduction, normalization of Whiteness remains a major problem in research agendas targeting or including African American youth and may be one of the major impediments to gaining a full understanding of development among diverse youth. White middle-class youth continue to represent the standard for normative outcomes (i.e., competence) with minimal reference to their sociohistorical status or their status as a racialized group (e.g., enjoying the "wages of Whiteness" (see Roediger, 1991). Helms' (1990) and McIntoch's (1989) work prompted examination of White racial identity and White privilege, respectively. The expansion of Whiteness and White identity studies was a major theme in research for a few years preceding conceptual considerations regarding White privileging status. Although studies have examined the impact of White identity on stereotype beliefs (R. T. Carter, Helms, & Juby, 2004), very few studies have examined White identity or privilege as a source of vulnerability (i.e., the intersection of available supports

and risks) on the mental health of White youth when they are challenged and on their developmental trajectories. Among the few that approximate these issues is a study that examines the "psychosocial costs" of racial attitudes for Whites. Although it examines the within-group impact of attitudes, it does not assess the influence of identity or unexamined privilege (Spanierman, Poteat, Beer, & Armstrong, 2006).

Although years have passed since frameworks exploring White privilege were presented, little empirical work has examined Whites as one of many diverse groups; rather Whites continue to represent a standard by which others are judged. Sociohistorical analyses regarding these issues remain empirically unaddressed. Much research documents the impact of experiencing discrimination, but significantly less research focuses on being a person of privilege. As an attribute of resilience, significant effort has been expended raising and integrating cultural competence into activities where adults have direct interaction with youth and impact their experiences. Assessments of cultural awareness and cultural knowledge suggest the significance of others' understanding (and subsequent acceptance) of cultural differences as normative rather than pathological. This orientation, while relevant in attempting to broaden perspectives on differences and mitigate stereotypes, has not resulted in improved outcomes associated with resilience; in fact, it reinforced an "othering" perspective (see Harris, 1995).

Training on cultural competence highlights the values different groups possess and generally introduces the implications of group history on the cultural strengths and sources of collective coping that influences current experiences. Professional training, however, seldom addresses the inherent biases of those being trained; nor does it provide sufficient time for the long-term engagement necessary to examine, challenge, and create new perspectives (Fouad et al., 2009; Hatcher et al., 2013; Rogers, 2006). For example, on average, a degree program requires one semester focusing on cultural influences relevant to individuals' development and lived experiences; only 1 to 4 hours per year are required through continuing education postgraduate training and licensing in select disciplines. Although culturally based training is seldom an explicit requirement in research-focused graduate programs, it is relevant in conceptualizing and assessing how empirically examined proximal relationships are studied. Even less frequently considered is the limited cultural perspective (i.e., ethnocentric) behind the development of youth-based policies intended to address issues related to African American youth and their families.

Although there remains substantial work to understand the influence of privilege as a source of significant support for youth with few known risks, there has been tremendous effort to understand how various groups live culturally. García Coll and Magnuson (1999) suggested the need to acknowledge cultural factors as

> an active part of the changes and influences on developmental processes. . . . This new treatment of culture reflects the need to "unpackage" culture, that is, to consider culture as a multidimensional evolving source of influence on developmental processes within any culture rather than as a monolithic nominal variable. The unpacking of culture also requires researchers to operationalize culture in concrete variables. (p. 3)

This focus in research on exploring and understanding cultural factors impacting development has been particularly true for many immigrant families and youth, although the degree of within-group diversity continues to be minimally acknowledged even for them (see Nakamura, Tummala-Narra, & Zárate, 2013; special issue on immigration status and within-group assessment considerations). Even so, less attention has been paid to cultural and historical factors shaping experiences and outcomes for African Americans that also considers their developmental needs.

Universal versus Group Dynamics

Tensions exist when conceptualizing intervention programs regarding the extent to which research studies exploring resilience from a developmental orientation are focused on universal versus group-specific factors. The perception that factors contributing to resilience are universally constant ignores the sociohistorical conditions that influenced the presence and type of vulnerabilities youth must navigate. As resilience research expands to better understand the broad factors related to positive outcomes for youth experiencing multiple risks, it is important to continue examining unique group differences as well. It is interesting to note that significant research has been conducted on within-group processes, outcomes, and trajectories, especially for African American and Latino youth (Cedeno, Elias, Kelly, & Chu, 2010; Edwards, & Romero, 2008; Gonzalez, Stein, Kiang, & Cupito, 2014; Pina-Watson, Ojeda, Castellon, & Dornhecker, 2013; Stevenson & Arrington, 2009; Travis & Leech, 2014). Findings from such studies, however, are utilized infrequently in studies involving diverse racial and ethnic groups. In searching empirical studies on research databases (i.e., PsycInfo) from 2000 to 2010, frequently cited literature reviews do not often reference group-specific studies. Although this is understandable, given a focus on universal attributes, a general

orientation toward excluding group-relevant research contributes to designs and interpretations of results reflecting a status quo orientation. Much of the multigroup research on resilience acknowledges group variability in reviewing the implications and generalizability of findings, but often it is limited to interpretations of findings within a universal orientation. Exploring similarities in parallel processes offers explanations and possible confirmation of universal trajectories potentially associated with developmental trajectories; considering implications associated with different processes and outcomes, however—both individual cultural factors and positionality of the group within broader societal experiences—contributes to greater interpretive understanding of group-differentiated experiences.

Examining within-group variability also receives attention as investigators increasingly attempt to differentiate experiences of native and immigrant African Americans. Due to different sociohistorical conditions, immigrant youth have a cultural reference that extends beyond American borders. Ogbu (1978; Ogbu & Simons, 1998) identified these groups as voluntary (immigrant) and involuntary (nonimmigrant) minorities to acknowledge the influence of their cultural histories within the United States. This classification was based on reasons for the different groups of African descent being in the United States and the involvement of White Americans in defining their status. Although identifying with an immigrant history can provide a specific source of support (i.e., cultural identity associated with country of origin), immigrants share the stigmatizing experiences associated with being identified phenotypically with native-born African Americans (Caldwell, Guthrie, & Jackson, 2006; Seaton, Caldwell, Sellers, & Jackson, 2008). Although not all studies will have sample sizes sufficient for within-group analyses, it is relevant to consider the implication of the diverse experiences within groups that could result in different findings or trajectories. The situation is relevant even in cases of PYD research that aims to be inclusive (see Spencer & Spencer, 2015).

SES is another area acknowledged in research relevant to within-group variability. African American youth in low-SES families experience risks directly associated with limited resource opportunities that continue to be the focus of much resilience research. Youth in middle- to high-income-status families experience risks associated with racial discrimination, for example, but the scope and impact of their vulnerability is less well understood (McNeil, Harris-McKoy, Brantley, Fincham, & Beach, 2014; Wood, Kurtz-Costes, & Copping, 2011). Lindsay (2011) confirmed persistent racial differences in academic performance when examining White and African American youth from middle-class families with similar resource capital. Similarly, McNeil et al. (2014) asserted the need for further examination of contextual risks and related demographic factors influencing of the nature and impact of discrimination among middle-class youth.

Developmental Trajectories and Transitions

Although many resilience models are developmental in that they focus on adolescence as a period in the life course, they vary in terms of the periods studied (e.g., early, middle, or late) and the age ranges in longitudinal designs. Research has focused on specific areas of impact influenced by vulnerability during adolescence, however, with far less attention to late childhood, the transition into adolescence, and late adolescence as an emerging shift into adulthood. Interpretational information is compromised when accounting for ages as a study condition without a concomitant acknowledgment of developmental factors associated with the ages as well. As suggested by the historical framing provided, a history of vulnerabilities and risks that is both cumulative and multiplicative suggests the presence of developmentally comprising issues that often exist long before pubertal development begins. Most research, therefore, does not focus on late adolescence within a resilience framing as the needs associated with a history of academic and psychosocial risks, and therefore sustainable intervention factors that influence resilience, are numerous and complex. Exceptions to this are studies examining the success of African American youth who attend college with attention to their mental health and college retention (see Hunn, 2014; McGee & Spencer, 2013; McGee, Hall, & Spencer, 2015; Solorzano, Ceja, & Yosso, 2000). More work is emerging around middle to late childhood as precursors to adolescent experiences (see Swanson, 2010).

Early childhood research provides a basis for understanding the impact of developmental processes in cultural awareness and self-processes as indicators of resilience. The relevance in particular of meaning making and the implications for children understanding and internalizing contextual supports was linked to their developing social cognition. A developmental pattern in the understanding of color connotations, for example, is a consequence of increases in social experiences and social cognition (Spencer, 1982b, 1985; Swanson, Cunningham, Youngblood, & Spencer, 2009). Three-year-old children of all race/ethnic backgrounds are generally Eurocentric in terms of racial attitudes, racial preferences, color concepts, and connotations. However, for Black children, an Afrocentric pattern of attitudes and preferences begins to appear at age 5 and continues through age 9. Different

developmental patterns emerge when SES is taken into account. Middle-income Black children are generally Eurocentric in terms of racial attitudes, racial preferences, color concepts, and connotations at age 3, while low-income children were neutral on the same dimensions at the same age. After age 3, both low- and middle-income children showed a clear Eurocentric orientation for color concepts. However, middle-income children became progressively more Afrocentric through age 9, while low-income subjects showed a pattern of neutrality.

This work by Spencer and colleagues, among others, became the basis of exploring the role of racial identity processes and the impact of discrimination experiences through adolescence as predictive of resilience. A broader, developmental perspective of youth experiences and outcomes necessitates the assessment of processes that are precursors to identity formation: cognitive development and opportunities for "industry." Findings on racial identity and discrimination experiences, for example, are broad in their exploration of mediating and moderating variables and assessments of discrimination (Eccles et al., 2006; Harris-Britt et al., 2007). Empirical reports should include information on the population criteria (i.e., middle school age versus high school age), measurement validity (i.e., assessing types of discrimination), and context of experience (i.e., racial demographics). Given differences in early opportunities received, cognitive shifts that occur during adolescence, and the general developmental needs and areas of vulnerability between early and late adolescence, aspects of resilience are unique at different periods. Research examining the middle school and high school periods often focus on academic outcomes, identity development, and relationships with adults and peers. Post–high school research (i.e., emerging adult years) explores issues largely related to academic experiences in college and university settings. Approaches that focus on the individual experiences and issues contributing to resilience have been necessary in understanding the impact of contextual factors on youth; they have also provided sufficient data demonstrating the extent to which unaddressed contextual factors can undermine long-term outcomes. Examinations of resilience therefore extend from the conceptual to the procedural.

Procedural Issues

As others have noted, the scope and quality of methodological procedures have implications for the value of research findings (see Schwartz et al., 2014; Veale, 2006). Two major areas of consideration are briefly highlighted here: (a) recruitment and sample characteristics influencing generalizability of findings and (b) psychometrics (e.g., assessment reliabilities and normed criteria).

Recruitment Considerations

Research participants provide data that inform the interpretation of findings relative to the questions being examined. Characteristics of the sample also affect attrition and generalizability of the findings. Inclusion and exclusion criteria are important to note in reporting studies. Recruiting in urban schools with high free-lunch participation or community mental health facilities to address issues relevant for a broader group is exclusionary by default; students in schools with diverse SES populations are excluded, as are youth receiving mental health services paid or supplemented through private insurance. Such inclusion and exclusion approaches are based on a priori decisions but can also reflect limited time or effort to establish relationships with individuals in locations that facilitate accessibility to diverse populations. *The impact, regardless of the reason, is suggestive of skewed results with limited generalizability. This issue is often addressed in discussing the implication of findings, but it is not frequently raised in considering future research strategies*. It can be difficult to gain access to youth identified as low risk because they are more likely to be protected, whether having high or low supports, from research efforts perceived as exploitive (Hatchett, Holmes, Duran, & Davis, 2000). Research briefs on effective recruitment approaches in conducting developmental research with African American youth or their families are generally not available but could broaden existing approaches used by investigators.

Psychometric Considerations

It is common, and often expected, for psychometric properties of new instruments to be investigated and documented. It is particularly critical to do so with instruments adapted for a developmental period or used with a population not previously tested. It is useful, although uncommon, for investigators to report the reliability of measures for each group being studied if there is limited documentation of the measure's prior use with each group. The assumption, and therefore the interpretation of results, is that all groups will interpret items (i.e., on self-reported measures) representing a construct similarly and consistently. This level of planning and reporting will enhance the likelihood of measurement strategies representing the constructs investigated.

Research with diverse groups may occasionally require alternative interpretations for established constructs. The

constructs of racial awareness and identity, for example, may be conceptualized as risk variables in exploring the impact of discrimination. However, youth have varying experiences of race as a risk factor related to their skin tone. African American toddlers and young children, for example, have not developed a racial identity but demonstrate awareness of color connotations, or concepts, as early as age 3. This early awareness of race and color connotation is related to the child's social cognitive ability to take the perspective or point of view of another, which becomes more differentiated in self-appraisal processes with maturation (Spencer, 1982b; Swanson et al., 2009). In essence, perceptions and stereotypes related to skin color can influence self-appraisal in conjunction with racial identity. Skin color biases pose a risk for youth of color, particularly African American youth, as skin color is the most visible and salient phenotypic feature associated with racial categorization and related biases.

There is a need to examine "norms," both in terms of attributes associated with typical development—emotional, cognitive, social—and in terms of data typically collected to assess specific constructs (e.g., connectedness, individuation, etc.). For example, in the absence of examined criteria that defines norms, there is potential for misinterpretation of developmental processes that underlie constructs in diverse groups. In using family structure as a construct of normed family patterns, Murry, Smith, and Hill (2001) reiterated the need for research to redefine family composition and family structure to more accurately capture the family supports available to African American families not represented in traditional assessments using two-parent and single-parent criteria. They noted that this construct maintains a consistent definition of single parents as representing both composition (i.e., the individuals in families) and structure (i.e., single, two-parent, intergenerational). Given the significant reporting and inclusion of family structure as a factor associated with vulnerability, greater differentiation can enhance empirical reports and account for the impact of extended family on the development of African American youth.

An understanding of racial attitudes in the context of social cognitive development suggests that some explanatory power can be lost when race (used as a categorical variable) is considered as a risk factor without additional variables that captures the experience of race (i.e., the youth's understanding of color connotations, racial attitudes, and preferences). In essence, identity development may also reflect processes by which a youth copes with her or his experiences of race (Swanson, Cunningham, & Spencer, 2003). For instance, research suggests that there is a difference between children's ability to perceive color connotations and their acceptance or internalization of those color connotations (Spencer, Harpalani, Cassidy, et al., 2006). A similar pattern is found among youth when exploring the impact of their experiences with discrimination and factors contributing to depression (Caldwell et al., 2006; Lambert, Herman, Bynum, and Ialongo, 2009; Seaton et al., 2008). Depending on the phenomena being studied, the internalization of negative stereotypes associated with being a member of a particular racial group may be a more important risk factor than belonging to the specific racial group. Social cognition among adolescents is seldom explored, yet it is a critical construct for exploring the meaning-making processes associated with self-appraisal processes and subsequent behavioral coping patterns.

Contextualizing Norms

Research with diverse groups also necessitates establishing new norms or reassessing the applicability of current conceptualizations. Often norms serve as benchmarks for determining whether behaviors and abilities are within the expected range versus below or above it. Without an understanding of norms for diverse groups, children from different groups may be mistakenly identified or overlooked for intervention when their behaviors or abilities are based on the degree to which expected norms are expressed. For example, there are standard criteria for classifying a child as anxious, yet there are group differences in the expression of anxiety (Morrissey & Werner-Wilson, 2005; Wiese, 2010). The limited degree to which cultural differences exist in coping expressions is a challenge. This is particularly relevant when examining a developmental period noted for heightened anxiety in addition to the criteria used for observer-rated assessment procedures to evaluate behavior problems. Clinical standards for assessing behavior problems would appear sufficient for identifying needs and subsequent treatment plans if there were not continuing concerns regarding overdiagnosing African American males for behavioral plans within schools (see Noguera, 2008).

As DiBartolo and Rendon (2012) found in their review of literature examining cultural factors influencing mental health outcomes, sociocultural factors significantly affected the expression of symptoms with implications for treatment. A child exposed to neighborhood violence may, over the course of time, exhibit behavioral impulsivity more consistent with hyperactivity or conduct disorder than with anxiety. National organizations approach

violence as a health risk (i.e., Centers for Disease Control) and a psychological risk (i.e., National Institute of Mental Health). The implications, however, of exposure to violence on youth resiliency has not been systematic or conclusive; the association between violence and trauma is defined quite broadly across various studies. Nevertheless, as noted, there is evidence of somatic complaints among youth who exhibit behavioral problems who have also, for example, witnessed violence. For African American youth, little research explores behaviors identified as a problem but interpreted as a normed response to the contextual experiences (see Swanson, 2010). As such, intervention efforts address the behavior, not the contextual conditionsor the emotional impact (without a primary focus on behavior). Among the sources of trauma for African Americans recently being reintroduced into social science research is cultural trauma. The intergenerational impact of cultural trauma, shaped by the historical experiences discussed earlier, draws on critical race theory and extends challenges regarding inferences based on reactive behavior.

According to Stamm, Stamm, Hudnall, and Higson-Smith (2004), cultural trauma is nonspecific and tends to help explain human interchange across cultures with differences in economic, social, and technological organization. Sociocultural trauma exists because of certain conditions either inherited or forced on people by dominating forces. Over the last few decades, cultural trauma has been examined for many groups worldwide. Alexander, Eyerman, Giesen, Smelser, and Sztompka (2004) defined its impact as "members of a collectivity [who] have been subjected to a horrendous event that leaves indelible marks upon their group consciousness, marking their memories forever and changing their future identity in fundamental and irrevocable ways" (p. 1).

Eyerman (2001) argued that "[t]here is a difference between trauma as it affects individuals and as a cultural process. As a cultural process trauma is linked to the formation of collective identity and the construction of collective memory" (p. 1). During the last 20 to 25 years, American media has consistently projected an expectation for citizens to be their own individuals, independently creating the life they envision, and take their piece of the "American Dream." The literature suggests that this type of socialization does not work well with an ethnic group whose highest value lies in relationships between people (Akbar, 1996; Degruy, 2005).

Alexander et al. (2004) suggested that an understanding of cultural trauma is relevant in exploring how it contributes to, or affects, everyday life. This framework implies that social-cultural traumas are fused into the collective identity and collective memory via generational transmission influencing the individual development and self-worth of those impacted. Although it is implied in relation to impacting socialization practices and youth outcomes, limited research connects parenting patterns and cultural socialization or practices used to raise children.

Training New Scholars

The 30 years of research on vulnerability and resilience created a shift from pathologically based studies to greater emphasis on developmental and contextual framing. In essence, earlier research involving African American children and adolescents was based on comparisons to Whites, was atheoretical, lacked developmental considerations, and was based on a priori assumptions regarding deviance (see Spencer 1985, 1990a). A shift toward exploring PYD offered hope in addressing these earlier issues: Studies explore within-group development, are theoretically conceptualized, and began to consider developmental processes. Since a priori assumptions remained unchallenged, the research continues to replicate biased assumptions. There is significant research on within-group processes for African American youth; a wealth of research also is available using multi-ethnic samples in which African American youth are compared to other youth. Limited developmental understanding is applied to exploring the social-cognitive and culturally based, meaning-making processes necessary to interpret contextual influences impacting youth outcomes. These trends have not only influenced the focus and nature of research but have also shaped the training of emerging scholars who will continue in this "tradition" of conceptualization.

The American Psychological Association (2008) task force guidelines for multicultural training and research recommend that consideration is given to the *impact of researcher perceptions on implementing a research plan*. These include the need to recognize:

(a) that psychologists are cultural beings that "may hold attitudes and beliefs that can detrimentally influence their perceptions of and interactions with individuals who are ethnically and racially different from themselves";
(b) "the importance of multicultural sensitivity/responsiveness, knowledge, and understanding about ethnically and racially different individuals"; and
(c) the importance of "conducting culture-centered and ethical psychological research among people from ethnic, linguistic, and racial minority backgrounds." (pp. 3–18)

The guidelines are to encourage an awareness of ethical research in conducting studies with diverse groups, but they fail to highlight the need for researchers to examine personal biases and perspectives of the groups being examined from the conception of a study through analysis and interpretation. As such, subsequent emerging scholars will not have an awareness of how positions of privilege and perceptions of others impact their research that can inform policies and practices for youth of color generally and African American youth specifically. Without such insights, researchers themselves are at risk for using publicly funded and federal research dollars to foster successful careers while perpetrating perspectives that compromise the potential effectiveness of policies and programs for youth and families most in needed of authentic supports.

As the examples offered suggest, integrating a developmental perspective into research on diverse groups requires an articulated understanding of the processes by which development takes place. In addition to the collective impact of historical experiences and cognitive maturation as relevant, these constructs are seldom explicitly examined in studies of vulnerability and resilience. They are also minimally addressed as an interpretational consideration that is particularly relevant when examining the meaning-making processes involved in negotiating experiences of stress.

TRANSLATIONAL PRACTICES

Since the mid-1990s, federal and foundation funding agencies have increasingly required accountability for the dissemination of results obtained from supported studies. These agencies have been linked to policies requiring explicit collaborations between researchers and providers along with a public expectation for research to inform services being provided or obtained. During President Johnson's administration, policies meant to address poverty were framed to provide opportunities for youth and families (see Swanson & Spencer, 1991). These practices, viewed by a later administration as an economic drain, were eliminated. Subsequent policies since the 1990s have focused on addressing families and youth as problems to be fixed or managed, resulting in significant attention on individual characteristics and significantly less on societal practices contributing to the noted problems. Consistent with research patterns historically, the developmental field has responded to these policy and societal shifts *without shifting the underlying individualistically oriented paradigms*. Support for identifying practices that meet the criteria for generalizability (i.e., wide dissemination) while identifying factors relevant for mitigating individual problems are the focus of recent research on resilience. These practices are identified as evidence-based.

Evidence-based practices (EBPs) offer best practices for facilitating positive outcomes for youth in various settings drawn from randomized control studies. They have been particularly relevant in addressing targeted mental and physical health risks, but they also are relevant in identifying effective universal strategies as noted earlier with regard to mentoring practices. Numerous standardized programs exist for addressing universal and targeted youth concerns across various institutional systems (J. L. Frank, Jennings, & Greenberg, 2013; Kusche & Greenberg, 2012). Dissemination and extension of these practices has, however, been limited for small-scale prevention and intervention practices, particularly for those needing to ensure cultural relevance. Community-based organizations and faith-based institutions are two areas that provide significant support for youth in which dissemination of findings has been slow. Research has been relatively effective in addressing individual issues, particularly in school and family contexts. Yet even within this framing, there is limited consideration of the developmental needs and cultural factors influencing sustainability of positive outcomes. Specifically, in providing culturally relevant universal interventions, there is no current mandate to adopt a developmental framework in guiding practice-related decisions; a "lack of knowledge and guiding framework can significantly impair [practitioners'] abilities to address the complexities [youth] experience that may call for tailoring or adapting treatment models" (DeRosa, Amaya-Jackson, & Layne, 2013, p. 199). Given the framework of the dual-axis model of vulnerability suggesting that, at some level, all youth are vulnerable (see Spencer, Harpalani, Cassidy, Jacobs, et al., 2006), programs should address youth needs by facilitating coping strategies and competence formation relevant in early adulthood. DeRosa et al. (2013) proposed that an essential approach is one that cultivates both lifelong learning and critical thinking in the knowledge obtained through emerging research and the utilization of evidence-based, trauma-informed assessments. With this knowledge of emgering science and evidence-based practices, programs are better equipped to critically appraise their approaches as they formulate conceptualizations and treatment recommendations for vulnerable youth. Concurrently, however, there is a need to address factors that contribute to youth vulnerability or that continue to exacerbate the concerns. Framing adolescence as a culture in itself, Nelson and Nelson (2010)

suggested that EBPs address the multiple components of adolescents' experiences (e.g., technology, peer relationships, identity processes) in developing and implementing intervention practices. They contended that "Whether modifying existing evidence-based protocols or designing new interventions to be evaluated, thoughtful attention to adolescent culture will help enhance adolescent engagement and promote improved treatment effectiveness" (p. 310). The increase understanding of assets associated with PYD contributes to explicit programmatic considerations of risks and supports.

Allison, Edmonds, Wilson, Pope, and Farrell (2011) further suggested that even when prevention or youth development programs are available, community residents may not know about nor access these resources. Community infrastructure (e.g., availability, quality) is important, but resource awareness is also necessary. If we build it and they do not use it, dissemination efforts that just target organizations may not result in ultimate benefits to youth and communities. Support for the prevention delivery system may need to explicitly address those organizational capacities that also engage and link community residents to prevention opportunities and resources. Intentional linkages at each step may be necessary.

Next we present two programs that utilize research on vulnerability and resilience in their design and implementation to mitigate challenges and enhance future trajectories of youth. Each program has a specific focus, but both provide a comprehensive approach that includes addressing racial disparities and societal incongruence through developmentally appropriate practices for African American youth. Numerous other programs are based on best practices from the research. We present these two to highlight how program practices can draw from resilience research and to explicitly illustrate the multilevel focus (i.e., individual developmental needs, contextual conditions) required of programs in which research can ensure knowledge of supportive strategies are available. These provide a novel conceptualization in translating research for practice that addresses youth as in need of support (rather than a problem to fix) the developmental tasks relevant for youth, and the contextual supports necessary for a sustainable positive trajectory.

Work Connections

Hillside Work-Scholarship Connection (HWSC) is a youth development program designed to help youth (most likely to leave school) to stay in school, graduate, and be prepared for the transition into work or postsecondary education. With several sites nationwide, HWSC assists youth with acknowledging, and achieving their potential to mitigate chronic, negative contextual influences surrounding them. HWSC also endeavors to change the negative educational trajectories of youth by connecting them with resources to become successful. As a secondary intervention, the focus is on youth already showing signs indicative of negative outcomes. Youth are identified based on having at least two risks associated with school dropout: failing a core subject, multiple school suspensions, overage for grade level, high rates of absenteeism, and a family that meets poverty guidelines (Swanson & Spencer, 2011; see Zimmerman et al., 2003, regarding resilience-compromising factors).

HWSC defines resilience as students' success in overcoming aversive barriers, created by poverty, as expressed through completing high school and obtaining some post–high school training. To accomplish this, HWSC serves as a bridge that connects its students to opportunities and resources often blocked or denied by their impoverished contexts. Recognizing its limits in changing students' aversive circumstances, the program positively impacts students' access to profitable skills and knowledge. HWSC offers the traditional resources associated with successful programs addressing academic vulnerabilities of youth: mentoring and academic supports. HWSC's work in translating research to practice, extends into providing work opportunities for youth (i.e., identity-enhancing opportunities), ongoing cultural and developmental training for the staff (i.e., to address perceptions of privilege, personal expectations, and assumptions about development), and training for partner organizations that offer employment (i.e., to address inherent biases in policies or expectations that compromise youth opportunities to learn and grow).

Youth are provided and connected to individualized resources to enhance their educational trajectories and the social-emotional development needed to succeed: long-term mentoring, academic support, life and social skills, employment, and postgraduation planning and support. Each component is designed to guide students toward academic achievement by directly addressing contextual barriers and risks (see Bauermeister, Zimmerman, Barnett, & Caldwell, 2007).

Long-term mentoring is a critical component to HWSC's overall functioning, and mission. This service is executed by Youth Advocates, who each serves as a mentor to an average caseload of 30 students. To best support and guide students toward the goal of graduation, Youth Advocates (i.e., mentors) build rapport with not only the student but also relevant stakeholders in the student's

life, such as family members, teachers, and employers. Through establishing meaningful connections, the Youth Advocate is able to best identify and address each student's specific needs.

As part of the life and social skill building service, HWSC staff members conduct weekly enrichments that follow the evidence-based curriculum included within the Teen Outreach Program (TOP; Allen, Spencer, & Brookins, 1985). During these sessions, students are provided opportunities to evaluate current and future life options. These are growth-promoting experiences that exist outside of potential challenges in their homes or neighboring communities. Since many of the students potentially become first-generation college students, they are also provided postsecondary planning and support (e.g., free SAT/ACT prep courses, Free Application for Federal Student Aid [FAFSA] workshops, resume/cover letter building, and organized college tours) to help them manage unfavorable contextual obstacles.

Offering students employment is an aspect of the program that encourages focus and a trajectory toward graduation. The skills prepare youth for the transition into future work roles. HWSC has established meaningful relationships with prominent local employers to support job placements. Students must initially meet the program's pre-employment criteria for "Triple-A Standard" (Academics, Attitude, and Attendance), which hold students accountable for average or better grades on recent report cards, good attitude (as denoted by school/program staff), and school attendance above 85%. Once youth are employed, Youth Advocates assist them with time management skills and in balancing obligations at school, work, and home. Employment opportunities through this program instill students with a greater sense of purpose and drive to succeed. HWSC students who are employed by an employment partner often experience greater access to opportunities and resources, which expands their social, cultural, and financial capital. Factors identified as enhancing youth resilience that are incorporated into this program include mentoring by adults who have shared experiences similar to the youth participants, academic supports, positive peer relationships, and an opportunity for financial autonomy. These factors, identified as particularly relevant for urban African American youth, have been integrated with TOPS as an EBP, to explicitly address the youth needs. An additional component not explicitly explored in developmental research but acknowledged as significant in this chapter is addressing the potential for biases: addressing stereotyped perceptions of the youth and positions of privilege among those who will hire and supervise them.

In complementary roles, the Youth Advocate supervisors maintain regular meetings and provide ongoing training for employee supervisors around unintentional biases and youth areas of strengths to utilize and enhance. This component of the program extends the use of existing research into practices addressing systemic biases and discriminatory practices that impact the nature of feedback and work opportunities youth receive consistent with research on youth employment. There is variability in the extent to which these employer meetings occur. However, while a process for establishing fidelity is needed, the initial piloting provides a novel orientation to programmatically maximizing supports for vulnerable youth. The current programmatic and practice guidelines are being refined and will offer potential for exploring translational approaches in the future.

Restorative Practices and Principles

Restorative practices, as previously noted, is an approach to addressing behavior problems in schools where the behavior is understood in social context. "Individuals are recognized as being part of a social web of relations, and building, maintaining and repairing relationships become priorities" (Morrison & Vaandering, 2012, p. 138). Restorative principles are based on the premise that harming others damages interpersonal and communal relationships and that justice is best achieved by seeking to repair relationships through reconciliation. Restorative practices, however, evolved from a philosophy of restorative justice that is essentially reactive in response to a disciplinary issue. However, a restorative approach within the context of education moves beyond reactive responses to wrongdoing to include proactive strategies that address the needs of students and staff members to work together in positive relationships as members of a community (Morrison & Vaandering, 2012; Wachtel, 2012): It is a universal intervention approach where behavior is understood in social context in supporting individual development.

The school-to-prison pipeline has recently received substantial acknowledgment in various fields but was identified as an emerging issue warranting immediate attention over two decades ago (Mulligan, 2009). This trajectory is traced to progressively harsher penalties for mild to moderate infractions that became linked to juvenile justice proceedings and is associated with discriminatory treatment of minority and marginalized students in many U.S. schools (Caton, 2012; Evans & Lester, 2012; Molsbee, 2008). In an

effort to reverse this process, restorative practice strengthen relationships responsible for the social context or climate. It involves creating an environment where (1) everyone is viewed and treated as valuable and (2) a process for examining the impact of one's behavior on another, beginning with restorative questions [e.g., what did you want (from the disruptive behavior?)], that encourages individual and collective responsibility consistent with cultural values of mutual cooperation and sharing (Murry et al., 2005. It is also conducive for adolescents who have the capacity to reflect and discuss their needs. Loosely drawn from nonviolence principles, questions are framed, and expected to be asked, in a manner supportive of youth development and their relationship with others.

Although restorative practices have been used in schools since the 1990s, little research has been done evaluating the effects of these programs using experimental or quasi-experimental methods (Stinchcomb, Bazemore, & Riestenberg, 2006). One exception to this is Wong, Cheng, Ngan, and Ma's research (2011). These authors conducted a quasi-experimental study of a restorative whole-school approach, which found that intervention group participants, as opposed to the partial intervention group and the comparison group that received no intervention, experienced a significant reduction in bullying, higher empathic attitudes, and higher self-esteem.

Other studies, examining components of the restorative practice process, suggest that when restorative practices are implemented, behavioral infractions are reduced, suspensions and expulsions decrease, academic achievement improves, school climate and school safety improve, student engagement and connectedness increase, and absenteeism declines (Drewery & Winslade, 2005; International Institute for Restorative Practices, 2009; Karp & Breslin, 2001; McCluskey et al., 2011; Mirsky & Wachtel, 2007; Rideout, Roland, Salinitri, & Frey, 2010; Stinchcomb et al., 2006). Importantly, school connectedness and engagement has been shown for minority students previously identified as having either struggling or as having discipline concerns.

Evaluations of discipline approaches in schools show the benefit of collective responsibility in establishing caring relationships and nonpunitive approaches to discipline. Freiberg and Lapointe (2006) evaluated 40 school-based programs that included evaluations of interventions in schools that specifically sought to reduce behavior problems. Of these 40 programs, 29 were implemented in schools with high minority and low-income student demographics. The authors found several commonalities among the successful programs: The programs moved beyond discipline, emphasizing student learning and self-regulation, not simply procedures for addressing rule infractions. They encouraged "school connectedness" and "caring and trusting relationships" between teachers and students (p. 65). Overall, the programs tried to increase students' positive experience of schooling by building mutually respecting relationships for all school staff and students and by moving away from a reliance on punitive reactions to misbehavior.

Restorative practices in education offer an approach that manifests itself in a variety of strategies. These practices take a universal approach and systems-based orientation toward creating and sustaining a climate conducive for positive relationships and academic engagement. It does, however, require substantive shifts in existing practices and policies that can exceed a district's or school's capacity for implementation and sustainability. In addition, the focus on establishing and restoring relationships is based on the premise of mutual respect. There is an expectation that individual differences are minimized in the process, which has been reported as a concern in some contexts. As respect and the nature of relationships are contextually defined, studies are currently exploring the impact of explicitly incorporating training to ensure personal and historical biases are mitigated in the implementation of the practices. Restorative practices do not negate the benefits of EBPs to understanding effective, theoretically framed strategies, yet substantial work is needed to understand and implement these into translational practices that consider contextual and cultural influences on effectiveness.

Restorative practice programs are shaped by available research on resilience relevant to their mission and the desired outcomes for their target populations. They acknowledge developmental needs and seek to explicitly integrate cultural influences in their attention to how relationships influence on youth outcomes. Particularly important is attention to providing accepting and caring relationships consistent with research regarding safe and impactful adults in the lives of youth. To varying degrees, restorative practice programs also address individual biases that contribute to youth trajectories and outcomes of concern. Sociohistorical factors related to untoward conditions are generally unknown and therefore unacknowledged. Efforts to explore individual biases and their bases (often from a position of privilege, regardless of race) are ways to better understand programs and their limitations in facilitating resilience among African American youth.

System-wide or comprehensive efforts such as HWSC and restorative practices are challenging to implement with

the type of fidelity required by EBPs. These types of programs draw from the research to identify what practices to consider as central and where flexibility might be allowed. Smaller programs that exist within community-based organizations and faith-based institutions often lack the resources needed to create conditions that are inclusive of developmental, cultural, and relational factors in order to retrofit them for their mission and youth population. Collectively, small, community level programs reach substantial numbers of youth, and invest significant time, effort, and resources in meeting youth needs with little knowledge of how and why their efforts should work. Translating research into action should involve mechanisms and networks that can explicitly inform those directly involved in meeting youth needs.

CONCLUSION: REFRAMING THE FUTURE

As developmental science is a data-based field that informs decisions within a data-driven society, there is a prevailing assumption that data and data sources represent reality. A primary proposition of this chapter is an acknowledgment that data alone are not always enough. Part of the challenge for research scholars is not only ensuring that their research accurately represents the populations investigated (and the unique historical experiences of each) but, additionally, disseminating the findings to those who can implement the work in a relevant manner. Acknowledging one's position of privilege and recognizing the need for accurately understanding others' experiences without automatically pathologizing differences is always a necessary first step in the conduct of science. Without that critical consideration, there is the risk of misrepresenting youth and their families due to preconceived and unchallenged assumptions about the meaning and impact of historical and contemporary experiences. Without question, consequent translational work is more complex than developing a treatment plan for problem behaviors. Sufficient data on culturally informed (and thus, historically embedded), contextually based, and developmentally explored phenomena are needed to support research and the implementation of practices. As important, however, is the necessity of examining the influence of investigator privilege and the "wages" of social science status quo adherence on these processes (e.g., the ease of procuring research funds and the securing of journal publishing, given adherence to "traditional perspectives" in the conduct of social science).

Multicultural training should be explicitly integrated into research training as a core component of professional ethics. As an extension of the traditional approach to exploring others, a core component of the training must integrate positions of privilege that shape how others are viewed, evaluated, and supported (i.e., resources provided, treatments recommended). Although multicultural training is a course requirement in clinical, counseling, and education programs, there is substantial variation in the extent to which this training is integrated into other core courses and subsequently extended into practice. In addition, multicultural training is not a course or practice requirement in other areas of psychology; frequently it is addressed only within studies exploring research ethics and some justifications associated with the human subjects review process. These approaches to understanding cultural practices suggest they are sufficiently important to be acknowledged but minimally relevant in clinical and research practices. More disconcerting, however, is the perspective that historical and cultural influences are focused on merely to be politically correct. Such an attitude removes personal responsibility to examine and address individual biases from the equation.

The need for cultural awareness grew out of grassroot efforts to impact federal policies and professional standards, such as those by the American Psychological Association. Federal policies have focused on nondiscriminatory practices in an effort to facilitate inclusion (e.g., affirmative action) but negated the sociohistorial factors rooted in the attitudes and behaviors that compromised equitable opportunities. Since the mid-1980s, policies influencing African American youth directly focused on addressing observable problems in contrast to the preceding two decades, which focused on providing opportunities: welfare reform did not provide support for the working poor; zero tolerance as a reform for school-based discipline did not mitigate referral biases or create safe environments conducive for learning. As research often follows trends highlighted in national and educational policies, a focus on problems without consideration for the contributing historical or contextual influences has remained in research.

There is considerable research regarding factors influencing resilience for African American youth; there is less acknowledgment of practices that continue to constrain their opportunities. Given what is known from basic and applied research, those within the field are positioned to better facilitate resilience by consciously acknowledging societal and professional culpability, in this way removing systemic barriers that compromise the opportunities and outcomes for African American youth. Until the noted changes occur, the Einstein quote at the beginning of

the chapter still holds sway, and virtually guarantees the misrepresentation of African American youth sources of high vulnerability and resilience.

INTRODUCTION

The developmental trajectories that render individuals vulnerable toward or resilient against diseases of the mind and body are major themes in stress theory, research, and practice. As the field of developmental psychopathology expands our understanding of the multicausal mechanisms involved, vulnerability and resilience are increasingly conceptualized not as static states but rather as probabilistic processes that vary according to the contexts and the consequences investigated (Cicchetti & Toth, 2009; Rutter, 1985; Rutter & Sroufe, 2000). *Resilience* is therefore defined as a dynamic process that promotes positive adaptation among individuals exposed to severe forms of adversity, stress, and/or trauma (Cicchetti & Garmezy, 1993; Luthar, Cicchetti, & Becker, 2000; Masten, Best & Garmezy, 1990; Rutter, 2012). In order to further identify the intertwined risk factors and protective factors associated with diverse developmental pathways that promote resilience, scientists require multilevel analyses and refined measures of biopsychosocial stress among disadvantaged populations.

The social determinants of health literature focusing on stress pathophysiology apply increasingly integrative mind-body perspectives to understand how social inequalities influence disease susceptibilities. In this spirit, the neurobiologist Sterling and the epidemiologist Eyer coined the term *allostasis* to describe dynamic, multifaceted biological processes that maintain physiological stability by recalibrating homeostatic parameters and matching them appropriately to meet environmental demands (Sterling & Eyer, 1988). Analogous to our understanding of resilient systems that have the capacity to dynamically adjust and stabilize systems to adapt to perturbations (Cicchetti, 2013), allostatic processes likewise alter metabolic functioning via compensatory and anticipatory mechanisms for which the brain is the commander in chief. In formulating the concept of allostasis that has since revolutionized our

Financial support for this work was granted to Robert-Paul Juster by means of a doctoral scholarship from the Research Team on Workplace Mental Health (L'Équipe de Recherche sur le Travail et la Santé Mentale) consortium primarily affiliated with the University of Montreal. Sonia J. Lupien held a Senior Investigator chair on Gender and Mental Health from the Canadian Institutes of Canada Institute of Gender and Health. Thanks are also extended to Jason Berhmann for constructive discussions on social justice.

views of what constitutes adaptive and maladaptive stress physiology, Sterling and Eyer (1988) proposed that age and socioeconomic differentials in cardiovascular hyperarousal represented physiological recalibrations to the needs of adversity.

Allostatic Load Model

Over the last quarter century, stress researchers have assimilated the concept of allostasis into understanding how biopsychosocial stress gets under our skin and skull (McEwen, 1998a). At a biological level, a stress response exemplifies an allostatic mechanism that integrates mind and body via the brain's perception of environmental stressors (for an earlier review, see Lupien et al., 2006). Under stressful situations, real or interpreted threats to homeostasis initiate a cascade of biological activities that leads to the sympathetic-adrenal-medullary (SAM) axis release of catecholamines such as adrenaline within seconds, followed by the hypothalamic-pituitary-adrenal (HPA) axis production of glucocorticoids such as cortisol within minutes (Sapolsky, Romero, & Munck, 2000). These activities ultimately serve to adaptively mobilize energy necessary for "fight-or-flight" behaviors (or female-specific "tend-and-befriend" behaviors (S. E. Taylor et al., 2000) that will be discussed in a later section on sex and gender diversity) that ensure survival, but at the cost of recalibrating many other biological functions in turn (McEwen & Wingfield, 2003). For instance, compensatory alterations during acute stress include decreased digestion, bodily growth/repair, and reproductive functions counterbalanced to accommodate increased neurological, cardiovascular, respiratory, and immune activities.

Although stress responses are adaptive in the short-term, long-term activations can result in the gradual dysregulation of allostatic mechanisms. Shonkoff, Boyce, and McEwen (2009) differentiated stress physiology using a useful taxonomy: (1) *positive stress* refers to moderate stress responses that are normal, short-lived, and appropriately deactivated; (2) *tolerable stress* refers to potentially damaging stress responses that get buffered and can even promote protection against future stressors; and (3) *toxic stress* refers to damaging stress responses occurring under conditions of severe adversity, stress, and/or trauma where there is a lack of internal and/or external resources to cope. In addition, such environmental perturbations can be exacerbated by genetic and epigenetic influences that render brain circuitry inadequate to promote emotional regulation. Under toxic stress, stress hormones become misbalanced and induce an interconnected domino effect on interdependent biological systems that collectively collapse as individual biomarkers topple and trail toward disease.

This multisystemic strain attributable to toxic stress is referred to as allostatic load (McEwen & Stellar, 1993). *Allostatic load* (AL) is defined as the multisystemic wear and tear the brain and body experience when repeated allostatic responses exact their noxious toll under conditions of chronic stress. Over time, chronic stress and AL can perpetuate unhealthy behaviors (e.g., poor sleep, diet, smoking, drinking, physical inactivity) that eventually lead to allostatic overload that in turn culminates in disordered, diseased, and deceased endpoints. In an evolutionary biology framework (McEwen & Wingfield, 2003), *allostatic overload* comes in two varieties. Type 1 allostatic overload occurs when energy demands exceed energy supply (negative energy balance), for example, when starving or migrating. By contrast, Type 2 allostatic overload occurs when energy supplies exceed energy demand (positive energy balance), for example, when overeating or hibernating. This conceptual distinction is important when we consider the multifaceted interactions between chronic stress and lifestyle choices exercised by people of diverse social strata. Ultimately, allostatic responses necessitate a biological balance that can shift over time in response to adversity that contributes to AL and allostatic overload.

Because vulnerability and resilience fall along a continuum (Cicchetti, 2013), applying triangulated methods represents a very powerful means to investigate biopsychosocial stress and AL using transdisciplinary perspectives that transcend disciplinary boundaries (Juster et al., 2011). For example, combining biometrics, psychometrics, and sociometrics together promotes triangulation amenable to both research designs and clinical approaches. The essence of the transdisciplinary tradition is illustrated in Figure 8.1, whereby the antecedents and consequences of AL thus far identified in the literature are holistically represented to exemplify the importance of comprehensive measurement approaches that collectively assess interconnected domains using multiple disciplinary tools. Beginning with operational definitions and the development of AL algorithms that have proven reliable in identifying developmental trajectories associated with stress-related disease vulnerabilities, the AL model has rapidly evolved and more recently has begun to be applied to detect pathways that promote resilience.

Operationalizing Allostatic Load

The AL model postulates that stress-related pathophysiology can be detected and objectively measured by assessing a battery of subclinically relevant biomarkers

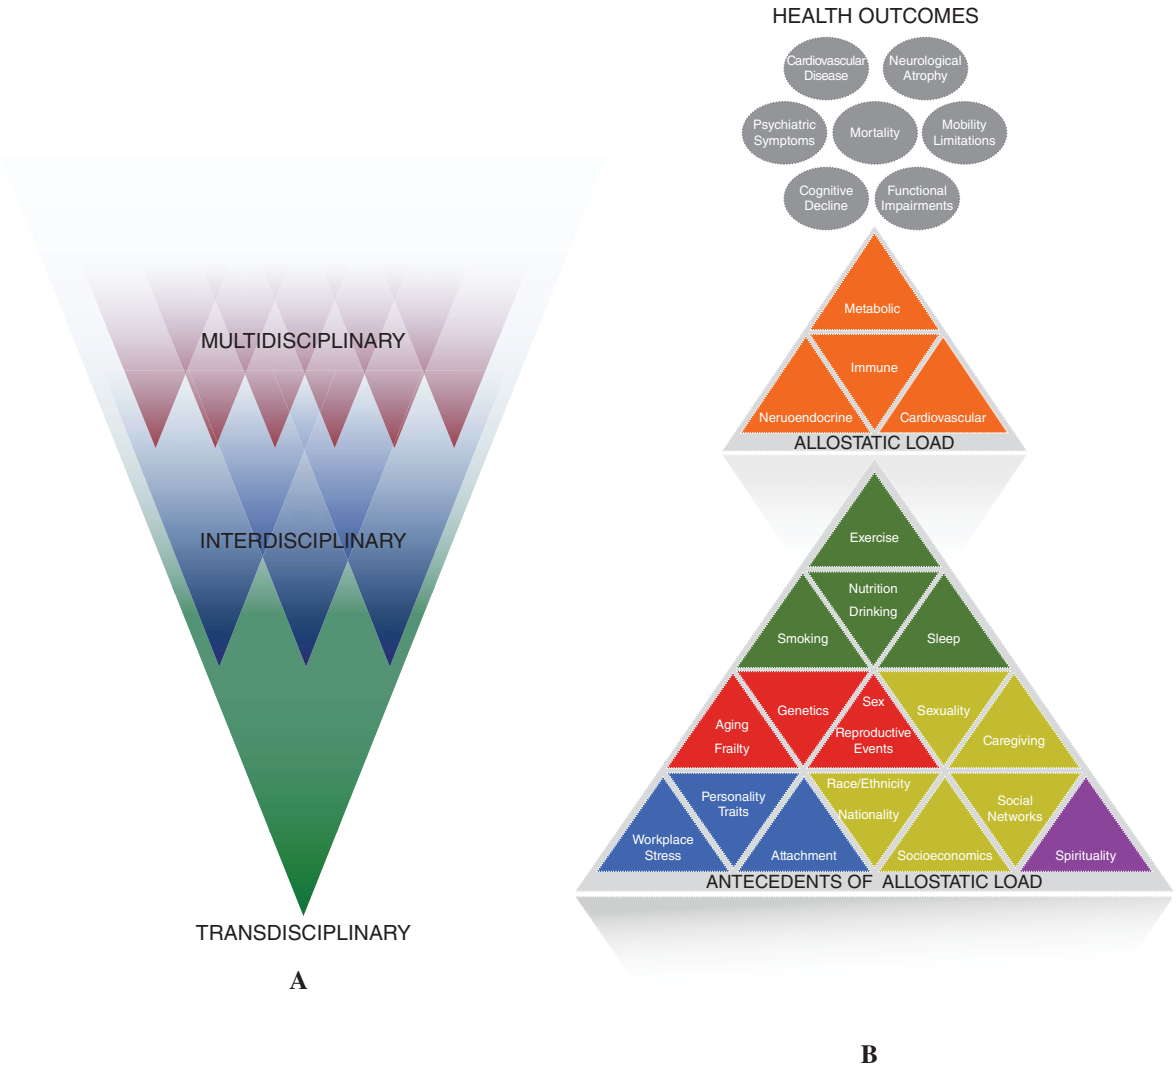

Figure 8.1 (A) A transdisciplinary framework in relation to other research frameworks (adapted from Juster et al., 2011). Multidisciplinarity approaches combine knowledge from different disciplines additively. Interdisciplinary approaches involve the appreciation of disciplinary overlap and the integration of discipline-based constructs into higher-order concepts encompassing several disciplines. Transdisciplinarity emerges as a higher-order framework that integrates all knowledge into new concepts and perspectives that encompass complex interactions reaching across disciplinary boundaries. This approach is consistent with perspectives espoused in the field of developmental psychopathology and is best measured by triangulating methods. Adapted from "A transdisciplinary perspective of chronic stress in relation to psychopathology throughout life span development," Development and Psychopathology, 2011, Volume 23, Issue 3, p. 761, Cambridge University Press. (B) Allostatic load is an exemplar of trandisciplinarism (Juster et al., 2011). Aspects of AL are illustrated here as topic triangles forming a holistic triangle according to diverse disciplines; namely, biological, psychological, sociological, behavioral, and spiritual. As reviewed in Juster, McEwen, and Lupien (2010), each of these life domains has been empirically substantiated in relation to multisystemic biomarkers representing AL that are consequently associated with clinical outcomes. In relation to Figure 8.A, AL is best understood from a transdisciplinary perspective whereby complex interactions among risk factors and protective factors can be identified. See footnote 1.

from multiple nonlinear and interconnected biological systems (McEwen & Seeman, 1999). When chronically stressed, the biphasic effects of numerous biomarkers eventually lead to AL and disease in a theoretical sequence embodied in our domino effect analogy: (1) overactivation of primary mediators such as stress hormones and pro- and anti-inflammatory cytokines induce primary effects on cellular activities, leading to secondary outcomes (2), whereby metabolic, cardiovascular, and second-order immune biomarkers become dysregulated and (3) culminate as tertiary outcomes or clinical endpoints (McEwen & Seeman, 1999).

The AL model proposes that by measuring the multisystemic, reciprocal interactions among primary mediators, primary effects, and secondary outcomes, individuals at high risk of tertiary outcomes can be identified (Juster, McEwen, & Lupien, 2010; McEwen, 1998a). This cascade has important implications not only in terms of research but potentially also clinically in detection and prevention of elevated AL; for example, patients with severe mental disorders are prone to developing comorbidities that could be proactively prevented (Bizik et al., 2013). Specifically, physicians routinely incorporate many related biomarkers in typical blood tests; however, attention is largely placed on values reaching clinically significant levels. By including additional biomarkers, identifying preclinical values, establishing clinical norms, and triangulating methods using combined transdisciplinary approaches (e.g., genetic assessment, neuropsychological testing, clinical interviews, psychometrics, sociodemographics), advances in diagnostics, treatment, and prevention can be improved using the AL framework (Juster et al., 2011; Lupien et al., 2006).

Pioneering epidemiological work by Seeman and colleagues has led to the development of AL algorithms predictive of numerous tertiary/clinical outcomes and predicted by diverse psychosocial factors. Validation using longitudinal data from the MacArthur Studies on Successful Aging cohort led to a count-based AL index representing the next 10 biomarkers (Seeman, Singer, Rowe, Horwitz, & McEwen, 1997): 12-hour urinary cortisol, adrenaline, and noradrenaline output; serum dehydroepiandrosterone-sulphate (DHEA-S), high-density lipoprotein (HDL), and HDL to total cholesterol ratio; plasma glycosylated hemoglobin; aggregate systolic and diastolic blood pressures (BP); and waist-to-hip-ratio. Participants' values falling within high-risk quartiles (clinical and preclinical ranges based on percentiles) with respect to the sample's biomarker distributions are dichotomized as "1" and those within normal ranges as "0." Once tabulated, these are summed to yield an AL index ranging from a possible 0 to 10, which can then be used to predict health outcomes. Beyond these traditional biomarkers, many others have been incorporated into numerous analyses worldwide using similar formulations and/or more sophisticated statistical analyses (e.g., multivariate reduction techniques) that continually refine AL measurement.

By using simple or complex AL algorithms, researchers are ever expanding our understanding of the psychosocial antecedents and health consequences of AL. To summarize (see Figure 8.1), increased AL indices are associated with a plethora of antecedents (e.g., socioeconomic disadvantage, poor social networks, workplace stress, maladaptive personality traits, lifestyle behaviors, genetic polymorphisms, etc.) and consequences using cross-sectional and longitudinal study designs (e.g., mortality, cardiovascular disease, psychiatric symptoms, cognitive decline, physical/mobility limitations, neurological atrophy, etc.) (Juster et al., 2010). There are five thematic advantages of applying an elevated-risk-zone system when scoring AL as AL algorithms represent: (1) early-warning signals, since thresholds are anchored at subclinical thresholds; (2) multi-finality, in that similar AL algorithms predict different tertiary outcomes; (3) flexibility, since calculations are based on different biomarker combinations; (4) synergism capturing the cumulative interaction of numerous biomarkers; and finally, most important for this chapter, (5) antecedent adversities predicting individual variation (Singer, Ryff, & Seeman, 2004). In sum, AL algorithms are objective reflections of biological functioning that are intricately interconnected with genetic, neurological, developmental, behavioral, cognitive, and social factors.

Modern societies face numerous challenges that are particularly pronounced among those from marginalized strata. In this chapter, we explore how AL disproportionably burdens public health in the developed and developing world. By taking a transdisciplinary perspective of life span development, the first sections of this chapter explore literature focusing on early adversity, socioeconomic status (SES) and health gradients, race/ethnicity and discrimination, shifting economic contexts using Brazil as a case study, the struggles of Indigenous peoples of North America and Australia, and finally the importance of biological sex differences and sociocultural gender diversity in understanding AL. Although the majority of studies focus on risk factors that propagate vulnerability toward AL and pathologies, emerging studies are increasingly identifying protective factors and trajectories that promote resilience, which we believe represents a new frontier.

SOCIAL INEQUALITIES INFLUENCING ALLOSTATIC LOAD

Many psychosocial stressors that contribute to AL are mirrored throughout the animal kingdom. Allostatic responses are conserved among species and help orchestrate adaptive metabolic changes, for instance, during hibernation or long-distance migration (Gotmann & Wingfield, 2004; Goymann & Wingfield, 2004; Korte, Koolhaas, Wingfield, & McEwen, 2005; McEwen & Wingfield, 2003). Among nonhuman primates and other social species,

social hierarchies are also important as dominant and subordinate members experience compromised health depending on the stability of rival competition for higher status (Sapolsky, 2005). Social inequalities therefore exert pernicious effects on health gradients across species.

Viewed from allostatic and AL perspectives, social inequalities are associated with specific physiological phenomena rooted in psychosocial determinants that often have origins in early life experiences. Although dozens of AL studies have linked socioeconomic differences to the prevalence of disease and even death, most reports initially focused on middle-aged and older adults (for reviews, see Beckie, 2012; Dowd, Simanek, & Aiello, 2009; Juster et al., 2011). In the last decade or so, an emerging body of literature has also successfully applied this framework to detect AL levels among disadvantaged children and adolescents exposed to adversity. Many of these have followed in the footsteps of Evans and colleagues (e.g., Evans et al., 1998) by assessing cumulative risk factors, a term that refers to a summary index of early adversities, such as crowding, noise, housing problems, family separation/turmoil, violence, low income-to-needs ratio, single parenthood, and low maternal education.

Early Adversity

Individuals exposed to greater social inequalities, such as socioeconomic deprivation, fare worst in terms of physical and mental health (Shonkoff et al., 2009). Nevertheless, our capacity to build on this knowledge to help prevent these negative outcomes is limited. One reason may be that the mechanisms whereby social inequalities underlie long-term vulnerability toward disease remain enigmatic. Specifically, how social inequalities during distinct periods of development shape allostatic systems—especially in early life—are not explicitly encompassed in existing theoretical models. Accordingly, we explore whether allostatic mechanisms are more sensitive to early environmental influences in a manner that affects long-lasting changes.

Shonkoff and colleagues (2009) proposed that health disparities are rooted in childhood and represent either latent or active sources of vulnerability found at multiple levels of analysis, including physiological systems sensitive to social environments. Akin to the allostasis concept and AL model, these authors postulate that accumulating exposures to adversity—both in terms of quantity or duration—overwhelm the physiological systems designed to support adaptation to stress and induce changes in their physiological set points. This could in turn increase vulnerability to disease in later life stages. In addition, a more profound impact of social inequalities is to be expected, provided they occur during sensitive developmental periods (Shonkoff et al., 2009). The general assumption here is that the earlier the adversity, the greater and more resistant these changes become due to the brain's immaturity and sensitivity to environmental tuning (A. B. Fries, Ziegler, Kurian, Jacoris, & Pollak, 2005).

Several lines of research highlight the importance of considering early adversity. This approach may prompt a better understanding of individual differences in later health, which could eventually be further integrated into the AL model. Through the invaluable use of longitudinal studies, epidemiology and developmental sciences have played a major role in substantiating this possibility (Anda et al., 2006; Felitti et al., 1998; Gilbert et al., 2009; Widom, DuMont, & Czaja, 2007). For example, adverse experiences in childhood—but not necessarily in adulthood—predict later psychopathology (Weber et al., 2008). The presumed causal effect of early adversity on later mental health is also supported by rare natural experiments (Costello, Compton, Keeler, & Angold, 2003) as well as experimental designs controlling for genetic and familial confounds (Arseneault et al., 2008). Thus, robust associations between early adversity and pathology are a starting point to uncovering physiological mechanisms bearing theoretical and potential clinical utility.

A second line of research stemming from developmental neurosciences and psychoneuroendocrinology also suggests that early adversity induces persistent differences in primary familial systems. For instance, maternal care in the first weeks of life, but not necessarily afterward, is associated with stable differences in the adult rodents' neuroendocrine and behavioral reactivity to stress (Meaney, 2001). Only indirect evidence suggests that such a period of increased sensitivity to cortisol surges exists in humans, for which the beginning is hypothesized to take place in the first year and persist until puberty (Gunnar & Vazquez, 2006; Neigh, Gillespie, & Nemeroff, 2009). Despite no clear delimitations established among humans (Gunnar & Vazquez, 2006), several brain structures involved in stress regulation are known to remain immature in childhood, adolescence, and early adulthood only to then undergo age-related changes in later life (Lupien, McEwen, Gunnar, & Heim, 2009). As we explore next, the maturity of these structures is particularly vulnerable to the timing and severity of environmental stressors.

Life Cycle Model of Stress

The brain is the central regulator of allostatic mechanisms that are continuously shaped by the environment. Stress

hormones bypass the blood-brain barrier to bind to three key receptor-dense regions; namely, the prefrontal cortex (PFC), the amygdala, and the hippocampus. Morphological and functional changes in these brain regions occur as adaptations to environmental demands that are essential to understanding pathways toward resilience or vulnerability (Cicchetti, 2013; McEwen, 2009, 2012). Chronic production of glucocorticoids is believed to contribute to frontal lobe malfunctioning, amygdaloidal hypertrophy, and hippocampal atrophy (Lupien et al., 2009). In addition to these neurological processes, individual differences in constitutional (genetics, period of development, environmentally mediated traits and experiences), behavioral (coping strategies and lifestyles), and historical (trauma/abuse, major life events, and stressful environments) factors interactively determine one's sensitivity to chronic stress and AL. Of critical importance is the timing and duration of perturbations, as this profoundly affects neurological development.

Lupien and colleagues (2009) have proposed that the consequences of chronic stress and trauma at different life stages depend on which brain regions are developing or declining at the time of exposure. Stress in the prenatal period affects development of the hippocampus, PFC, and amygdala, leading to well-substantiated programming effects. From the prenatal period onward, all developing brain areas are sensitive to the effects of stress hormones; however, some areas undergo rapid growth during key critical windows. For example, from birth to 2 years of age, the developing hippocampus is extremely vulnerable to glucocorticoid surges. By contrast, in late childhood (10 years old), the amygdala appears to be more vulnerable to hypertrophy in the context of lifelong exposure to maternal depression (Lupien, King, Meaney, & McEwen, 2001). During adolescence, the amygdala continues to develop until young adulthood, and finally the frontal lobe undergoes important maturation. Consequently, stress exposure during this transition into adulthood can have major effects on the PFC. Studies show that adolescents are highly vulnerable to stress because of pubertal changes in gonadal hormones and sensitivities of the HPA axis that can persist into adulthood as potentiation/incubation effects. In middle and older adulthood, the brain regions that undergo the most rapid decline as a result of senescence are once again highly vulnerable to the effects of stress hormones. This period leads to the manifestation of incubated effects from earlier life on the brain referred to as maintenance effects (Lupien et al., 2009).

Lifelong brain perturbations can diminish an individual's ability to adapt, leading to subtle recalibrations in stress responsivity that could be used to detect disease trajectories (McEwen, 1998a). According to the life cycle model of stress, regional volumes of these neurological structures in conjunction to biological signatures (e.g., hypercortisolism or hypocortisolism) can be used to predict differential risk profiles for specific psychopathologies (e.g., depressive or posttraumatic stress disorder) in adulthood as well as inform when certain traumas might have occurred in early life (Lupien et al., 2009). This hypothesis complements the AL model. Given that direct measurement of central nervous system substrates are costly and potentially invasive, indirect assessment using peripheral biomarkers routinely collected in blood draws could be used to measure AL algorithms (Juster & Lupien, 2012a). By this same logic, developmental trajectories that promote resilience at a neurological level could also be identified.

Neuroendocrine responses triggered by early adversity are thought to play a pivotal role in the life cycle model of stress and the AL model. The concentration of glucocorticoid receptors (GR) in the PFC, amygdala, and hippocampus (Sapolsky, 2000) are consistent with the proposed mediating pathways translating exposure to early adversity into lasting changes in perceiving, responding, and coping with stressors (e.g., health behaviors such as sleep, diet, and exercise) as well as nonrandom exposures (e.g., distinct living environments, such as crowded, unattractive, dangerous, noisy, and polluted spaces). The next three subsections provide brief overviews of how changes in cortisol, immune, and epigenetic mechanisms following early adversity may become biologically embedded (Hertzman, 1999) to render individuals vulnerable to future pathologies. Consistent with the life cycle model of stress, such processes can affect the long-term transaction between individuals' (mal)adaptation to their environment.

Hypothalamic-Pituitary-Adrenal Axis

Evidence from animal and human studies demonstrate that the HPA axis is integral to the physiological and behavioral adaptation required to face stressors (Sanchez, 2006; Tarullo & Gunnar, 2006). However, significant associations have been documented between a wide range of adverse life circumstances and distinct cortisol profiles (e.g., cortisol awakening response; Engert, Efanov, Dedovic, Dagher, & Pruessner, 2011) and disrupted diurnal rhythms (Bruce, Fisher, Pears, & Levine, 2009; Cicchetti & Rogosch, 2001; Cicchetti, Rogosch, Gunnar, & Toth, 2010; Lupien et al., 2001; Neigh et al., 2009); for review, including conflicting findings, see Dowd et al. (2009) and Tarullo and Gunnar (2006). Early adversity is also linked to disrupted patterns of cortisol reactivity to stress, manifested in higher (Heim

et al., 2000) and lower responsivity (Carpenter et al., 2007; Lovallo, Farag, Sorocco, Cohoon, & Vincent, 2012).

More recently, early life stress has also been linked to higher cortisol levels in hair. Hair cortisol is an increasingly validated matrix to monitor cumulative cortisol secretion retrospectively (Kirschbaum, Tietze, Skoluda & Dettenborn, 2009). For example, reports of higher hair cortisol have been shown among hospitalized newborns (Yamada et al., 2007), preschoolers growing up with less educated parents (Vaghri et al., 2013), as well as young adults reporting major stressors (e.g., death of a relative) or psychological problems (Karlen, Ludvigsson, Frostell, Theodorsson, & Faresjo, 2011). Similar to findings in regard to salivary cortisol (J. H. Fries, Hellhammer, & Hellhammer, 2005), prolonged stress has also been associated with lower hair cortisol in young adults (Stalder et al., 2012), not just with higher levels. Concurrent mental health as well as the nature, timing, and prolonged adversity have been hypothesized to explain these seemingly opposite patterns of cortisol secretory patterns (Gunnar & Vazquez, 2001; Miller, Chen, & Zhou, 2007). Direct tests of these hypotheses are unfortunately scarce in humans (Trickett, Noll, Susman, Shenk, & Putnam, 2010) and should be the focus of continued transdisciplinary research.

Timing of stressor exposure is essential to understanding the heterogeneity of future HPA axis functioning. Preliminary evidence suggests that adversity taking place before age 11 (including pre-/postnatal) is associated with higher cortisol responsivity during psychosocial stress whereas adversity experienced after age 11 is linked to lower levels (Bosch et al., 2012). Future studies with repeated measures of adversity collected prospectively, beginning at birth and persisting into adolescence, could further our understanding of these time-sensitive trajectories hypothesized to differentially affect HPA axis functioning. Such studies could include, but are not restricted to: the timing when adversity occurs; stress-sensitization effects of pre-/postnatal adversity when adversity is again experienced at later time points (Bosch et al., 2012); the length of time since the adversity ended (Miller et al., 2007; Trickett et al., 2010); differential maturational processes of brain structures regulating reactivity to stress (Lupien et al., 2009); and age- and puberty-related changes in HPA axis functioning (Dahl & Gunnar, 2009; Shirtcliff et al., 2011; Stroud et al., 2009; Trepanier et al., 2013).

Several considerations should be noted to guide future directions. Studies that link early adversity to HPA axis functioning are often constrained by a limited number of cortisol samples or other biomarkers during restricted periods of development. Moreover, study designs are generally correlational in nature and only partially address confounders. Intervention studies (often quasi-experimental) have shown that improvement (or alleviation) of detrimental proximal environmental influences help to normalize HPA axis functioning (Fisher, Gunnar, Dozier, Bruce, & Pears, 2006). Yet it remains unclear whether the same mechanisms are at play in the context of early adversity and whether these pervasively exert a causal effect on AL primary mediators. For ethical reasons, studies involving manipulations of these variables are not possible to conduct among humans. Nevertheless, complementary designs could be used (Rutter, 2007), including the investigation of teratogenic prenatal influences in the context of in vitro fertilization and discordant monozygotic (MZ) twin designs.

In the context of peer victimization, distinct patterns of cortisol reactivity to stress in a subsample of identical twins discordant for bullying victimization from the Environmental Risk Longitudinal Twin Study is consistent with a causal impact of early adversity on cortisol reactivity to stress (Ouellet-Morin et al., 2011). Specifically, nonbullied twins showed increases in cortisol following social stress whereas bullied cotwins did not exhibit this increase. Because of the study design, the difference in neuroendocrine response to stress cannot be explained by the genetic background, shared familial influences, or other individual experiences or characteristics. Since these factors cannot be disassociated, this suggests that bullying victimization exerts an environmentally mediated effect on the HPA axis. More generally, inadequate HPA axis responsivity in the context of adversity may indicate that these experiences have become biologically embedded and thus more resistant to positive changes of interventions.

Finally, few studies have examined prospectively whether neuroendocrine changes triggered by early adversity persist beyond adolescence. Preliminary evidence of a flattened pattern of morning cortisol secretion found in middle-age adults with a history of childhood maltreatment ascertained prospectively suggests that early adversity indeed biologically embeds future biological functioning (Power, Thomas, Li, & Hertzman, 2012). Future studies including repeated measures of adversity and HPA axis functioning collected prospectively across the life span will contribute to better understanding of the roots of health disparities.

Immune Functioning

In addition to investigations of HPA axis functioning, research indicates that inflammation is associated with an increased risk of pathology, including cardiovascular

diseases, autoimmune diseases, obesity, and affective disorders (Buckley, Fu, Freeman, Rogers, & Helfand, 2009; Howren, Lamkin, & Suls, 2009). Although acute stress enhances adaptive immune functions via cortisol and catecholamines, chronic stress and poor health behaviors ultimately suppress adaptive immunity and further lead to a chronic inflammatory state as immune mediators cease to promote innate immune defenses and adaptive immunity (Dhabhar, Malarkey, Neri, & McEwen, 2012). Interest in the early origins of individual differences in inflammation and its hypothesized consequences on health has recently grown and could constitute another pathway linking early adversity to later pathology (Felitti et al., 1998; Green et al., 2010).

In a series of studies, Danese and his team (2009) reported persistent changes in the innate immune system of children exposed to early adversity. They reported higher levels of inflammation in 32-year-old adults who were maltreated or socially isolated as children in comparison to controls. Such experiences accounted for approximately 13% of the cohort with elevated inflammation (high sensitivity c-reactive protein [CRP] > 3 mg/L). Other longitudinal studies corroborate the hypothesized impact of early adversity persisting into adulthood, as associated with CRP (S. E. Taylor, Lehman, Kiefe, & Seeman, 2006), interleukin-6 (IL-6), and fibrinogen (Slopen et al., 2010). Likewise, among older adults these associations persist, as suggested by higher levels of proinflammatory cytokines IL-6 and tumor necrosis factor-α (TNF-α) in caregivers and noncaregivers with a history of childhood abuse (Kiecolt-Glaser et al., 2011). Interestingly, these patterns of inflammation were also detected in the context of acute stress in both a standardized protocol and a natural setting (Carpenter et al., 2010; Gouin, Glaser, Malarkey, Beversdorf, & Kiecolt-Glaser, 2012).

Additional studies also suggest that the impact of early adversity on inflammation, including socioeconomic factors, may already be detectable in late childhood (Danese et al., 2011) and adolescence (Miller & Chen, 2010). Higher CRP levels were reported in children living in Indigenous Canadian communities; this finding represents a higher risk of impending cardiovascular problems and further supports the idea that the early roots of adult diseases implicate inflammatory mediators (for an extended review, see (Danese & McEwen, 2012; Fagundes, Glaser, & Kiecolt-Glaser, 2013). Beyond primary mediators representing neuroendocrine and immune parameters, increasing attention has focused on genetic propensities in interaction with environmental triggers. In the same spirit as recent studies of the HPA axis, future studies should explore whether individual (genetic background) and stress-related factors that affect stress responsivity, AL, and disease trajectories.

Deoxyribonucleic Acid Methylation

In the last decade, innovative experiments using animal models of early-life stress have shown that the genome is not as immutable as previously thought. Rather, it responds dynamically to the environment through the regulating influence of epigenetic processes (Bagot & Meaney, 2010). *Epigenetics* refers to a series of modifications in the chemistry of deoxyribonucleic acid (DNA) and its associated proteins (collectively termed *chromatin*) that have the potential to alter expression without changing its sequence. The epigenome is conceptualized as an interface between the environment and the genome. In addition to the intrauterine environment, recent evidence suggests that postnatal social environments can also alter epigenetic signals (Szyf, McGowan, & Meaney, 2008), which represent another biological mechanism by which childhood adversity could have long-lasting influences on health (Jirtle & Skinner, 2007; Shonkoff et al., 2009; Tsankova, Renthal, Kumar, & Nestler, 2007).

To date, most empirical findings supporting the epigenome construct come from animal models of early-life stress. Specifically, maternal care received by rat pups during the first week of life changes DNA methylation of the GR gene promoter in the hippocampus, GR expression, and stress reactivity in adulthood (Meaney & Szyf, 2005). DNA methylation is one of several epigenetic mechanisms but is often regarded as the most stable and representative (Talens et al., 2010). Additional studies have since extended these findings to other genes regulating stress and neurodevelopment, such as the arginine vasopressin (AVP) and brain-derived neurotrophic factor (BDNF) genes (Murgatroyd et al., 2009; Roth, Lubin, Funk, & Sweatt, 2009). The impact of early stress on DNA methylation has also been documented in nonhuman primates (Kinnally et al., 2010; Provencal et al., 2012).

Comparatively less research has investigated the epigenetic remodeling following early adversity in humans. Preliminary reports of higher methylation of the GR gene and the serotonin transporter (SERT) gene in adults with a history of childhood abuse or low SES (ascertained retrospectively) are consistent with animal data supporting the epigenome (Beach, Brody, Todorov, Gunter, & Philibert, 2010; Labonte et al., 2012). Similarly, differential clustering patterns of DNA methylation have been reported across the genome in children raised in institutional care (Naumova et al., 2011). Birth cohorts with prospective measures

of adversity have recently contributed to clarifying the temporal sequence of these associations and reported distinct DNA methylation profiles in adults exposed to different levels of socioeconomic adversity during childhood (Borghol et al., 2012).

To the best of our knowledge, only two longitudinal studies have explored the associations between early adversity and DNA methylation patterns with diverse measures of adversity (not only SES) collected prospectively throughout childhood (Essex et al., 2011; Ouellet-Morin et al., 2013). The first study comprises 109 adolescents exposed to maternal stress during their first year who showed elevated DNA methylation in 139 sites located across the genome (Essex et al., 2011). The second study showed that bullied twins had higher SERT DNA methylation compared to their nonbullied MZ cotwins, again supporting an environmentally mediated effect of childhood adversity (Ouellet-Morin et al., 2013).

Childhood adversity is theorized to differently affect DNA methylation depending on the developmental periods when these experiences occur (Roth & Sweatt, 2011). Preliminary findings in humans tend to support this hypothesis. For instance, early adversity affects DNA methylation around the time of conception but not in late gestation for famine exposure; in the first year of life but not during the preschool years for maternal stress; and in the second but not the third trimester for maternal depressed mood (Devlin, Brain, Austin, & Oberlander, 2010). By and large, the understanding of the role of DNA methylation is constrained by the few studies conducted in humans and the lack of repeated measures of adversity and DNA methylation across development. This makes it difficult to establish clear-cut temporality and thus to evaluate whether the time when adversity is experienced should be a concerted focus in integrated revisions of the AL model. Moreover, the role of DNA methylation within the GR promoter (or other genes directly or indirectly affecting stress regulation) and the underlying biological pathways by which these changes affect GR expression remains poorly understood in humans. The studies reviewed are nevertheless crucial to our continued understanding of how DNA methylation could eventually be integrated in the allostasis and AL framework, as GR plays a key role in adaptive functions as well as pathophysiology (namely by turning on and turning off the HPA axis). Future research in this promising area also will contribute to existing frameworks delineating the mechanisms by which early adversity exerts long-lasting influences on physical and mental health.

Akin to emerging epigenetic studies in humans, AL studies have also revealed intergenerational associations of lower SES. For example, non-Hispanic Caucasian and African American children with less educated parents have higher AL levels, driven heavily by insulin dysregulation (Goodman, McEwen, Huang, Dolan, & Adler, 2005). Within an allostatic framework, insulin dysregulation is part of a broader network of disrupted allostasis related to cortisol, inflammation, and a myriad of processes that differ markedly as a function of social inequalities. In the next section, we explore literature linking AL indices to SES mostly in adulthood but also increasingly at earlier life stages.

Socioeconomic Status and Health Gradients

SES represents education, income, neighborhood, and occupational features that interact strongly with AL throughout life (Szanton, Gill, & Allen, 2005). The MacArthur Study of Successful Aging used to validate the AL model consistently found that higher AL predicts incidences of cardiovascular disease, physical declines, cognitive impairments, and all-cause mortality (Seeman et al., 1997; Seeman et al., 2004a; Seeman, McEwen, Rowe, & Singer, 2001b). Interestingly, even in this representative group of successful agers from diverse race/ethnicity and SES, lower education was a powerful contributor to higher AL levels (Seeman et al., 2004a). This patterning provides evidence of health gradients found not only between but also within socioeconomic strata (Adler & Snibbe, 2003).

Likewise, a cross-cultural study of Taiwanese elders from the Social Environment and Biomarkers of Aging Study (SEBAS) revealed that higher AL as well as lower education and income were independently associated with health status (P. Hu, Wagle, Goldman, Weinstein, & Seeman, 2007). By combining the Taiwanese and MacArthur cohorts, lower SES (lower education, occupational status, and finances) together with greater social challenges (e.g., recent widowhood, high family demands) related to higher AL (Weinstein, Goldman, Hedley, Yu-Hsuan, & Seeman, 2003). This finding suggests that SES and adversity might synergize among different older adults from North America and Asia.

Some of the most compelling epidemiological evidence in support of the AL index has come from the large-scale American National Health and Nutrition Examination Survey (NHANES). Findings show that AL mitigates the effects of education and income gradients predictive of ischemic heart disease and periodonal disease (Sabbah, Watt, Sheiham & Tsakos, 2008). Tracking about 15,000

participants from the same cohort over 6 years, it was shown that those living in poverty show sharper increases in AL up until middle age and then plateau around ages 70 and above (Crimmins, Johnston, Hayward, & Seeman, 2003). Strikingly, those with high AL have a life expectancy that is 6 years shorter than those with low AL but with similar poverty status and matched for sex (Crimmins, Kim, & Seeman, 2009).

Beyond individuals and households, AL studies on SES have also begun assessing neighborhood characteristics. A cross-sectional analysis of 12- to 20-year-olds from NHANES assessing multiple levels nested at the levels of individuals, families/households, and census tracts elegantly demonstrated gradients in AL levels that increased incrementally among adolescents living under low-, medium-, to high-cumulative-risk neighborhoods (Theall, Drury & Shirtcliff, 2012). Likewise, a large-scale multiethnic analysis revealed that Detroit-area neighborhood poverty was positively associated with AL independent of household income and covariates and was furthermore mediated by perceived environmental stress within one's neighborhood (Schulz et al., 2012).

Socioeconomic factors may affect AL differently according to one's sex and age. A recent study of 199 healthy Montreal workers revealed that higher occupational status (classified using a pure-type scaling system based on median education and income in a given occupation) was associated with higher AL in men, whereas the reverse occurred for women (Juster, Moskowitz, Lavoie, & D'Antono, 2013a). As has been substantiated in primate research that parallels socioeconomic inequalities in humans (Sapolsky, 2005), males at the top of the hierarchy might be challenged by unique sets of adversity that exacerbate rather than attenuate physiological functioning. Specifically, socially dominant male primates experience the highest physiological dysregulations when reigning in unstable hierarchies in which subordinates continuously challenge their authority (Sapolsky, 2005). This finding has been confirmed in a comparative study of social status, AL, and glucocorticoid profiles among free-ranging animals (Goymann & Wingfield, 2004). When translated to humans, it is plausible that this pattern also exists among men occupying higher occupational status at the price of higher AL. Given the worldwide changes in wealth and health as a function of women further occupying the workplace, it will be important for future studies to also understand the experiences and health of women in higher occupational statuses who have so often faced unique challenges, unknown to men, to reach the top.

Resilient "Shift-and-Persisting" and Life Histories

AL studies identifying pathways toward resilience among low-SES individuals are emerging. Among women of different socioeconomic strata, workplace stress moderates AL levels: Those with lower occupational status, but who have higher decision latitude or job control at work, experience lower AL levels (Juster, Moskowitz, Lavoie, & D'Antono, 2013a). In the Biomarker Sub-Study of the Study of Midlife in the United States (MIDUS) cohort, it has been proposed that individuals of either sex who are able to "shift-and-persist" out from low childhood SES might be more resilient to AL. This survival strategy is of particular importance to individuals faced with social adversity, as it combines shifting one's cognitive appraisals and emotional regulation positively to adapt to stressors while persisting by maintaining hopes for the future (Chen & Miller, 2012; Chen, Miller, Lachman, Gruenewald & Seeman, 2012). In addition, increased job control may be another way in which positive working conditions can moderate the otherwise negative effects of lower SES. Within the framework of the shift-and-persist hypothesis, we propose that protective workplace characteristics represent one avenue whereby individuals can promote their health even when unable to shift into higher SES boulevards.

Life histories in socioeconomic mobility and social and family relationships are increasingly explored in the AL literature. Using the Wisconsin Longitudinal Study, Singer and Ryff (1999) have applied such pathways and demonstrated that childhood parental bonding and household income categories are associated with AL. Contrasting childhood context with adult finances and relations revealed that increased downward mobility—that is, a depreciation in one's SES over time—was related to increased AL, as was low parental income coupled with negative social relationships. Most important, this approach can be used to identify resilient pathways whereby, for example, economically disadvantaged individuals can compensate by developing positive social relationships that buffer against AL (Singer & Ryff, 1999).

This approach can also be used to track the pervasive effects of adversity that accumulate throughout life. Concordantly using the MIDUS cohort, individuals who grew up in low-SES contexts (low parental education, income, and welfare status) and who remained in disadvantaged circumstances in middle and later adulthood (indexed according to educational attainment, household income, difficulty paying bills, availability of money to meet basic needs, and current financial situation) showed the highest AL levels, followed by individuals classified as downwardly

mobile, upwardly mobile, and individuals who always had high SES (Gruenewald et al., 2012). Although these results may be related to elusive critical thresholds in developmental processes, the authors stated that their findings supported the cumulative risk hypothesis that accumulated SES adversity accelerates biological damage. As we explore next, cumulative risk and differences in SES are more pronounced among marginalized groups within society.

Race/Ethnicity and Discrimination

Gradients in AL related to SES are compounded by race/ethnic disparities. For instance, African Americans with peripheral arterial disease in the NHANES had the highest AL levels compared to other race/ethnicities (Nelson, Reiber, Kohler, & Boyko, 2007). In another multi-ethnic analysis of NHANES, African Americans of both sexes had higher AL levels than matched Caucasians, partially explaining a greater overall risk for cardiovascular and diabetes-related mortality after adjusting for education, poverty status, and health insurance status (Duru, Harawa, Kermah, & Norris, 2012). It has been proposed that African American women are particularly vulnerable as they show the most consistently elevated levels of AL across age groups. Moreover, neighborhood characteristics and race/ethnic segregation were found to be particularly damaging to African American women in terms of their increased rates of obesity (Chang, Hillier & Mehta, 2009).

The "weathering hypothesis" states that the health of non-Caucasian women deteriorates in early adulthood as the physical consequences of cumulative socioeconomic deprivation manifest themselves (Geronimus, Hicken, Keene, & Bound, 2006). This chronic strain in turn contributes to intergenerational effects that complicate reproductive activities and lead to decrements in health at greater rates than among other more privileged societal groups. In this vein, another NHANES analysis of women between the ages of 17 and 30 revealed that those with high AL levels were two times more likely to have experienced early menarche (10 years old or earlier); early menarche was in turn more common among women who were African American, less educated, currently poorer, smoked, and/or had a history of depression (Allsworth, Weitzen, & Boardman, 2005). Consistent with this sex-specific vulnerability, data from the Jackson Heart Study found that AL indices and constituent biomarker clusters are more consistently dysregulated among African American women, but less so among African American men (Hickson et al., 2012). Adding insult to injury, African American women who have had breast cancer also experience higher AL levels; however, in the NHANES cohort, Caucasian women do not (Parente, Hale & Palermo, 2013).

Beyond the weathering hypothesis, the deleterious interaction effects of race/ethnicity and SES factors can be amplified by psychosocial adversities, such as discrimination or acculturation (Chapman et al., 2009; Friedman, Williams, Singer, & Ryff, 2009; Kendall & Hatton, 2002; Mays, Cochran, & Barnes, 2007; Myers, 2009). For instance, social isolation, single motherhood, early parenthood, and numerous other factors must be further identified as effect modulators of sex and race/ethnicity specific associations. Moreover, although the influence of discrimination is difficult to quantify, a report suggests that in adolescence, the association between poverty and elevated AL is mediated by perceived discrimination (Fuller-Rowell, Evans, & Ong, 2012). Notably, impoverished Caucasians are less likely than nonimpoverished African Americans to have higher AL. For individuals of lower neighborhood SES in the NHANES cohort, the risk of having the highest AL levels is 200% for African Americans, 70% for urban Mexican Americans, and 30% for Caucasians (Merkin et al., 2009). Beyond objective sociometrics, it is possible that many of these findings are driven by interaction effects with subjective factors like discrimination that are experienced in distinct ways.

For instance, U.S.-born Mexican Americans and African Americans show higher levels of AL than foreign-born Hispanics and Caucasians, suggesting that migration interacts with SES effects in compromising immigrants' health and well-being (Seeman et al., 2008). Regardless of racial/ethnic stratifications, however, lower education and income are consistently associated to AL. A recent cross-sectional analysis of NHANES confirmed that low-SES adolescents and African American adolescents experience elevated AL levels; however, the relative advantage of Caucasians and Mexican Americans in comparison to African American adolescents diminishes around age 15, at which point metabolic markers increase specifically among Mexican American (Rainisch & Upchurch, 2013).

Resilient "John Henryism" and Familal Support

In terms of potential resilient pathways, a fascinating research program developed by Brody and colleagues (2013b) has investigated the John Henryism theory among African American youth. Legend says that John Henry was an industrious African American railroad worker in the late 1800s who challenged and defeated a steam-powered mechanical drill in a steel-driving contest, but died thereafter of exhaustion. The John Henryism theory (James,

1994) therefore refers to behaviors that involve high-effort coping and hyperarousal that fuel single-minded mental concentration and drive physical energy needed to succeed when faced with overwhelming odds (Brody et al., 2013b). Resilience may thus be seen in key life domains (e.g., overt behaviors, academic performance), but it comes at a physiological price.

This proposition was tested among a cohort of rural African American youth from the southern United States who had cumulative risk factors (higher scores indicating lower SES) and teacher-reported issues wih self-control and competence measured from ages 11 to 13. At follow-up when 19 years old, depressive symptoms, externalizing behaviors, and AL levels (overnight urinary cortisol, adrenaline, and noradrenaline; resting diastolic and systolic BP; and body mass index [BMI]) were measured. Results revealed that preadolescents from low-SES environments with high competence displayed low levels of teacher-reported adjustment problems, but at the cost of higher AL at age 19. These findings support the John Henryism theory and sadly suggest that resilience may be skin deep (Brody et al., 2013b). Said otherwise, adaptation in domain-specific areas may come at a physiological cost. This finding highlights the notion that resilience is not a status or a generalized state of global "resiliency" but rather a constellation of adaptations to life's challenges in terms of both positive and negative domains.

In a separate investigation of genetic and contextual associations using the same cohort, a three-way interaction effect was found for environmental adversity (low family support) with genetic susceptibilities (e.g., short allele of serotonin transporter-linked polymorphic region genotype) predicted AL levels in early adulthood (Brody et al., 2013c). In the hopes of identifying different developmental trajectories, another analysis also using genetic information as well as psychological adjustment between ages 14 and 18 applied latent profile analysis to demarcate two developmental profiles: (1) a physical health vulnerability profile characterized by high cumulative SES risk/high AL/low adjustment problems; and (2) a resilient profile characterized by high cumulative SES risk/low AL/low adjustment problems (Brody et al., 2013a). While carrying the s allelle for the 5-HTTLPR genotype (diathesis) and receiving less peer support (stress) predicted membership in either profile, so did protective parenting and emotional regulation. Brody and colleagues argued that while resilience may be skin deep, the positive influence of family support can help "thicken" skin regardless of color and render protection against genetic susceptibilities and adverse SES conditions.

More broadly, parental support appears to be a powerful pathway toward long-standing protection against elevated AL. An analysis of the 27-year longitudinal northern Swedish cohort showed that high parental involvement in children's academic studies (measured by teacher and pupil ratings) at age 16 was associated with low AL (16 biomarkers) at age 43 while accounting for an array of life course sociodemographics (Westerlund, Gustafsson, Theorell, Janlert, & Hammarstrom, 2013). Taken together, this impressive body of work is consistent with findings on resilience in the field of developmental psychopathology more broadly. This fact attests to the vast heterogeneity and multifinality manifested by differential configurations of genetic processes and contextual challenges (Cicchetti et al., 2010). Moreover, these findings also speak to the importance of race/ethnic, life experiences, and genetic interactions in explaining pathways toward vulnerability or resilience that can be modulated by modifiable behaviors as simple as parental involvement in scholastics.

Shifting Major Economies: Brazilian Context

Contextual factors beyond SES and race/ethnicity influence health outcomes internationally. It is important to highlight that the majority of studies linking SES to stress pathophysiology (Cohen et al., 2006; Hajat et al., 2010; Lupien et al., 2001) are based on samples from the developed world. Despite such adversity, low-SES individuals from the developed world are generally living in better conditions than those of comparative SES living in the developing world. This fact presents an important interpretive issue when we consider that 80% of Earth's population lives in developing countries, where the majority of chronic disease burden for conditions like hypertension and depression occur (Ibrahim & Damasceno, 2012; World Health Organization [WHO], 2012). In this section, we substantiate the importance of context in relation to stress-related diseases using Brazil's shifting socioeconomic conditions as a case study and as a cross-cultural contrast to the Canadian context.

Social inequalities related to unemployment, deprivation, and income disparities are pronounced in countries with emerging economies that further widen gaps between social classes (WHO, 2012). As elsewhere, those at the bottom of the social hierarchy consistently demonstrate poorer health than those at the top (Demakakos, Nazroo, Breeze, & Marmot, 2008; Kawachi & Kennedy, 2002). In particular, subjective feelings related to unfavorable social comparisons—in other words, *feeling* poor (subjective

SES)—may further explain why low SES predicts poorer health (Adler, Epel, Castellazzo & Ickovics, 2000; Sapolsky, 2005; Wilkinson, 1996). Ultimately, the large gap between social positions strongly promotes discrimination (Jackman, 1994), which intensifies the consequences of poverty.

Perceived discrimination—racial or otherwise—is associated with stressful life experiences and adverse health outcomes (Clark, Anderson, Clark, & Williams, 1999; Dion, 2001; Harrell, Hall, & Taliaferro, 2003; Harrell, Merrit, & Kalu, 1998). For example, perceived unfairness, racial discrimination, and nonracial discrimination are positively associated with coronary calcification (Lewis et al., 2006), and are independent predictors of coronary events (De Vogli, Ferrie, Chandola, Kivimaki, & Marmot, 2007). Although these findings are based on minority groups living in developed countries, discrimination is an especially important contextual factor in countries with emerging economies. Indeed, discrimination generates social inequalities that transcend group membership(s) as part of minority or majority groups. For example, native Africans living in South Africa exhibit higher levels of psychological distress than the Caucasian minority, with perceived chronic discrimination positively associated with distress (Williams et al., 2008).

In contrast, social support and social integration are protective factors that are each mitigated by different mechanisms (Cohen, 2004). Although social support attenuates stress through psychological and material resources provided by social relationships, social integration influences health based on the participation of the individual in the social relationships and the sense of belonging this creates (Brissette, Cohen, & Seeman, 2000; Cohen, 2004). Social supports are coping strategies that dampen stress by (a) altering the appraisal or perception of a potential threat and (b) modulating reappraisals of the potential threat after exposure (Cohen & Wills, 1985). First, stress reactivity might not be activated as intensely among individuals who feel supported. Indeed, social support seems to benefit health only for individuals under adverse circumstances since there is no effect in the absence of highly stressful demands (Cohen, 2004; Cohen, Gottilieb & Underwood, 2000). Second, after perceiving an event as threatening, individuals with greater social support show enhanced emotional regulation and reduced physiological responsivity. Several studies demonstrate that high social support corresponds to lower cortisol levels in comparison to those with low social support (Eisenberger, Taylor, Gable, Hilmert, & Lieberman, 2007; Rosal, King, Ma, & Reed, 2004; Uchino, Cacioppo, & Kiecolt-Glaser, 1996).

In the context of countries with emerging economies, we know of only one study showing that individuals with higher social support display lower BP as well as self-report less perceived stress and depressive symptoms compared to those with limited or no access to social support networks (Dressler, Balieiro, & Dos Santos, 1997). Regarding social integration, one's active engagement within social networks can promote positive psychological health and can facilitate health-promoting behaviors. In contrast to social support, the benefits of social integration on health are independent of whether an individual experiences adversity or not (Cohen, 2004). Interestingly, greater social integration is associated with lower rates of mortality (Berkman & Glass, 2000) as well as lowered risk of cancer recurrence, psychopathology, and cognitive decline with aging (Cohen et al., 2000).

In sum, these findings suggest that psychosocial factors, such as negative feelings related to unfavorable conditions, perceived discrimination, social support, and social integration, represent significant risk factors or protective factors associated with stress and health. Within the frame of advancing the AL model at an international level, these findings in turn raise questions: for example, do contextual differences explain discrepancies in perceived stress and physiological functioning between nations with developed and developing economies?

Psychosocial Stress: Canadians versus Brazilians

A recent cross-national collaborative study conducted between our Canadian and Brazilian research groups revealed significant differences in self-reported psychosocial stressors as well as differential patterns of basal and stress-reactive cortisol profiles. A rich literature on the psychosocial determinants of neuroendocrine responses reveals that situations that are novel, unpredictable, threatening to the self, and uncontrollable additively contribute to stress hormone responses (Dickerson & Kemeny, 2004; Lupien et al., 2006; Mason, 1968). With this in mind, 1,156 healthy youngsters, adults, and elderly participants from Canada and Brazil—developed and emerging economies, respectively—were asked to indicate among a list of nine different factors (novelty, unpredictability, low sense of control, social evaluation, time pressure, work overload, conflict, unbalance and children) which factors elicited the greatest distress.

For Canadians, "children," "novelty," and "unpredictability" were the major stressors; Brazilians indicated "time pressure," "work overload," and "conflict" as

their major stressors. Differences regarding education level, SES, work organization, and experiences may synergistically influence these perceptions and in part explain the discrepancies between Canadian and Brazilian contexts. In particular, Brazilians experience long workdays (between approximately 40 to 44 hours a week on average), work overload (43.6% of Brazilians work overtime), informal sector or under-the-table employment (10.7% of Brazilians work without the coverage of labor laws and employment insurance), and low payments associated with low purchasing power (Institute for Applied Economic Research, 2009). In addition, Brazilian inhabitants must routinely face such challenges as unequal access to public health services, education, and transportation as well as frequent exposure to violence, overcrowding, and traffic. These contextual factors explain the differences in stressor sensitivities between Canadians and Brazilians.

Beyond the geographical and contextual factors that influence perceived distress, people from different environments may present different patterns of physiological stress responsivity. To the best of our knowledge, only a handful of studies have investigated cortisol profiles among nondeveloped nations living in disadvantaged conditions (Decker, 2000; Flinn & England, 1997; Nyberg, 2012; Pike & Williams, 2006) and demonstrated both hyper- and hypocortisolemic profiles; therefore, any conclusions at this time are limited. None of these studies, however, compared stress response profiles between countries, each with its own distinct cultural, economic, political, and social realities. Continued cross-cultural investigations will help the scientific community and health organizations better understand pathways toward vulnerability or resilience in diverse and ever-changing contexts.

In delineating cross-cultural patterns linking stress to disease, factors related to migration, immigration, and nativity are important to consider. To date, two cross-cultural studies have shown that difficulty verbalizing (Kim, 2008) and race/ethnicity (Hajat et al., 2010) represent factors associated with both low and high cortisol levels among adult immigrants in contrast to native inhabitants. This finding may, however, be due to acculturation biases that may underestimate the differences observed. For example, higher basal cortisol levels were also observed in Australian Aboriginal communities compared to British inhabitants from Oxford (Harrison, 2001). Conversely, mean basal cortisol levels of Tsimane Amazonian adult foragers were lower compared to American participants from the Coronary Artery Risk Development in Young Adults (CARDIA) study (Cohen et al., 2006; Nyberg, 2012). In addition to these findings among different international communities, Kim (2008) demonstrated an influence of culture on cortisol response to a speech task comparing European Americans with Asian Americans. In sum, nationality and inherent sociocultural factors related to race/ethnicity and acculturation influence stress.

Although Canadians and Brazilians share Western cultural roots, they differ vastly with respect to urban conditions, physical conditions (e.g., climate/light exposure, noise, pollution, crowding), history, sociocultural views, and organizational values that may ultimately modulate their respective sensitivities and HPA axis adaptation to daily stressors with important health disparities. For instance, a WHO report showed 39.4% prevalence of raised BP among male adults aged $\geq$ 25 years among Brazilian inhabitants (WHO, 2012). Similarly, higher rates of diabetes (421 cases per 100,000 population by case) and unipolar depressive disorders (1,410 cases per 100,000 population by case) were reported among Brazilian inhabitants. These findings collectively suggest that chronic stress exposure, cortisol dysregulation, and AL are heightened among inhabitants of countries with emerging economies, such as Brazil, in addition to differences attributable to SES.

The importance of cross-cultural studies has been well represented in several AL studies. A recent study scrutinizing the association between perceived stress and AL among Russians, Americans, and Taiwanese revealed important nation-specific sex differences in magnitudes and directions: strongest positive association for Russians of both sexes, weaker association among American women, and an unexpected negative association among Taiwanese men (Glei et al., 2013). The importance of urban and rural locations is also an important consideration, given a recent finding among Polish men who had lower AL levels if they were more educated, married, and residing in an urban area (Lipowicz, Szklarska, & Malina, 2013). In summary, it is imperative to expand international investigations among individuals living in different sociocultural contexts in order to understand unique vulnerabilities and culture-specific protective factors that propel pathways toward potential resilience.

Resilient Hispanic Effects in Emerging Economies

There is a paucity of research on resilience among inhabitants from emerging-economy countries. Nevertheless, a burgeoning literature and several AL studies (for a review, see Beckie, 2012) report positive health outcomes among Hispanic populations, due perhaps to unique sociocultural contexts and value systems that might promote resilience (Gallo, Penedo, Espinosa de los Monteros, & Arguelles, 2009). Despite substantial adversities (e.g., immigration,

discrimination, low incomes, less education, unequal opportunities, limited health care access), Hispanic populations living in the United States have at times shown equal and sometimes even better health outcomes in comparison to Caucasian populations (Gallo et al., 2009). Similarly, Hispanic individuals with non-American nativity exhibit better health than those born in the United States. Features of Hispanic culture (e.g., allocentrism, family-oriented values) represent attitudes and behaviors that might exert a protective influence on health outcomes (Gallo et al., 2009).

The sociocultural dimensions of Brazilians exhibit similarities to those of Hispanics. Interestingly, Brazilian inhabitants score equally with populations from the developed world on psychometrics of resilience (Ferreira, Santos, & Maia, 2012; Fortes, Portugues, & Argimon, 2009; Gaiolli, Furegato, & Santos, 2012; Rodrigues, Barbosa, & Chiavone, 2013; Tavares, Barreto, Lodetti, Silva, & Lessmann, 2011) that actually increase with age (Gaiolli et al., 2012; Tavares et al., 2011). Among Brazilian children living under adverse conditions, a father's ability to adequately respond to his child's needs, ability to promote expression of the child's potential, and engagement in gratifying familial activities have been identified as key protective factors (Silva, Lacharité, Silva, Lunardi, & Lunardi-Filho, 2009).

Similarly among young Brazilians from low-SES backgrounds, the cultivation of interpersonal relationships (e.g., family, friends, teachers) and personal resources (e.g., personality traits, optimism motivation, spirituality) promote resilience in the face of future life challenges (Silva et al., 2009). It is interesting to note that different studies reveal that resilience is independent of SES among adult and elder Brazilians (Gaiolli et al., 2012; Tavares et al., 2011). These protective factors include personality characteristics such as self-confidence, self-control, self-esteem, empathy, optimism, and sense of meaning (Rodrigues et al., 2013). Future cross-cultural research could investigate these cultural distinctions by delineating important differences between the sexes around the world. As presented next, biological sex and sociocultural gender factors influence physical health and well-being.

Sex Differences and Gender Diversity

Every cell is sexed, every person gendered, and every organism stressed (Juster & Lupien, 2012c). Whereas the term *sex* refers to a multidimensional construct that includes genes, anatomy, gonads, and hormones that collectively define us as male or female, *gender* refers to the implicit and explicit dissimilarities in an array of socioculturally constructed roles, orientations, and identities that generally predominate in one sex or the other (Juster et al., 2011). Relatedly, gender roles represent the social norms and stereotypes we assimilate and endorse through the enactment of masculine traits (e.g., independence, assertiveness, competitiveness, instrumentality) and feminine traits (e.g., empathy, compassion, helpfulness, expressivity (O. Evans & Steptoe, 2002; Johnson & Repta, 2011). One's sexuality also comprises its own constituent sexual behaviors, identities, and orientations that correspond with health inequalities (Institute of Medicine [IOM], 2011). In the next sections, we summarize an ongoing research program on the effects of sex, gender roles, and sexual orientation on AL.

Biological Sex and Aging

Sex differences in AL depend on sample-based and age-related factors (Juster et al., 2010). For example, successive analyses of the MacArthur cohort provide evidence for age-specific sex differences in the biological signatures linking AL to tertiary outcomes, such as all-cause mortality. An early analysis found that cardiovascular biomarkers were more often dysregulated for men, whereas neuroendocrine biomarkers were more often dysregulated for women (Seeman, Singer, Ryff, Dienberg Love, & Levy-Storms, 2002). In a 12-year follow-up that used recursive partitioning, high-risk pathways of AL biomarker clustering for men included adrenaline, noradrenaline, IL-6, CRP, and fibrinogen, while women included IL-6, CRP, glycosylated hemoglobin, and systolic BP (Gruenewald, Seeman, Ryff, Karlamangla, & Singer, 2006). Interestingly, elevated systolic BP occurred in 100% of high-risk pathways for women but only 17% for high-risk pathways among men, principally driven by elevated fibrinogen, noradrenaline, and adrenaline levels otherwise absent for women. These findings from the MacArthur cohort measured at different time points reveal that sex differences in AL pathways might emerge only with advanced age. This is consistent with numerous studies demonstrating links between chronic stress and advanced aging at molecular, social, and environmental levels (Epel, 2009; Epel et al., 2004; Tomiyama et al., 2012).

Identification of sex-specific thresholds in individual biomarkers and systemic clustering of AL at different ages should be a priority, given increasing older populations worldwide (Singer et al., 2004). In a first attempt, a 15-year follow-up of CARDIA participants in their 40s found no differences between sexes or by race/ethnicity. Nevertheless, it must be noted that aggregate metafactors including

heart rate variability, BP, and inflammatory, metabolic, catecholaminergic, and glucocorcoticoid biomarkers captured 84% of the statistical variance, suggesting that AL biomarkers indeed form a constellation of shared interrelations consistent with theory (Seeman et al., 2010). Yet subtle physiological dysregulations of intertwined systems may not be easily detected or differ between the sexes when assessing younger adults. Consequentially, determining meaningful subclinical biomarkers cutoffs between sexes at different ages is essential.

In this regard, sociocultural differences also must be considered cross-culturally. For example, a pilot study of Japanese elders measuring AL based on 33 parameters revealed that they were leaner with slightly more elevated BP than Europeans and Americans, in addition to having higher total HDL cholesterol (Crews et al., 2012). Despite a lack of age differences, sex differences were also found for dopamine, uric acid, glutamic-pyruvic transaminase (liver enzyme), and white blood cells. Although preliminary and requiring continued cross-cultural comparisons, we propose that delineation of sex- and age-specific differences will require gender-based perspectives that appreciate differential socialization patterns (e.g., social networks, diet and alcohol consumption, leisure activities) and the consequent risk and protection this engenders. In addition, do gender effects interact with sociocultural factors to modulate AL in an international context? For instance and as discussed next, one could imagine the stressful circumstances of, say, a feminine Japanese American woman with conflicting traditions of collectivism versus individualism or perhaps a masculine male nurse, since each may embody mismatches to societal and occupational expectations of them.

Sociocultural Gender

Our understanding of sex differences can be complemented by incorporating gender perspectives when interpreting the AL literature (Juster & Lupien, 2012a). Sex differences in biological constitution, in concert with individual differences in elusive gender-based factors, are known to influence patterns of physiological stress responsivity (Dedovic, Wadiwalla, Engert, & Pruessner, 2009). For example, women generally self-report more environmental stressors and psychosocial distress, while men are generally more biologically stress responsive compared to women in the follicular phase of their menstrual cycle or on oral contraceptives. These sex differences stem from lifelong exposure to sex steroids, anthropometry, and sociocultural factors that construct one's gender that collectively drive diverse patterns of threat processing and coping mechanisms. It has been argued that sociocultural factors may be more important than biological factors in explaining mysterious sex differences in stress responsivity (Lundberg, 2005). For instance, it would seem that women demonstrate increased cortisol levels when facing social rejection (Stroud, Salovey, & Epel, 2002), whereas men tend to be more reactive when confronted with achievement-based stressors in laboratory paradigms (Dickerson & Kemeny, 2004).

A complementary evolutionary hypothesis put forth by S. E. Taylor and colleagues (2000) states that men and women generally cope differently under stressful situations. Accordingly, the primary stress response pattern for men are fight-or-flight responses, whereas women might be more prone to engage in tend-and-befriend responses, such as nurturing and affiliation-based behaviors that protect against the demands of pregnancy, nursing, and child care (S. E. Taylor et al., 2000). The central tenet of Taylor et al.'s proposal is that instead of utilizing physical retaliation when faced with threats, women focus on behaviors that protect vulnerable offspring and maintain social bonds. Compelling animal and human studies have substantiated this theory; however, it is not clear whether these responses are due to sex, gender, or both—or perhaps even influenced by how our own gendered assumptions factor into our research designs (Juster & Lupien, 2012c). For instance, S. E. Taylor et al. underlined that prior to 1995, women represented a mere 17% of participants in human studies of stress due to the alleged complications of female reproductive functions.

Importantly for the present discussion, the tend-and-befriend hypothesis sheds some light on sex and age differences found throughout the stress and AL literature vis-à-vis social networks and relational factors that likely also differ internationally according to socialization and gender stereotyping. For instance, AL levels were lower only for Taiwanese elderly men with a spouse, while both sexes benefit from ties with close friends and neighbors in a SEBAS analysis (Seeman et al., 2004b). Interestingly, the perceived quality of these social relationships was not consistently linked to AL, suggesting that cross-cultural differences to between Eastern and Western societies may be influenced by sociocultural factors (e.g., virtues of collectivism/interdependence, social obligation, and the absence of "self") that are inherently influenced by gender-based constructs related to societal patriarchy and/or matriarchy.

In this spirit, one's sex and gender role might divergently influence biopsychosocial stress. In particular, extremely traditional or hegemonic masculine gender roles

(e.g., hostile, dictatorial, impatient) are strongly linked to coronary-prone behaviors (e.g., inhibited emotional expression, lack of empathy, homophobia) that overlap with hostile personality traits shown to mediate the association between low SES with increased AL levels (Kubzansky, Kawachi, & Sparrow, 1999; J. Sun, Wang, Zhang, & Li, 2007). As women increasingly occupy non-traditional professions around the world (WHO, 2006), changing gender roles might incur both health-promoting and health-damaging consequences (Lundberg & Frankenhaeuser, 1999). It follows that individual differences in unique configurations of AL psychosocial antecedents might differ according to gender and related behaviors that might ultimately contribute to AL health consequences (Juster et al., 2011; Lupien et al., 2006).

Our group recently investigated whether age, sex, and gender roles were associated with AL levels and physical complaints among Montreal workers from diverse occupations (Juster & Lupien, 2012b). Preliminary results revealed that: (1) increased masculinity (e.g., independent, assertive) and age predicted high AL levels, while sex did not; (2) increased masculinity and being female together predicted increased physical complaints; and finally, (3) high AL corresponded to increased physical complaints. That higher masculinity was related to increased objective physiological dysregulation and subjective physical complaints (e.g., nausea, dizziness, and pain) suggests an overall increased vulnerability to hyperarousal pathologies such as cardiovascular disease among masculine-typed individuals. These triangulated findings are clinically important. In particular, atypical prodromal symptoms of acute coronary syndrome for women include physical complaints (Pilote et al., 2007). This fact provides preliminary support for the inclusion of gender roles in studies investigating AL with differences otherwise attributable solely to sex or age.

Interpreting sex differences in pathophysiology and AL levels involves consideration of gender-based factors that need to merge qualitative and quantitative approaches. For example, widespread assumptions that men are vascular reactors and women that are cardiac reactors do not address intra-individual differences between, as well as within, the sexes (Legato, 2010). Many of the antecedents of AL, such as social support, personality traits, occupational characteristics, and lifestyle behaviors (see Figure 8.1), are influenced by sociocultural factors for which gender perspectives can be applied. In synthesizing existing literature with future directions in mind, we postulate that the synergism or interactions among sex- and gender-based factors modulate biological signatures (diurnal cortisol, reactive cortisol, AL) more strongly than the main effects of either set of factors alone (Juster et al., 2013a). In addition to sex and gender roles, one's sexual orientation has received limited attention in the biopsychosocial stress and AL literature, an area to which we turn to next.

Sexual Orientation

Lesbian, gay, and bisexual (LGB) individuals, as a result of their minority sexual identities, frequently experience stress resulting from living in a society that negates or denigrates their identity. Specifically, LGB individuals face heterosexism on a regular basis. Herek (1992) defined heterosexism as an ideological system that denies, denigrates, and stigmatizes any non-heterosexual form of behavior, identity, relationship or community. Heterosexism encompasses homophobia, an irrational fear or hatred of nonheterosexual individuals, as well as bias against LGB individuals. Manifestations of heterosexism can be subtle, such as assuming someone is heterosexual, or overt, such as using anti-LGB epithets, engaging in violence against LGB individuals, or discriminating against LGB people in hiring or housing.

Experiences of heterosexism are common in the lives of LGB individuals. For example, Mays and Cochran (2001) found that LGB individuals were twice as likely as heterosexuals to have experienced prejudice. Likewise, Herek, Gillis, and Cogan (1999) found that up to 25% of their LGB participants had experienced physical violence or property crimes because of their sexual orientation. Recent national data from the Canadian Centre for Justice Statistics show that hate crimes based on sexual orientation are the third most prevalent type of hate crime after race/ethnicity and religion. Moreover, hate crimes based on sexual orientation are characterized by violence more often than other types of hate crimes. For example, 56% of hate crimes based on sexual orientation in 2006 were violent, whereas 38% and 26% of hate crimes based on race/ethnicity and religion, respectively, were violent (Dauvergne, Scrim, & Brennan, 2008). Both overt and subtle heterosexism increase stress for LGB individuals. This increased stress can lead to AL and negative health outcomes.

This form of sociocultural stress has been termed *minority stress* (Meyer, 1995; Meyer, 2003), which refers to the stress of living in an environment that is stigmatizing of nonheterosexual sexual orientations. Meyer (2007) identified three overarching characteristics of minority stress:

1. Minority stress is *unique*. The stress of living in an environment that stigmatizes nonheterosexual sexual orientation is unique to LGB individuals and different

from mundane stressors encountered by all people and moreover is additive to the stress caused by normal everyday stressors.

2. Minority stress is *chronic*. LGB individuals experience this form of stress on a daily basis from events ranging from mundane offenses to extreme instances of harassment and violence.
3. Minority stress is *socially based*. Minority stress is caused by factors outside the individual by other people, institutions, and social-political processes.

Meyer (1995, 2003) divided minority stress into five separate components: (1) internalized homophobia, (2) perceived stigma, (3) prejudice events, (4) sexual orientation concealment, and (5) subsequent coping strategies. *Internalized homophobia* refers to negative views of homosexuality/bisexuality that have been internalized by the LGB individual. *Perceived stigma* relates to the view that a person will be treated unfairly because of her/his sexual orientation. *Prejudice events* are the actions of others toward a LGB individual that are discriminatory, biased, or violent; these can vary in intensity from overt physical or verbal attacks to more subtle instances of bias. *Sexual orientation concealment* refers to attempts to hide one's sexual orientation or "pass" as heterosexual. These components of minority stress require individuals to engage in compensatory coping strategies in an attempt to ameliorate negative effects.

Minority stress is linked to negative health outcomes. Indeed, a recent review of the literature by the Institute of Medicine (2011) highlighted that LGB individuals tend to have elevated levels of psychological distress, increased incidence of suicidal ideation and attempts, and increased substance use relative to their heterosexual peers. Early studies noted the high incidence of minority stressors and their relationship to health outcomes. For example, Ross (1990) found that the majority of his sample of gay men had heard antigay jokes, had to associate with someone who was homophobic, and had been harassed or threatened. In addition, 25% of his sample had been the victim of antigay physical assault. Moreover, these experiences of discrimination were positively related to somatic symptoms, anxiety, and insomnia.

Other studies have continued to demonstrate links between minority stress and a variety of negative mental, physical, and behavioral health outcomes. As reported by the Institute of Medicine (2011), the negative outcomes of minority stress include psychological distress, anxiety, depression, suicidal behaviors, insomnia, physical symptoms, health complaints, substance abuse, prostitution, increased number of sexual partners, and unprotected anal intercourse to name but a few. In particular, behavioral outcomes associated with minority stress include substance use and unprotected sexual intercourse that are important risk factors for the transmission of the human immunodeficiency virus (HIV) among gay and bisexual men in particular. The high incidence of HIV among gay and bisexual men—and the role of minority stress as a risk factor for HIV transmission—has been explained by the concept of syndemics.

A *syndemic* is defined as "a set of closely intertwined and mutual enhancing health problems that significantly affect the overall health status of a population within the context of a perpetuating configuration of noxious social conditions" (Singer, 1996, p. 99).With regard to gay and bisexual men, psychosocial health problems, including depression, substance use, and antigay victimization, are related to HIV risk. When these psychosocial variables combine, the resulting impact on HIV risk is greater than the sum of their individual effects (Safren, Reisner, Herrick, Mimiaga, & Stall, 2010; Stall, Friedman, & Catania, 2008; Stall et al., 2003). For example, Mustanski, Garofalo, Herrick, and Donenberg (2007) found that gay and bisexual men who engaged in binge drinking were over five times more likely to use street drugs; those who used street drugs were almost four times as likely to engage in unprotected anal intercourse. Moreover, they found that for each additional psychosocial health problem (e.g., alcohol use, drug use, psychological distress, violence), the odds of engaging in unprotected anal intercourse increased by 42%. Research on syndemics suggests gay and bisexual men's increased HIV risk can be understood in the context of living in a stigmatizing environment that results in victimization, mental health problems, and substance use. From a transdisciplinary perspective, these sociocultural outcomes interact with each other syndemically to increase risk for HIV.

The accumulated findings over the past several decades suggest that minority stress plays an important role in the psychological, physical, and behavioral health of LGB individuals. However, this rich body of psychological research is matched by a paucity of biopsychosocial research. Research examining biological data among LGB individuals has been sparse, with earlier research examining biological outcomes among HIV-positive gay and bisexual men (and sometimes matched HIV-negative controls), and research focusing on healthy LGB populations only emerging later. Most of the research that includes a focus on biological data has examined the relationship between psychological distress and physical

health, often in HIV-positive gay and bisexual men. For instance, Leserman and colleagues (2000) found that faster progression to AIDS among HIV-positive gay and bisexual men was associated with more stressful life events, use of denial coping strategies, lower satisfaction with received social support, and lower serum cortisol levels. Greeson et al. (2008) found that the relationship between HIV disease progression and psychological distress was mediated by decreased natural killer cell immunity (fewer cells and less cytotoxic function) and increased cytotoxic T-cell function. In a study of both HIV-positive and HIV-negative gay men, Kertzner Goetz, Todak, and Cooper (1993) found that urinary free cortisol was related to depressed and anxious moods.

Resilience When "Coming Out of the Closet"

Early research on the minority stress factor of sexual orientation concealment revealed that both HIV-positive and HIV-negative gay men evidenced worse health outcomes when they concealed their sexual orientation. Cole and colleagues (1996b) found that HIV-negative gay men who were closeted had significantly higher incidence of cancer and infectious diseases than those who were out. In addition, HIV-positive gay men who were closeted reached a critically low CD4 cell count, received an AIDS diagnosis, and died significantly faster than those who were out (Cole, Kemeny, Taylor, Visscher, & Fahey, 1996a).

Likewise, among healthy LGB, disclosure represents an important source of distress. Indeed, "coming out of the closet" (Riley, 2010) to family, friends, and coworkers is considered one of the most significant stressors in the lives of LGBs (Hershberger, Pilkington & D'Augelli, 1997). To date, only one study of healthy sexual minority men showed that disclosure at work was unexpectedly associated with higher cortisol levels and negative affect in comparison to nondisclosed workers (Huebner & Davis, 2005). Shedding light on this unintuitive finding are those from a qualitative study showing that gay men who disclosed their sexual orientation to supervisors reported significantly more hostility in their work environment, significantly fewer perceived promotion opportunities, and significantly higher turnover intentions (Tejeda, 2006). Disclosure of one's sexual orientation is a complex phenomenon that has been purported to involuntarily incite harassment and discrimination among work colleagues (Waldo, 1999) and in the community more broadly (Huebner, Rebchook, & Kegeles, 2004). As noted, however, disclosure can eventually promote positive health and well-being, as evidenced by less distress reported than with nondisclosure (Greene, Derlega, & Matthews, 2006; Morris, Waldo & Rothblum, 2001).

A recent study by our group assessed psychiatric symptoms, diurnal cortisol, and AL levels as a function of sexual orientation as well as disclosure status. The results revealed that sexual minorities did not manifest more stress-related problems than heterosexuals (Juster, Smith, Ouellet, Sindi, & Lupien, 2013b). Quite to the contrary, gay/bisexual men had lower depressive symptoms and AL levels than heterosexual men, which is inconsistent with a sexual minority stress model. Differences in AL levels were driven by lower levels of triglycerides, body mass indices, and TNF-α levels among the gay/bisexual men that could be explained behaviorally by their increased focus on thinness and muscularity by means of diet and exercise compared to heterosexual men (Juster et al., 2013b). Alternatively, the differences may be due to sample-based features or potentially even be influenced by resilient pathways related to the rites of passage associated with sexual minority status and coming out. Given that two-thirds of LGB participants had completely disclosed their sexual orientation, we ascertained whether disclosure might explain these surprising reversals. Accordingly, those who had completely come out to friends and family had less symptoms of anxiety, depression, and burnout as well as lower levels of morning cortisol than those who remained closeted (Juster et al., 2013b).

In a secondary analysis by our group, retrospective coping strategies used during disclosure (problem-focused, seeking social support, wishful thinking, blaming self, and avoidance) were assessed in relation to current indices of environmental, psychological, and biological stress. This period of sexual identity formation represents the elapsed time since first recognizing same-sex attraction or disclosing to family and friends. The increased use of avoidance coping behaviors was associated with increased self-reports of daily hassles and perceived stress, as well as increased AL levels. Interestingly, coping that involved seeking social support buffered against current perceived stress. Could prosocial behaviors and disclosure represent respective coping strategies and life transitions that promote resilience among sexual minorities? Stigma-related stress can promote individual differences in adaptive behavioral responses among stigmatized individuals that can render them more resilient and effective at managing future stressors, especially if they are well supported socially and are able to develop adaptive coping strategies (Hatzenbuehler, 2009).

Although these novel findings link sexual orientation, life transitions, and coping strategies to psychological

outcomes, cortisol, and/or AL levels, we cannot assume that our results generalize to all LGB communities. Specifically, participants were all recruited from the liberal city of Montreal, and Canadian social policies are progressive vis-à-vis sexual minority rights. As such, our findings might not generalize to more conservative locations in particular. Moreover, differences among specific LGB groups *intersect* according to age cohorts, race/ethnicity, SES, culture, and geographic location (IOM, 2011). For instance, younger generations of LGBs are 16 times more likely to have disclosed than older generations (Gates, 2010), and African American gay/bisexual men experience higher levels of internalized homophobia and are therefore less likely to disclose than other racial/ethnic groups (Peterson & Jones, 2009).

Intersectionality is an inductive research framework that appreciates the reality that individuals are members of multiple social groups and identities that will contextually determine their experiences, chances, opportunities, and ultimately health (Johnson, Repta & Kaylan, 2011). Moreover, there are many environments where disclosure may be a dangerous option. At a societal level, however, these findings have social implications: If individuals are to garner any benefits from disclosing, there must be established social policies that reduce stigma and intolerance (Chaudoir & Fisher, 2010).

Institutionalized stigma and heterosexism includes, for example, the denial of marriage rights, disadvantaged treatment in schools and workplaces, and disenfranchisement of sociocultural resources like religion and spirituality that often dehumanize LGBs and contribute to psychosocial distress (Herek & Garnets, 2007; IOM, 2011). These social inequalities have health consequences that can be reversed when policy changes are made (Hatzenbuehler, 2010). Compelling research shows that American LGBs living in states without policies that protect them from hate crimes and employment discrimination experience significantly higher rates of psychopathology than LGBs living in states with protective policies (Hatzenbuehler, Keyes & Hasin, 2009). Likewise, LGBs living in states with constitutional amendments banning same-sex marriages experience increased rates of generalized anxiety disorder, depressive disorders, and alcohol abuse. By contrast, those living in states that recognize same-sex marriages show no increased development of these conditions (Hatzenbuehler, McLaughlin, Keyes, & Hasin, 2010).

A recent study showed that following the Massachusetts legalization of same-sex marriage, there were significant decreases in general medical and mental health care visits and costs 12 months afterward among gay men (Hatzenbuehler, O'Cleirigh, Mayer, Safren & Bradford, 2012). This body of research demonstrates how changes in distal policies can progressively eliminate institutionalized stigma and promote public health benefits (Hatzenbuehler et al., 2012). In a pioneering study, Hatzenbuehler and McLaughlin (2013) examined stress-reactive HPA axis functioning emphasizing discrimination among sexual minorities exposed to varying degrees of stigma. Results indicated that LGB young adults who lived in states with high structural stigma (e.g., states without policies that protect sexual minorities from hate crimes, ensure employment nondiscrimination, and support same-sex marriage) as adolescents showed blunted cortisol responses following the Trier Social Stress Test (TSST) compared to those from low-stigma states. This finding suggests that the stress of growing up in environments that target sexual minorities for social exclusion may result in HPA axis dysfunction (Hatzenbuehler et al., 2014). Given ongoing debate in the United States and worldwide concerning same-sex marriage, assessing AL levels in states with and without protective policies over time would contribute further to our understanding of the relation between social policy and biology.

Beyond sex and gender diversity, the plight of Indigenous peoples within our national borders must not be ignored or forgotten. Especially troubling is the fact that few biopsychosocial studies have been conducted among Indigenous peoples, especially for studies quantifying chronic stress. In the next section, we discuss the American Samoans, Nunavik Inuit, and Australian Aborigines as Indigeneous populations at risk of higher AL.

Indigenous Peoples of North America and Australia

American Samoans

American Samoa is a group of five volcanic islands and two coral atolls located in the South Pacific that is an unincorporated U.S. territory (Central Intelligence Agency, 2012). As early as 1000 B.C., proto-Polynesians settled the islands. Today, native American Samoans are descendants of the Lapita culture and are one of the few remaining Polynesian societies (Bellwood, 1987). In 2012, the native American Samoan population was estimated at 49,782 individuals (Central Intelligence Agency, 2012). American Samoan women have a life expectancy of 75.9 years in comparison to 69.3 years for men (WHO, 2011), which is about 5 to 7 years lower than that of the general American population as of 2009 (80.9 years for women in comparison to 76.0 for men [WHO, 2012]). Migration of many Samoans to Hawaii and the American mainland has led to

a number of communities with widely varying sociocultural characteristics. Investigations on the challenges of changing social contexts and acculturation on health have been undertaken (Baker, Hanna, & Baker, 1986).

Public health reports reveal that American Samoans have alarming rates of metabolic disorders. American Samoans have the highest prevalence of adulthood obesity in the world: 74.6% of the adult population classify as obese, according to their BMI (WHO, 2011). Additionally, diabetes mellitus cases have doubled and are a leading cause of death for American Samoans (WHO, 2011). Metabolic diseases are strongly associated with chronic stress (Kyrou & Tsigos, 2007, 2009; Mattei, Noel, & Tucker, 2011; Stumvoll, Tataranni, & Bogardus, 2004; Tamashiro, Sakai, Shively, Karatsoreos, & Reagan, 2011) that can synergize with acculturated dietary factors to increase AL and therefore increase vulnerability to diabetes mellitus. In a landmark study, it was shown that Pima Indians living traditionally in rural Mexico were in better health than those living in Arizona for whom diabetes incidence was much higher (Ravussin, Valencia, Esparza, Bennett, & Schulz, 1994). Studies that can assess such adverse acculturation and consequent AL could provide powerful evidence to inform policymakers.

In a first study, Crews (2007) investigated the association between AL and diabetes mellitus among American Samoans. AL was significantly associated with diabetes mellitus (Crews, 2007), consistent with higher prevalence among American Samoans. While Samoan inhabitants are well integrated into a cosmopolitan way of life, recent acculturation has led to increasingly overlapping sociocultural risk factors for metabolic diseases common to the larger American population. As a consequence, clusters of "new" risk factors (e.g., industrial food production) are generally lower in the oldest portion of the population (Bindon, Knight, Dressler, & Crews, 1997) who grew up and developed before these massive changes in their lifestyle. Interestingly, AL was negatively associated with age in men but was more strongly positively associated with age in women. In sum, the oldest Samoans are those who grew and developed before massive sociocultural changes, the middle-age Samoans experienced many of these changes, and the youngest generation are the now the most obese Samoans (Crews, 2007).

These differences may be driven by interactions among age, biological sex, and sociocultural gender-based differences like those discussed in the previous section. It is important to highlight that gender issues are of high importance in Samoan society, with active promotion and protection of women's rights and equalities in addition to equality with men with respect to participation in the paid labor force, educational attainment, and occupation of several senior positions in the public sector (WHO, 2011). Yet sociocultural changes may have caused greater disruption of women's traditional way of life that may have contributed to their higher levels of AL. Although the exact mechanism is unclear, obesity, hypertension, and diabetes are more common among older Samoan women in contrast to men (Baker et al., 1986; Crews, 1989). This suggests that AL might reflect sociocultural changes in the life style of Indigenous populations and might be useful to predict future health vulnerabilities to metabolic disorders among others.

Nunavik Inuit

The Inuit are a group of native inhabitants of the Arctic regions of Russia, the United States, Canada, and Greenland that share similar culture and ancestors as the descendants of the Thule culture that migrated from eastern Asia to Alaska by crossing the Bering land bridge around 1000 BC. By the thirteenth century, the Inuit had settled across the continent toward eastern Arctic territories of Canada, such as Nunavik (McGhee, 1978). Nunavik is a vast territory (larger than California) north of the fifty-fifth parallel in the province of Quebec, Canada. In 2006, the Nunavik Inuit population comprised 10,950 people living in 14 coastal communities (Statistics Canada, 2006a). With a median age of 20.8 years, they have the lowest mean age in Canada (Statistics Canada, 2006a).

Nunavik Inuit are the most vulnerable Canadian Inuit population to health problems (Statistics Canada, 2006b, 2006c, 2008). Since 2004 to 2008, they have had the lowest life expectancy at birth in Canada and the lowest overall life expectancy, at 66.5 years (68.5 years for females and 64.5 years for males) in comparison to 80.6 years for the Canadian average (82.9 years for females and 78.2 years for males (Statistics Canada, 2008). Moreover, life expectancy is 5.6 years lower than the average of any other Canadian Inuit (Statistics Canada, 2008). The AL model could be applied to further understand the social determinants of these disturbing demographics.

In particular, housing conditions are a major source of distress (G. W. Evans, Lepore, Shejwal, & Palsane, 1998) and a potential determinant of compromised Indigenous health (Gracey & King, 2009). Approximately half of Nunavik Inuit live in overcrowded houses, defined as more than one person per room, compared with 33% for the average of any other Canadian Inuit and 3% for non-Indigenous Canadian households (Statistics Canada, 2006c). This situation is explained in part by high birth

rate, housing shortage, and high cost of construction (Rochette, St-Laurent, & Plaziac, 2007). The association between household crowding and AL was recently assessed by our group using data from the Nunavik Inuit Health Survey (Blanchet & Rochette, 2008; DeWailly et al., 2007a, 2007b; Kirmayer & Paul, 2007; Rochette et al., 2007) that calculated AL by incorporating 14 biomarkers from on a cross-section of 839 Inuit between the ages of 18 and 79. Results show that higher household crowding was significantly associated with elevated AL levels while controlling for the effects of age, sex, income, diet, and involvement in traditional activities (Riva et al., 2014)

Another major risk factor for the Nunavik Inuit that overlaps with household conditions is low SES. In particular, educational level is very low in Nunavik: Only 25% of Nunavik Inuit over 15 years old have a high school diploma or above (Statistics Canada, 2006b). Unemployment is also an important issue for the Inuit from Nunavik with only 56.1% over 15 years of age employed (Statistics Canada, 2006b). The proportion of this population with stable and well-paying employment is also relatively limited in Nunavik: income is exceedingly low (42.6% earning less than $20,000/year) and only 32.2% have full-time employment (Statistics Canada, 2006b). This low income in turn leads to food scarcity reported by 25% Nunavik Inuit (Blanchet & Rochette, 2008).

Finally, exposure to environmental contaminants is a well-known problem in the Canadian Arctic. Members of our group have previously proposed that environmental toxins might modulate AL and exacerbate health outcomes (Juster et al., 2011; Loucks, Juster, & Pruessner, 2008; McEwen & Tucker, 2011). Accordingly, a recent cross-sectional analysis of the NHANES cohort demonstrated that high AL levels amplify the damaging effects of exposure to lead in terms of elevated BP (Zota, Shenassa, & Morello-Frosch, 2013). This is likely much more problematic for Nunavik Inuit inhabitants who are exposed to a plethora of environmental contaminants that are carried from southern to northern latitudes by atmospheric and oceanic currents that are then bioaccumulated in the Arctic food chain. Specifically, the traditional Inuit diet contains high levels of fish (Arctic char) as well as land (caribou) and marine mammals (beluga, seal, and walrus) that are at the top of the food chain (Blanchet & Rochette, 2008). Consequently, the Nunavik Inuit are more exposed to environmental contaminants than the average population from southern Quebec (Muckle, Ayotte, Dewailly, Jacobson & Jacobson, 2001). This exposure includes exposure to traditional legacy contaminants (heavy metals like lead, methylmercury, and cadmium) and persistent organic pollutants (mainly polychlorinated biphenyls [PCBs]) and chlorinated pesticides (DeWailly et al., 2007a, 2007b).

Environmental contaminants can exert endocrine-disrupting effects that modulate allostatic processes (Juster et al., 2011). For example, among wildlife, impaired ability to mobilize glucocorticoids in response to an acute stress is related to heavy metal exposure and environmental organic contaminants (e.g., PCBs, solvents, pesticides) in fish (Benguira, Leblond, Weber, & Hontela, 2002; Hontela, Dumont, Duclos, & Fortin, 1995; Hontela, Rasmussen, Audet, & Chevalier, 1992), amphibians (Gendron, Bishop, Fortin & Hontela, 1997), birds (Love et al., 2003), and large mammals (Oskam et al., 2004). In rodents, altered HPA axis functioning has been reported following early exposure to PCBs (Meserve, Murray, & Landis, 1992) and heavy metals (Vyskocil, Fiala, Ettlerova, & Tenjnorova, 1990). Human studies demonstrate that some PCBs even act as antagonists of glucocorticoid receptors (Johansson, Nilsson, & Lund, 1998) and alter glucocorticoid biosynthesis in human adrenocortical cells (L. A. Li & Wang, 2005). This finding has also been shown at low levels of lead exposure: Exposure to lead increases glucocorticoid responses to acute stress in 9- to 10-year-old children (Gump et al., 2008). Likewise, a recent study reported an association between lead exposure and higher cortisol levels in occupationally exposed workers (Fortin et al., 2012). Beyond the HPA axis, environmental toxins influence cardiovascular functioning. For example, elevated exposure to methylmercury is pathophysiological and increases heart rate, BP, and coronary heart disease (Ayotte et al., 2011; Valera, Dewailly, & Poirier, 2008, 2009, 2013; Valera et al., 2012). Finally, prenatal exposure to PCBs has been related to incidence of acute respiratory infections in Inuit children (Dallaire et al., 2006).

Numerous environmental contaminants are related to adverse mental health outcomes. For Inuit infants, postnatal lead exposure is linked to increased inattention, impulsivity, and irritability (Plusquellec et al., 2007, 2010), while pre- and postnatal PCB exposure is linked to increased unhappiness, anxiety, and inattention (Plusquellec et al., 2010; Verner et al., 2010). This finding is clinically important as postnatal lead exposure increases the risk of hyperactivity and attention-deficit disorder in Inuit children (Boucher et al., 2012), while prenatal methylmercury exposure increases inattention in Inuit infants (Verner et al., 2010). Thus, environmental contaminant exposure may alter stress physiology and influence developmental psychopathology.

In summary, comprehensive biopsychosocial studies of Indigenous people in North America are needed. As reviewed, American Samoans and Inuit from Nunavik are

both at high risk of chronic stress through socioeconomic factors, health behaviors, and environmental contaminants. There is therefore a strong need for continued research using the AL model to understand the health disparities of Indigenous peoples and to inform public health policies. Turning now to Oceania, we explore how the AL model can be further cross-culturally tailored to the challenges of Australian Indigenous peoples.

Australian Aborigines

Aboriginal people have lived in Australia for at least 60,000 years. Today, there are two main groups of Indigenous Australians: those from the Australian continent and the island state of Tasmania and those from the Torres Strait. With an estimated population of 575,552 and projected annual growth rate of 2.2%, the Aboriginal and Torres Strait Islander population of Australia represent 2.5% of the total Australian population. The Australian Aboriginal population is relatively young, with a median age of 21 years compared to 37 years for the non-Indigenous population as of 2006 (Australian Bureau of Statistics, 2007). Prior to the arrival of European settlers in the late eighteenth century, Indigenous Australians were healthier than most Europeans (Webb, 2009). As elsewhere around the world (e.g., among Native American communities), European settlers arrived with diseases that subjected Indigenous people to widespread changes that included loss of land and livelihood, as well as restricted civil rights and forced familial breakdown by religious missions that removed Indigenous children from their families (Chesterman & Galligan, 1997). These dramatic changes have destroyed their traditional way of life and have had abysmal effects on their health and well-being.

Mortality rates are much higher among the Australian Indigenous population when compared to the general Australian population. Causes of morbidity and mortality include cardiovascular disease, diabetes, and tobacco-related conditions that collectively account for half of health disparities in comparison to non-Indigenous Australians (T. Vos, Barker, Begg, Stanley, & Lopez, 2009). Life expectancy is 67.2 years for men (11.5 years lower than for non-Indigenous men) and 72.9 years for women (9.7 years lower than for non-Indigenous women). Roughly 87% of all Australians reach age 65; this is reduced to 24% and 35% of Australian Aboriginal men and women, respectively. These statistics are lower than in Nigeria, Bangladesh, and several other developing countries (UN, 2003).

Cardiovascular diseases and diabetes are much more common for Indigenous people than for non-Indigenous people (Australian Bureau of Statistics, 2006) and have a much younger incidence. Young and middle-aged Indigenous adults surprisingly drive these differences: the death rates for the 35 to 44 age groups and 45 to 54 year age groups are 8 to 12 times higher than corresponding non-Indigenous rates by age (Australian Institute of Health and Welfare, 2008). Although the prevalence of diabetes increases with age, here too the pattern of onset is much earlier: prevalence for Indigenous people aged 25 to 34 years old was almost seven times that of non-Indigenous people, while the prevalences reported by Indigenous people aged 35 to 44 as well as 45 to 54 years are more than five times those reported by age-matched non-Indigenous people (Australian Bureau of Statistics, 2006). This rate represents a strain on the health care system, as hospitalization rates for diabetes among Indigenous men and women are 3.4 and 5 times, respectively, the rates of non-Aboriginals after adjusting for age (Australian Institute of Health and Welfare, 2011).

Chronic stress and AL likely mediate associations among social inequalities and health disparities among Australia's Indigenous population. Like previous cross-cultural AL studies (e.g., Taiwanese SEBAS cohort), psychosocial stressors—such as death of a family member or closed friend, serious injury or disability—are major contributors of cardiovascular and metabolic problems among Australian Indigenous people (Australian Institute of Health and Welfare, 2008). In a large community sample of Australian Aboriginal and Torres Strait Islanders, glycosolated hemoglobin was measured and interpreted as a biological indicator of social environmental stress (Daniel, O'Dea, Rowley, McDermott, & Kelly, 1999). As an important biomarker of diabetes, mean glycosylated hemoglobin concentrations were 18.2% higher for both Indigenous groups in comparison to Caucasian Australians and for Greek migrants who experience unique distress due to acculturation.

Despite recent major efforts to study the social determinants of disease that disproportionately affect Indigenous Australians, relatively few studies have investigated AL biomarkers in community samples to serve as contrasts. Schmitt and colleagues (1995) studied urinary cortisol and adrenaline excretion rates in three Aboriginal communities in the Kimberley region of northwest Australia and compared them to samples from Oxford in the United Kingdom. They found that both cortisol and adrenaline secretion was significantly higher in the Aboriginal communities than in the Oxford sample, which was already quite high by international standards.

Mental health burden is similarly much higher among Indigenous people. Psychiatry-related hospitalizations

have also increased: schizophrenia, schizotypal personality disorder, and delusional disorders are 4 times higher, substance use disorder is 3.8 times higher, and suicide attempts are 2.7 times higher among Indigenous people. High rates of psychosis and alcohol and cannabis use have also been reported among the Indigenous populations of Cape York and the Torres Strait, who experience heightened distress (Hunter, 2013; Hunter et al., 2012). Large-scale surveys reveal that prevalence for symptoms of depression and anxiety are 3 times higher than for non-Indigenous adults (Jorm, Bourchier, Cvetkovski, & Stewart, 2012). Qualitative research among Aboriginal men in central Australia reveals that depressive symptoms are mostly attributable to a sense of loss and connection with the social and cultural fabric of Aboriginal life as well as with the cumulative stress of marginalization (Brown et al., 2012). Low SES (Cunningham & Paradies, 2012) and other social inequalities, including transgenerational trauma, discrimination, and racism, may underlie these health inequalities among Indigenous Australians (Marmot, 2011). Research that can further assesses intersections within marginalized groups (e.g., sexual minority Indigenous peoples) are needed. These statistics demonstrate pernicious effects of social marginalization among Indigenous populations that ultimately exacerbate trajectories toward mental and physical morbidity. Utilizing the AL model to demonstrate this conclusively would provide an important platform by which to assess the needs of marginalized groups and in turn inform policymakers of intervention efficacy that address these needs.

In conclusion to this first part dedicated to social inequalities, we have reviewed an impressive breadth of research linking AL to mental and physical health. Studies clearly demonstrate that lower SES is associated with greater risk of increased AL, concomitant with important inequalities in Indigenous status, race/ethnicity, geography, as well as differences related to sex, gender, and sexual orientation throughout life that ought to be addressed in the evolution of public policies. Fundamental conclusions surface from this analysis of AL. AL represents a reliable measure of physiological dysregulations underlying illnesses that are influenced by social inequalities, such as with socioeconomic gradients, discrimination, homophobia, and adverse environments. In the interest of promoting continued advances in the measurement of AL in relation to biological, neurological, and cognitive indices of vulnerability and resilience to pathologies, we turn next to innovative approaches that should be incorporated into future research endeavors.

INNOVATIVE BIOCHEMICAL, NEUROLOGICAL, AND COGNTIVE PERSPECTIVES

In the first part of this chapter, we explored the psychosocial aspects of social inequalities influencing vulnerability toward, and resilience against, AL. Elevated AL hastens the development of age-related disease outcomes, such as cognitive and functional decline, cardiovascular disease, and mortality. However, the cellular mechanisms by which social inequalities and adverse experiences promote disease remain elusive. More specifically, the "primary effects" of allostatic mediators in the AL model (e.g., specific alterations in cellular functioning) have received limited empirical substantiation. The reader is reminded that primary mediators (glucocorticoids, catecholamines, cytokines) exact a domino effect on secondary outcomes (e.g., glycol-lipid profiles, cardiovascular functioning) via primary effects—that is, cellular changes in tissue and organ functioning.

Allostatic mechanisms like the stress response are diverse and span the spectrum of adaptive and maladaptive response patterns. In considering stress and resilience at a biological level—or what is referred to herein as *biological resilience*—we wish to first define three key interconnected concepts outlined by Karatsoreos and McEwen (2011) regarding resilience, resistance, and recovery. First and consistent with previous sections, *resilience* is defined as an organism's ability to rebound from adversity when its ability to physiologically function has been tampered with in some negative way; however, the organism is able to adapt by activating allostatic mechanisms that can promote resistance. Second, *resistance* is defined as an organism's ability to withstand adversity and face future stressors with little or no stress response. Resistance is conceptually akin to vaccination or stress inoculation that helps bolster immunity to future stressors. Third, *recovery* is defined as an organism's ability to shut down the stress response and other related biological activities back to baseline levels (Karatsoreos & McEwen, 2011). All three of these constructs are related to adaptation at a biological level and are central to our understanding of biological processes that promote resilience. Although the AL framework is embedded within such processes, we present diverse research areas to provide food for thought to help guide future research.

In this section, we focus on biological pathways that might mediate the adverse effects of chronic stress on health and ultimately modify vulnerability and resilience across the life span. We begin this discussion at a cellular level central to energy metabolism and the aging

process—namely, the mitochondrion (Picard, 2011). Next, we present advances in hippocampal neurogenesis to underline an important development in neurosciences that has redefined our understanding of neural plasticity of the hippocampus. Finally, we explore the concept of cognitive reserve among the elderly to highlight continued research on AL and cognitive functioning. In the next three sections, we highlight the importance of assimilating new techniques and perspectives to refine our understanding of social inequalities in AL and navigating potential routes toward resilience.

Mitochondria

Each of the approximately 10 trillion cells of the human body contains hundreds of mitochondria within their cytoplasm. *Mitochondria* are cellular organelles that arose 2.2 to 2.5 billion years ago when the ancestor of the mammalian cell fused or engulfed an aerobic bacteria capable of utilizing oxygen for energy production (Sagan, 1967). The bacteria thereafter remained and evolved into today's mitochondria. Through this endosymbiotic fusion, the mammalian cell *de novo* acquired from the ancient bacterium—now mitochondria—the capacity to produce large amounts of energy by oxidative phosphorylation (OXPHOS), which allowed the evolution of complex genomes and multicellular life-forms (Lane & Martin, 2010; Wallace, 2010). Cells of the human brain, muscles, vasculature, heart, and other organs, therefore, rely heavily on mitochondria for energy production and other cellular functions that sustain life (Scheffler, 1999). For this reason, mitochondria that do not function normally can cause death in infancy or severe multisystemic diseases in childhood and adulthood (Koopman, Willems & Smeitink, 2012). Beyond regulating life and death at the cellular level, mitochondria also produce signals within cells (Liu & Butow, 2006), between cells (Taivassalo, Ayyad, & Haller, 2012), and across organ systems (Taivassalo et al., 2003) that shape the body's allostatic mechanisms and thus the capacity to adapt to environmental challenges.

As reviewed in previous sections, environmental and perceived stress initiates allostatic mechanisms and cellular processes. These adaptive physiological processes involve metabolically expensive neuronal activities, increases in heart rate and BP, secretion of neurochemicals, and hormone synthesis. At a more fundamental level, they require changes in gene expression regulated in part by epigenetic writers and modifiers that ultimately regulate protein synthesis. All of these adaptive processes are energy dependent and thus increase cellular energy demand. Given that mitochondrial function provides the necessary energy reserve to fuel these adaptive processes, mitochondria have been regarded as a key component of the stress response (Manoli et al., 2007). These organelles also contain receptors for glucocorticoids (S. R. Lee et al., 2013) as well as other steroid hormones (Psarra & Sekeris, 2009; Yang et al., 2004) that regulate mitochondrial function in the brain and throughout the body (Rettberg et al.,2014). Taken together, this evidence attests to the importance of conceptually linking the biological stress response to mitochondrial function.

Differences in mitochondrial content and function that determine cellular energy capacity could therefore contribute to vulnerability or resilience to stress-related diseases (Morava & Kozicz, 2013). For example, following acute stress, the combination of a rapid rise in cellular energy demand with insufficient endogenous energy capacity to sustain this demand could cause a bioenergetic mismatch. Because cellular energy is a rate-limiting step for many protective cellular processes, a transient mismatch causing energy deficiency would generate cell stress, damage, and possibly elevated AL over time. Applied to stress physiology, inadequate capacity for mitochondrial energy production may thus be a source of cellular AL. Conversely, fostering a reserve capacity for mitochondrial energy production, such that capacity exceeds stress-induced energy demand, could permit rapid and effective adaptation to stressors and promote timely recovery from stressors. This adaptation might prove particularly critical in situations of prolonged and repeated stressors known to cause AL (McEwen, 1998b). The following section considers factors that influence mitochondrial content and function, including behavioral and genetic factors, in the context of social inequality. We conclude by considering conditions wherein mitochondrial energetic capacity may be exceeded, leading to mitochondrial stress, mitochondrial AL, and downstream allostatic consequences such as cellular senescence (Picard, Juster, & McEwen, 2014).

Behaviors Influencing Mitochondrial Function

The effects of physical activity and other protective behaviors that foster biological resilience may lie in improved mitochondrial energy production. The amount of energy cells can use and produce is in large part dictated by the quality and quantity of mitochondria they contain (Schwerzmann, Hoppeler, Kayar, & Weibel, 1989). For instance, cells with more healthy mitochondria can perform more work than those with fewer mitochondria. Equally important, high mitochondrial content enables

cells to sustain function at a given workload for longer periods before fatigue onset. For instance, individuals with mitochondrial diseases (where mitochondria cannot normally produce energy for muscles to contract) can exercise only at low intensities and can maintain given workloads only for limited periods of time (Taivassalo et al., 2003).

In response to increased energy demand, cells adapt by increasing the number of energy-producing mitochondria in their cytoplasm via a process called mitochondrial biogenesis (Handschin & Spiegelman, 2008). Physical activity, which increases the energy required and consumed by the contracting muscles and the working brain, triggers mitochondrial biogenesis. Resulting rises in energy demand initiate cellular signaling cascades that consequentially increase mitochondrial content in muscles (Hood, 2009), in different brain regions (Steiner, Murphy, McClellan, Carmichael, & Davis, 2011) and systemically in other organs (Little, Safdar, Benton, & Wright, 2011). Changes in mitochondrial content and morphological shape as well as other concomitant antioxidant, quality control, and anti-inflammatory processes are thought to underlie the beneficial effects of health behaviors that transiently increase energy demand, such as exercise (Handschin & Spiegelman, 2008; Picard & Turnbull, 2013).

Health behaviors that increase cellular energy capacity can promote successful adaptation. Equipped with a healthy pool of well-functioning mitochondria, cells can more easily meet the energy cost of stress and thus minimize AL. In the long run, this reserve would contribute to biological resilience. In line with this, regular exercise may prevent the deleterious effects of chronic psychosocial stresses on cellular senescence as measured with telomere length (Puterman et al., 2010). It is important to recall that lifestyle factors are integral behavioral components of AL. For instance, caloric overload and excessive dietary sugar generates free radicals and inflammation. Similarly, physical activity can also contribute significantly to the association between stress/depression and cardiovascular disease, with physically active and fitter individuals appearing to be more resilient to stressors (Hamer, 2012). Likewise, aging is associated with a decline in mitochondrial content and function (Short et al., 2005), which is partially normalized by physical activity (Lanza et al., 2008). Physical activity, which stimulates mitochondrial biogenesis and affects other cellular processes that improve mitochondrial function, is therefore a potential source of cellular resilience.

Conversely, factors that reduce cells' energy-producing capacity are associated with adverse health outcomes, including cardiometabolic diseases and cognitive decline (F. B. Hu et al., 2004; Mattson, 2012). Behaviors leading to reduced mitochondrial content and function include physical inactivity and excess calorie intake (overeating) or type 2 allostatic overload. Because organs require less glucose and lipids when they are inactive, food substrates accumulate systemically. This accumulation leads to the oversupply of energetic substrates (glucose and lipids) relative to demand, also known as a state of metabolic oversupply (Picard & Turnbull, 2013). Metabolic oversupply can compromise mitochondrial health in three major ways: (1) by suppressing mitochondrial biogenesis, thereby reducing the synthesis of new mitochondria and lowering of mitochondrial content within cells of the body (Petersen, Dufour, Befroy, Garcia, & Shulman, 2004); (2) by inhibiting the removal of damaged and dysfunctional mitochondrial, which normally occurs on a continuous basis and contributes to normal mitochondrial function (Liesa & Shirihai, 2013); and (3) by causing prolonged mitochondrial fragmentation (Picard & Turnbull, 2013), which leads to the accumulation of mitochondrial DNA damage (Fukagawa et al., 1999), oxidative stress, and molecules that trigger cell death (Yu, Robotham, & Yoon, 2006). Thus, behaviors that promote metabolic oversupply and reduce mitochondrial energy-producing capacity can lead to AL.

Environmental and social factors inherent to social inequalities can significantly shape one's behavior and mitochondria, at least in part via physical activity and diet. Neighborhoods and social environments that encourage the regular practice of physical activity (e.g., access to facilities, safe walking or biking paths, social engagement) or promote sedentary lifestyles (e.g., urbanized neighborhoods, unsafe environments, social desirability, stigmatization, self-perceptions, and discrimination (Sabiston & Crocker, 2008)) may exert strong indirect influences on metabolic state and thus affect biological resilience. Altered behaviors (physical activity and diet) and primary AL mediators (cortisol, cytokines) might synergistically influence mitochondrial function. Thus, psychosocial and behavioral factors linked to social inequalities may influence AL and vulnerability/resilience to disease by contributing to mitochondrial health and the organism's adaptive capacity. In addition and as is explored next, factors intrinsic to mitochondria could influence how cells adapt to stress.

Mitochondrial Genome, Haplogroups, and Telomeres

Essential to mitochondrial energy production is mtDNA, a circular genome residing within mitochondria that encodes only 37 genes and is inherited from the mother

only (R. W. Taylor & Turnbull, 2005). Although this genome is approximately 200,000 times smaller than the nuclear genome, 98% of the mtDNA encodes essential components of energy production. Pathogenic mutations in the mtDNA therefore have severe health consequences (DiMauro & Schon, 2003). However, other "milder" genetic variations in the form of single nucleotide polymorphisms (SNPs) exist in the mtDNA and appear to have subtle effects on the function of mitochondria (Gomez-Duran et al., 2010). mtDNA SNPs have historically segregated as groups—called haplogroups—during human evolution and migration (Wallace, 2005). To date, several studies have linked mtDNA variants to disease susceptibility (Wallace, 2013), such that specific haplogroups appear to predispose to specific illnesses, such as schizophrenia and bipolar disorder (Rollins et al., 2009; Sequeira et al., 2012), AIDS progression (Hendrickson et al., 2008), and diabetes (Crispim et al., 2006). By contrast, specific mtDNA haplogroups have also been associated with athletic performance (Niemi & Majamaa, 2005) and longevity (De Benedictis et al., 1999), indicating that subtle changes in mtDNA can confer susceptibility or resistance to age-related disease.

It is informative to consider the origin of human mtDNA haplogroups. mtDNA haplogroups arising 50,000 to 200,000 years ago are thought to have permitted the migration of humans out of Africa, from warmer to colder climates based on differences in mitochondrial function (Wallace, 2005). According to this theory, individuals with a certain mtDNA haplogroup would have mitochondria that are well coupled electrochemically, which makes them ideally suited to warm climates and possibly certain types of food; whereas other individuals with certain mtDNA haplogroups would be better suited to tolerate colder climates and thus could migrate out of Africa (Wallace, 2005). As a result, race/ethnic groups with ancestry originating from geographically distinct regions (e.g., Africa, Asia, North Europe, Siberia) characterized by warmer or colder climates harbor divergent mtDNA haplogroups. In other words, in addition to the sociocultural variables typically associated with race/ethnicity (e.g., cultural differences, diet, family structures, value sets, visible minority features that are often sources of discrimination), different "types" of mitochondria could further modulate disease susceptibilities.

In particular, different mtDNA haplogroups may generate mitochondria that respond differently to environmental factors, behaviors, and psychosocial factors influencing energy metabolism (Liou et al., 2007). This alteration might contribute to shape an individual's responses to chronic stress and thus AL. For instance, a specific mtDNA haplogroup or SNP may exert little or no effect under normal circumstances but can become deleterious in the presence of chronic metabolic stress (type II allostatic overload) when mitochondria are challenged (Liou et al., 2007). Studies are needed to disentangle the biological effect of mtDNA haplogroups from those of other sociocultural factors that frequently correlate with race/ethnicity. It may be that inherited mtDNA haplogroups differentially alter disease susceptibility in conjunction with social inequalities, particularly in the context of racially and culturally diverse study samples.

A related biomarker related to aging is the length of telomeres, the protective DNA-protein complexes at the end of chromosomes that shorten as cells age. Telomere shortening is therefore a marker of cellular senescence (Chan & Blackburn, 2004). Interestingly, individuals exposed to chronic psychological stress (Epel et al., 2004) or with low SES (Needham, Fernandez, Lin, Epel, & Blackburn, 2012; Needham et al., 2013) have shorter telomeres in blood cells, and A mtDNA haplogroups are associated with blood cell telomere length (Fernandez-Moreno et al., 2011). This finding substantiates the notion that cellular senescence and the aging process are characterized by telomere shortening, which is also interconnected with mitochondrial dysfunction (Sahin & Depinho, 2010). Despite its popularity as a biomarker of senescence, telomere erosion can occur early in life: A recent study demonstrated that 5-year-old children exposed to heightened domestic violence displayed significantly more telomere erosion than counterparts when adjusting for sex, SES, and BMI (Shalev et al., 2013). In summary, mitochondria, mtDNA haplogroups, and telomeres are biomarkers that should be assessed in AL research on vulnerability and resilience. However, other neurobiological factors also mediate the effects of stress on AL and psychiatrically relevant phenotypes, including hippocampal neuroplasticity involved in regulating HPA activity and stress response.

Hippocampal Neurogenesis

The central organ of stress physiology and AL is the brain because it determines what is threatening and then orchestrates the appropriate physiological and behavioral responses needed to cope. The brain is also a plastic and vulnerable organ and changes in the architecture of key brain regions, such as the hippocampus, PFC, amygdala, and nucleus accumbens, alter how these brain regions respond. In determining susceptibility to

negative outcomes following chronic stress, it is important to consider the neurobiological underpinnings of neuroplastic responses to stress in the brain.

In this respect and consistent with the life cycle model of stress, the hippocampus is particularly important as it modulates HPA axis activity through its inhibition of the hypothalamus (Herman, Ostrander, Mueller, & Figueiredo, 2005; Pruessner et al., 2005, 2008, 2010). The hippocampus is also relatively unique among brain structures in that it undergoes substantial neurogenesis (the creation and integration of new neurons) throughout life (Knoth et al., 2010). This process has particular significance to stress (Schloesser, Manji, & Martinowich, 2009; Snyder, Soumier, Brewer, Pickel, & Cameron, 2011), affective modulation (Mahar et al., 2011; Perera et al., 2011; Santarelli et al., 2003; Snyder et al., 2011; J. W. Wang, David, Monckton, Battaglia, & Hen, 2008), and psychiatric phenotypes (Boldrini et al., 2013; Perera et al., 2011; Reif et al., 2006). It may also play an important role in the mechanism by which social inequality affects AL.

Hippocampal neurogenesis results in the continual addition of new granule cell neurons to the dentate gyrus (DG) of the hippocampus (see Kempermann, 2011, for review). These neurons originate from local neural stem cells, which produce rapidly amplifying neuronal precursors. Following several weeks of development, during which these cells differentiate into neurons and extend neurites, these immature neurons functionally integrate into existing DG circuits, contributing to hippocampal plasticity. In addition to constantly shaping the organization of DG circuitry, these cells also individually show increased plasticity in their firing activity relative to mature neurons (Ge, Yang, Hsu, Ming, & Song, 2007). Neurogenesis is modulated by a wide variety of factors, including exercise (Kiuchi, Lee & Mikami, 2012; Kronenberg et al., 2006; Trejo, Carro, & Torres-Aleman, 2001), sleep (Meerlo, Mistlberger, Jacobs, Heller, & McGinty, 2009; Mirescu, Peters, Noiman, & Gould, 2006; Mueller, Mear, & Mistlberger, 2011; Mueller et al., 2008), age (Knoth et al., 2010; Kronenberg et al., 2006; Kuhn, Dickinson-Anson, & Gage, 1996), diet (J. Lee, Duan, Long, Ingram, & Mattson, 2000; J. Lee, Duan, & Mattson, 2002; Lindqvist et al., 2006), neurotrophic factors (Aberg, Aberg, Hedbacker, Oscarsson, & Eriksson, 2000; Jin et al., 2002; J. Lee et al., 2002; Mahar et al., 2011; Schmidt & Duman, 2010), biological sex (Boldrini et al., 2009; Chow, Epp, Lieblich, Barha, & Galea, 2012; Perfilieva, Risedal, Nyberg, Johansson, & Eriksson, 2001), antidepressant medication (Boldrini et al., 2009, 2012; Malberg, Eisch, Nestler, & Duman, 2000; Perera et al., 2011), and (of particular relevance) stress (Dagyte et al., 2011; Elizalde et al., 2010; Jayatissa, Henningsen, West, & Wiborg, 2009; Mineur, Belzung, & Crusio, 2007; Perera et al., 2011).

In animal models, chronic stress induces depressive-like behavior and decreased hippocampal volume and hippocampal neurogenesis (Brummelte & Galea, 2010; Dagyte et al., 2011; Elizalde et al., 2010; Jayatissa et al., 2009; Mineur et al., 2007; Perera et al., 2011; Schmidt & Duman, 2010; Valente et al., 2012; Veena et al., 2009; Wong & Herbert, 2004). The latter is thought to result from the stimulation of GR receptors on neurogenic cells by cortisol, leading to decreased transforming growth factor-β-SMAD2/3 and hedgehog signaling and subsequent decreases in cell proliferation, neuronal differentiation, and survival (Anacker et al., 2012; Dagyte et al., 2011; Elizalde et al., 2010; Jayatissa et al., 2009; Mineur et al., 2007).

Neurotrophic factors, including insulin-like growth factor (IGF; Aberg et al., 2000), vascular endothelial growth factor (VEGF; Jin et al., 2002), and neuregulin-1 (NRG1; Mahar et al., 2011), also regulate adult hippocampal neurogenesis and affective behavior. They may also govern biological resilience or susceptibility to HPA axis dysfunction and psychopathology in the context of adverse life circumstances. Notably, brain-derived neurotrophic factor (BDNF) is thought to mediate the interaction between neurogenesis and stress (Suri & Vaidya, 2012). Indeed, hippocampal (including DG) BDNF levels: decrease following chronic stress (Shi, Shao, Yuan, Pan, & Li, 2010; Smith, Makino, Kim, & Kvetnansky, 1995a; Smith, Makino, Kvetnansky, & Post, 1995b); increase following antidepressant treatment (Altar, Whitehead, Chen, Wortwein, & Madsen, 2003; Czubak et al., 2009; Gersner, Toth, Isserles, & Zangen, 2010; Hanson, Owens, & Nemeroff, 2011; Musazzi et al., 2009; Nibuya, Morinobu, & Duman, 1995), and indirect modulate hippocampal neurogenesis and affect.

Specifically, higher BDNF levels are associated with increases in neurogenesis and antidepressant effects (Scharfman et al., 2005; Schmidt & Duman, 2010; Shirayama, Chen, Nakagawa, Russell, & Duman, 2002), whereas lower levels have been associated with decreased neurogenesis, depressivelike behavior, and behavioral insensitivity to antidepressants (Adachi, Barrot, Autry, Theobald, & Monteggia, 2008; Rossi et al., 2006; Sairanen, Lucas, Ernfors, Castren, & Castren, 2005; Taliaz, Stall, Dar, & Zangen, 2010). In addition, expression of Tropomysoin receptor kinase b or *TrkB*, the gene encoding the BDNF receptor, is required in hippocampal neuronal precursors (but not mature granule cells) for neurogenic

and behavioral responses to antidepressants (Y. Li et al., 2008). Finally, genetic alterations of BDNF or *TrkB* in humans have been associated with depression and altered antidepressant response as well as suicidal behavior and other psychopathology (Ernst et al., 2011, 2012; Licinio, Dong, & Wong, 2009; Perlis, Ruderfer, Hamilton, & Ernst, 2012). Thus, reduction of hippocampal BDNF levels and signaling represent an alternative putative mechanism by which increased stress reduces hippocampal neurogenesis.

Underlining the complex nonlinear network of interconnected allostatic mechanisms, an emerging body of research has revealed that mitochondria can function as neuromodulators (Picard & McEwen, 2014). Indeed, the very process of synaptic transmission that constitutes the foundation of current theories for brain function and cognition is modulated by the presence of mitochondria in presynaptic terminals (Ivannikov, Sugimori, & Llinas, 2013; T. Sun, Qiao, Pan, Chen, & Sheng, 2013; M. Vos, Lauwers, & Verstreken, 2010). A recent study further found that the morphology of PFC presynaptic mitochondria—which is contingent on their function and oxidative stress—correlated with synapse morphology and memory performance in living monkeys (Hara et al., 2014). Likewise, the genetic mixing of different types of mtDNA in mice resulted in severely impaired spatial learning and memory retention capacity, indicating that subtle bioenergetic changes have significant functional consequences on brain function and cognition (Sharpley et al., 2012). It is also noteworthy that several widely used drugs to treat affective spectrum disorder affect mitochondrial function (Gardner & Boles, 2011), and new-generation antidepressive agents also have preferential action on mitochondrial energy metabolism (Nasca et al., 2013). Mitochondrial remodeling of brain function is an emerging additional mechanism of great interest whereby environmental and biological factors can impact neuroplasticity.

Septotemporal Axis and Stress Response

As with the life cycle model of stress described earlier, the hippocampus has been extensively implicated in stress reactivity and HPA axis function (Herman et al., 2005; Pruessner et al., 2005, 2008; Schloesser et al., 2009), and hippocampal neurogenesis in particular has also been implicated in these functions (Schloesser et al., 2009; Snyder et al., 2011). The involvement of hippocampal neurogenesis in HPA axis function and stress response is likely related to its anatomy and functional connectivity. Specifically, the posterior hippocampus in humans (analogous to the dorsal hippocampus in rodents) is associated with learning and memory, and projects to the lateral septum (O'Keefe & Nadel, 1978), whereas the anterior hippocampus (ventral in rodents) is more involved with affective functions, and connects to the PFC, amygdala, and, most relevantly, the paraventricular nucleus of the hypothalamus via the bed nucleus of the stria terminalis (Bannerman et al., 2004; Fanselow & Dong, 2010). Notably, long-term plasticity in the ventral hippocampus in animals is selectively affected by stress and glucocorticoids (Maggio & Segal, 2007), and lesions to areas of this subregion specifically projecting to the hypothalamus induce changes in stress regulation (Nettles, Pesold, & Goldman, 2000).

Hippocampal neurogenesis has been extensively implicated in stress modulation. More specifically, chronic stress has been demonstrated to decrease neurogenesis in the ventral hippocampus (Elizalde et al., 2010; Jayatissa, Bisgaard, Tingstrom, Papp, & Wiborg, 2006; Jayatissa, Bisgaard, West, & Wiborg, 2008; Tanti, Rainer, Minier, Surget, & Belzung, 2012), whereas increases in neurogenesis restricted to the same subregion have been associated with antidepressantlike effects as well as normalization of hippocampal GR expression following stress (Mahar et al., 2011; Paizanis et al., 2010). Conversely, the ablation of neurogenesis disrupts HPA response to stress (Schloesser et al., 2009; Snyder et al., 2011) and prevents antidepressants from normalizing hippocampal HPA axis regulation in response to chronic stress (Surget et al., 2011). Taken together, these studies support the role of ventral (anterior in humans) hippocampal neurogenesis in regulating HPA axis activity via its connections to the paraventricular nucleus of the hypothalamus. This finding suggests that chronic stress-induced decreases in neurogenesis decrease hippocampal suppression of the HPA axis, leading to increased GC secretion in response to stress, further suppressing neurogenesis, causing HPA dysregulation and ancillary deleterious effects.

By extension, an initial deficit in neurogenesis could predispose individuals to HPA axis dysregulation following chronic stress, and proneurogenic factors could act as prophylaxis against neurogenesis-related HPA axis dysregulation following stress. If individuals experiencing social inequality are indeed vulnerable to HPA axis dysregulation, as discussed, they in particular might benefit from proneurogenic interventions, such as antidepressant medication or exercise, in order to prevent or reverse neurogenesis deficit–related HPA axis dysregulation. Thus, prestress levels of hippocampal neurogenesis may serve as a vulnerability/resiliency factor to the stress-related effects of social inequalities and other diverse stressors.

Social Inequalities and Neurogenesis

To the extent that social inequality affects HPA axis activity, the effects of social inequality on AL are likely exacerbated through the suppression of hippocampal neurogenesis and resulting HPA axis dysregulation. As such, it is critical to determine the extent to which social inequality increases glucocorticoid secretion and HPA axis dysregulation. Animal models of social stress have revealed that social defeat decreases hippocampal neurogenesis (see Schoenfeld & Gould, 2012 for review) and induces submissive behavior (Vivian & Miczek, 1999). In addition, environmental enrichment facilitates recovery from social stress–induced submissive behavior through a neurogenesis-dependent mechanism (Schloesser, Lehmann, Martinowich, Manji, & Herkenham, 2010).

Although it remains to be demonstrated in human studies that social inequality itself is directly associated with decreased hippocampal neurogenesis, human social inequality and societal disadvantage have been shown to provoke abnormal physiological stress responses and HPA axis dysregulation. These social adverities have included, for example, low childhood SES (Lupien et al., 2001), childhood abuse (Cicchetti & Rogosch, 2001; Cicchetti et al., 2010), low maternal care (Pruessner, Champagne, Meaney, & Dagher, 2004), psychiatric illness (Staufenbiel, Penninx, Spijker, Elzinga, & van Rossum, 2012), low self-esteem (Pruessner, Hellhammer, & Kirschbaum, 1999; Pruessner et al., 2005), caregiver burden (Davis et al., 2004; de Vugt et al., 2005), minority sexual orientation (Huebner & Davis, 2005; Juster et al., 2013b), and perceived racial discrimination (Fuller-Rowell, Doan, & Eccles, 2012; Zeiders, Doane, & Roosa, 2012). One mechanism by which social inequality may affect AL is by decreasing hippocampal neurogenesis (particularly in the anterior hippocampus). This would ultimately lead to decreased inhibition of the HPA axis (specifically via the *paraventricular nucleus* of the hypothalamus), resulting in increased glucocorticoid release and further HPA axis dysregulation through neurogenic and nonneurogenic mechanisms.

In conclusion, human hippocampal neurogenesis in the specific context of social inequalities has yet to be examined. This is due in part to the difficulty of assessing neurogenesis in vivo as well as a paucity of postmortem samples from individuals characterized by their stressful exposure to chronic social inequality. However, as techniques for measuring neurogenesis advance and as large-scale longitudinal cohorts potentially lead to the collection of more thoroughly characterized postmortem brain samples, future studies should be well positioned to confirm or revise the hypothesis that the effects of social inequality on subsequent HPA axis dysregulation are exacerbated or mediated by decreases in hippocampal neurogenesis. Further research into hippocampal neurogenesis may also contribute to our understanding of the effects of glucocorticoid neurotoxicity on hippocampal volume and cognitive functioning in elders (Lupien et al., 1998) as well as the factors driving morphological hippocampal changes throughout life (Lupien et al., 2007; Lupien et al., 2009). Along these lines, our next and final section of this part of the chapter explores the concept of cognitive reserve as a form of cognitive resilience in old age and is of importance for future AL research.

Cognitive Reserve

Aging is often associated with cognitive impairment and worsening health that is consistently associated with increasing AL. Yet a considerable degree of variability in cognitive performance as well as health status exists among older adults (Mattson, Chan, & Duan, 2002; Rowe & Kahn, 1997; Wilson et al., 2002a). Epidemiological studies have consistently shown that life experiences are associated with risk for cognitive impairments (Fratiglioni, Paillard-Borg, & Winblad, 2004; Scarmeas, Levy, Tang, Manly, & Stern, 2001; Stern, 2012). To address this probabalistic process the notion of cognitive reserve helps account for interindividual differences in the risk for dementia in the presence of brain pathology and the various factors that may allow one's brain to respond appropriately to pathology and postpone the onset of symptoms (Stern, 2002; Whalley, Deary, Appleton, & Starr, 2004). It is believed that individuals with more cognitive reserve are able to tolerate more pathology prior to the appearance of symptoms, representing an important form of cognitive resilience in the face of aging and AL. This adaptation may occur through the use of neuronal compensatory mechanisms and the use of existing cognitive processes established by the individual (Stern, 2002), which we explore in this section before concluding with clinical and social implications.

Various factors throughout life span development contribute to enhanced cognitive reserve that buffers the adverse biological effects of senescence. First, higher educational attainment consistently plays a protective role in epidemiological studies, whereas low educational attainment increases the risk for dementia and Alzheimer's disease (Karp et al., 2004; Launer et al., 1999; Ngandu et al., 2007; Ott et al., 1995; Qiu, Backman, Winblad, Aguero-Torres, & Fratiglioni, 2001). Similarly, benefits are

observed among healthy older adults, such that those with higher educational attainment show a slower rate of cognitive decline compared to those with fewer years of formal education (Chodosh, Reuben, Albert, & Seeman, 2002; Cullum et al., 2000). As described earlier, this finding is consistent with a large body of research linking lower SES to higher AL among different social groups throughout the life span.

An important factor that contributes to cognitive reserve is occupational attainment and skill sets exercised during working adulthood. Specifically, job complexity is an extremely important factor in light of the extensive amount of time people engage in work and work-related activities throughout adulthood. Some studies show that jobs consisting of manual work increase the risk for dementia in comparison to nonmanual jobs (Bonaiuto et al., 1995; Mortel, Meyer, Herod, & Thornby, 1995). The nature of job demands may also protect against dementia and Alzheimer's disease; those requiring the use of extensive vocational training, academic skills, and complex work are protective due to their high mental demands (Andel et al., 2005; Kroger et al., 2008; Potter, Helms, Burke, Steffens, & Plassman, 2007), while results are mixed when it comes to job complexity (Andel et al., 2005; Kroger et al., 2008; Potter et al., 2007). Moreover, the risk for cognitive decline is higher among individuals with both low educational and occupational attainment (Stern et al., 1994). In line with this finding, a recent study revealed that older women with low psychological demands at work experience elevated levels of AL (Juster et al., 2013a). Taken together, demanding jobs may function as a form of mental exercise, consistent with the use-it-or-lose-it principle (Katzman, 1995).

Although educational and occupational attainment are factors that occur earlier during working adulthood, experiences later in life can also play a marked role in decreasing the risk for dementia (Stern, 2009). For example, participating in leisure activities—especially those that are cognitively stimulating—can promote cognitive capacities and reduce the risk for dementia (Crowe, Andel, Pedersen, Johansson, & Gatz, 2003; Scarmeas et al., 2001; Wilson et al., 2002b). Benefits are also observed among patients with Alzheimer's disease (Friedland et al., 2001; Kondo, Niino, & Shido, 1994). A systematic review demonstrates that the protective effects of leisure activities are observed even after controlling for factors such as age, health status, education, and occupation (Valenzuela & Sachdev, 2006). Importantly, engaging in leisure activities postpones cognitive impairment and slows the rate of decline among individuals who eventually develop dementia (Crowe et al., 2003; Scarmeas, Albert, Manly, & Stern, 2006; Stern, Albert, Tang, & Tsai, 1999; Wilson et al., 2002b).

Despite the strong evidence for the benefits of higher cognitive reserve, it is noteworthy that patients with Alzheimer's disease who have higher cognitive reserve show accelerated progression of symptoms and more rapid cognitive decline (Scarmeas et al., 2001, 2006; Stern et al., 1999). This finding suggests that cognitive reserve might play an important role in "masking" existing pathology while postponing the appearance of clinical symptoms until the underlying pathology becomes more severe (Stern, 2006). Future research could investigate this paradox further by assessing how cognitive reserve manifests among diverse social strata and whether this mechanism corresponds with specific biological signatures of AL and thresholds of severity linked to neuropathology and clinical symptoms.

Neuroimaging Cognitive Reserve

Imaging studies using various techniques support the protective role of cognitive reserve. The first studies investigated cerebral blood flow, which decreases among patients with Alzheimer's disease (Hirao et al., 2005; Kogure et al., 2000). Findings showed that patients with higher cognitive reserve (based on educational attainment) showed dampened overall cerebral blood flow compared to patients matched for clinical severity (Stern, Alexander, Prohovnik, & Mayeux, 1992). Similar findings have been shown as a function of occupational attainment and leisure activities (Alexander et al., 1997; Perneczky et al., 2006; Scarmeas et al., 2003; Stern et al., 1995). Collectively, these studies indicate that those with higher cognitive reserve are able to resist senescence while showing similar clinical symptoms (Alexander et al., 1997; Bennett et al., 2003; Perneczky et al., 2006; Stern, 2009). Education, occupational attainment, and leisure activities may also interact with each other to enhance the protective role they each play individually.

Functional magnetic resonance imaging (fMRI) studies investigating neural compensatory mechanisms have found two separate networks used when performing a working memory task. The more efficient structure, the left precentral gyrus, is used by both young and older adults, whereas the less optimal structure, in the left precentral region of the supplementary motor area, is used only by older adults and is predictive of poorer performance (Steffener, Brickman, Rakitin, Gazes, & Stern, 2009). This finding is hypothesized to be due to the fact that the first network no longer functions as effectively during aging, and this fact is partially compensated for through the increased use of

the second network; however, it does not necessarily result in comparable memory performance (Stern, 2012). It also appears that individuals with higher cognitive reserve can withstand more atrophy in the first network and maintain cognitive performance, avoiding or delaying the need to resort to the second network (Steffener, Reuben, Rakitin & Stern, 2011). Among users of the second network, those with higher cognitive reserve show better cognitive performance than those with low cognitive reserve (Steffener et al., 2011). Whereas higher cognitive reserve is associated with less activation when performing a memory task in healthy older adults, more activation was observed among individuals with mild cognitive impairment and Alzheimer's disease (Sole-Padulles et al., 2009). In sum, more effective neural mechanisms are present among those with higher cognitive reserve (Stern, 2012).

Structural MRI studies also tend to support that notion of cognitive reserve. Importantly, atrophy of the hippocampus is a marker for dementia and Alzheimer's disease (Barnes et al., 2009). In one longitudinal study, more frequent lifelong engagement in complex activities was associated with a lower magnitude of hippocampal atrophy measured 3 years later (Valenzuela, Sachdev, Wen, Chen, & Brodaty, 2008). In one longitudinal study, more frequent lifelong engagement in complex activities in working adulthood was associated with a lower magnitude of hippocampal atrophy over time (Valenzuela et al., 2008). Such activities were related to education, occupation, reading and writing, creative arts, socializing, and daily habits during young adulthood (13–30 years of age), middle age (30–65 years), and older adulthood (65 years and above). Similarly, hippocampal-dependent neuroplasticity is found among London, UK, taxi drivers who undergo intensive training in order to navigate through complex routes (Maguire et al., 2000). In a landmark study, their posterior hippocampi were found to be larger than those of age-matched controls. These studies provide parallel evidence for the beneficial role of experience-dependent hippocampal plasticity that may potentiate cognitive reserve.

Cognitive reserve has also been examined in relation to beta-amyloid, a protein that appears to accumulate in Alzheimer's disease (Ghiso & Frangione, 2002). Patients with higher educational attainment perform better than expected on cognitive tasks than would be otherwise expected considering their elevated beta-amyloid levels (Roe et al., 2008), highlighting a protective pathway against dementia-related pathophysiology (Kemppainen et al., 2008). This is an excellent example of biological and cognitive resilience as promoted by higher educational attainment that could be explored further in future AL research on geriatric neurobiology. Further identifying protective factors against AL and disease will illuminate our understanding of trajectories toward resilience to age-related diseases.

Another important recurring protective factor in this chapter that may prevent or delay dementia onset is physical exercise. The performance of aerobic activities among healthy older adults can prevent cognitive impairment (Kramer & Erickson, 2007) and may therefore represent a factor that promotes cognitive reserve and biological resilience. Whereas epidemiological studies demonstrate that inactivity increases the risk for cognitive impairment and Alzheimer's disease (Andel et al., 2008; Larson et al., 2006), evidence from clinical randomized trials shows that aerobic activities can reverse cognitive decline prior to the development of dementia (Colcombe et al., 2006; Kramer et al., 1999). Consistently, meta-analyses and reviews on exercise find that it improves cognitive performance among individuals with mild cognitive impairment and Alzheimer's disease. Specific cognitive benefits have been observed for memory performance, attention, executive functioning, and processing speed (Heyn, Abreu, & Ottenbacher, 2004; P. J. Smith et al., 2010).

Neuroimaging studies likewise reveal that aerobic fitness is associated with larger hippocampal volume and better memory performance among older adults (Erickson et al., 2009). In one study, exercise training increased hippocampal volume over the course of a year, whereas in the control group, a decrease in hippocampal volume was observed (Erickson et al., 2011). Interestingly, the augmentation in hippocampal volume was associated with higher levels of BDNF (a marker that tends to be reduced among Alzheimer's patients; Peng, Wuu, Mufson, & Fahnestock, 2005). Aerobic exercise also increases gray and white matter volume in the PFC and improves executive functioning (Colcombe et al., 2004, 2006; Rosano et al., 2010) as well as whole-brain volume among Alzheimer's patients (Burns et al., 2008). These studies demonstrate that aerobic exercise has important benefits for cognitive aging. In the broader context of resilience, it would be very interesting for future research to assess whether these associations are observed in older adults exposed to adverse life conditions.

Another important factor recurring throughout this chapter is social support, which consists of a quantitative component (the number of individuals in one's social network) and a qualitative component (the quality of relationships, frequency of socialization, and the perception of available social and emotional support). Both dimensions of one's social network protect against

cognitive impairment in senescence (Seeman, Lusignolo, Albert, & Berkman, 2001a). Large community-based studies show that having few social contacts and, in particular, being unsatisfied with the quality of contacts is associated with increased risk for dementia (Fratiglioni, Wang, Ericsson, Maytan, & Winblad, 2000), whereas more frequent participation in social and mental activities decreases risk for dementia (H. X.Wang, Karp, Winblad, & Fratiglioni, 2002). Additional support for this association has been provided by various longitudinal studies (Bassuk, Glass, & Berkman, 1999; Fratiglioni et al., 2004; Seeman et al., 2001a).

In conclusion, higher cognitive reserve decreases the risk for dementia (by up to 50%; Valenzuela & Sachdev, 2006). Importantly, while formal education and occupational attainment may be relatively fixed by older adulthood, findings demonstrate that engagement in stimulating cognitive and social activities in older adulthood can independently play protective roles (Valenzuela & Sachdev, 2006). Collectively, evidence suggests that engagement in social, mental, and physical activities, in addition to having adequate social support, can protect against dementia in late life, and this finding provides an important avenue for prevention efforts (Fratiglioni et al., 2004; Stern, 2012). The concept of cognitive reserve represents an important construct in our discussion of resilience that we believe future AL studies could help progress by further assessing specific biological processes involved.

CONCLUSIONS

Clinical Implications

The AL model has the potential to become a powerful tool in clinical contexts. Perhaps the most promising approach would involve tracking changes over time in AL to examine the efficacy of clinical interventions using transdisciplinary perspectives informed by triangulated combinations of biometrics, psychometrics, and sociometrics. As future studies further our understanding of which configurations of risk factors and protective factors potentiate pathways toward resilience, it will be imperative to design prospective studies tailored to reduce AL. To date, however, no treatment options aimed at lowering AL levels exist. Nevertheless, many therapeutic options could be implemented based on the antecedents associated with AL and its clinical repercussions (see Figure 8.1). The vast array of identified risk factors and protective factors associated with vulnerability toward or resilience against AL provide scientist-practitioners with a wealth of information to help guide targeted interventions in the future.

Notwithstanding, interventions attempting to reverse developmental trajectories from vulnerability toward resilient pathways may be much more complicated than simply switching risk factors into protective factors at micro- to macro-levels (e.g., hypercortisolism to hypocortisolism, physical inactivity to activity, low to high SES, etc.). Although it cannot be denied that an accumulation of protective factors promotes health and well-being, resilience as defined from a developmental psychopathology perspective implicates some history of risk factors related to adversity, stress, and/or trauma that have been modulated to allow individuals to thrive and survive, even if specific adaptations can come at a cost in other domains (e.g., academic performance and AL in John Henryism). This reality highlights the importance of trandisciplinary approaches to interventions orchestrated by teams of professionals (e.g., nurses, psychologists, psychiatrists, social workers, nutritionists, educators, etc.).

A key question outlined by McEwen (2007, 2012) is whether approaches to reducing AL levels are best tailored in relation to top-down modifications versus conventional biomedical remediation. At an individual level, brain-centered programs that encourage improved sleep quality and quantity, social support, sense of purpose, self-esteem, healthy diet, substance avoidance, and physical activity would be undoubtedly beneficial. Interventions at social levels might include policies that create incentives for beneficial or best practices in the workplace, cleaner and safer neighborhoods, and encouraging advanced education. Specifically for the elderly, well-being therapy emphasizing autonomy, purpose in life, personal growth, positive relations with others, environmental mastery, social activities, and self-acceptance could be coupled with more traditional cognitive and physical interventions. Assessing changes in AL provides a powerful, multisystemic means to assess salubrious processes in a comprehensive manner amenable to clinical investigation (McEwen, 2012).

To the best of our knowledge, no studies have assessed intervention effects on AL. Notably in an analysis of unaccountable changes in AL levels in the MacArthur cohort over the span of 2 to 5 years, deceases in AL were significantly related to reductions in all-cause mortality regardless of one's sex (Karlamangla, Singer, & Seeman, 2006). An important consideration is whether any decrease in AL is random, or whether could there be distinct neuroendocrine, immune, metabolic, or cardiovascular

system(s) driving downward and/or upward shifts. It will be important for future studies to determine what combinations of health-promoting and damaging factors correspond to AL and systemic clustering at different ages and among different social groups that cope with stress in diverse ways. As described in this chapter, the direction of these interacting risk and protective factors is complex and at times contradictory. For instance, one report found that African Americans—but not Caucasians—who self-reported increased environmental stressors and engaged in more unhealthy behaviors (e.g., overeating) had lower levels of depression but an overall greater risk of chronic physical conditions (Jackson, Knight, & Rafferty, 2010). Thus, it is possible that unhealthy behaviors have different modulatory effects depending on sociocultural factors. Identifying salubrious pathways could help guide health care approaches that are recognizing of the fact that one glove does not fit all.

Throughout life span development, behavioral modification is complex and multifaceted but ultimately essential for reducing AL. In the context of the obesity epidemic, for example, interacting factors such as poor sleep hygiene, sedentary behaviors, and pollution are ubiquitous in modern societies and can compromise the efficacy of dieting among obese individuals (Tremblay & Chaput, 2012). Such unhealthy behaviors can also exacerbate interacting genetic and behavioral vulnerabilities. For instance, a novel study of Puerto Rican adults living in the United States showed that genetic polymorphisms related to lipid metabolism were only related to AL in interaction with unhealthy dietary intake (Mattei, Bhupathiraju, & Tucker, 2013). This finding has important implications for advancing our understanding of acculturation effects among different groups that can be compounded by intersecting social pressures. By the same logic, identifying and informing individuals with genetic vulnerabilities that specific diets are especially dangerous based on their constitution and circumstances is an important preventive approach that must be considered in the evolution of person-centered health care and consultation. Given cultural differences in dietary intake, and given the links among genetics, metabolism, and diet to name a few, future studies could assess associations among stress, diets, and AL in various social groups and between the sexes over life span development.

Another important health behavior is sleep-related behaviors that regulate allostatic mechanisms (e.g., circadian clocks) and AL levels (Karatsoreos & McEwen, 2011; McEwen, 2006). Following sleep restriction, elevations in AL biomarkers occur (decreased glucose tolerance, increased evening cortisol, increased sympathetic activity); however, these allostatic processes are particularly pronounced for low-SES individuals who consequently experience increased risk of sleep problems, obesity, diabetes, and hypertension (Van Cauter & Spiegel, 1999). More broadly, researchers studying stress-related phenomena should account for sleep, given its important bidirectional association to psychiatric symptomatologies. Measuring AL in such investigations would provide important information for stress and sleep researchers alike who are studying overlapping mechanisms.

Advances in neuroscience are also providing compelling insights into complex pathways of biological resilience wherein brain plasticity is modulated by behavior and environment (McEwen & Gianaros, 2011). For example, French stroke patients treated early with antidepressant medication in conjunction with physiotherapy experience better recovery of motor deficits over time (Chollet et al., 2011). In the spirit of "stress inoculation," short periods of food restriction in rats predictably increases stress hormone levels, but in a positive manner that can help cure amblyopia (lazy eye) otherwise considered irreversible (Chollet et al., 2011). Whereas the mechanisms involved require further elucidation, the concept of *hormesis*, that is, evolutionarily conserved biological patterns wherein mild stressors can buffer against noxious effects of subsequent stressors (Pijl, 2012), provides some insights. Studying how hormesis might function vis-à-vis mitochondrial sustainability, neurogenesis proliferation, or cognitive reserve and other biopsychosocial processes that ultimately foster resilience is a fascinating frontier for future AL research.

As AL represents multisystemic, subclinical physiological dysregulations often predating the emergence of clinical outcomes, treatment options targeting psychological, behavioral, cognitive, and social domains discussed in this chapter could be alternatives or complements to biomedical approaches (Juster & Lupien, 2012b). These clinical approaches could perhaps even improve compliance and facilitate proactive prevention instead of reactive prescription. Indeed, we strongly believe that implementing person-centered approaches to diminishing AL collectively represents viable alternatives or complementary approaches to pharmacological strategies. For instance, the effects of chronic stress can be improved via pharmaceutical agents such as sleep medications, anxiolytics, antidepressants, and beta-blockers as well as by drugs that reduce oxidative stress and inflammation such as statins, insulin resistance treatments, and painkillers (McEwen, 2007). Yet there are counterarguments against pharmaceutical remediation, especially as polypharmacy

relates to the widespread systemic dysregulations inherent in AL. In Sterling and Eyer's (1988) original formulation of the allostasis concept, they argued that medical practices based on homeostatic models were in danger of potentially damaging side effects and polypharmacy, as treatment problems can arise when correcting one parameter causes other systems to become dysregulated (Sterling, 2004).

Allostatic regulatory systems interact in a hierarchical, dynamic, and nonlinear manner in response to stressors that prompt compensatory behaviors. From this perspective, lifestyle choices can be considered as "higher-order" allostatic mechanisms activated in reaction to external and internal cues. As such, maladaptive behaviors have the propensity of increasing AL levels even further. Taken together, unhealthy lifestyle behaviors may often represent behavioral compensatory mechanisms used to counteract negative affective states related to inherent neurobiological predispositions. From this perspective, these coping behaviors are allostatic mechanisms because they compensate for dysfunction, but ultimately at the expense of long-term health. With this in mind, therapeutic interventions targeting either specific neural pathways or the substitution of damaging behaviors for less or nondamaging ones (e.g., physical exercise, dietary restriction) would be beneficial.

In addition, several psychotropic agents seem to interact with illness-related predispositions to synergistically worsen some unhealthy lifestyle behaviors and ultimately induce a type of "pharmacological" AL. As first described by our group (Juster et al., 2011), *pharmacologicalcal AL* (PAL) refers to the adverse effects medications can exert that then inadvertently prompt individuals to remediate the biological system(s) affected by unhealthy means . For example, smoking is often used to dampen adverse side effects of antipsychotic medications among those with severe mental illnesses, such as schizophrenia or bipolar disorder, but this compensatory behavior further amplifies AL levels (Bizik et al., 2013). Such behavioral side effects represent maladaptive allostatic mechanisms whereby individuals strive to reregulate medicinally altered neurotransmitter functions linked, for instance, to cognition and motivation. We propose that using AL indices could provide insights into PAL in the context of psychiatric remediation (Bizik et al., 2013). To quote Jackson and colleagues (2010): "[S]uccessful interventions to reduce the use of unhealthy coping behaviors over the life course among populations living under chronically stressful conditions depend upon the recognition that such behaviors may have adaptive, neurological effects that alleviate negative psychological and physiological states." (p. 7).

The PAL concept goes beyond the known side effects of psychopharmacology; it endeavors to understand how interventions meant to treat primary diagnoses inadvertently prompt physiological dysregulations and comorbidities via patients' behavioral compensations. We propose that applying the AL model to the interpretation of the results from standard laboratory reports can provide medical professionals with a sensitive tool to monitor patients' global response to treatment (Bizik et al., 2013; Juster & Lupien, 2012b). The PAL concept also constitutes an advantage compared to focusing solely on numerous known side effects because it provides a global measure that subsumes the direct effects of the primary pathology, treatment, the effects of maladaptive compensatory behaviors, as well as other as-yet unidentified contributors to AL. Given that many of the biomarkers collected in routine blood work are the same as those used in constructing AL indices, applying simple calculations could be easily integrated into a typical clinical follow-up (Juster & Lupien, 2012b).

AL indices can also serve as a starting point for a discussion between the patient and the health practitioner regarding adaptive behaviors and prevention of the development of negative sequelae related to the illness and its treatment (Bizik et al., 2013). Moreover, from an empirical standpoint, it is not yet known what constitutes critical levels of AL and how such thresholds could be used to predict specific stress-related conditions. For example, does an AL score greater than 5 represent a critical threshold for developing cardiovascular disease, and which biomarkers are more important? Because the AL index is an objective reflection of biological functioning that is intricately interconnected with genetic, neurological, developmental, behavioral, cognitive, and social factors, AL captures complex interactions that cannot be easily deduced until clinical research is conducted. Ideally, the richness of data collected in clinical practice by various professionals could be compiled and explored in relation to AL levels.

All individuals have the capacity for considerable resilience in the face of adversity via beneficial processes and the appropriation of protective factors. In identifying salubrious pathways, greater appreciation must be exercised in our search for the biological mechanisms that drive resilience and how these can be harnessed to improve health (McEwen, 2003). The stress of inequality may manifest at a cellular or subcellular level, and understanding this relationship may drive further efforts in preventing and treating the pernicious effects of inequality on AL and its clinically relevant phenotypes. As explored next at a societal level, reducing social inequalities should

also minimize conditions that elevate AL, thus preventing disease onset or progression.

Social Policy Implications

The AL model could be used at a macro-level to inform public health and the implementation of social policies. Daniels, Kennedy, and Kawachi (2000) have argued that reducing socioeconomic gradients and providing equal opportunities to all members of society will produce dramatic health benefits. Using AL algorithms to assess the efficacy of an intervention or policy could be a powerful way to substantiate this proposal. AL increases the risk of developing morbidities that currently burden population health worldwide to a disproportionate degree. The array of mediators and moderators constituting AL represents a physiological mechanism at the heart of socially determined health inequalities. We propose that knowledge derived from the AL model can provide policymakers with tools to help prioritize and substantiate tentative public health interventions aimed at reducing social inequalities in population health. By quantifying changes in AL over time, policymakers can also determine the efficacy of such policies. In so doing, public health officials may curb growing inequalities and monitor progress in programs that promote health. Ultimately, the biological sciences need to provide policymakers with the much-sought-after causal links for these effects and with the tools necessary to effectively evaluate health and well-being (McEwen, 2001). Our overview on social inequalities influencing AL provides a biological bridge linking social injustice to health inequalities.

Although social contexts are generally measured using aggregates of individuals, diseases occur at the level of the individual, making it very difficult to assess the impact of social policy implementation (Thisted, 2003). Advances in biological sciences should therefore be applied to tease apart the factors that contribute to the paradox that while we generally live longer, health and wealth are shared so unequally. Policies often fail to attend adequately to determinants of health upstream from the provision of medical interventions (Daniels, Kennedy, & Kawachi, 2000) like those discussed in our previous section on clinical implications. Furthermore, there is growing recognition within numerous disciplines that significant risk factors associated with developing numerous pathologies are socially determined (Marmot, 2005).

Likewise, Daniels, Kennedy, and Kawachi (2000) proposed that suboptimal aggregate health measures result from unnecessary differentials in the distribution of resources among social classes. The current means by which societies allocate resources within their populations is therefore a key contributor to socioeconomic gradients in disease (Daniels et al., 2000). As social inequalities are bad for our health and are socially constructed, differentials in health measures would undoubtedly lessen through a more equal reorganization of society. Knowledge generated by the AL model at theoretical and empirical levels expands epidemiological evidence of population health inequalities. Complementarily, social justice focuses on the premise of equality of opportunity. Social and political institutions should mitigate the effects of social inequalities that prevent less fortunate members of society from obtaining equal health opportunities and chances to flourish in life.

Importantly, there are potential critical periods to identify and prevent individuals from developing elevated AL. Indeed, findings from the large-scale NHANES reveal that AL steadily increases with age up through the 20s to 60s and then plateaus throughout the 60s to 90s, during the period of greatest mortality risk (Crimmins et al., 2003). From life course perspectives, these trajectories represent decades-long windows of opportunity to intervene before individuals succumb to disease and death. Could there be windows of opportunity for best periods in life to develop resilience in specific life domains that could minimize AL? Despite sensitive periods that occur early on in life during critical windows of development, positive health can be achieved at any age (Cicchetti, 2013).

The best way to assess the real impact of interventions on AL would be to measure their potential for changes at different ages, different sexes, different SES, and different cultures internationally. It is also important to recognize the potential to improve health and well-being at every life stage. For example, a fMRI study of African American older women of lower SES who were at risk of cognitive deterioration showed improvements in left PFC and anterior cingulate cortex functioning matched by behavioral improvements in executive functioning 6 months after volunteering in the social service Experience Corp. program compared to wait-list controls (Carlson et al., 2009). This finding has important implications for the implementation of interventions that can target social inequalities and age-related cognitive deterioration even in late life.

To summarize the implications for the field of developmental psychopathology, the AL model has proven powerful in explaining the pervasive and long-lasting consequences of social inequalities on physical and mental health. In many ways, the AL model adopts numerous principles guiding developmental psychopathology. For example, it focuses on bidirectional transactions

occurring between the individual and the environment, and it proposes progressive rather than discrete transitions between normal/adaptive responses (allostasis) and pathological states (AL and allostatic overload). Moreover, it emphasizes the cumulative and synergic impacts of changes occurring at multiple levels of analysis, including vertical- and horizontal-level interactions. Furthermore, the AL model follows transdisciplinary perspectives (Juster et al., 2011) and process-oriented approaches that provide explanations for underlying differences between individuals exposed to similar life circumstances (multifinality). All of these constructs are considered conceptual landmarks in developmental psychopathology (Cicchetti, 2013).

In conclusion, the AL model originated with the study of vulnerabilities to stress-related disease and has recently evolved to include approaches toward greater understanding of resilience. This paradigm shift is important for three key reasons. First, AL studies of resilience are consistent with a central tenet in developmental psychopathology over and above those just mentioned; that is, that probabilistic pathways toward vulnerability or resilience fall along a continuum over life span development. Second, a focus on resilience to AL allows researchers to further identity protective factors integral to biological integrity despite preexisting risk factors associated with life histories of stress, strain, and stigma. And third and most broadly, scientific investigations that can reveal success stories among socially marginalized groups represent an important platform from which to change social perspectives. If the majority of individuals can learn of the remarkable resilience exemplified by hardy individuals exposed to social inequalities, a connectedness between social groups is fostered. This connection is otherwise more difficult to achieve with doom-and-gloom perspectives focused solely on vulnerabilities to AL since it overlooks the inspiring potential among all people to change their destiny.

A core theoretical feature of developmental psychopathology is the simultaneous consideration of normal and abnormal development; this is historically prominent and ongoing to the present day, shaping research agendas for the future (Cicchetti, 1984, 2013; Rutter & Sroufe, 2000; Sroufe & Rutter, 1984). The developmental psychopathology perspective comprises several tenets that guide investigation, including a focus on processes that unfold over time, a consideration of interactions across multiple levels of analysis, and an appreciation for diverse developmental pathways through concepts of equifinality and multifinality (Cicchetti, 2006, 2013; Cicchetti & Rogosch, 1996; Masten, 2006; Pickles & Hill, 2006). Based on these foundational tenets, in this chapter we review the interrelations of adaptive and maladaptive functioning, broadly considered. Rather than focus on one specific mental disorder or diagnostic category, we detail theory and evidence on associations among prominent domains of competence (e.g., academics, social relationships) and broad dimensions of psychopathology (e.g., internalizing and externalizing symptoms) in youth. Several specific diagnostic categories of psychopathology are considered in the process. Overall, we aim to provide a review of empirical work detailing the nature of these associations as well as theoretical and methodological discussion of how one might interpret the empirical findings.

The chapter is divided into three main sections. First, we briefly review historical and theoretical discussions of the concept of competence, particularly from a developmental tasks framework. Second, in the central part of the chapter, we discuss empirical reports on the links between competence and psychopathology, working from two main traditions: (1) classification systems for mental illness, in which competence can be considered the opposite of functional impairment, and (2) statistical models relating competence and psychopathology, with attention to details of analytic methodology as well as common substantive findings. The latter section focuses particularly on a class of longitudinal mediation models termed cascade models (Masten & Cicchetti, 2010). Finally, we consider the literature on competence-promoting prevention and intervention programs, with a prominent focus on results from randomized controlled trials, which has the potential

Acknowledgments: We thank Glenn I. Roisman and Michael F. Troy for comments on a prior version of this chapter.

to provide both crucial practical benefits to youth as well as rigorous testing of causal claims.

DEFINING COMPETENCE AND PSYCHOPATHOLOGY: HISTORICAL LEGACIES AND THEORETICAL WORK

Here we briefly recapitulate selected key developments in the evolution of thinking on competence and psychopathology; for more detailed discussions, please see the two prior editions of this chapter (Masten, Burt, & Coatsworth, 2006; Masten & Coatsworth, 1995). Definitions of psychopathology have evolved considerably since the mid-twentieth-century advent of the *Diagnostic and Statistical Manual* of the American Psychiatric Association (the *DSM* system), but debates continue on the nature of mental disorder, in particular to what extent mental illness can be conceptualized as categorically versus continuously distributed in the population (Coghill & Sonuga-Barke, 2012; Pickles & Angold, 2003) and how best to assess the core features of disorder, especially for some youth whose problems may be more distressing to family members or school personnel than to themselves. We consider definitional issues of mental disorder further later.

We have previously presented a working definition of competence as "a family of constructs related to the capacity or motivation for, process of, or outcomes of effective adaptation in the environment, often inferred from a track record of effectiveness in age-salient developmental tasks, and always embedded in developmental, cultural, and historical context" (Masten et al., 2006, p. 704). This definition is indebted to historical work on developmental tasks: the adaptive, age-related criteria by which cultures, families, and individuals judge how well development is proceeding (see McCormick et al., 2011). The concept of developmental tasks was advanced significantly by educational theorist Robert Havighurst's (1972) work on the idea of a progression of achievements that children, adolescents, and adults are expected to accomplish by members of the broader society. Developmental task theories are in turn based partly on (a) earlier psychoanalytic work on the resolution or persistence of psychosocial crises in an individual progression through specific stages (Erikson, 1968); and (b) work on ego psychology and personality development that focused on the integration of cognition, affect, and behavior (Loevinger, 1966) and constructs of ego control and ego resiliency (Block & Block, 1980). The latter two constructs describe not only the effective modulation of impulses but also the flexible control of that modulation.

In addition, the history of developmental tasks research owes a substantial debt to work on intellectual functioning in youth, which has had a strong focus on assessing the ability of children to act effectively in their particular environmental context (Binet & Simon, 1905; Charlesworth, 1979; Sternberg, 1985; Wechsler, 1958). Although intelligence (the inferred ability) and "intelligent behavior" have been closely linked to other domains of competence in theory and research, they often are distinguished from other competence domains in assessment and diagnosis. For example, in diagnosis of intellectual disability, the psychometric assessment of intellect is joined with a judgment of adaptive behavior, which often includes practical or social skills from a formal assessment, such as the Vineland Adaptive Behavior Scales (VABS; Sparrow, Cicchetti, & Balla, 2005).

Finally, researchers interested in the development of self-concept and mastery motivation have developed theories on the intrinsic motivation of humans to master their environment (White, 1959), building on evolutionary and biological foundations to integrate cognitive and behavioral constructs such as self-perception, locus of control, and self-efficacy (Bandura, 1997; Harter, 1978). This work has advanced definitions of competence by focusing attention on the interrelations between internal judgments of effectiveness across domains as well as judgments made by others.

Each of these areas has informed the study of developmental tasks. Havighurst (1972) proposed that specific age-salient tasks form the basis by which members of society judge whether or not an individual's developmental trajectory has been successful. His initial series of specific tasks was grounded in middle-class mid-twentieth-century American values. For example, at earlier ages in development, these tasks included learning to communicate and distinguishing right from wrong; at older ages, developmental tasks included academic success, forming close relationships, and civic responsibility. Other writers have proposed organized sequences of developmental challenges and tasks, in which successful achievement of prior tasks set the stage for those coming later (Greenspan, 1981; Sroufe, 1979; Waters & Sroufe, 1983). More recent examples of developmental tasks in contemporary industrialized societies organized by developmental period can be found in several of our collaborative publications (Masten & Coatsworth, 1998; Masten et al., 2006; McCormick et al., 2011). In similar historical and cultural contexts, independent investigators often identify similar developmental tasks. Nonetheless, developmental task theorists have posited that there also would be some tasks unique to

a particular context of development, reflecting the values and requirements for success in different cultures, ecologies, or periods of history (Masten et al., 2006; McCormick et al., 2011).

Over the decades, there also have been significant debates about the definition and assessment of competence. Salient points of debate include whether to include internal adaptation (e.g., subjective well-being) as well as external adaptation (relationship-based or otherwise) in criteria for competent functioning; to what extent processes versus individual attributes are highlighted; and, crucially, how broad or narrow each domain of competence should be (see Masten et al., 2006; McCormick et al., 2011). For example, some theories about developmental tasks view identity as a key task (e.g., Erikson, 1968) or sequence of tasks (see Motti-Stefanidi, 2015) whereas others focus on meeting criteria for expected behavior in the environment (such as schoolwork or work achievement, friendship, or law-abiding conduct).

Finally, we emphasize that the study of positive development and the nature and measurement of developmental tasks is an active area of research. For example, international work to develop a core set of child well-being indicators is ongoing. One such effort is UNICEF's *Innocenti Report Card 7*, derived from the United Nations Convention on the Rights of the Child and including domains of material well-being, health and safety, education, peer and family relationships, subjective well-being, and behavior and risk (United Nations Children's Fund, 2007). More generally, Mahoney and Bergman (2002) have discussed conceptual and statistical aspects of positive development work from a holistic and person-centered perspective. Much of their discussion dovetails with the work described earlier, although they provide a helpful reminder that both developmental tasks themselves and the processes by which youth may attain (or fail to attain) them often vary by context (e.g., high- versus low-risk youth). Mahoney and Bergman write from the vantage point of positive psychology and thus provide connections from this work to other (largely adult-based) research on challenging but crucial constructs such as optimism, wisdom, and agency.

RELATIONS BETWEEN COMPETENCE AND PSYCHOPATHOLOGY

There are several reasons to expect consistent associations between measures of competence and measures of psychopathology. Unfortunately, there is a continuing and persistent risk of misinterpreting associations, in part because of the conceptual and methodological overlaps in the definitions and operationalization of these concepts. First, the concepts themselves may overlap, as when certain diagnostic categories (e.g., conduct disorder in the *DSM* system) share defining criteria with certain developmental tasks (rule-abiding conduct), a problem relevant to debates on impairment and mental disorder discussed later. Although not of great interest theoretically, this permeable boundary between constructs has the potential to mislead research if one is not extremely careful about operational definitions. In addition, even constructs that are nominally discrete may share overlapping assessment criteria, a problem that is well known in research on associations between temperament and psychopathology and has led to calls for revised assessed instruments in that area (Lahey, 2004). As noted in our prior work (Masten et al., 2006), many common measures of functional impairment contain content closely related to content of competence measurements, albeit with a focus on a more negative range of functioning. Thus, to the extent that impairment might be considered the purview of mental disorder, these concepts will be confounded.

If overlapping definitions and shared assessment content can be convincingly ruled out or minimized, research focus shifts to three non-mutually exclusive categories well-known for explaining an association between two constructs A and B: Either A causes B, B causes A, or one or more additional constructs cause both A and B. This presentation of competence-psychopathology relations is somewhat reductionistic, in that processes underlying these directional, causal effects likely operate simultaneously and continuously, consistent with the nature of dynamic systems (Gottlieb, 2007; R. M. Lerner, 2002; Overton, 2013). Nonetheless, we feel that the delineation of these competing explanations is of value, as it can help identify areas for further conceptual and methodological/statistical work.

For the constructs considered here, this logic means that successes or failures in competence cause changes in psychopathological symptoms (improvements or exacerbations), that symptoms (or their immediate effects) alter subsequent competence, or that one or more of a series of third variables operate to cause changes both in competence and behavioral or emotional problems. Importantly, in this chapter, we usually discuss the directional causal hypotheses in terms of failures in competence contributing to psychopathology or psychopathology undermining adaptive competence. This is because the majority of theory and research in this area is conceptualized in terms of failure. However, it should be kept in mind throughout

that associations of the continuous, dimensional variables that index levels of competence or psychopathology are also consistent with the possibility that competence successes prevent the development or exacerbation of future symptoms or that improvement in symptoms leads to greater subsequent competence (Masten, 2001; Masten et al., 2006).

Potential third-variable explanations between competence and symptoms can take several forms. Masten and colleagues (2006) detail a number of examples that show how individual difference variables (e.g., intelligence and personality traits such as impulsivity, introversion, and conscientiousness) and other contextual variables (e.g., received parenting and child maltreatment) might serve as common causes of both psychopathology and competence. Central to this discussion is the idea of cumulative risk and risk gradients: the well-documented finding of an increased likelihood of problems across multiple domains with increased aggregate number of risk factors (Masten, Morison, Pelligrini, & Tellegen, 1990; Rutter, 1979; Sameroff, 2000; see also Obradović, Shaffer, & Masten, 2012).

Although delineation of common-cause variables is clearly of importance, there are also ambiguities in interpretation of the statistical finding when a third variable accounts for the association between two others. As a simple but likely fairly common example, there may be situations in which the third variable serves as a proxy for a prior assessment of one of the two focal variables, complicating inferences about direction of effects (see also Card & Barnett, 2015). Even in situations where such ambiguity is clearly implausible, a larger (and near-ubiquitous) concern is that it is in practice impossible to include all relevant common-cause variables in a given analysis. This fact makes the theory-driven selection of key covariates of primary importance, as well as the integration of results across studies and the replication of key results with experimental evidence (from either randomized prevention/intervention studies or natural experiments) wherever possible. Helena Kraemer and her colleagues (1997) have attempted to clarify this picture with reference to risk factors by generating a taxonomy that distinguishes causal risk factors from fixed or variable markers (noncausal factors) as well as a more differentiated system describing how risk factors might work together as mediators, moderators, or proxies to affect an outcome of interest (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001).

Of course, these three primary explanations for competence-symptom associations can operate in tandem, which makes testing of unique predictions that convincingly elevate one or more of the potential reasons for competence-psychopathology co-occurrence extremely difficult. Developmental theorists have strengths in recognizing the complexity of forces at work in this arena: In particular, as noted, writers in this area have specified broader theoretical orientations that explicitly acknowledge the bidirectional nature of the relation between competence and psychopathology and the importance of context, at multiple levels, in moderating that association (e.g., Mahoney & Bergman, 2002; Overton, 2013; Sameroff, 2010). But a continuing challenge for the field is the translation of such theories into testable and falsifiable predictions that can begin to rule out one or more possible explanations for observed associations, despite explicit acknowledgment of the interplay between complex theories and relatively new statistical methods (Jelicic, Theokas, Phelps, & Lerner, 2007). In general, some of the theories that have been most influential in guiding competence-psychopathology work have been more specific, aiming to lay out in detail the processes by which a specific failure of competence is connected with a specific aspect of psychopathology.

One example of a well-developed framework for competence failures contributing to subsequent psychopathology is the dual failure model proposed by Patterson, Capaldi, and colleagues, which posits that failures in the key developmental tasks of academics and social relationships/peer acceptance lead to increased depressive symptoms (Capaldi, 1992; Patterson & Stoolmiller, 1991). This model, supported by well-controlled longitudinal evidence, suggests that early behavior problems and family conflict can lead to disrupted school achievement and spreading of negative interaction patterns to peers, which in turn appear to result in increased dysphoric mood. Cole and colleagues have proposed a similar direction of effect between social failure and increased depressive symptoms, one that is mediated by perceived competence (Cole, Martin, Powers, & Truglio, 1997; Tram & Cole, 2000). Cascade modeling work from each of these research teams is reviewed in more detail in a subsequent section. Importantly, these theories have proved generative for diverse other work: for example, data from the male Developmental Trends Study informed by the failure model has suggested that oppositional defiant disorder (ODD) predicted both later conduct disorder (CD) and also later affective disorder, while CD was related to later affective disorder indirectly via functional impairment (Burke, Loeber, Lahey, & Rathouz, 2005).

The second edition of this chapter presented several additional examples of possible competence failures

contributing to increases in symptoms of psychopathology as well as the reverse—scenarios in which clearly defined mental illness leads directly or indirectly to problems in age-salient developmental tasks (Masten et al., 2006). As a group, these examples represent a wide array of disorders, tasks, and problems, with ample initial evidence for effects in both directions. It is important to recognize that a search for a single, universal mechanism of action for these effects might be misguided. Indeed, the cascade work reviewed later in the chapter has dealt with this complexity of constructs by limiting primary focus to the key competence domains of academics and social competence—the latter itself a complex construct containing facets of self-concept, peer acceptance and reputation, victimization and bullying, and close friendship—and the broad problem domains of internalizing and externalizing. However, selected papers have expanded the methodology to other constructs, as detailed further later.

We now turn to a more detailed consideration of work linking competence and psychopathology through the broad areas of impairment in mental disorder classification systems and longitudinal cascade models. Although mutually informing, these two bodies of work have been conducted by separate research teams working from somewhat different theoretical perspectives and using different samples and methods. We focus primarily on work published since the prior edition of this chapter in 2006.

IMPAIRMENT AND MENTAL DISORDER: SYSTEMS, MEASURES, AND RESEARCH SUPPORT

In the second edition of this chapter, we highlighted how competence has been incorporated into the major diagnostic systems for psychiatry and psychology, which is primarily through the opposite of competence, namely functional impairment (Masten et al., 2006). We also discussed Jerome Wakefield's (1997) harmful dysfunction analysis of the concept of mental disorder, which has been influential in some of the philosophical work underpinning prior revision cycles of the *DSM*. Although the revision process leading to the current version, the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-5*) (American Psychiatric Association, 2013), included discussion of the nature and definition of mental disorder itself, the issue of impairment in defining mental disorder has been relatively uncontroversial. For example, minor wording changes to the global definition of mental disorder were added to explicitly describe distress and/or impairment as a consequence of disorder, which was implicitly assumed to be the case in prior editions (First & Wakefield, 2010).

At the same time, the topic of impairment was raised as an important issue for working groups to consider when revising disorder criteria (C. Lord, personal communication, February 2013). Partly to align the system more closely with the *International Classification of Diseases* (*ICD*) system in use throughout much of the rest of world, *DSM* working groups were charged with considering the implications of separating out functional impairment from the criteria sets themselves. However, it appears that this task was extremely difficult, as many criteria sets are difficult to measure without some reference to impairment, especially those related to social functioning (e.g., multiple criteria for autism spectrum disorder), and *DSM-5* has retained the clinical significance criterion while acknowledging international efforts to separate symptoms from impairment (American Psychiatric Association, 2013).

Despite this situation, concerns have continued to be raised regarding the confounding of symptoms and impairment across multiple aspects of *DSM*, including some criteria sets (especially in the externalizing domain). The collapsing of symptom severity and functional impairment into a single numeric score for Axis V, the Global Assessment of Functioning (GAF), received particular criticism—so much so that *DSM-5* revamped the entire multiaxial system, in the process replacing the GAF with the World Health Organization (WHO) Disability Assessment Schedule—Second Edition (WHODAS 2.0, detailed later). However, some researchers continue to explore the SOFAS (Social and Occupational Functioning Assessment Scale) and GARF (Global Assessment of Relational Functioning) scales from prior editions, which are the closest cousins to the GAF. For example, Smith and colleagues (2011) showed in a sample of psychotic patients that symptom severity ratings contributed to substantially more of the variance in GAF scores than did impairment, largely due to rating conventions that set a ceiling for functioning scores in the presence of psychosis. However, database searches indicate that SOFAS research continues to consist primarily of relatively modest-size intervention studies that employ the scale to track patient progress. Although valuable, this work does not provide data for critical evaluation of competing theoretical frameworks for impairment.

Turning specifically to youth disorders, a review by Rapee, Bögels, van der Sluis, Craske, and Ollendick (2012) gave careful consideration to a number of important conceptual issues related to impairment. To begin with,

the authors noted that aspects of context, culture, gender, and developmental stage will influence the nature and extent of functional impairment. For example, parents or other family members may consciously or unconsciously "accommodate" child behavioral or emotional problems in such a manner that the current functional impact is limited, with either adaptive or maladaptive consequences for later development. In addition, Rapee and colleagues detailed the myriad ways in which impairment has been assessed, from single-score global measures to highly differentiated tools. The latter are used mainly in research settings or in specialty clinics, and a subset of these measures was reviewed in the second edition of this chapter (for additional reviews, see Kutash, Lynn, & Burns, 2008; Winters, Collett, & Myers, 2005). This topic is highly relevant for our broader discussion of competence and psychopathology, because it highlights how researchers and theorists working from a mental disorder classification standpoint have measured impairment. There is reasonable agreement that, for youth, areas of social functioning (including family relationships), academics (and work for adolescents in some contexts), and self-care/leisure activities are primary measurement domains for impairment. For example, Bird and colleagues (2005) developed the 23-item Brief Impairment Scale (BIS) as an impairment measure that maintains not only the reliability and fast administration of scales such as the GAF or Children's Global Assessment Scale (CGAS; Shaffer et al., 1983) but also the breakdown of impairment across core domains that is characteristic of more differentiated scales; the items are grouped into interpersonal relations, school/work functioning, and self-fulfillment, which includes hobbies and other activities.

Rapee and colleagues (2012) also detail the challenges inherent in impairment research in youth as compared with adult populations. The issue of multiple informants arises in a related fashion as it does for symptom assessment: It is sometimes unclear who is the most reliable or valid informant on impairment and, when information gathered from multiple informants is discrepant, how to best aggregate it (Sanford, Offord, Boyle, Peace, & Racine, 1992). This issue is of particular concern given evidence that, in adults, the diagnostically reported "clinically significant impairment" criterion does not always map onto objective measures of impairment, such as work days lost (Breslau & Alvarado, 2007). Additionally, for youth who are assigned more than one mental disorder diagnosis, it is often extremely difficult to disentangle which aspects of impairment are consequences of which disorder, independent of broader concerns regarding the validity of specific pairs of comorbid diagnoses (Angold, Costello, & Erkanli, 1999a; Sroufe, 1997). Thus, issues of impairment connect with broader critiques of *DSM* and proposals to move the field toward mixed categorical-dimensional systems of taxonomy (Drabick, 2009; Yates, Burt, & Troy, 2011), which may require different systems across different classes of disorders (see Coghill & Sonuga-Barke, 2012, for relevant evidence and discussion, as well as the Research Domain Criteria initiative discussed later).

Despite thoughtful reviews such as that by Rapee and colleagues (2012), research on impairment continues to be fragmented, due in part to the diverse stakeholders in classification systems and the significant implications for "caseness" represented by different uses of impairment. For example, Leclair, Leclair, and Brigham (2009) detailed the complications of recent changes to the American Medical Association's process for rating medical impairment for determination of Social Security disability status in the United States and the difficulties of how to reliably and validly apply these standards to mental illness. In addition, distinctions between symptoms and disability have implications for community care, since disability-related care is often provided by organizations other than traditional mental health services (Whiteford, 2009). To help advance this discussion, we consider some specific taxonomic systems of impairment and new dimensional approaches for mental disorder research in more detail as well as recent work on the association of disorder symptoms with impairment.

Formal Systems and Instruments for Assessing and Classifying Impairment

The study of impairment has been complicated by the existence of several closely related classification systems that have arisen for specific purposes. One of the most influential is the *International Classification of Functioning, Disability, and Health* (*ICF*; WHO, 2001). The *ICF* is a wide-ranging classification system designed to categorize the various ways in which both physical and mental illness can impact an individual's life: major groupings of this system are (1) bodily functions and structures, (2) activities, and (3) participation, with allowance for coding of external environmental factors and an overarching biopsychosocial conceptual model of disability (Kostanjsek, 2011). The domains of impairment most relevant for this chapter fall into the *ICF*'s activities and participation categories, which contain some entries similar to widely studied competence domains as well as others that are less often discussed. For example, detailed aspects of interpersonal relationships

can be coded, as well as learning and educational skills, various modes of communication, civic engagement, formal education and employment. Consistent with a dual focus on physical and mental health, the *ICF* also contains detailed codes related to mobility and self-care.

A measurement tool referenced earlier, the WHO's Disability Assessment Schedule—Second Edition (WHODAS 2.0) has been developed to assess key domains from the *ICF* (Üstün et al., 2010). The WHODAS 2.0 was refined via factor analysis and extensively field-tested globally and has been translated into 27 languages. Although items load on a common disability factor, content is also divided into six categories: cognition, mobility, self-care, getting along with others, life activities (e.g., school, work, and household tasks), and community participation. Overall, the WHODAS 2.0 is an impressive undertaking, albeit one developed and validated solely on adult samples; study of its potential application to diverse child samples is more recent (e.g., Scorza et al., 2013). As described earlier, it has replaced the GAF for assessment of impairment in *DSM-5*.

Although the *ICF* has been an impressive attempt to provide a universal categorization of impairment applicable across all types of health/illness, in many respects it is not developmental in nature, with implicit adult norms and frames of reference. Therefore, it is promising to see the development of the *International Classification of Functioning, Disability, and Health–Children and Youth Version* (*ICF-CY*), a closely related classification system of impairment and disability focused on children and adolescents (WHO, 2007). The *ICF-CY* adds codes for items such as babbling, accepting novelty and adapting one's activity level that may be more applicable to youth; however, most items remain identical to the adult *ICF*, and developmental norms are not discussed. Although discrete assessment measures directly based on the *ICF-CY* have to our knowledge not yet been developed, recent research has linked existing measures of adaptive behavior to *ICF-CY* codes. For example, a content analysis of one widely used scale of adaptive behavior in youth suggests that most scale items were reasonably well captured by the codes (Gleason & Coster, 2012). In addition, work attempting to link assessment measures to the *ICF-CY* is ongoing (e.g., Castro, Ferreira, Dababnah, & Pinto, 2013; Gan, Tung, Yeh, & Wang, 2013), as is work building consensus on the subsets of *ICF-CY* elements most relevant to ADHD (Bölte et al., 2014a; de Schipper et al., 2015) and autism spectrum disorder (Bölte et al., 2014b).

Others have also attempted to link adaptive behavior to impairment and disability within narrower domains of disorder. Writing mainly from a background in intellectual disability and autism spectrum disorder research, Ditterline and Oakland (2009) provided a comprehensive review of relations between the constructs of adaptive behavior and impairment, as experts in these domains have been grappling with effective ways of classifying impairment for some time. As detailed by Ditterline and Oakland, the American Association on Intellectual and Developmental Disabilities (AAIDD) groups adaptive skills into ten narrowband domains: communication, community use, functional academics, home/school living, health and safety, leisure, self-care, self-direction, social (skills), work (skills), and motor skills (AAIDD/AAMR, 2002). These 10 areas are grouped in turn into three broad categories: conceptual skills, social skills, and practical skills. Ditterline and Oakland also briefly reviewed well-validated measures of adaptive functioning, such as the Scales of Independent Behavior-Revised (SIB-R; Bruininks, Woodcock, Weatherman, & Hill, 1996) and the VABS (Sparrow et al., 2005), designed to tap into some or all of the above-mentioned areas. The clear overlap among the constructs and domains highlighted by the AAIDD and by the WHO in their respective systems is evident from comparing these lists.

Some investigators have tried to capture a middle ground between extremely brief impairment measures, such as the GAF, and more extensive measures, such as the SIB-R or VABS. Whiteside (2009) described a youth adaptation of the widely used Sheehan Disability Scale designed to tap child and parent social, educational/occupational, and family functioning. Initial validation results showed that this measure contributed unique predictive power beyond symptom severity for the outcome of presentation for treatment. In addition, a promising report by van der Knaap and colleagues (2009) described the development of the Adolescents' Tasks and Skills Questionnaire (TASQ), designed to assess impairment in youth living in residential facilities. This measure is noteworthy for its rare focus on positive outcomes in a clinical setting with seriously disturbed youth. The broad dimensions of the TASQ include peer relations, autonomy and self-management, school competence, job competence, romantic competence, and self-care. Initial validation shows expected negative associations between competence domains and behavioral and emotional problems; further validity evidence, including incremental validity for future outcomes, is needed.

Finally, recent work by Russell Barkley, focused primarily on impairment resulting from attention disorders, has argued strongly for a statistical-normative conceptualization of impairment. Thus, for both youth and

adults, individuals are compared to age- and gender-based norms on a series of impairment areas. Barkley has developed impairment scales for adults (the Barkley Functional Impairment Scale [BFIS]; Barkley, 2012a) and youth (Barkley Functional Impairment Scale for Children and Adolescents [BFIS-CA]; Barkley, 2012b) that show promise as a middle ground between GAF ratings and more time-consuming instruments. For adults, the BFIS includes domains such as home and work responsibilities, social relationships, finances, sexual relationships, and self-care. For youth, the BFIS-CA includes many domains already discussed, including friendships, schoolwork, chores, and family relationships. These measures have already proven useful in differentiating attention-deficit/hyperactivity disorders (ADHD) from other putative disorders, such as Sluggish Cognitive Tempo (SCT), in a large-scale adult sample (Barkley, 2012).

Overall, the measures just cited are promising developments for the field, although careful analysis of item content is also needed, as ostensibly overlapping domains may nonetheless mask divergent association with other variables. For example, Weissman (2009) noted how three "work impairment" scales all differentiated healthy from mentally ill adults but were only modestly intercorrelated themselves because they assessed different aspects of the work experience (e.g., workdays lost versus performance/problems at work versus interest/motivation).

Separating Impairment from Definitions of Mental Disorder

Paralleling the struggle to develop comprehensive and valid systems of impairment, theorists and diagnosticians have grappled with the role of impairment in taxonomic systems for mental health. In 2009, a special section of the journal *World Psychiatry* was dedicated to discussion of a forceful proposal by Üstün and Kennedy (2009) for the *DSM* system to separate judgment of disability or impairment from the diagnosis of mental disorder, in a manner similar to the *ICD* and *ICF* systems. The authors noted that the *DSM*'s inclusion of the "clinically significant impairment" criterion creates several inconsistencies with diagnosis in physical medicine, in addition to inconsistencies with the international systems used by the WHO. Reactions to this proposal were broadly supportive of this ideal: For example, Lehman (2009) noted that the current system of requiring clinical significance for a *DSM* diagnosis is analogous to leaving primary hypertension, absent other complications, untreated in physical medicine. However, respondents also raised various implementation concerns. More specifically, Narrow, Kuhl, and Regier (2009) noted that the *ICF* domains contain content very closely related to symptom criteria for several *DSM* disorders, making the separation of impairment and disorder difficult in practice.

In commenting on the above-mentioned proposal, Wakefield (2009) pointed out that *DSM* implicitly allows the presence or absence of impairment to distinguish between disorder and nondisorder via not otherwise specified (NOS) categories (changed to other specified and unspecified disorders in *DSM-5*): that is, individuals can be diagnosed if impaired but not meeting full symptom criteria. Although this is desirable from the standpoint of maximizing access to diagnosis-dependent services, it potentially undermines the scientific basis of the *DSM* system. There is no simple solution to this problem, and Wakefield noted that even the *ICD* system contains many criteria that are impairment-related, despite the overarching goal to separate out impairment into the *ICF*. Ultimately, Wakefield argued for a close concept analysis of each disorder to determine how best to assess underlying biological/evolutionary dysfunction, as well as impairment.

Associations Between Psychopathology and Functional Impairment: Empirical Evidence

Several recent reports have focused on the relations among symptoms of mental illness (both categorical *DSM*/*ICD* as well as broad dimensional problems) and measures of functional impairment. In general, these studies either demonstrate significant impairment from subthreshold conditions, replicating the seminal report by Angold, Costello, Farmer, Burns, and Erkanli (1999b), or else investigate what type or class of problems may result in more or less impairment. As an example of the former, Balázs and colleagues (2013) reported data from the large-scale Saving and Empowering Young Lives in Europe (SEYLE) study on subthreshold depression and anxiety and functional impairment (assessed via the extended form of the Strengths and Difficulties Questionnaire). The authors found that both subthreshold anxiety and subthreshold depression were associated with increased risk of functional impairment controlling for the association across the two illness domains as well as demographic variables. Other work has demonstrated significant functional impairment even at the first visit for early-intervention services for affective disorders (Hamilton, Naismith, Scott, Purcell, & Hickie, 2011). In addition, the large-scale international Global Burden of Disease study began

inclusion of CD and ADHD impacts in 2010, showing (despite various assessment and methodological challenges) that both conditions result in significant disability and quality-of-life impairments in youth, particularly males (Erskine et al., 2014).

Other investigators have explored how the association of symptoms and impairment may differ across disorder categories. Often this work is motivated by relatively low to moderate associations between disorder symptoms and impairment, which can result in dramatic lowering of prevalence rates, depending on whether clinically significant impairment is included as part of the diagnostic criteria. For example, Lewandowski, Lovett, and Gordon (2009) gave a detailed discussion of impairment in ADHD, documenting that correlations between symptoms and impairment measures are generally no higher than .5 (i.e., 25% of shared variance) and are often substantially lower in this domain. Depending on how cutoffs for impairment are used, dramatic differences in ADHD rates will be seen (Gathje, Lewandowski, & Gordon, 2008). Low associations between symptoms and impairment have also been documented in the domain of separation anxiety disorder, with minimal incremental validity of impairment for future symptoms; the authors argued that distress, rather than impairment, may be a more focal predictor for this particular disorder (Foley et al., 2008). Relations among distress and impairment have been broadly studied by Ezpeleta, Reic, and Graner (2009), with results suggesting demographic differences in distress levels (with females and adolescents displaying greater distress overall) and disorder differences in impairment: broadly, externalizing disorders such as ADHD, ODD, CD, and substance use problems were associated with more significant impairment than most anxiety disorders but not more than major affective illness. In fact, the negative impact of ODD and CD (independently) on functional impairment across multiple domains has been corroborated longitudinally into young adulthood by Burke and colleagues (2014) using data from the Developmental Trends Study.

Further complicating matters, associations among problem domain and impairment may vary depending on the specific measure of impairment used and the informant assessed. For example, Francis, Ebesutani, and Chorpita (2010) analyzed scores from the highly detailed Child and Adolescent Functional Assessment Scale (CAFAS) and the GAF in a diverse sample of youth ages 5 to 17 years living in Hawaii and referred for mental health evaluation. The study compared the proportion of youth meeting standard cutoffs for serious emotional disturbance on each measure for both broad externalizing and internalizing disorders. Of note, Francis and colleagues reported that the CAFAS identified more youth with externalizing disorders as meeting serious emotional disturbance criteria compared with internalizing disorders, whereas the GAF showed more equivalent rates across broad disorder categories. Unfortunately, absent both additional information and a gold standard for serious disturbance, it is difficult to ascertain whether this result represents an oversensitivity of the CAFAS to externalizing problems versus an undersensitivity of the GAF to the same domain. Regarding multiple informants, research suggests that the informant specificity characterizing symptom ratings may also generally apply to impairment ratings, making for complex patterns of associations when both symptoms and impairment are assessed across multiple settings (Gadow, Kaat, & Lecavalier, 2013).

Although work on impairment and symptoms to date has been largely cross-sectional, Cleverley, Bennett, and Duku (2013) reported a longitudinal study of functional impairment and internalizing symptoms through early adolescence (ages 10–15) in a large-scale, nationally representative and nonreferred Canadian sample. Measures of internalizing were available each year whereas impairment assessment was more limited (a single item for each of three domains: academics, peer relationships, and organized activities, with significant problems in any domain at any time resulting in classification of "impairment"). However, impairment status was associated with baseline internalizing symptoms, controlling for change in internalizing over time. Thus, there was consistent evidence for a main effect of impairment on internalizing (but not growth in internalizing) in this study. Other work examining associations between symptoms and impairment using epidemiological sampling has been conducted by Stringaris and Goodman (2013) in the United Kingdom, finding modest associations between symptoms and "impact" (impairment + distress) as well as incremental prediction of impact to future disorder status above symptom counts.

Relatively little work has centered on either cultural variation in impairment or racial and ethnic differences in the relation between symptoms and impairment. When such efforts have been made, results suggest the importance of taking into account cultural context when discussing impairment. As a brief example, Jayawickreme, Jayawickreme, Atanasov, Goonasekera, and Foa (2012) demonstrated incremental validity in predicting WHO-DAS 2.0 functional impairment by using local idioms of distress in addition to Western-based symptom measures in an adult Sri Lankan sample. Additionally, data from an evaluation study of community mental health services

for children and families in the United States suggested that relations between behavioral/emotional strengths and functional impairment may vary by ethnicity (Barksdale, Azur, & Daniels, 2010). There is evidence that youth social withdrawal may be less impairing in Asian cultures as compared to Western cultures and that parents' likelihood of seeking professional help for their children's symptoms (a potential indicator of impairment) may vary cross-culturally (Rapee et al., 2012). However, not all investigations show evidence for cross-cultural differences related to impairment, as Zwirs et al. (2011) found evidence for similar relations between symptoms and impairment (though mean differences of each) across ethnic Dutch and immigrant Moroccan, Turkish, and Surinamese children living in the Netherlands.

NIMH Research Domain Criteria Project

Although it is distinct from the *DSM* and *ICD* systems, there has been a high-profile effort to link mental disorder research with a system of constructs developed to emphasize multiple levels of analysis and, in particular, neurobiological substrates of disorder. The National Institute of Mental Health (NIMH) Research Domain Criteria (RDoC) project is a collaborative effort among researchers from basic science, clinical, and translational backgrounds to move diagnostic efforts closer toward identifying the pathophysiological mechanisms underlying disorder (Insel et al., 2010; Sanislow et al., 2010). This work is grounded in the long-known study of endophenotypes: well-specified physiological or behavioral indices that act as intermediaries between genetic influence and clinical disorder (Gottesman & Gould, 2003). The RDoC initiative aims to define dimensional constructs relevant to disorder at multiple levels of analysis, making the endophenotype concept more explicit and potentially more useful (Insel & Cuthbert, 2009). Levels of analysis as defined in the RDoC include genes, molecules, cells, circuits, physiology, behavior, self-reports, and paradigms: Each is crossed with multiple constructs within each broad domain to generate matrices of information to guide further research, construct validation, and ultimately new diagnostic classification systems (Cuthbert & Kozak, 2013).

There are promising connections between the RDoC constructs chosen for initial study and constructs central to this chapter. The initial RDoC domains/systems include positive affect, negative affect, cognition, social processes, and regulatory systems (Sanislow et al., 2010). Several narrower constructs within these broad domains have clear connections to competence in our framework of success in developmental tasks. In particular, the RDoC domain of social processes, which includes affiliation and attachment, reception and production of facial and nonfacial communication, and perception and understanding of self and others (NIMH, 2014), contains multiple connections to our focus on social competence. However, the RDoC's emphasis on constructs closely linked to biology and neuroscience has tended to focus attention on narrower, behaviorally assessed traits/abilities such as behavioral inhibition and the recognition of facial expressions (see Lilienfeld, 2014, for related discussion of the limitations of RDoC's biological focus). Although the RDoC project is a sweeping and ambitious step toward increased validity of clinical syndromes, to date it has been approached in a largely nondevelopmental manner, and its ultimate utility may be gauged in part by how well it can be integrated with a comprehensive science of developmental psychopathology. Early steps in such integration have been taken by Franklin, Jamieson, Glenn, and Nock (2015), who highlight, among other points, the importance of multiple methods and integration of findings across levels of analysis.

Impairment: Conclusions

As discussed in the second edition of this chapter (Masten et al., 2006), some of the debates surrounding the role of impairment in psychiatric diagnostic systems parallel those in the realm of competence. Issues of construct validation, choice of specific assessment measure, and aggregation of data from multiple informants are crucial factors in both areas. Certainly the field remains far from a consensus on any of these issues with regard to impairment. Indeed, discussions such as the debate over inclusion versus exclusion of impairment in *DSM-5* diagnostic criteria suggest that research and theory on impairment remains in the fairly early stages. However, the presence of both widely cited empirical demonstrations of the importance of impairment (e.g., Angold et al., 1999b) and compelling recent conceptual reviews (e.g., Rapee et al., 2012) offer promise for the future.

More specifically, when one studies the actual domains and item content assessed in measures of functional impairment, the links with the developmental study of competence are obvious. Indeed, it is not much of an exaggeration to say that impairment is the negative pole of competence. However, we can go beyond this basic relation to compare and contrast the domains that are deemed salient by each broad research tradition. A complication

here is the relatively nondevelopmental nature of much impairment research, with the notable exception of careful work creating age-based normative data for measures of adaptive behavior such as the VABS (Sparrow et al., 2005) and the Scales of Independent Behavior-Revised (SIB-R; Bruininks et al., 1996). The broad developmental tasks of academic functioning and social relationships (broad peer acceptance and/or close friendship) have prominent placement in nearly all youth impairment instruments. In turn, many impairment measures focus on domains of youth's lives, such as self-care, leisure activities, and broader community engagement, that are less often seen as central in other developmental task work, with one exception being the positive youth development framework (e.g., R. M. Lerner, von Eye, Lerner, & Lewin-Bizan, 2009), discussed in more detail in the "Conceptual Models" section of this chapter.

Finally, impairment has clear relevance for interventions with disturbed youth, as it is conceptualized as the visible impact of underlying disorder, is often the reason for referral for services, and often is (or should be) the primary target for intervention (Barkley, 2009). In fact, a recent discussion of evidence-based interventions argues that the standards for what qualifies as evidence-based should include measurements of practically significant reductions in functional impairment in addition to clinically significant reductions in symptoms (Becker, Chorpita, & Daleiden, 2011). Of note, Becker and colleagues described the relative lack of an evidence base on reductions in impairment among classic randomized clinical trial (RCT) designs, which is due to both omissions of such measures from many study designs and greater challenges in influencing impairment for those studies that include such instruments. Others have noted that reducing impairment can be crucial for the "social validity" of an intervention (essentially, participant and family buy-in) and argue that measures of impairment should be included in RCT designs and should also be tailored in some degree to the particular aspects of functioning directly or indirectly targeted by the intervention (Fabiano & Pelham, 2009).

CASCADE MODELS

Conceptual and Statistical Background

Cascade models are both conceptual models and research designs that emphasize spreading effects across domains, generally through inclusion of three or more target constructs at three or more time points in a single study (Masten & Cicchetti, 2010). These models have roots in theoretical conceptualizations of cumulating problems or advantages across major adaptive domains (Cicchetti & Schneider-Rosen, 1986). As in many other domains, methodology in this area remains under close scrutiny and continued development: Conceptual and statistical discussions are prevalent and important for adequate communication and advancing theory. For example, Gonzalez (2009) has provided a thoughtful discussion of various methods for the analysis of transactional models: Like cascade models, transactional models emphasize interconnection of distinct constructs over time, although the two classes of models are not identical (Sameroff, 2009). In particular, Gonzalez highlighted the need to consider individual heterogeneity and nonlinearity in testing theories of development and change.

Cascade models are statistically similar to longitudinal mediation models, especially the subset of models in which the predictor variable, mediator, and outcome are all measured on at least three occasions. In a series of methodological papers, David Cole and Scott Maxwell have provided comprehensive discussions of the major analytic issues related to longitudinal mediation models, highlighting both their clear advantages over models using only cross-sectional data and the potential concerns and additional assumptions needed for accurate inference. To begin with, they noted that prior levels of the dependent variable represent an unmeasured confound in most cross-sectional analyses of mediation, which increases the challenge of assessing the magnitude of indirect effects in such designs (Cole & Maxwell, 2003). Subsequently, Maxwell and Cole (2007) demonstrated that estimates of the magnitude of the indirect effect from cross-sectional analyses can be either positively or negatively biased relative to the estimates from longitudinal data, depending on a number of factors, such as the stability of the predictor and the mediator. They also illustrated that the presence or absence of such bias can be substantial and difficult to predict in advance without making stringent assumptions.

Cole and Maxwell (2003) went on to emphasize several additional points relevant for our discussion. First, they noted the importance of timing in longitudinal assessments, including the obvious but rarely acknowledged point that timing of measurement does not always equate with timing of causal action for a construct (see R. M. Lerner, Schwartz, & Phelps, 2009, for related discussion). Thus, whenever possible, researchers should engage in pilot work to establish the minimum estimated lag time for both a predictor's effect on a mediator to emerge and

(separately) for the effect of the mediator on the outcome to emerge, and they should design longitudinal assessments to bridge those time intervals, which will not necessarily be equal. Longer and shorter intervals than these standards can bias estimates of indirect effects, related to the bias introduced by a cross-sectional design. We should point out that, in practice, statistically optimal lag times remain unclear in many areas of developmental psychopathology, a fact that parallels concerns about our lack of knowledge of causal structure and ambiguous constructs generally (e.g., Aalen, Røysland, Gran, & Ledergerber, 2012). Second, Cole and Maxwell also emphasize the importance of estimating and reporting *overall indirect effects* for studies designed with more than three time points, in which several mediating paths (i.e., unique tracings from the predictor to the outcome) are estimated; others have stressed the calculation of confidence intervals for total indirect effects in longitudinal designs (Little, Preacher, Selig, & Card, 2007). Third, they discuss the complex and unpredictable effects of measurement error, noting that mediators in particular should be assessed using multiple broad manifest indicators in a latent variable framework whenever possible and that informant variance should be noted as a possible biasing factor.

Building in part on this work, Selig and Preacher (2009) discussed the wider use of longitudinal mediation analysis in developmental research. In particular, they highlighted the fact that cross-lagged panel designs do not directly assess intraindividual change, for which latent growth curve models (Preacher, Wichman, MacCallum, & Briggs, 2008) are needed. Panel designs also do not allow change in one construct to serve as a predictor of another construct, for which growth curve models or latent difference score models (McArdle, 2009) are needed. Importantly, Selig and Preacher detailed how mediation models can be combined with either latent growth or latent difference models to answer developmental questions. Although we detail examples of some of these approaches in this chapter, these methods remain underused and may offer new windows for elucidating the nature of relations between competence and psychopathology from a perspective of individual differences in intraindividual change. Note that the relevant interpretive challenges do not simply go away with use of these methods, since each type of analysis allows for several different types of indirect effects (e.g., effects via slope versus intercept for growth curve models; effects via latent change scores versus initial values for latent difference models).

It is important to stress that the cascade models discussed in this chapter do not all follow a single, prescriptive analytic framework. However, the majority of studies conducted within this conceptual area have a longitudinal panel design structure with at least three constructs of interest assessed on at least three occasions of measurement. In addition, the estimation of indirect effects, through various paths, is of substantial interest for this area of work. In reviewing the work to be discussed, there is clearly a greater need to incorporate some of the tenets of Cole and Maxwell's (2003; Maxwell & Cole, 2007) methodological studies to obtain the most accurate estimates of effects in the future. For example, even modelers who are most interested in testing whether effects from one domain assessed early in a longitudinal study (e.g., externalizing behavior problems) eventually spread out to affect multiple later domains are implicitly testing for the presence of a nonzero longitudinal indirect effect. However, given the current state of the science, we also applaud the use of multiple analytic methods in this domain. For example, some work uses latent growth curve modeling to test whether effects in one domain "spill over" to affect the change in a separate domain (Klimes-Dougan et al., 2010). Other work makes use of intervention designs to test whether hypothesized cascades can be interrupted (McClain et al., 2010; Patterson, Forgatch, & DeGarmo, 2010).

Cole and Maxwell (2009) provided further elaboration of methodological issues related to studying longitudinal relations among constructs. Their work highlighted the sensitivity of results to variations in individual patterns of change and specified several additional potential analytic approaches (e.g., random coefficient modeling, latent state-trait modeling) that are of potential interest in this domain. Relatedly, Selig, Preacher, and Little (2012) emphasized the explicit modeling of varying time lags across individuals and potentially the random assignment of participants to different measurement lags, if one's focus is on elucidating the timing of a developmental process. The largely variable-focused nature of these methods can be complemented by person-oriented methods that aim to identify relatively homogeneous subgroups of a sample, either concurrently or via patterns of change over time (Masten, 2001; Nagin & Tremblay, 1999; Von Eye & Bergman, 2003).

Unfortunately, none of the statistical techniques just described eliminate well-known and fundamental causal inference problems for nonexperimental data. Social scientists have long been aware of the need for experimental, or quasi-experimental, manipulation of constructs for establishing causal inference, and new statistical and theoretical work has drawn closer attention to the conditions

under which causal inference can be justified (Foster, 2010). Recent advances suggest ways in which careful selection of exogenous predictors in a model can move the field closer to causal inference, given specific assumptions (Pearl, 2000, 2012). This work on *causal mediation analysis*, largely developed outside of psychology, is nonetheless having an impact on the field. In a key contribution, Imai, Keele, and Tingley (2010) detailed the assumptions required to make causal attributions from both experimental and nonexperimental data and provided routines to conduct sensitivity analyses for key assumptions and bootstrapping to estimate the magnitude of mediating effects through a psychological research example. Few of the studies to be reviewed have been directly informed by these approaches. However, prevention scientists have considered this body of work in efforts to clarify mechanisms of mediation and reduce selection bias (Coffman, 2011; Crowley, Coffman, Feinberg, Greenberg, & Spoth, 2014), and a highly accessible treatment of modeling confounds in resilience research has been presented by Card and Barnett (2015). This is clearly an area for further research and application; nevertheless, we caution researchers in this area to be conservative in their discussions of causality and to detail all attempts made to justify the necessary analytic assumptions.

Empirical Findings

Here we review findings from selected empirical investigations that are consistent with our understanding of testing developmental cascades. We highlight in particular the series of papers published in two special issues of *Development and Psychopathology* in 2010 (Masten & Cicchetti, 2010) as well as selected additional papers. Because these papers focus on a variety of constructs, samples, and age ranges, they are somewhat difficult to classify. However, given this chapter's focus on competence and psychopathology, we have organized this discussion by areas of competence that have been assessed. We first focus on studies including academic competence in patterns of relations with risk and psychopathology, followed by studies including social competence and studies testing both academic and social functioning. We then discuss other studies that have examined a wide range of target constructs. Where possible, we draw attention to convergent empirical evidence across age ranges as well as the implications of differences in statistical/data analytic methods. In most cases, research is focused on estimating cross-domain longitudinal paths between competence domains and either externalizing or internalizing problems.

Testing Cascade Effects through Academic Competence

Several investigations have examined the longitudinal links among behavioral/emotional problems and academic competence. Masten and colleagues (2005) reported results from the Project Competence longitudinal study, demonstrating that childhood externalizing problems were negatively associated with later academic achievement in late adolescence/emerging adulthood, and academic competence in turn was negatively associated with internalizing problems in young adulthood. Key cross-domain paths remained statistically reliable when adding a subset of potential common-cause variables, namely socioeconomic status (SES), intellectual ability, and quality of received parenting. In addition, the authors noted a negative longitudinal path from internalizing to externalizing, one possible interpretation of which was the personality construct of behavioral inhibition simultaneously acting as a protective factor for externalizing problems but as a risk factor for internalizing problems (Kerr, Tremblay, Pagani, & Vitaro, 1997).

Following Masten and colleagues (2005), in recent years the associations among externalizing, internalizing, and academic competence have continued to be studied across different samples and age ranges. A subset of these studies have extended this work by longitudinally testing the role of alcohol and substance use in cascade findings that relate to academic competence (or failure) and broader externalizing problems, given long-standing work on the associations across these domains. Other work has expanded the range of samples, age ranges, and assessment intervals that are employed. Finally, as discussed in subsection "studies including both academic and social competence," some work has examined reciprocal and joint paths among academic competence, social competence, and behavioral and emotional problems.

An investigation by Moilanen, Shaw, and Maxwell (2010) tested longitudinal links among externalizing problems, internalizing problems, and academic competence in a sample of low-income boys and their families, with rich multi-informant assessments of each construct spanning ages 6 to 12. In the best-fitting structural equation model for their data, Moilanen and colleagues reported consistently high rank-order stability of each of their primary constructs across this developmental period. Above and beyond stability and concurrent association, the authors reported negative cross-domain paths from externalizing problems to academic competence (from ages 6–10) and from academic competence to internalizing problems (from ages 8–11), as well as "feedback" negative paths from academic competence back to later externalizing.

Contrary to Masten and colleagues (2005), positive externalizing-to-internalizing paths were observed at the start and end of the study. However, consistent with Masten and colleagues' (2005) results, primary cross-domain paths were largely unchanged when including additional early constructs of neighborhood advantage, IQ, and parenting in the model. Moilanen and colleagues (2010) interpreted their results in terms of "adjustment erosion," positing that early externalizing problems in particular could have both direct and indirect effects on functioning in the classroom, especially during the transition to formal schooling and the transition to middle school, transitions that bookended their assessments.

Starting at a similar age range as Moilanen and colleagues (2010) but extending farther into adolescence, Englund and Siebenbruner (2012) reported cascade model results from the Minnesota Longitudinal Study of Risk and Adaptation, an intensive long-term study of youth at developmental risk due to poverty. Findings were again broadly consistent with prior work, especially in terms of academic failure (here, at age 9) predicting longitudinally to future externalizing and internalizing problems as well as a negative internalizing-externalizing link consistent with results of Masten and colleagues (2005); covariates included SES, minority status, and age of mother at participant's birth. However, in the Englund and Siebenbruner (2012) study, longitudinal links from externalizing to academic competence were not observed, although the two constructs were associated at the first time point in their model (age 7; standardized path estimate of –.22). Importantly, and consistent with much prior work, Englund and Siebenbruner reported that prediction of substance use in adolescence was mediated through earlier (and concurrent) externalizing problems, although they also noted an unexpected positive association from academic competence to use versus nonuse of alcohol, suggesting that presence of alcohol use, distinct from amount of drinking, may have been quasi-normative for this at-risk sample. Other work examining links between academic achievement and substance use, although not conducted from a full cascade framework, has supported a consistent longitudinal association between marijuana use and academic underperformance throughout high school in an affluent sample (Ansary & Luthar, 2009).

Other work in this area has focused more closely on the longitudinal associations among academic competence and either broad internalizing problems or key subsets of internalizing, such as depressive symptoms. For example, Hishinuma, Chang, McArdle, and Hamagami (2012) examined the longitudinal links between academic functioning and depressive symptoms in a large ($N > 7{,}000$) sample of Hawaiian youth across grades 9 to 12. In contrast to the traditional cross-lagged structural equation modeling (SEM) design, this study employed a sophisticated bivariate latent difference score model, although it should be stressed that this analytic approach does not fully remove the potential criticism of unobserved confounders preventing causal inference. Of interest, Hishinuma and colleagues (2012) found stronger evidence for depressive symptoms being associated with future changes in academics (with somewhat stronger effects for native Hawaiian youth), which contrasts with several of the cross-lagged studies already discussed. It is unclear whether this discrepancy in findings may be related to analytic differences or perhaps differences in the sample or assessment: For example, the Hishinuma et al. study relied primarily on self-report measures for both academics and depressive symptoms. In addition, latent difference scores were set up annually; as discussed by Cole and Maxwell (2003), lag time between assessments may have influenced the pattern of findings.

More frequent assessments entered into an extensive analysis of data from the Pittsburgh Youth Study (a longitudinal study of over 1,500 boys oversampled for antisocial behavior) from ages 11 to 15 (Defoe, Farrington, & Loeber, 2013). The authors tested a series of models linking SES, academic achievement, hyperactivity, delinquency, and depressive symptoms annually over this age period. Although due to complexity some constructs were split into separate models, the results showed impressive consistency in terms of direction of effects. Briefly, evidence was obtained for a longitudinal chain of effects starting with early joint influences of hyperactivity and low SES on academic achievement to delinquency and finally to depressive symptoms. Although cross-domain paths tended to be small in magnitude, they were obtained in excess of both single-year and 2-year lagged continuity estimates, which themselves were generally moderate in strength.

Other work has examined academic achievement itself as an outcome of cascading effects that cumulate from early childhood. Notable for its prediction from very early in childhood, a report by Bornstein, Hahn, and Wolke (2013) demonstrated indirect effects from habituation efficiency at age 4 months to cognitive testing at 18 months and 8 years (indirectly affecting and affected by 36-month behavior problems) to academic achievement at age 14. In this study, using data from the Avon Longitudinal Study of Parents and Children, behavior problems and maternal education had both direct and indirect effects

on later academic achievement. Early cognitive measures had small but reliable effects on childhood intelligence, which was the largest single predictor of academics in adolescence. Further work by this same research team has demonstrated two additional findings of interest. First, infants' early physical development and motor exploration (at 5 months of age) appear to act as catalysts for their later intellectual development, with cascading effects seen to IQ at ages 4 and 10 years and subsequently to academic achievement at age 14 (Bornstein, Hahn, & Suwalsky, 2013c). Second, language abilities in early childhood showed cross-domain paths to subsequent internalizing problems in two samples controlling for a series of potential common-cause variables (Bornstein, Hahn, & Suwalsky, 2013b). Although language facility has only rarely been studied from the cascade modeling perspective, it is a promising candidate for future research due to its status as a key developmental task of the early childhood years (McCormick et al., 2011) and is a clear foundational task for academic achievement. In addition, longitudinal evidence using bivariate growth curve models has shown stronger prediction from language skills—specifically, receptive vocabulary—to (reduced) growth of externalizing problems and inattention/hyperactivity from ages 7 to 13 (Petersen et al., 2013).

Summary of Academic Competence Cascade Evidence

To date, several independent data sets have shown evidence for cross-domain longitudinal prediction from externalizing behavior problems to lowered academic competence. In addition, there is generally consistent evidence for links from lowered academic competence to increased internalizing problems, although this association is less consistent than the former one. Effects appear to be stronger when indexed with somewhat longer time intervals, excepting very young childhood; indeed, in this body of work, the chosen time intervals are not always justified by developmental considerations, and an argument can be made to vary assessment intervals based on the expected pace of change in a given developmental period. Overall, however, this work affirms the role of adequate academic performance as a key developmental task in the overwhelmingly North American and Western European societies from which these data have been drawn. In the majority of cases where gender differences in cross-domain paths have been tested, evidence has not been found for differences. However, it should be emphasized that power analysis for SEM is evolving, and it is not entirely clear how large sample sizes need to be to convincingly rule out Type II error for tests of gender differences. Target sample size will depend on the predicted effect size of key model paths, which is an extension to this research that is still in early stages.

Not all investigations have found robust associations between early externalizing problems and academic achievement: Duncan and colleagues (2007) pooled results across six data sets and found negligible predictive power of early socioemotional variables (including internalizing and externalizing) to academic achievement later in elementary school when also controlling for early school readiness variables, attention, and a wide set of demographic control variables. Rather, preacademic skills and attention skills appeared to be stronger predictors. It is likely that choice of covariates and potentially the direct versus indirect assessment of socioemotional variables play a role in differences in findings in this domain, as discussed further later. Although not focused on broad internalizing problems, a separate meta-analysis by Huang (2015) showed evidence for a modest negative relation (mean $r = -.15$) between academic competence and subsequent depression, which was reduced when including prior depression in the analysis and not moderated by gender, ethnicity, birth cohort, or measurement strategy.

Testing Cascade Effects through Social Competence

Cascading relations among social competence and behavioral/emotional problems have been even more frequently studied than links with academics. Using the same sample and parallel analytic techniques to the Masten et al. (2005) study, subsequent Project Competence research examined the longitudinal links among externalizing, internalizing, and social competence (Burt, Obradović, Long, & Masten, 2008), finding evidence for moderate to strong negative longitudinal associations from social competence to internalizing problems, both from childhood to adolescence and from emerging adulthood to young adulthood. Although longitudinal links were not seen between externalizing problems and social competence in this study, the latter constructs were strongly negatively associated (standardized coefficient of –.48) in the initial middle-childhood assessment.

A limitation of the study by Burt and colleagues (2008) was reliance on relatively large time lags between assessments, on the order of several years. In addition, although constructs were assessed comprehensively through multi-informant and multimethod assessments, the study took a big-picture view of key constructs, treating social competence as a single measure (consistent with confirmatory factor analytic evidence for those data). However, other studies have examined related constructs, such as popularity and peer social preference, in more

detail and across narrower time ranges. Generally speaking, this work confirms that failures in social competence in both childhood and adolescence can have negative links to later internalizing (and sometimes externalizing) problems. In addition, multiple studies have found longitudinal links from early externalizing problems to subsequent problems with peers. In each case, peer rejection and/or victimization are likely to be key elements.

Following the core analytic strategy of Burt and colleagues (2008) but using annual assessments including family adversity exposure in the oldest cohort (ages 9–14) of the Pittsburgh Girls Study (a group oversampled for neighborhood disadvantage and followed annually), Obradović and Hipwell (2010) replicated an externalizing-social competence-internalizing cascading effect across ages 9 to 12. In addition, child behavior problems predicted later family adversity exposure (e.g., parental depression, harsh parenting, and perceived parental stress) in these models, consistent with a "child effects" framework and with work to be discussed suggesting that preventing child problems is associated with changes in parental and family functioning (Patterson et al., 2010). Finally, pubertal status had negative links with internalizing problems early in the study, but the direction of this effect shifted as the majority of the sample reached puberty, suggesting that pubertal effects may vary depending on the larger peer context. Similar to the Project Competence report, this study assessed a broad social competence construct made up of both peer and friendship social status and social self-worth, although competence assessment was solely self-report.

Other work from a cascades framework has found evidence for social competence as a key predictor in middle childhood and has extended this work to examine diverse samples and potential moderators. For example, Rogosch, Oshri, and Cicchetti (2010) tested social competence cascades in a sample of maltreated and nonmaltreated but demographically matched youth. They found robust main effects of maltreatment on all major constructs (externalizing, internalizing, and social competence) at the first time point (ages 7–9) and evidence for social competence at ages 10 to 12 as a negative predictor of later externalizing problems; earlier internalizing was a negative predictor of social competence. Rogosch and colleagues (2010) were interested in predicting cannabis abuse and dependence in late adolescence, and showed both direct and indirect (through internalizing and externalizing) links from maltreatment history. In a separate study, Bukowski, Laursen, and Hoza (2010) demonstrated that friendship status moderated the effect of peer rejection on growth curves of peer-reported sad affect across 3 years of middle childhood. That is, among youth with high initial scores of peer avoidance and peer exclusion, depressed affect increased over time for youth without close friends but decreased for youth with at least one close friend. Although the latter study used a different analytic strategy from most studies discussed in this section, the use of growth curve models may be of special importance for future study of developmental cascades, and we consider several additional examples of this analytic strategy later. Taken together, the previous studies show the importance of social competence as an organizing construct in middle childhood across diverse samples and methods.

Several investigations have pushed back the developmental time frame of cascade models, assessing social competence and peer relations earlier in childhood while sometimes still maintaining assessments through adolescence and into adulthood. This extensive time frame is particularly challenging since typical longitudinal structural equation models require similar measurement of constructs through the duration of the study, to avoid confounding change in measurement with true construct differences. In a study extending this broad work to the early childhood years (beginning at age 2), Blandon, Calkins, Grimm, Keane, and O'Brien (2010) examined links between early externalizing problems, developing emotion regulation and social skills (beginning at age 4), and later sociometric status. Consistent with greater fluidity of development and less differentiation in the early years, Blandon and colleagues found evidence for less stability of constructs than similar studies with older participants and noted very high associations between early emotion regulation and social skills measures, both of which serve to limit detection of any nonzero cross-domain effects. Nonetheless, negative cross-domain paths were noted from social skills to later externalizing problems at multiple time points, providing evidence for the importance of these emerging skills early in childhood.

Two additional studies have examined social competence and peer relations in early childhood and their associations with later behavioral/emotional problems. First, Bornstein, Hahn, and Haynes (2010) showed evidence for negative links from age 4 social competence to age 10 and 14 externalizing and internalizing problems, effects above the moderate stability in each domain and which were unchanged when including child intellectual functioning, maternal education, and maternal social desirability in the path model. The authors noted that their results reinforced the historical importance granted to early social competence by attachment researchers

(e.g., Sroufe, Egeland, & Kreutzer, 1990). The same research group demonstrated cascading effects from externalizing problems at age 4 to broad adaptive functioning (communication, socialization, motor and living skills on the VABS) at age 10, controlling for IQ (Bornstein, Hahn, & Suwalsky, 2013a). Second, Lansford, Malone, Dodge, Pettit, and Bates (2010) tested a series of paths connecting social information processing (SIP), peer rejection, and aggression over 12 assessment periods spanning kindergarten through third grade in the Child Development Project, building on earlier work from that sample and others examining SIP as a partial mediator of effects of early rejection on aggression (Dodge et al., 2003). In brief, Lansford and colleagues found evidence for a series of "snowballing" effects in which SIP deficits were associated with later rejection, which was associated with both aggression and further SIP changes, with aggression also providing a separate link to subsequent peer rejection. The authors noted that the lower stability of SIP relative to rejection and aggression implies that SIP should be a key target for prevention and intervention efforts.

As evidenced by Lansford and colleagues (2010), closer waves of assessment allow for the development of feedback loops over time among constructs. In this vein, two further studies specifically highlight the "vicious cycles" that can arise during multiple developmental periods when child behavior problems are first linked with peer problems and those further exacerbate children's problems over time. Focusing on the early school years, van Lier and Koot (2010) aimed to clarify how different aspects of broad social functioning (social preference, victimization, and friendedness) related to externalizing and internalizing in a Dutch sample. Results from this study supported transactional links between externalizing and poor social preference over time, with initial externalizing predicting all three social constructs in expected directions. Victimization also became "entangled" with poor social preference in this study, suggesting complex relations among social competence constructs that also mediated longitudinal links between externalizing and internalizing problems, with key results invariant by gender. Follow-up work with this sample has replicated the bidirectional links between peer rejection and externalizing problems when including best friend's externalizing in the model, which did not add to cross-domain prediction at this age range (Sturaro, van Lier, Cuijpers, & Koot, 2011). Additional work by this team in a separate sample using linked growth curve models has shown that kindergarten conduct problems are linked to early-elementary-school depressive symptoms via experiences of peer rejection (Gooren, van Lier, Stegge, Terwogt, & Koot, 2011). Relatedly, but moving into middle childhood and adolescence, an analysis of the Multimodal Treatment of ADHD (MTA) sample by Murray-Close and colleagues (2010) showed evidence for transactional effects between low social skills and aggressive behavior problems throughout the course of their study (ages 10–16). Aggression was also linked to antecedent inflated self-beliefs and prospectively to peer rejection in this sample, with paths invariant by gender and ADHD status.

Finally, we wish to draw particular attention to two studies conducted by Dodge and colleagues, using parallel analytic methods to test a long-ranging cascade of effects from early problem behavior to the development of serious violence and substance use problems in adolescence across two samples. This work is an example of how the cascade metaphor links to programmatic developmental work without necessarily prescribing a single analytic method. First, Dodge, Greenberg, Malone, and the Conduct Problems Prevention Group (2008) used this framework to examine a progression of effects from early contextual disadvantage to adolescent serious violence in the high-risk control sample of the well-known Fast Track intervention study. Key constructs spanned time periods from kindergarten through eleventh grade and were assessed via multiple informants and methods. Rather than traditional SEM, Dodge and colleagues chose a two-stage partial least squares (PLS) predictive modeling procedure, which seeks to maximize predictive power and has somewhat less restrictive assumptions as compared with other uses of confirmatory factor analysis and SEM. When matched with specific theory, PLS can provide important model testing, albeit with a different focus from typical SEM: one that emphasizes an aggregate index of items for prediction that is not hypothesized to be caused by a single latent variable. Results from this study suggested that each step of the hypothesized cascade—adverse context, early harsh parenting, poor school readiness, early school conduct problems, grade school academic failure, low parental monitoring in later grade school, affiliation with deviant peers in early adolescence, and violent behavior in adolescence—was related to the prior and subsequent steps. More specifically, each domain partially mediated the effects of the immediately preceding domain, and each added incrementally to the overall prediction of adolescent violence. Although most paths were invariant by gender, there was some evidence that social context and early parenting had greater prediction of later violence for females whereas early externalizing and school problems predicted for males. Among other contributions,

these results confirm previous work on the bidirectional relations between school failure and externalizing behavior problems and provide compelling evidence for the early contextual and familial difficulties that precede the rapidly developing school problems for some externalizing youth. As the authors noted, a detailed cascading chain of effects also points toward places and time points that may be ripe for preventive intervention efforts. In fact, subsequent mediation work using the Fast Track intervention sample has shown that over 25% of the impact of the intervention on reducing adolescent antisocial behavior could be accounted for via three earlier social-cognitive processes: reducing hostile attributions, increasing competent responses to social challenges, and reducing favorability of aggressive responses (Dodge, Godwin, & the Conduct Problems Prevention Research Group, 2013).

Second, a monograph by Dodge and colleagues (2009) employed parallel methods to study the development of illicit drug use in the previously mentioned Child Development Project sample, with associated commentary by Schulenberg and Maslowsky (2009). In this comprehensive study, Dodge and colleagues demonstrated how early child, family, and peer factors systematically build to predict the initiation of illicit substance use by the end of high school. Although effects at each time point were small to moderate in magnitude, the cumulative effect of these cascading influences is striking, with person-oriented analyses describing risk of substance use initiation that varied from 25% among youth following the lowest-risk sequence to 91% among youth following the highest-risk sequence. These analyses were complemented by variable-oriented tests of the full model (i.e., from parenting problems in early childhood to adolescent substance use initiation via early child behavior problems, early peer problems, adolescent parenting problems, and association with deviant peers) again using composite variates and PLS modeling. Above and beyond the key cascading path of effects, continuity was seen for parenting problems and peer problems from childhood to adolescence. Similar to several of the studies reported earlier, mean gender differences were observed on many constructs, but developmental progression did not vary by gender. Perhaps most important, each piece of the hypothesized progression mediated (either partially or fully) the prior step in the sequence. Commentary on this study emphasizes the strong theoretical basis of the proposed sequence of effects, the utility of a parsimonious model with a low risk of overfitting to a specific data set, and the need for close study of developmental transitions (Schulenberg & Maslowsky, 2009).

Summary of Social Competence Cascade Evidence

An impressive body of work has arisen in recent years testing cascading effects between social competence and both externalizing and internalizing problems, spanning childhood and adolescence and employing several different methodologies. It is clear that, like academics, social competence represents a core developmental task beginning in young childhood and continuing throughout development. Several studies show the pernicious effects of externalizing problems on social adjustment, and multiple investigations show paths consistent with failure model theories that predict increased internalizing, and sometimes externalizing, problems from lower social competence.

More specifically, findings from the social domain generally show somewhat less longitudinal stability in constructs but somewhat more cross-domain links as compared with academics. In addition, findings vary, albeit often in predictable ways, depending on the domain of social adjustment that is assessed (e.g., broad judgments of competence, peer rejection, social cognition). Of particular note are findings of "vicious cycle" links across time between peer relations and externalizing problems, and the programmatic work by Dishion, Dodge, and others that demonstrates how deviant peer association and constructs such as deviancy training and coercive joining of an antisocial peer group operate to reinforce and amplify aggression and antisocial behavior (Van Ryzin & Dishion, 2013).

It should also be noted that the broad social competence construct has been linked to adult psychopathology in different ways. For example, although not tied to social competence as measured by many of the studies already discussed, Lenzenweger (2010) has proposed a theoretical cascade that posits absence of parental "proximal process" (reciprocal interactions with a child that foster psychological functioning) impairing the broad affiliative system observable via child temperament and leading to the development of schizoid personality disorder in adulthood.

Studies Including Both Academic and Social Competence

There are multiple reasons to highlight longitudinal cascade studies that include both social and academic competence domains: Longitudinal SEM studies statistically control for other constructs in the model, thus providing more stringent tests of prior findings with single domains; relations between academics and social functioning themselves can be modeled in these studies; and key theories, such as the dual failure model for depressive symptoms, that rely on joint effects from failure in these

two broad domains are more fully tested. In general, this research has supported dual failure theories in which the combination of problems with academics and one's peers interact to elevate risk for future mental health problems (e.g., Capaldi, 1992).

Two reports from the Project Competence data set have explored the potential joint relations of academic and social competence with externalizing problems, internalizing problems, and the subsequent competence domain of effective work functioning. First, Obradović and colleagues (2010) demonstrated that earlier longitudinal cross-domain effects from academic and social competence in childhood and emerging adulthood to internalizing problems in young adulthood maintained when both domains were included in the statistical model, with academics also showing a positive longitudinal relationship to social competence. Second, subsequent work with this sample focused on the crucial young adult outcome of work functioning, demonstrating a longitudinal cross-domain path from childhood social competence to the domain of employment functioning (e.g., reliability, achievement) in emerging adulthood, which in turn was highly stable into young adulthood (Masten, Desjardins, McCormick, Kuo, & Long, 2010). Although academic competence did not show unique longitudinal prediction to the work domain, this may have been in part due to the high concurrent association (standardized path estimate of .59) in emerging adulthood.

Other work has extended the dual failure cascade modeling to independent samples, while also looking at the timing of effects at narrower intervals. Burt and Roisman (2010) tested similar effects in the National Institute of Child Health and Human Development (NICHD) Study of Child Care and Youth Development (SECCYD), using maternal reports of behavior problems and social skills and standardized academic achievement testing at five time points from age 54 months to 15 years. They found evidence for indirect effects of early externalizing problems through academic competence/failure to internalizing in early childhood as well as indirect effects through social competence later in childhood (feeding back to externalizing and academic problems in adolescence), consistent with other work emphasizing social relations in predicting trajectories of externalizing and internalizing problems in the same data set (Fanti & Henrich, 2010). However, effects seen by Burt and Roisman were generally of small magnitude. At first glance, these findings conflict with Duncan and colleagues' (2007) report that also included the NICHD SECCYD as part of six meta-analyzed data sets. However, closer inspection of the analytic plan from each report suggests that it is the presence of specific covariates that affected whether the externalizing-academics association is present: In the Duncan et al. (2007) paper, earlier externalizing behavior (age 3) was also controlled for when examining age 4.5 aggression to kindergarten academic skills in this data set. Consistent with this finding, the early externalizing to academics link reported by Burt and Roisman dropped to marginal significance when the covariates of maternal sensitivity, income/needs ratio, and early cognitive ability were also included in the model.

Related work from the Québec Longitudinal Study of Child Development, focused more narrowly on the early school years, showed evidence for cascading effects from externalizing problems at age 6 through both academic problems and peer victimization at age 7 to internalizing problems at age 8. Peer victimization also fed back to externalizing, and early school readiness measures predicted negatively to internalizing 1 year later; again, cross-domain effect sizes tended to be small in the face of strong continuity and contemporaneous associations among constructs (van Lier et al., 2012). Subsequent work by this research team provides evidence for a cascade from peer rejection through (low) social self-concept to internalizing problems across second grade into third grade (Spilt, van Lier, Leflot, Onghena, & Colpin, 2014). Extending this work to slightly older youth, Vaillancourt and colleagues (2013) presented cascade evidence through the middle school years for internalizing problems leading to increased future peer victimization and for academic problems predicting future externalizing, both cascade effects persisting when controlling for household income and parental education.

Finally, Chen and colleagues (Chen, Huang, Chang, Wang, & Li, 2010; Chen, Huang, Wang, & Chang, 2012) have presented two studies from a Chinese sample of elementary school students investigating these topics. Their first report supported paths from early aggressive behavior problems to lowered social and academic competence, and cross-domain longitudinal paths between social competence and academics, even in the context of high rank-order stability (Chen et al., 2010). A follow-up report supported a consistent link between aggression and poor peer relationships (seen at each annual window from grades 3–6) but also demonstrated that starting levels of aggression are associated with the growth of peer problems over the 4-year duration of data collection (Chen et al., 2012). For all of these studies, although mean gender differences were frequently observed for key constructs, the longitudinal cross-domain paths generally did not vary by gender, suggesting the operation of similar processes.

The authors highlighted the strict socialization away from externalizing problems in Asian culture (i.e., self-control and maintaining group harmony are highly valued) while noting their results were generally consistent with data from Western societies.

Given the increased salience of peer relationships in adolescence, several longitudinal studies have focused on the preteen, teenage, and young adult years in testing links among behavioral and emotional problems and academic and social competence, the latter broadly defined to include deviant peer affiliation and peer victimization. First, work from the University of Oregon has modeled the longitudinal development of violent behavior in late adolescence via early problem behavior and academic failure, leading to gang involvement and deviancy training—the highly stable mutual reinforcement of deviant talk in friendships (Dishion, Véronneau, & Myers, 2010)—with consistent patterns of associations (despite mean differences) across African American and European American youth. Second, a major study of children at risk for alcohol problems using cascade methods has shown that effects of parental alcoholism on offspring substance use disorders in adulthood is mediated through adolescent substance use, academic achievement, and affiliation with a substance-using peer group (Haller, Handley, Chassin, & Bountress, 2010), with some differences in effects for alcohol versus other drugs (e.g., less evidence for selection effects for binge drinking as compared to illegal drug use). Third, data from the Seattle Social Development Project have shown longitudinal prediction from depressive symptoms at age 10, through school failure in adolescence, to risk for a major depressive episode at age 21 (McCarty et al., 2008); however, this longitudinal mediated path was evident only for girls, in contrast to several other reports already noted. Although early social problems were also tested in this model and showed a zero-order correlation with earlier depressive symptoms, they did not show independent prediction to adult depressive episode risk for either gender. McCarty and colleagues (2008) noted that in their study, stronger prediction may have been seen for girls for both academic failure and early conduct problems to later major depression due to gender differences in base rates of the former problems: that is, girls identified with these problems may have been relatively more severe cases. Evaluation of one's competence in the school context may also have different consequences by gender on average, although other cascade studies have generally not shown supportive evidence for this assertion.

Although not employing the typical cascade methodology, Nocentini, Calamai, and Menesini (2012) studied a bivariate growth curve model of delinquent behavior and depressive behavior across 3 years of Italian high school (grades 9–11). Interestingly, the authors found a somewhat different pattern of time-invariant versus time-varying effects for the two domains, with stronger evidence for distal effects (i.e., present at the start of the study and operating uniformly throughout) of academic and social failure on delinquent behavior but proximal effects (varying year to year, and sometimes operating indirectly) of dual failure for both delinquent behavior and depressive symptoms.

Examining developmental task domains more broadly, Staff and colleagues (2010) emphasized the nature of role transitions across adolescence and young adulthood in analyzing data from the Monitoring the Future study, focusing on prediction of substance use. Similarly to comparing social selection versus social causation effects (Martin et al., 2010), a focus was on comparing role selection versus socialization explanations for associations between adult family and work roles and reduced substance use. Generally, their results showed strong support for the socialization hypothesis, showing that changes in social roles lead to changes in substance use controlling for several prior risk factors. Looking across domains, Staff and colleagues found that changes in family roles (e.g., marriage, parenthood) appeared to have stronger effects than did changes in social and work roles, controlling for age to account for differential timing of role transitions. Changes in socializing (spending evenings out for fun and recreation) and religiosity partially mediated these effects. This work suggests that the emerging adulthood years can be a key point of change for the continuation versus reduction of substance use, one aspect of their importance in developmental psychopathology more generally (Schulenberg, Sameroff, & Cicchetti, 2004).

Summary and Future Directions: Academic and Social Competence Cascades

The research reviewed is compelling in its broad support of dual failure models across wide ranges of the childhood and adolescent years. In particular, the inclusion of both academic functioning and social competence (or related constructs, such as peer rejection and victimization) in single longitudinal models demonstrates that these two aspects of global competence can themselves interact and that cross-domain effects seen via one domain are not typically proxies for the other but rather may compound in interesting ways. For example, there is evidence that high academically achieving students generally self-select into peer groups with other high-achieving students by early adolescence (Véronneau, Vitaro, Brendgen, Dishion, & Tremblay, 2010). One implication from these findings,

highlighted by van Lier and Koot (2010), is that early prevention efforts should be focused on enhancing *both* academic success *and* effectiveness in social relationships wherever possible, especially since peer affiliative groups may be easier targets for intervention compared to global peer status (Véronneau et al., 2010).

Common to many studies of cascade modeling, important future directions for research include better delineation of the timing of effects, testing of moderators, including but not restricted to gender, and consideration of additional mediators. As an example of potential mediators, one study has shown evidence for increased parent-child conflict as a mediator of longitudinal externalizing-internalizing links from grades 4 to 8 in a model that also included academic and social competence (Yong, Fleming, McCarty, & Catalano, 2014). Regarding timing of effects, it is broadly seen that longer time intervals have resulted in stronger magnitudes of cross-domain predictive paths in this research. However, very few studies have explicitly planned time intervals to maximize strength of effect, as recommended by Cole and Maxwell (2003). It is possible that careful reanalysis of data sets with many time points, systematically testing subsets of varying time lags, could prove useful in clarifying this issue. However, any such work should be theoretically informed and should account for issues of multiple statistical comparisons rather than being purely data-driven. Future studies would also do well to heed Dodge and colleagues' (2008, 2009) method of systematically isolating and combining the most theoretically relevant predictive variables at each assessment period. In addition, it is an obvious but important point that the influence of a specific process cannot be tested unless it is accurately assessed. Thus, work by Dishion et al. (2010) demonstrating the key impact of deviancy training in close friendships (and highlighting the importance of identifying and preventing the growth of deviant peer clusters) was possible only by employing observational recording of adolescent dyadic friendships. Many of the studies reviewed are more limited in their range of measurement, often relying on primarily questionnaire-based assessment due to the resource cost of assessing multiple constructs across several time points (cf. Cox, Mills-Koonce, Propper, & Gariépy, 2010).

Additional Studies of Cascade Methodology: Links Across Generations and Diverse Constructs

Although not focused explicitly on broad developmental task domains, several additional recent studies have advanced the literature on developmental cascades by extending aspects of the studies reviewed by use of new populations, new methods, and broader key constructs. Some of the ways in which cascade studies have been extended include studies of continuity and change in behavioral/emotional problems across generations as well as expanding established cross-domain links to encompass additional constructs such as life stress, effortful control (EC), and broad self-regulation. In addition, other studies represent potential methodological strengths, such as the use of latent growth curve models in studying cross-domain effects and/or the inclusion of intervention or prevention designs.

As a key example of studying intergenerational effects from this perspective, Garber and Cole (2010) presented longitudinal data from adolescents ages 12 to 18 years and their mothers, oversampled for a history of depressive symptoms. In a similar fashion to the study by Nocentini and colleagues (2012) described earlier, Garber and Cole distinguished between distal effects of maternal depression, which affected the *intercept* of adolescent depressive symptoms in a growth curve model, and proximal effects via other intermediate variables, which affected the *slope* of adolescent depressive symptoms in a growth curve model. Mediating variables included risk factors of negative family life events, overall family climate, and self-worth, all assessed in early adolescence. Importantly, the direction of effects was consistently from the risk factors to growth in depressive symptoms rather than the reverse. Despite the strengths of this design, one limitation is the inability to parse the interplay of genetic and environmental influences across generations. However, other work focused earlier in development (ages 9–27 months) used an adoption design to separate out risk for toddler externalizing problems from both biological maternal depressive symptoms (which appeared to operate via pregnancy risk) and risk from each adoptive parent's depressive symptoms (Pemberton et al., 2010). This work highlights the potential for bidirectional influences between children and their environment, which is consistent with work examining links between SES and adolescent problem behavior across two generations in the Iowa Family Transitions Project (Martin et al., 2010). Although not focused on biological variables, results from this model suggested support for both social causation (parent SES influencing adolescent behavior problems) and social selection (adolescent behavior problems influencing their adult SES) processes.

Other research on intergenerational associations in antisocial behavior has emphasized potentially differing mediating pathways depending on which parent is the focal point of investigation. For example, Thornberry, Freeman-Gallant, and Lovegrove (2009a,b) demonstrated that in the ethnically diverse Rochester Intergenerational Study, parental delinquency and drug use in adolescence

were associated with offspring externalizing behaviors primarily via effective parenting for mothers (nearly all of whom lived with their children) but via multiple mediating paths (parenting stress, effective parenting, and parent's age at first birth) for fathers who had high levels of contact with children; some influence of parental depressive symptoms was also noted. Importantly, the intergenerational associations were not present for fathers who had low contact with their children. Related intergenerational research from the Seattle Social Development Project has reported that although harsh discipline was associated with childhood externalizing problems across two generations, the intergenerational association of externalizing was mediated more by parental substance use than by harsh discipline (Bailey, Hill, Oesterle, & Hawkins, 2006, 2009). Despite some differences in findings, both data sets support the clear disruptive effects of parental substance use problems on offspring adjustment.

Given the importance of behavioral and emotional regulation for the development of broad competence across childhood, it is not surprising that multiple investigations have examined longitudinal links between EC or other aspects of regulation and preceding, concurrent, and subsequent externalizing and internalizing problems. Examples from this literature include a study of 18- to 42-month-olds by Eisenberg and colleagues (2010) that examined parenting, EC, and internalizing and externalizing problems at three time points. Briefly, study results showed support for maternal unsupportive reactions during an observational session negatively predicting subsequent EC; however, a mediating role of EC was not evident. This may have been due to high rank-order stability among the tested constructs in this sample (e.g., many standardized paths >.80). Work from the same research team has focused on later childhood, using bivariate semiparametric mixture modeling techniques to examine subgroups of youth with distinct trajectories of externalizing and two indices of EC: attention focusing and behavioral persistence (Zhou et al., 2007). This work suggests that although the population association of EC and externalizing may be driven by a subgroup of well-adjusted youth who are persistently high on the former and low on the latter, trajectories of externalizing for youth with more mixed longitudinal profiles of EC are more variable. Other work supports the importance of behavior regulation by demonstrating mediating effects of self-regulation in later years on associations between cumulative risk and externalizing, controlling for earlier externalizing problems (Doan, Fuller-Rowell, & Evans, 2012). In addition, work from a positive youth development (PYD) perspective analyzing the well-known 4-H study of Positive Youth Development has shown cross-domain longitudinal links across late elementary and middle school from positive parenting, to child internal self-regulation, to an integrative PYD construct (Lewin-Bizan, Bowers, & Lerner, 2010), which we return to in more detail when discussing prevention.

Cascade research has also examined how individual- and family-based stressful life events interact with externalizing and internalizing problems over time. Yates, Obradović, and Egeland (2010) presented data from the Minnesota Study of Risk and Adaptation, drawing on three assessments spanning 24 to 72 months of age, showing both direct and indirect (through child dysregulation) longitudinal paths between maternal contextual strain (a combination of stressful life events, social support, and romantic relationship quality) and child externalizing. In addition, Herrenkohl and colleagues (2010) used data from the Seattle Social Development Project to demonstrate independent prediction from family adversity and conduct problems in middle childhood to health risks and service use in young adulthood.

Focusing on self-reported stressful events, Brody, Chen, and Kogan (2010) demonstrated that self-reported negative emotions mediated the association between life stress, including racial discrimination, and the slope of a risk behavior growth factor (alcohol use, drug use, and having sex under the influence) in a sample of rural African American youth assessed through late adolescence and early adulthood: Data were collected as part of a family-based prevention program, which we discuss further in a subsequent section. Overall, their results were consistent with theories of stress proliferation in which major life stressors lead to secondary stressors (e.g., increased negative affect and problems in close relationships) that have enduring consequences (Pearlin, Schieman, Fazio, & Meersman, 2005). Although not directly assessed, the authors speculated that processes of peer differential affiliation and perceptions of risk behavior and substance use among peers operate to "carry" the observed effects.

A potential advantage of the methodology employed by Brody et al. (2010) over traditional cross-lagged panel designs is the ability to draw inferences on intraindividual (within-person) change in the construct of interest. That is, Brody et al. were able to demonstrate that paths from life stress, through increased negative emotions, predicted actual increases over time in risk behavior, not just the rank-ordering of youth in the sample on this variable, although their statistical analysis was conducted in two steps (SEM then linked to a separate latent growth curve model). Other researchers interested in developmental

cascades have employed similar analytic methods to tap into within-person or within-group change over time in constructs of interest, such as broad externalizing and internalizing problems, interparental conflict, and substance use. For example, in related fashion to the analysis conducted by Brody et al. (2010), Lynne-Landsman, Bradshaw, and Ialongo (2010) used growth mixture modeling to identify separate subgroups of cigarette, alcohol, and marijuana use across high school in a predominantly African American and urban sample. The authors embedded this growth mixture model in a larger mediation model, allowing prediction both from middle school risk factors to high school substance use classes and from high school substance use to young adulthood outcomes. Results suggested that male gender, lower parental education, and earlier oppositional behavior and peer rejection were associated with increasing trajectories of cigarette and marijuana use. Substance-using peer affiliation in middle school mediated effects of earlier predictors, including academic performance, on trajectory of alcohol use in high school. Overall, results are consistent with earlier cascade theories of the development of problem behavior (e.g., Patterson, DeBaryshe, & Ramsey, 1989) and suggest potential differences of effects across class of substance (cigarettes versus alcohol versus marijuana).

The latent growth curve model can be applied to more than one construct of interest at a time, in an analysis termed parallel process modeling (Cheong, MacKinnon, & Khoo, 2003). This approach was employed by Kouros, Cummings, and Davies (2010) to test relations among trajectories of interparental conflict and child externalizing problems in a community sample throughout early childhood (ages 6–8). Parallel process growth modeling allows testing of associations between both initial level (intercept) and within-person change over time (slope) across multiple constructs, and Kouros and colleagues showed that slope of interparental conflict predicted slope of externalizing, while the reverse was not the case. In addition, slope of externalizing predicted social competence/prosocial behavior across multiple informants later in childhood (age 12), suggesting that externalizing problems mediated an association between changes in interparental conflict and later social competence. Gender differences were observed in mean levels of constructs of interest but not in associations. This work extends earlier in development the processes between marital conflict and behavior problems previously identified in adolescence by Cui, Conger, and Lorenz (2005), and is notable for operationalizing an environmental risk (interparental conflict) as a dynamic process unfolding over time.

Klimes-Dougan and colleagues (2010) provided an intriguing example of how one might employ a growth curve modeling approach to examine cascade-related processes, analyzing relations among externalizing, internalizing, and thought problems in a sample of offspring of healthy versus unipolar depressed versus bipolar depressed mothers (youth assessed at four time points from approximately ages 5 to 20). Drawing from concepts in systems biology, Klimes-Dougan and colleagues argued that a cascade across domains can be conceptualized as a cumulative process in one domain affecting change in another domain of interest. More specifically, this approach used a cumulative externalizing problems score as a focal predictor of the growth curve of internalizing problems and thought problems (considered separately), with interactions with parental mood disorder status also tested. Key results of this analysis showed evidence for cumulative externalizing problems (rather than concurrent problems) predicting estimated age 20 thought problems and internalizing problems, accounting for change over time in the latter domains. In addition, there was some evidence that the cascade to thought problems was more characteristic of offspring of bipolar mothers while the cascade to internalizing problems was more characteristic of offspring of unipolar depressed mothers.

Cascade Research Employing Randomized Controlled Trials

Reports from prevention trials often test longitudinal links among constructs of interest within the framework of a randomized controlled trial (RCT), typically by including group assignment as a key exogenous predictor in the model. This analysis is potentially quite powerful, since it blends the causal-inference strengths of an RCT with the statistical controls of cross-lagged panel SEM. For example, McClain and colleagues (2010) tested longitudinal relations among several adolescent outcomes 6 years after families were randomized to an intervention program for middle childhood youth who experienced a recent parental divorce and were living primarily with their mothers (see also Zhou, Sandler, Millsap, Wolchik, & Dawson-McClure, 2008). Results suggested that program participation caused changes in two key parenting constructs—the mother-child relationship and effective discipline—which were then associated longitudinally with different classes of problems. More specifically, an improved mother-child relationship mediated program effects on child internalizing problems, while improved discipline practices mediated program effects on child externalizing problems. Although effects were generally

small in magnitude, the impressive 6-year prediction in this study shows promise for theory-driven interventions for youth adjusting to divorce (McClain et al., 2010).

Striking evidence for cascading positive effects following successful intervention for childhood behavior problems are discussed in detail by Patterson et al. (2010), who provided an overview of four decades of work from the Oregon Social Learning Center on the development of serious antisocial behavior and aggression in youth: the Parent Management Training—Oregon Model framework. Two points from this work are of particular relevance. First, work from the Oregon group broadly parallels the work by Dodge and colleagues (2009) just described, detailing a progressive sequence in which disrupted early parenting and minor-to-moderate forms of child externalizing lead to association with deviant peers, broader ranges of externalizing problems and continued family conflict, eventuating in high risk for adult criminality. Second, Patterson and colleagues described somewhat unexpected and long-lasting positive "spillover" effects into parents' own lives, following successful reduction in child behavior problems through the intervention. More specifically, mothers with children whose problems were reduced reported subsequent improvements in their own social relationships. This exciting set of findings provides evidence that intervening early in one domain can show systemic effects across other domains. In addition, reported effect sizes from this series of analyses were larger than many seen in nonintervention studies, and in some cases maintained or even increased over time, suggesting that at least for some families, intervention participation created lasting changes in the family context (Patterson et al.). We review additional results from these two research groups later when discussing model prevention programs.

Cascade Models: Summary

The work just reviewed shows interesting convergence of broad findings across a variety of domains, samples, and methods. Generally speaking, these empirical investigations confirm the crucial significance of early behavioral regulation and rule-abiding conduct (i.e., lack of externalizing problems/aggression) for transitioning to school and success in the childhood years. At the same time, when such problems affect academic functioning and social relationships, effects can feed back to amplify externalizing difficulties as well as lead to difficulties in the broad internalizing domain (i.e., anxiety and depressive symptoms). Extensions of cascade modeling have noted related empirical findings in domains of EC and self-regulation, alcohol and substance use, and several other areas of interest for developmental psychopathology.

Importantly, cascade-related research can also be informative in cases where cross-domain longitudinal links are absent. For example, Tully, Iacono, and McGue (2010) reported analyses from the Minnesota Twin Family Study examining the covariation across ages 15 to 21 of two prominent mental/behavioral disorder symptoms: nicotine dependence and major depressive disorder. Results from this genetically informed study, which also noted increasing heritability of both constructs with age, supported models in which the two sets of symptoms were related only through concurrent covariation, ruling out one domain having a direct effect on the other.

The work just reviewed opens methodological and statistical avenues for future research on the interplay of competence and psychopathology over time. In particular, the use of latent growth curve modeling and the embedding of growth models within larger mediation models (Brody et al., 2010; Klimes-Dougan et al., 2010) may allow for more detailed testing of some of the theoretical predictions made in this area of research. More generally, the papers reviewed show that both cascade theories and developmental psychopathology orientations have motivated researchers to expand their statistical and analytic toolboxes, often resulting in intriguing modeling combinations. Although the contribution of these different modeling approaches is expected to vary across future work, it is heartening to see the simultaneous exploration of new theory and new methods. It is also consistent with broader recent calls in psychology for modeling-based inference (Rodgers, 2010), even if models are developed within narrow domains, as well as calls for building analytic models that rule out observations as well as rule them in (Roberts & Pashler, 2000).

However, at the current stage of cascade research, it seems clear that additional theoretical work is also crucially needed. That is, the field is in need of stronger theories that make more precise predictions about how varied domains of competence and psychopathology will interact and affect each other. It is likely that as with so many other domains of social science research, progress in theory development is slowed by a continuing reliance on null hypothesis significance testing, which does not motivate more stringent theoretical predictions (Meehl, 1967; Roisman, Booth-Laforce, Belsky, Burt, & Groh, 2013). One possible way forward is a move toward theories that make rank-order predictions regarding the values of model parameters rather than ones that posit the presence or absence of nonzero parameters. This work will be difficult,

since some of the strongest theoretical advances to date have focused on specific domains of functioning across relatively narrow time ranges. However, the integrated work by Patterson, Dodge, and others regarding the chain of effects in the development of violence and other antisocial behavior provides a model for related work in other areas of functioning, as does the work by DeFoe and colleagues (2013) unpacking the chain of effects surrounding contextual disadvantage, low academic achievement, juvenile delinquency, and depressive symptoms. More generally, an increased focus on effect sizes and their interpretation in cascade research is needed.

With very few exceptions, the work reviewed above relies on passive, nonexperimental study of target samples. One of the strongest means the field has to test causal theories in development is by intervening in hypothesized processes and observing whether the externally manipulated change in a target process or mediator then changes the (downstream) target outcome and comparing that to a group which did not receive the experimental manipulation. Well-designed and implemented prevention and intervention studies can represent a powerful window of observation on developmental process. We now turn to a review of selected prevention and intervention work that focuses on the bidirectional associations between competence (success in age-salient developmental tasks) and psychopathology.

INTERVENTIONS TO PROMOTE COMPETENCE AND REDUCE PSYCHOPATHOLOGY

In the second edition of this chapter, we argued that preventive interventions are a particularly useful tool for examining the associations between competence and psychopathology, because randomized controlled trials can serve as true experiments in testing hypothesized causal relationships among variables or as tests of developmental theory (Cicchetti & Hinshaw, 2002). Often researchers think of their interventions as "interactions with development" (Coie et al., 1993; Kellam & Rebok, 1992; Tolan, 2002), such that the intervention is altering one developmental process or trajectory—for example, promoting a specific cognitive, emotional, or behavioral skill—in an effort to achieve a different developmental outcome, such as health and well-being or reduced problem behavior or psychopathology. Theories of how and why competence and psychopathology are connected in individual development have important implications for practice and policy, particularly given the twin societal goals of increasing competence and reducing the psychological, social, and economic suffering associated with psychopathology. Empirically supported conceptual models that link healthy adaptation or competence with behavior problems or psychopathology can serve as conceptual guides for developing and evaluating interventions. We also noted that prevention science was distinct from health promotion or PYD in some important ways, yet the two disciplines seemed to be converging toward a more unified framework for understanding intervention effects (Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2004).

Competence has been a central target of prevention efforts for decades, although this focus has not always been acknowledged, with some criticizing prevention science as maintaining a deficit orientation (Benson, 1997; R. M. Lerner & Benson, 2003). Indeed, the 1994 Institute of Medicine report on prevention science, *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*, explicitly excluded mental health promotion efforts. Nonetheless, as we noted in our 2006 chapter, competence promotion efforts have been a fundamental aspect of prevention from the time of President Kennedy's efforts to build community mental health (Kennedy, 1963), to President Carter's Task Panel on Prevention (1978) as part of his Commission on Mental Health, through the American Psychological Association's Board of Professional Affairs Task Force on Promotion, Prevention and Intervention Alternatives in Psychology and its efforts to promote prevention through publication of *14 Ounces of Prevention* (Price, Cowen, Lorion, & Ramos-McKay, 1988), one of the first compendia of efficacious prevention programs. Of the ten programs described in that document that focused on working with children and adolescents, eight are designed to enhance competence by building specific social, emotional, intellectual, or behavioral skills that are linked with successful adaptation. Four also emphasize building strengths in other social environmental contexts, such as parenting, as a method of influencing youth development.

Since our 2006 chapter, there have been several tangible markers of the convergence in approaches to explicitly link a PYD/health promotion framework with a prevention science approach. One of the best examples of this change in philosophy is the name change for one of the premier venues for accessing information about prevention programs. Since 1996, the Center for the Study and Prevention of Violence at the Institute for Behavioral Sciences at the University of Colorado, Boulder has produced the *Blueprints for Violence Prevention*, a website and list of efficacious prevention programs to combat violence, problem

behavior, and deviance. The outcome criteria for programs to be included on the list were rigorous and narrowly focused on violence as an outcome. Over the years, its website and publications have been some of the primary and most well-respected resources for learning about evidence-based programs for both community members and researchers seeking information about prevention programs that work. *Blueprints* is now funded by the Annie E. Casey Foundation and has extended its focus from problem behavior exclusively to broader developmental outcomes in the areas of behavior, education, emotional well-being, health, and positive relationships. In doing so, the name also has been changed to *Blueprints for Healthy Youth Development*. The criteria remain rigorous with less than 5 percent of reviewed programs making the list of model or promising programs. This change represents more than just a shift in language; it appears to be an indicator of the broad conceptual shift that we referenced in the second edition.

Equally informative over the intervening years has been the continued accumulation of empirical evidence that preventive interventions work. A rapidly increasing number of interventions to prevent the occurrence of mental, emotional, and behavioral (MEB) disorders have been implemented and evaluated over the past two decades. Many of these have been tested in RCTs, the gold standard of evaluation, and shown to reduce risk factors, increase protective factors, and decrease the rates of MEB disorders and/or substance abuse for individuals receiving the intervention. It is no longer correct to note that there is no evidence that interventions can change the rates of MEB disorders (National Research Council [NRC] & Institute of Medicine [IOM], 2009). The number of efficacious programs has grown substantially, and this increase, coupled with communities' needs to implement high-quality interventions that work, has generated a variety of mechanisms to disseminate the information about effective programs and best practices for implementing them. Many different websites now contain lists of model or promising programs selected by expert panels after review of the literature or compendia of programs with documentation of their relative efficacy available for community organizations to review.

Along with progress in documenting the evidence of interventions have been advancements in the conceptual foundations of these interventions; of note is the extent to which the interventions are guided by an understanding that MEB disorders are developmental. That is, prevention science has reoriented toward a focus on the question "What does the child need 1, 3, and 5 years down the line?" (Beardslee, Chien, & Bell, 2011, p. 248) and emphasizes intervening with children and adolescents because of the high rates of MEB disorders seen by age 24 (Kessler et al., 2005). Similarly influential has been a refocusing of the conceptual models that undergird intervention design, implementation, and evaluation toward a developmental framework that focuses on both MEB disorders and aspects of positive health, referred to in the Institute of Medicine report "Preventing Mental, Emotional and Behavioral Disorders Among Young People" as "developmental competencies" (NRC & IOM, 2009).

In the most recent Institute of Medicine (IOM) report on prevention (NRC & IOM, 2009), the committee reconsidered the evidence regarding mental health promotion and determined that although it can be distinguished from prevention of mental disorders in many ways, there is considerable overlap in these approaches conceptually and practically, and mental health promotion is an important component of the intervention spectrum (see also Weisz, Sandler, Durlak, & Anton, 2005). This conceptual shift acknowledges that promoting mental health (a goal of youth development programs) and preventing problems (a goal of prevention science) need not be competing endeavors (Catalano, Berglund, Ryan, Lonczak, & Hawkins, 2004). The primary tenets of these two approaches seem to derive from many common roots; they appear to have arrived at similar conclusions about the essentials for helping young people develop successfully, and both now reflect a developmental approach that includes building competence or wellness as a mechanism for preventing problems (Catalano et al., 2004; E. L. Cowen, 1991, 1995; Masten & Coatsworth, 1998; Weissberg & Greenberg, 1998). This advancement appears to return us to a point in which "prevention at its best represents both an effort to foster competence and prevent problems" (Masten & Coatsworth, p. 216). Although the connections are strong at the broadest level of conceptual organization, specific conceptual models still differ across philosophical approaches and even within approaches across interventions. We note that across these models, competence is conceptualized at different levels of measurement. For example, some models emphasize specific skills (e.g., problem solving, emotional awareness) while others conceptualize competence as broad constructs akin to our developmental task approach. Clear understanding regarding which specific skills or "developmental competencies" are linked directly or indirectly to psychopathology and should be promoted to prevent MEB disorders is at a relatively early stage. In the effort to integrate promotion and prevention, several different conceptual models have been

proposed across psychology, social work, and education (e.g., Collaborative for Academic Social and Emotional Learning, 2005; Guerra & Bradshaw, 2008; Haegerich & Metz, 2009; Kia-Keating, Dowdy, Morgan, & Noam, 2011; Kurtines et al., 2008; Schwartz, Pantin, Coatsworth, & Szapocznik, 2007). We highlight three of these models: core competencies, social emotional learning (SEL), and positive youth development (PYD).

Conceptual Models

Core Competencies Model

One promising framework that has been proposed as a mechanism linking theoretical and empirical work across promotion and prevention is the *core competency framework* (Guerra & Bradshaw, 2008). Based on a review of the basic developmental and intervention literatures, a panel of experts in developmental and intervention science selected five core competencies as markers of healthy development. These five competencies were selected because they were closely aligned with assets and strengths proposed in the PYD literature (discussed later), were securely grounded in the human development and developmental psychopathology literature, and captured important aspects of promotive and preventive interventions (Guerra & Bradshaw, 2008). Moreover, these competencies showed empirical linkages to a variety of risk behaviors, problem behaviors, or psychopathology. The five proposed core competencies build on a broad developmental model that incorporates concepts of competence and developmental tasks (Havighurst, 1972; Masten & Coatsworth, 1998). However, core competencies are not isomorphic with competence in age-salient developmental tasks. Specifically, the core competencies in this model are: (1) a positive sense of self; (2) self-control; (3) decision-making skills; (4) a moral system of belief; and (5) prosocial connectedness.

Each of these core competencies may actually comprise several more specific skills. Positive sense of self reflects three aspects of the sense of self that emerge early in development and remain salient across important points of increased risk for problem behaviors. First is "self-awareness," which captures a realistic and accurate assessment of one's psychological and behavioral characteristics. This awareness becomes more acute and sophisticated with age such that during adolescence, youth can provide a more refined assessment of who they are and where they are going. Success in adolescence is partially dependent on youth constructing a positive future perspective, clear goal orientation, and positive and realistic possible selves (Cross & Markus, 1991). A positive view of oneself and one's future is positively associated with good developmental outcomes and negatively related to problems. Self-esteem, high aspirations, and a sense of mastery is related to less frustration in school, better academic outcomes, and less school dropout (Harter, Bresnick, Bouchey, & Whitesell, 1997); youth with a positive future orientation are also less likely to use alcohol (Henry, Swaim, & Slater, 2005; Robbins & Bryan, 2004). Second, agency, or a sense of volition over one's behavior, is critical for development as youth become more able to direct their own development. Having a strong belief in one's ability to control their actions and environment may be critical for success in many developmental domains (Bandura, 2001) but also with regard to preventing specific problem behaviors, such as substance use, through mechanisms such as developing strong peer refusal skills (Schier, Botvin, Diaz, & Griffin, 1999). Third, self-esteem is often used as a marker of PYD, although it is controversial what high self-esteem means and whether it is associated more with positive or negative outcomes (Baumeister, Campbell, Krueger, & Vohs, 2003). Self-esteem seems to be related to indices of well-being and life satisfaction (Diener, 1984), but relatively little evidence suggests that a global sense of self-esteem is promotive (Fearnow-Kenney, Hansen, & McNeal, 2002): rather, domain-specific evaluations may be more important to one's overall functioning (Marsh & O'Mara, 2008).

Self-control, or the ability to regulate and manage one's emotions and actions, is the second core competency. Developing effective self-control skills is a critical developmental task that spans childhood and adolescence (Zelazo & Carlson, 2012). Better regulation in young children is associated with fewer problem behaviors, better peer relationships, and better academic achievement. During adolescence, effective self-control (as reflected in planfulness, problem-solving ability, willingness to delay gratification and restrain impulses) reduces risk for problem outcomes, such as aggression/violence, substance use, and criminality (Gottfredson, 2007; Wills, Walker, Mendoza, & Ainette, 2006). Longitudinally, cascade evidence for EC as a mediator of stress-psychopathology relations is emerging, as already discussed.

The third core competency is effective decision-making skills, which also increases with age. By adolescence, youth may be capable of coordinating future goals and perspectives with decisions to be made at the present time and are more capable of understanding the linkages between their decisions and consequences (Reyna & Farley, 2006). SIP models have been implemented in a wide variety of longitudinal and intervention studies and indicate that

better decision-making skills reduce the likelihood of drinking and smoking (Epstein, Bang, Zhou, & Botvin, 2007) or being aggressive with peers (Crick & Dodge, 1994) and increase the probability of doing well in school (Zins, Weissberg, Wang, & Wahlberg, 2004) and graduating from high school (Hawkins, Catalano, Kosterman, Abbott, & Hill, 1999).

A moral system of belief, the fourth proposed core competency, includes judgments about moral issues such as fairness and involves development of aspects of perspective taking and empathy (Guerra, Nucci, & Huesmann, 1994). A sense of morality has been proposed as central to prosocial action and development of a moral identity (Damon, 2004). Moreover, related aspects, such as sense of respect, trustworthiness, caring, and citizenship, are related to this broad competency and are constructs promoted in character education and PYD programs (Benson, 1997; Berkowitz & Beir, 2007). For example, youth who believe that it is morally wrong to drink alcohol tend not to (Beyers, Toumbourou, Catalano, Arthur, & Hawkins, 2004), youth who are empathic and more prosocial tend not to be aggressive (Pardini, Lochman & Frick, 2003), and youth who are better able to take another's perspective, respond empathically and resolve interpersonal problems effectively are more likely to do well in school as well (Roeser, Eccles, & Sameroff, 2000; Wentzel & Wigfield, 1997).

The fifth competency, prosocial connectedness, is broad and encompasses constructs such as attachment and bonding across families, schools, and peers. A variety of conceptual models propose that youth connections across these domains are primary determinants of adjustment. For example, the Social Development Model proposed by Catalano and colleagues (1996) hypothesized that prosocial bonding to parents, schools, and positive peers will reduce the likelihood of problem behaviors, such as delinquency and substance use. When opportunities, involvement, and rewards are in place, youth are more likely to develop strong bonds with positive role models and to internalize the moral messages and positive values that are being taught. This, in turn, reduces the likelihood of poor developmental outcomes, including aggression, substance use, and poor academic performance.

The primary contention of this framework is that mastery of the five core social and emotional competencies naturally or through intervention will yield healthy development and reduce the likelihood of problem behavior. This conceptual model helps researchers organize their intervention approaches, provides specific targets for intervention, and helps guide evaluation of an intervention's effects. This model shows marked similarities to the broad developmental models of competence proposed by our prior writing (e.g., Masten & Coatsworth, 1998; Masten et al., 2006).

Social Emotional Learning

A second model integrating the prevention and promotion perspectives is the SEL model, which has also received a substantial amount of interest and research attention over the past 15 years. Building from a foundation of developmental and intervention research indicating that inability to master core social-emotional competencies can lead to a variety of problem behaviors and social difficulties (Masten & Coatsworth, 1998; Weissberg & Greenberg, 1998), researchers hypothesized that promoting social and emotional learning in schools would enhance health and well-being and reduce the problems of students. Moreover, leaders in the SEL movement contended that schools' roles in promoting healthy development for children and youth include promoting ways that students can behave responsibly and interact well with others socially and emotionally while also building academic skills. The SEL approach is inherently developmental and focuses on helping youth acquire the competencies that allow them to recognize and manage emotions, set and achieve positive goals, appreciate the perspective of others, establish and maintain positive relationships, make responsible decisions, and handle interpersonal situations constructively (Elias et al., 1997). The five key competencies in the SEL framework were developed in a review of theoretical models of emotional intelligence, social emotional competence promotion, SIP, as well as behavior change and learning theories (e.g., the Health Beliefs Model and the Theory of Reasoned Action). The SEL framework shares considerable overlap with the core competencies model, so is described more briefly here.

The framework proposes that a key set of SEL competencies is related to youth health and well-being, academic achievement, and risky or problem behaviors. In establishing their core competency framework, the leaders of the Collaborative for Academic Social and Emotional Learning (CASEL) drew from theories of SEL, theories of behavior change and empirical findings linking children and youth social adjustment with their health outcomes (Payton et al., 2008). The five key SEL competencies are: (1) self-awareness; knowing what one is feeling, having a realistic assessment of one's abilities and a well-grounded sense of self; (2) self-management, meaning handling emotions well, delaying gratification and persevering in the face of obstacles to goals; (3) social awareness, meaning understanding what others are feeling and being able to take

their perspective, and maintaining appreciation for and positive interactions with diverse groups; (4) relationship skills, meaning handling emotions in relationships well, maintaining mutually positive relationships, having the ability to negotiate conflict and resist peer pressure; and (5) responsible decision making, making decisions based on accurate appraisal of the information available and the likely consequences of action and taking responsibility for one's decisions (CASEL, 2005).

Beyond articulating this list of competencies, the SEL framework also describes characteristics and features of quality SEL programs that are likely to improve overall effectiveness (Durlak, Weissberg, & Pachan, 2010; Payton et al., 2008). Basic features of the program, such as whether the conceptual rationale was sound and clear, whether the program used effective teaching strategies, whether it was coordinated across an entire school with good connections to the community, and whether it provided adequate teacher training and technical support and used high-quality research methods to evaluate its outcome, are included as recommended features of quality programs that will increase the probability that a program will alter the competencies (Payton et al., 2008). Moreover, CASEL contends that interventions that are Sequenced, Active, Focused, and Explicit (SAFE) will be more effective than those that do not have these characteristics. This acronym suggests that for effective programming, skills should be taught in a sequenced manner in which they build on each other over time, curricula should incorporate active learning techniques that provide sufficient time and focused attention to learning the skills at hand, and finally that there are clear and explicit objectives for what is being taught and learned.

Positive Youth Development: The Five Cs

The Five Cs model was conceptualized and constructed to provide a concise description of PYD and a simple model for youth practitioners that could effectively and efficiently capture outcomes of natural positive development and specific youth development program effects. It was also intended to be more parsimonious than lengthier lists of PYD attributes, such as the 40 developmental assets proposed by the Search Institute (Scales & Leffert, 1999) or a proposed list of ten tasks of adolescent development (Simpson, 2001; Simpson & Roehlkepartain, 2003), although there are clear connections between these and related constructs from resilience research (Masten, 2014). This model highlights five dimensions representing healthy youth development: Caring, Character, Competence, Confidence, and Connections (R. M. Lerner et al., 2005). Together, these dimensions form a holistic overview of youth development that includes positive personal development, social-emotional skills, moral values, and cognitive competence (Catalano et al., 2004; Moore & Lippman, 2005). Featured protective factors include positive self-concept, perceived competence, youth-parent relationships, and interpersonal skills. In addition, the framework includes multiple aspects of a person, from internal representations (confidence), values and moral compass (character), empathy and concern for others (caring), efficacious behaviors, skills, and knowledge (competence in personal and interpersonal situations), to external networks with others (connections; R. M. Lerner et al., 2005; Pittman, Irby, Tolman, Yohalem, & Ferber, 2003).

Several youth studies have utilized the Five Cs model (e.g., R. M. Lerner et al., 2005), and studies in the United States have demonstrated that parents', youth, and youth practitioners' conceptualizations of thriving and positive development can be summarized using the Five Cs framework (King et al., 2005). At the same time, empirical evidence that the Five Cs can be categorized as a second-order factor of PYD has been demonstrated by R. M. Lerner and colleagues (2005). Although this early work focused strongly on understanding the structure of the Five Cs PYD model and how attainment of the Five Cs promoted thriving, or contribution, described as youth active engagement in citizenship (R. M. Lerner, 2009), the broad PYD model hypothesized negative associations between PYD and risk behaviors (R. M. Lerner et al., 2005). In more recent work, Lerner and colleagues (see Bowers, Geldhof, Johnson, Lerner, & Lerner, 2014; J. V. Lerner et al., 2012; R. M. Lerner et al., 2011) have more clearly integrated these associations into their model. This clearer articulation of the processes by which PYD leads to positive outcomes, such as thriving, and is associated with negative outcomes, such as risky problem behavior (Arbeit et al., 2014), parallels the recent conceptual advancements made in prevention science.

Substantial similarities exist across these models, even if the language describing their core aspects is different for each. Other broad and more narrowly defined developmental contextual models also exist (e.g., Kia-Keating et al., 2011; Kurtines et al., 2008) that incorporate many similar features to the three described here. Broadly speaking, they all reflect to some degree an individual's ability to manage emotions, gain a clear and positive sense of self, make responsible decisions, and show respect and cooperation in interacting with others. These dimensions are similar to those broad domains described by Masten and

Coatsworth (1998). When considered in their entirety, they reflect the developmental perspective articulated by Waters and Sroufe (1983) in defining a competent person as one who is able to generate and coordinate flexible adaptive responses to interact effectively with the environment.

Overview of Interventions Targeting Improvements in Core Competencies

The broad integrative models just discussed are drawn from and have inspired intervention studies to demonstrate the associations between the models' core competencies and outcomes of healthy and unhealthy behaviors. In one of the largest meta-analytic studies of SEL interventions to date, Durlak and colleagues (2011) analyzed results from 213 studies involving 270,034 students from grades kindergarten through high school. This study expanded the already substantial body of research examining effects of school-based interventions (e.g., Durlak & Wells, 1997; Losel & Beelman, 2003; Tobler et al., 2000; S. J. Wilson & Lipsey, 2007) primarily because it included studies published in the preceding decade and focused on both positive social emotional skills and risk/problem outcomes. The primary aim of this analysis was to examine whether SEL programs yield positive effects across social and emotional skills, attitudes toward self and others, positive social behavior, conduct problems, emotional distress, and academic achievement. Results indicated that mean intervention effects (calculated using Hedge's *g*, a measure similar to Cohen's *d*) ranged from a high effect size (ES) of .57 for program influence on social emotional skills to a low of .22 on conduct problems and were statistically significant for all six categories of outcomes. Follow-up data, with a median elapsed time of 52 weeks, showed a slight decrease in size of effects, but all remained statistically significant (ES = .11 to .32). Quality of implementation was an important moderator of these overall effects: Programs that were delivered following the SAFE criteria were significantly more likely to obtain stronger effects. Non-SAFE programs failed to show significant effects in all measured outcomes except three—attitudes, conduct problems, and academic performance—and programs that reported implementation problems showed significant effects on only two outcomes, attitudes and conduct problems. These results highlight that high-quality and well-implemented SEL programs can promote development in key social emotional competencies (i.e., promote PYD) and reduce problem behaviors (e.g., prevent conduct problems). Interestingly, the poorly implemented SEL programs may not have influenced competencies but still seemed to have some effect on youth problem behavior. This meta-analysis helps support findings from other analyses and reviews (Durlak, Weissberg, & Pachan, 2010; Greenberg et al., 2003; Weissberg & Greenberg, 1998) indicating that SEL acts as both a promotive and a preventive intervention. More information, however, is needed to support conceptual models that hypothesize change in skills competencies and change in problem outcomes. Mediation, as described, is a critical step in demonstrating these linkages. Next we describe select programs with evidence that promoting competence mediated the effect of program participation on problem behavior reduction or prevention.

The largest study to date that evaluates the PYD framework is the 4-H Study of Positive Youth Development (J. V. Lerner et al., 2012). The study is not a randomized controlled trial of a specific intervention curriculum; rather, the 4-H study is a naturalistic longitudinal study of youth, many of whom are participating in various competence promotion activities through 4-H and other organizations. The study started when youth were in fifth grade in 2002–2003 and has collected data through grade 12 from over 7,000 youth in 42 states (R. M. Lerner et al., 2011). Although not a controlled test of youth development program participation, the study has yielded important information about participation in structured youth activities, the promotion of youth competence and well-being, and the prevention of problem behaviors. The strength of the PYD approach has always been on understanding the positive aspects of youth behavior, but the inherent approach to understanding development across time has consistently examined how positive development was associated with problem behaviors (e.g., Jelicic, Bobek, Phelps, Lerner, & Lerner, 2007; R. M. Lerner et al., 2005) and how involvement in youth development programs could affect positive and negative development and their associations (e.g., Mueller et al., 2011).

Findings confirm hypothesized associations among participation, PYD, and negative behaviors but also suggest some interesting complexities (Arbeit et al., 2014; Lewin-Bizan et al., 2010; Mueller et al., 2011; Phelps et al., 2007). When focused on broad constructs in variable-centered analyses, findings from the 4-H study generally support the hypothesized negative association between a second-order PYD factor and problem behaviors such as depression, substance use, and delinquency (Jelicic, Bobek, et al., 2007; Phelps et al., 2007). And when examining specific outcomes rather than broad composites, PYD shows a significant negative association with tobacco use, with marijuana use and sexual initiation for girls, and with hard drug use for both boys and girls (Schwartz

et al., 2010). When accounting for individual difference variations in patterns of PYD and problem behaviors over time, however, and when examining associations of different longitudinal patterns, the findings are more complex. Although most youth cluster into stable patterns of high, moderate, or low positive or negative behaviors, some youth show more marked change in these characteristics across time (Mueller et al., 2011; Phelps et al., 2009). Additionally, although youth with high PYD over time tend to also show a pattern of consistently low problem behaviors and depressive symptoms across time, this is not uniform. Some youth with consistently high PYD show a pattern of increasing risk behaviors (substance use and aggressive/delinquent behaviors) around grades 7 to 9 and then declining in grade 10 (Lewin-Bizan et al., 2010). Similarly, although a pattern of increasing or stable high depressive symptoms was generally related to stable low PYD, some youth also showed relatively high levels of PYD and increasing depression. These patterns are similar for youth who participated in youth development programs. Using latent class analysis, Arbeit and colleagues (2014) examined profiles of problem behaviors (e.g., delinquency, substance use, depression) when youth in the 4-H study were in sixth to twelfth grades and tested whether these were associated with the Five Cs. Distinct profiles of problem behaviors emerged (e.g., "low risk," "alcohol and aggression") across time points and demonstrated complex associations with the Five Cs. For example, although youth in both the "alcohol and aggression" and "mental health and other risks" groups were using alcohol, their patterns of use differed, and the "alcohol and aggression" group showed higher scores on confidence and competence, while youth in the "mental health and other risks" group scored higher on character and caring.

In general, the findings indicate that youth are involved in many out-of-school activities, with sports being the most common (Zarrett, Peltz, Fay, Carrano, Li, & Lerner, 2007), but it is the combination of sports and participation in more structured activities, such as Boys & Girls Clubs and the YMCA, that has the largest association with broad PYD in sixth to eighth graders. Using a matched comparison design, youth who participated in 4-H activities were compared to youth who participated in other out-of-school activities. Results from eighth grade indicated that 4-H youth reported higher levels of PYD, were more likely to be in the optimal PYD group (i.e., high levels across multiple indicators), had greater contribution, and had higher expectations to go to college (R. M. Lerner et al., 2008). These youth also had lower likelihood of expressing depressive symptoms and of showing other risk behaviors. In grade 11, youth who had participated in 4-H activities and for whom longitudinal data were available reported greater contribution, more overall school engagement and academic competence, and lower rates of engaging in health risk behaviors (e.g., drug use, sexual intercourse; R. M. Lerner et al., 2011). Agans and colleagues (2014) extended this work to examine how patterns of involvement across a variety of activities (breadth of involvement) are associated with positive and problematic outcomes. Results indicated that youth who participated in a broader variety of activities across time generally showed higher levels of the Five Cs and contribution, but youth with high participation also showed higher rates of depressive symptoms. Across time, a pattern of maintaining high involvement in multiple activities was strongly related to higher scores on PYD and less problem behavior. Patterns that showed a decline in involvement across time were associated with greater chances of substance use, depression, and delinquent behaviors.

The findings linking program participation to outcomes are not as strong as might be found in a randomized controlled trial that specifically accounts for baseline differences in important individual characteristics and experiences. Often those baseline characteristics may be related to selection into activities and to outcome measures. For example, when modeling how intentional self-regulation skills (e.g., setting goals, planning how to achieve them, and mounting internal and external resources when confronted with barriers to achieving goals) and participation in youth development programs in grades 8 and 9 relate to PYD outcomes (i.e., the Five Cs and contribution) in grade 10, findings show strong associations of intentional self-development with PYD outcomes and only modest associations between participation and contribution. Participation in grade 8 had a weak association with intentional self-regulation at grade 9, suggesting that these programs may affect PYD at least in part by building self-regulation skills. However, more detailed analyses of the mediating effects are needed.

Promotion and Prevention by Building Nurturing Environments

A commonality of the SEL, PYD, and prevention approaches is the emphasis each places on the contextual characteristics necessary to promote positive behavior and prevent problem behavior. Each identifies the important contribution that nurturing environments, whether they be schools, families, or out-of-school programs, have for reducing adverse social conditions, promoting

and reinforcing "prosociality" (D. S. Wilson, O'Brien & Sesma, 2009), limiting problem behaviors, and promoting psychological flexibility (Biglan, Flay, Embry, & Sandler, 2012). This approach is clearly seen in SEL interventions due to their emphasis on providing safe, supportive, and caring learning environments to foster a strong bond to school that will in turn facilitate the youth's acquisition of social-emotional skills (CASEL, 2005; Greenberg, 2003). Reviews of PYD programs emphasize characteristics of programs that work, including positive adult-youth bonds, in a safe environment in which youth can build mastery through challenging experiences and feel valued by their communities (e.g., Eccles & Gootman, 2002). Prevention programs also focus on building protective resources in the environment, such as parenting and family skills (Sandler, Schoenfelder, Wolchik, & MacKinnon, 2011) or community mobilization and organization (Oesterle et al., 2010).

Schools and families are the two contexts that have been studied more comprehensively in association with PYD and problem behavior. Not surprisingly, these are also the two contexts that are the foci of many prevention and promotion programs (e.g., Greenberg, 2003; Spoth, Kavanagh, & Dishion, 2002). Various reviews and meta-analyses, with a focus on RCTs, have illustrated the ability of well-conceptualized and well-implemented interventions to influence parenting practices (Kaminski, Valle, Fiese, & Boyle, 2008; Lochman & van den Steenhooven, 2002; Sandler et al., 2012; Taylor & Biglan, 1998) and school contexts (Durlak & Wells, 1997; Durlak et al., 2011; Foxcroft & Tsertsvadze, 2011; Greenberg, 2004; Greenberg, et al., 2003; Weissberg & Greenberg, 1998). Parenting interventions for parents of infants, children, and adolescents have successfully changed ways in which parents provide guidance, support, discipline, and nurturance. Parent- and family-focused interventions are able to change important processes associated with youth positive and negative behaviors: parents' sense of competence (Sanders, Markie-Dadds, Tully, & Bor, 2000), maternal responsiveness (Brotman et al., 2008), parents' use of effective discipline (Tolan, Gorman-Smith, & Henry 2004; Wolchick et al., 2007), positive communication (Kosterman, Hawkins, Spoth, Haggerty, & Zhu 1997), family problem solving (DeGarmo & Forgatch, 2005), parent youth relationship quality (Coatsworth, Duncan, Greenberg, & Nix, 2010; Dishion & Andrews, 1995), and parental monitoring (Coatsworth et al., 2010; DeGarmo & Forgatch, 2005; Soper, Wolchik, Tien, & Sandler, 2010). School-based interventions alter the context of school by creating a safe, caring learning environment, improving classroom management, and building a community in which youth are interested and invested (CASEL, 2005; Elias et al., 1991; Hawkins et al., 2004; Pianta & Hamre, 2009; Schaps, Battistich, & Solomon, 2004). Moreover, as noted earlier, these school-based interventions effectively promote the development of critical social-emotional skills (Durlak et al., 2011). Finally, there is ample evidence from both school-based and family-based interventions to indicate that that these effects persist over time, with some effects from family-focused interventions sustaining for up to 20 years (Botvin & Griffin, 2004; Durlak et al., 2011; Sandler et al., 2012).

The same interventions that foster nurturing environments promote healthy youth development and can also influence problem behaviors. Many parenting and family-focused interventions as well as school-based interventions are effective in reducing youth mental, emotional, and behavioral problems (Durlak & Wells, 1997; Durlak et al., 2011; NRC & IOM 2009; Tobler et al., 2000). Effects are evident on a wide range of outcomes, including externalizing problems (e.g., Greenberg, Kusche, Cook, & Quamma, 1997; Sandler et al., 2010; Tolan, Gorman-Smith, Henry, & Schoeny, 2009), internalizing problems (e.g., Cowan, Cowan, & Hemming, 2005; Trudeau, Spoth, & Acevedo, 2007; Wolchick et al., 2002), delinquency (e.g., Botvin, Griffin, & Nichols, 2006; DeGarmo & Forgatch, 2005; Eckenroade et al., 2010) academic engagement and performance (e.g., Elliott, 1997; Oyserman, Bybee, & Terry, 2006; Spoth, Randall, & Shinn, 2008; Stormshak, Connell, & Dishion, 2009; Tolan et al., 2009), substance use (Botvin & Griffin, 2004; Prado et al., 2007; Spoth, Shin, Guyll, & Acevedo, 2006; Wolchik et al. 2002), and risky sexual behaviors (Pantin et al., 2009; Wolchik et al., 2002).

Testing Mediating Processes

The true scientific benefit of these kinds of interventions comes when they are conducted in a rigorously employed and rigorously evaluated RCT with a prospective longitudinal design that can capture changing developmental processes and cascades (MacKinnon, 2008). In such studies, mediation analyses can be used to examine whether the intervention affects proximal processes, which, in turn, affect other positive or negative developmental outcomes. In these instances, the intervention trials can serve as tests of a theoretical model of development (Cicchetti & Hinshaw, 2002), including a theoretical model of how competence and psychopathology are related. Careful attention to what is manipulated is needed, however, as

most RCTs of prevention programs change several core constructs at once (Peterson, 2013).

Results from mediation analyses of experimental intervention studies are beginning to accrue and yield important information about how interventions operate and how building specific social emotional skills or constructing a nurturing environment can account for an intervention's effect on problem behavior (Biglan et al., 2012; Sandler et al., 2010). Most mediation analyses have investigated processes that operate to produce short-term positive developmental outcomes (12 or fewer months postintervention) for youth. Much less common are analyses testing the mediating processes that produce long-term (e.g., greater than 5 years) intervention effects (Sandler et al., 2011). Yet results from several exemplary programs illustrate how mediating mechanisms can identify the sequential and cascading developmental chains produced by an intervention.

Parent Management Training—Oregon Model

As discussed in our section on cascade models, Parent Management Training—Oregon Model (PMTO^{TM}) is a set of evidence-based intervention practices that was developed at the Oregon Social Learning Center by Gerald Patterson and colleagues (2010) that focuses on decreasing and reducing the development of antisocial behavior problems in youth. The practices have been packaged in a variety of interventions designed to influence problem behavior in youth whose families are experiencing a variety of social and contextual challenges. For example, Forgatch has applied these to the context of divorced mothers to develop Parenting Through Change, a 14-session intervention designed to increase skill encouragement, limit-setting, problem solving, monitoring, positive parenting, and decrease coercive parenting in the short term and reduce mental health problems in youth in the long term (DeGarmo & Forgatch, 2005; Forgatch & DeGarmo, 1999; Forgatch et al., 2009). PMTO has been adapted and implemented successfully for diverse communities, including native Norweigians (Ogden & Almlund-Hagen, 2008) and immigrant Somali and Pakistani parents living in Norway (Bjørknes & Manger, 2013); and parents in Iceland (Sigmarsdóttir, DeGarmo, Forgatch, & Guðmundsdóttir, 2013), the Netherlands (Bekkema, Wiefferink, & Mikilajczak, 2008), and Mexico City (Baumann et al., 2014).

This intervention has produced short- and long-term reductions in youth internalizing and externalizing behaviors and long-term effects on more serious delinquency (DeGarmo et al., 2004; Forgatch & DeGarmo, 1999, 2002). Parenting practices were shown to be significant mediators of youth noncompliance, aggression, internalizing and externalizing, teacher-rated delinquency, and appropriate school behaviors 1 and 3 years postintervention (DeGarmo et al., 2004; Forgatch & DeGarmo, 2005). At 9 years postintervention, effects on both teacher-rated delinquency and number of arrests as documented by police records were mediated by both positive parenting (which included both positive interactions and low coercive interactions) and association with deviant peers (Forgatch et al., 2009). These analyses were strong tests of developmental processes hypothesized by Dishion and Patterson (2006) to contribute to the onset and escalation of antisocial behavior and enhanced understanding of mechanisms of change in the Parenting Through Change intervention.

New Beginnings

New Beginnings is a theory-based psychosocial parent training and youth coping enhancement intervention for divorced mothers. The intervention was designed to alter parenting processes and enhance youth coping in 9- to 12-year-old children (Wolchick, Sandler, Weiss, & Winslow, 2007; Wolchick et al., 2000). Results have shown that compared to a home study condition, participation in the intervention significantly improved mothers' parenting postintervention and also reduced child mental health problems but did not directly influence youth coping (Wolchik et al., 2000, 2002). At 6-year follow-up, intervention effects were found on youth internalizing and externalizing, alcohol use, drug use, number of sexual partners, and grade point average (Dawson-McClure, Sandler, Wolchik, & Milsap, 2004; Wolchick et al., 2000, 2002).

The New Beginnings research team has systematically tested hypothesized mediating mechanisms for this intervention, and analyses have revealed important information about how the program produced both short- and long-term effects on youth functioning. Analyses showed that program effects on adolescents' grade point average at 6-year follow-up were mediated by intervention-produced improvements on maternal effective discipline (Zhou et al., 2008). For youth who were at elevated risk of problems at baseline, program-induced improvement in mother-child relationship quality mediated the intervention effect on adolescents' mental health problems 6 years later (Zhou et al., 2008). Intervention effects on substance use and risky sexual behavior at 6 years postintervention for those youth who were at higher risk at baseline were mediated by program-induced changes in parental monitoring (Soper et al., 2010). RCTs of the New Beginnings program have been conducted primarily with Caucasian samples

(around 90%), but as the program enters into a stage of testing program effectiveness through delivery within the court system, adaptations are being made to ensure it is culturally appropriate for a diverse population (Wolchik et al., 2009).

As noted in our cascade discussion, mediation analyses have also shown cascading effects on different dimensions of youth functioning. For example, the program produced immediate improvements in mother-youth relationship quality, which in turn was related to decreases in child internalizing 3 to 4 years later, which led to increases in self-esteem and decreases in internalizing disorders 6 years postintervention (McClain et al., 2010). Another theoretically postulated mediating pathway was supported that showed that increases in effective discipline immediately postintervention led to fewer child externalizing problems at 3 to 4 years postintervention and then to decreased externalizing disorders, decreased substance use, and increased academic achievement (McClain et al., 2010). Moreover, although early tests of the intervention indicated no effect on youth coping (Wolchik et al., 2000), additional analyses indicated that program-induced improvements in mother-child relationship quality led to greater youth coping at 6 months and at 6 years postintervention (Velez, Wolchik, Tien, & Sandler, 2011). Altering the nurturing environment had subsequent effects on youth development of effective coping skills. Similarly, analyses revealed cascading effects such that intervention effects on high-risk youth's educational expectations and job aspirations at 6 years postintervention were mediated by intervention-induced changes in mother-child relationship quality and externalizing and internalizing behaviors (Sigal, Wolchik, Tien, & Sandler, 2012). These carefully constructed analyses yield important information about how the intervention produced both short- and long-term effects on youth adaptive and maladaptive functioning. Moreover, these analyses begin to test models of how changes in parent variables might mediate long-term intervention effects on youth outcomes by maintaining good-quality parenting, changing youth competencies, or changing the transactions between parent and youth (Sandler et al., 2011).

Positive Action

Positive Action is an evidence-based PYD and social-emotional and character development program delivered in schools that attempts to promote improvements in prosocial skills, self-control, and academic achievement while also reducing negative behaviors (Flay & Alred, 2010). It is a comprehensive, schoolwide prekindergarten-through-twelfth-grade intervention focusing on helping youth take a positive attitude toward the self, which aims to affect their self-concept, physical and intellectual actions, social-emotional skills for managing their behaviors, and positive interactions with others. Outcome analyses from quasi-experimental and experimental trials of the program have demonstrated its effectiveness in modifying overall school quality and enhancing student academic achievement and school involvement while also influencing violence, substance use, and risky sexual behaviors. Separate trials were conducted in Hawaii and Chicago with multiethnic samples (Beets et al., 2009; Lewis et al., 2012; Li et al., 2011; Snyder, Vuchinich, Acock, Washburn, & Flay, 2012). Main effects were generally comparable across studies, and moderation effects by ethnicity were not reported.

Mediation analyses of this PYD intervention have demonstrated that program-induced effects on violence, substance use, and sexual activity were mediated by changes in youth positive academic behaviors (setting goals, motivation, problem solving; Snyder et al., 2010, 2013). Focusing on the proximal social-emotional mediators, analyses from data in three separate trials show that the program reduces the decline in positive behaviors (social-emotional and character development behaviors) that occurs with the transition to adolescence (Washburn et al., 2011). Moreover, mediation analyses indicate that the relatively higher social-emotional skills of youth in intervention schools mediate the effects on substance use. This is one of the first studies to illustrate a mediation pathway in a comprehensive, schoolwide social-emotional and character development program bridging the skills taught in the program and problem behavior outcomes.

Moderation of Prevention Effects via Gene–Environment Interaction

In addition to studies of mediation, a compelling future direction for successful prevention programs is identifying moderators of program effects on outcome: that is, determining for whom programs work most effectively. Indeed, the search for mediators and moderators is often complementary, since moderation implies differential effects which may be "carried" via different paths. Although multiple classes of moderators are of interest to those who design and implement prevention programs, work of particular novelty has focused on moderation of prevention outcomes by genetic variation, thus serving as a class of gene–environment interaction (G×E) research termed gene–intervention (G×I) interaction.

An early example of this work has focused on the Strong African-American Families (SAAF) and Strong African-American Families-Teen (SAAF-T) programs, aimed at reducing substance use and other risk behaviors among African American youth living in the rural South; data from this project have also contributed to the cascade literature, as noted earlier (Brody et al., 2010). Selected findings from these studies have demonstrated that youth with the 5-HTTLPR short allele variant who were randomized to the prevention program showed risk behavior comparable to control youth (Brody et al., 2009); that a continuous multilocus genetic "risk" variable (markers from DRD4 and GABA-related loci) interacts with program status in predicting an increased frequency of alcohol use for control participants but not prevention participants (Brody, Chen, & Beach, 2013); and that prevention program participation attenuates the association of negative parenting and diminished telomere length, a biomarker associated with aging (Brody, Yu, Beach, & Philibert, 2015). Major advantages of this randomized design are the ability to rule out gene-environment correlation as a competing explanation for differential effects as well as more accurate effect size estimates for different subgroups of youth (Brody, Beach, et al., 2013). Using data from this project and several others, meta-analytic work confirms moderating effects of genotype on randomized prevention and intervention programs (Bakermans-Kranenburg & van IJzendoorn, 2015; van IJzendoorn & Bakermans-Kranenburg, 2015), emphasizing that such genetic moderation can be conceptualized in the framework of differential susceptibility to environmental effects, for better and for worse (Boyce & Ellis, 2005).

Prevention Programs: Summary

Because our chapter focus is broad links between competence and psychopathology, our review of prevention research based on competence promotion is of necessity selective. However, from this research, we can note several exciting developments. First, program terminology is evolving so as to emphasize positive aspects of development, strengths, and assets, and linguistic conflicts between prevention, competence promotion, and positive psychology are fading, as is appropriate. In addition, the empirical evidence base on prevention programs is growing, in particular work that includes large sample sizes followed longitudinally over several years and incorporates relatively intensive assessments.

Theoretically, we also observe broad similarities and connections among conceptual frameworks such as the Core Competencies model, SEL, and the Five Cs of PYD, and between these frameworks and our earlier discussion of developmental tasks. Each of these models highlights the importance of skills such as self-awareness, empathy, connections to others, and effective decision making in promoting positive development and, therefore, competence in age-salient developmental tasks. Of particular interest and relevance is the growing body of prevention program evaluations that test theoretically specified models of how proximal variables mediate the positive effects of program participation as well as recent work on genetic and biological moderation of prevention program effects. For mediation, we see similarities across programs and research teams, with parenting practices (e.g., effective discipline and monitoring), positive parent-child relationships as well as youth goal setting, problem solving, and SIP coming to the fore as key mediators in selected studies. Clearly there is more work to be done in this area: In particular, it will be important to have ongoing communication between intervention and naturalistic researchers in terms of the assessment and measurement of some of the constructs. Many, but not all, of the constructs included by prevention scientists have close referents in naturalistic longitudinal work on competence; it will be important for future work to refine taxonomies of these constructs to avoid both unnecessary overlap as well as excessive fragmentation.

CONCLUSIONS AND FUTURE DIRECTIONS

One notable change in work on competence and psychopathology seen in recent years is the acknowledgment that these two ostensibly separate areas of inquiry are mutually interdependent and mutually influencing; that this basic idea is now often implied rather than explicitly defended is progress for the field. However, we have advanced to the point where more specific claims about influences among competence and psychopathology should be made, and where, as appropriate, potential limitations of newer methodologies are starting to emerge.

First, it is clear that the dominance of the *DSM* system for the classification of mental disorders creates significant challenges for an integrated science of competence and psychopathology. Although explicitly acknowledged as a system with many stakeholders who often have competing interests, and although created from a governing body with input from developmental psychopathologists (but not guided primarily by them), the *DSM* nonetheless exerts tremendous direct and indirect influence on the

questions posed by researchers in this area. This is particularly evident in the work on functional impairment, where work that seeks to test critical alternatives to *DSM*-based scales remains limited outside of a few select instruments and where efforts to separate out impairment from diagnostic criteria, although admirable from a scientific viewpoint, are likely to be extremely difficult. Although functional impairment encompasses a very broad range of content—and includes domains less often studied in modern developmental task research, such as physical mobility, self-care, and hobbies and leisure activities—it remains important for our consideration. In particular, the inclusion of impairment measures as part of outcome batteries (and, we hope, intermediate assessments) for intervention RCTs (Becker et al., 2011; Fabiano & Pelham, 2009) is a welcome development that could help clarify the mechanisms of action for some of the field's best-documented treatments for youth mental illness.

Second, the organizing idea of developmental cascades has motivated a substantial body of recent research on longitudinal links between salient constructs. As noted, the focus of this work has broadened from early studies focusing on major competence domains and broad psychopathology dimensions of internalizing and externalizing, to studies that include a wide range of other individual and contextual variables, such as effortful control, stressful life events, and divorce. Both early and more recent work have demonstrated the key significance of academics and social competence as broad-based developmental tasks that, in multiple studies, have mediated the longitudinal associations between externalizing and internalizing problems in paths that support, among other theories, dual failure models of the development of depressive symptoms (Capaldi, 1992). Work focused on academics underscores the early development of important linguistic and pre-academic skills and the generally high rank-order continuity of academics throughout childhood and adolescence; nonetheless, multiple studies show evidence for externalizing problems potentially undermining academic achievement and for academic failures potentially contributing to increases in internalizing problems. Academic skills themselves can be predicted all the way from infancy, albeit modestly, through pathways involving physical mobility and exploration (Bornstein et al., 2013c).

Work focused on social competence has shown compelling evidence for its mediating role between externalizing and internalizing problems. In addition, multiple reports show evidence for increasingly entangled associations between social functioning and externalizing through middle to late childhood and early adolescence. Although the presence of a close friend can serve to mitigate some of the negative associations between social difficulties and internalizing problems, the nature of friendships must be considered carefully, since deviant peer associations (via deviancy training) are a key driver of escalation from moderate externalizing problems to more serious violent behavior in adolescence (Van Ryzin & Dishion, 2013).

Social competence is a particularly difficult target construct and is perhaps better conceptualized as a family of constructs. Associations between social functioning and other competence and problem domains are expected to vary depending on the breadth of assessment and, more specifically, whether peer status and friendship measures are included; they may also vary by context and rater (Dirks, Treat, & Weersing, 2007). For example, a full cascade from externalizing through self-reported peer victimization to internalizing problems was found in early childhood by van Lier and colleagues (2012), but not using a maternal-report measure of broad social competence by Burt and Roisman (2010), suggesting possible differences by either informant or construct breadth. However, we still have relatively little basis on which to theorize differential prediction depending on these varied assessments; thus, further work delineating key aspects of social competence is needed. One intriguing example, related to the NIMH RDoC initiative described earlier, is research by Iarocci, Yager, and Elfers (2007) on G×E interactions in social competence that argues for developing social endophenotypes for molecular genetic study possibly based on well-defined constructs such as sociability, face recognition, emotion recognition, and theory of mind, and the study of extreme groups formed via crossing of these constructs. Very few of the cascade studies reviewed herein assess these more specific facets of social competence.

It is important to emphasize that although our general focus on and organization of cascades by academics and social competence represents the primary salience of these two broad domains for childhood adaptation, there is a clear need for cascade-informed work that examines aspects of competence outside of these two areas. Several examples of this broader work have been noted earlier, such as work on EC (Eisenberg et al., 2010) and work on the multifaceted construct of PYD (Lewin-Bizan et al., 2010). The work we have highlighted from prevention programs provides examples of additional target constructs for future work, such as effective decision making and problem solving in youth, as well as a host of parenting-related variables that have only been rarely studied intensively over time from a cascade framework.

There is also a need for careful consideration of neuroscientific, biological, and genetic levels of analysis for future work on competence and psychopathology. Other than the prevention program G×E research discussed and a handful of other studies (e.g., Riggs, Greenberg, Kusché, & Pentz, 2006), the cascade and prevention work reviewed has not included these levels of analysis in structural models. However, blending the multiple-level assessment approach inherent in much biological and molecular genetic studies with the longitudinal and statistically sophisticated work reviewed here is a natural direction for future work. This is especially important given recent interest in the biological embedding of social and environmental experiences—work that tests how both positive and negative environments affect biological processes such as gene expression, promotion of genetic transcription factors, inflammatory immune responses, and other biomarkers of both stress and health (e.g., Boyce, Sokolowski, & Robinson, 2012). Emerging domains of inquiry in population neuroscience (blending demography insights with neuroimaging; Falk et al., 2013) and human social genomics (Slavich & Cole, 2013) highlight new visions of the "social brain" and the potential for cascading effects across levels of analysis that help elucidate precursors and consequences of social relationships as well as new moderators at both behavioral and biological levels.

Such work can clarify competence-psychopathology associations in different ways. For example, a recent twin study by Boivin and colleagues (2013) has shown evidence for the short-term longitudinal association between disruptive behaviors in kindergarten and peer problems in first grade being primarily genetically mediated, with controls for continuity in each domain. That is, via mechanisms consistent with evocative gene-environment correlation, genetically influenced disruptive behavior problems appear to lead to negative peer experiences over time. Additionally, as outlined in an earlier section, the NIMH RDoC initiative promises to focus greater research attention on multiple levels of analysis with a particular emphasis on the genetic, molecular, and neurobiological underpinnings of constructs central to this review. The potential further unpacking of social competence is a striking example, but new perspectives in epigenetics and brain-behavior interplay will also influence future causal models of academics, externalizing, internalizing, and many other constructs discussed in this chapter.

More generally, we expect that the future will bring more focus on delineating and testing explicit processes at multiple levels of analysis that may account for naturally occurring and intervention-induced connections and cascades among domains of adaptive function encompassed by the broad concepts of competence and psychopathology. Although advances in theory and empirical methods linking competence and psychopathology are clearly evident in the decade of work highlighted in this chapter, much of the theory remains quite general and abstract when it comes to explaining how competence and psychopathology become linked in development. Better specification of change processes will inform intervention as well as theory.

Additional work on measurement of key constructs also is needed. For example, although the questionnaire-based assessments of much internalizing and externalizing research have an extensive history in the field, parsing the boundaries between normal and abnormal functioning in a nuanced way and capturing the complexities of contextual interactions will likely require integration of observational and dyadic methods in addition to well-validated questionnaire and checklist measures. For example, the careful theoretically informed creation of structured observational methods, joined with novel questionnaire measures, has led to potential advances in the refinement of developmental models of disruptive behavior problems in preschoolers (Wakschlag, Choi, et al., 2012; Wakschlag, Henry, et al., 2012).

Other general considerations are important for future work on competence and psychopathology. First, as in all other areas of science, replication across independent samples is essential for continued progress (e.g., Dodge et al., 2008, 2009; Patterson et al., 2010). Although several broad findings have now shown replication in the cascades literature, amassing a more detailed body of work will continue to be challenging as research teams across the field have invested tremendous time and resources in longitudinal studies that may or may not contain equivalent assessment measures.

Second, we hope that future theoretical and empirical work in this broad domain will include a focus on both effect sizes and potential moderators of observed cross-domain longitudinal associations. We applaud the work by Durlak and colleagues (2011) who have illustrated the value of reporting effect sizes from large-scale meta-analyses in prevention work on SEL and encourage the broader reporting and discussion of effect size. In terms of moderators, it is striking that the large majority of tests of gender moderating cross-domain paths have not found evidence for differences in their strength between males and females. Thus, despite well-known mean gender differences in many of the constructs studied, the processes that link these domains may be largely similar across

gender. However, gender is only one potentially relevant moderator of competence-psychopathology associations, making the careful selection of new moderators a key task of future work. Importantly, increased attention to effect size and a search for moderators are complementary goals, because a moderator is relevant largely to the extent that effect size differences across levels of the moderator exceed a meaningful threshold. Those thresholds will necessarily vary across specific research topics, and further refinement of our theories is needed for their establishment.

Third, work on competence and psychopathology will benefit from close consideration of recent work on causal inference and causal mediation (Foster, 2010; Imai et al., 2010; Pearl, 2012). Integration of this technical work will allow for a more explicit consideration of assumptions made in both nonexperimental and experimental work related to causality and will help the field, both by using consistent terminology and also by motivating new research designs and analytic methods that may help us get closer to identifying key causes and intermediary processes that bring about these observed associations.

Finally, the field lacks comprehensive evidence on how culture, race, and ethnicity affect relations between competence and psychopathology; this gap is evident across all three major topics of this chapter. In terms of functional impairment, the growing research base on cross-cultural variation in psychopathology almost uniformly focuses on *symptoms* and only rarely considers the impairment presumably caused by those symptoms (or contributing to them). Although competence judgments based on developmental tasks can be seen as culturally-bound value judgments, less work in this area has examined processes of acculturation systematically, making this an important future direction (Chen, Fu, & Leng, 2014). In terms of race and ethnicity, several cascade studies reviewed include ethnicity as an analytic covariate, but aside from a few exceptions (e.g., Dishion et al., 2010; Hishinuma et al., 2012; Huang, 2015), these studies do not test for ethnic status as a moderator of key associations. Ideally, future cascade work will test theory-based moderators and include constructs relevant to the development of ethnic minority youth, such as discrimination and ethnic identity, which may elucidate pathways of interest. And although several successful prevention programs have been expanded cross-culturally and cross-nationally, the adapting of program content to new countries and cultures raises challenges for testing cultural moderation of program effects. For all three areas of focus, the integration of cultural context and biology through study of gene–culture interplay and cultural epigenetics (Causadias, 2013) will likely be of importance to future research in domains covered in this chapter.

It is instructive to consider the concluding remarks from the prior edition of this chapter and assess their focus, impact, and continued relevance (Masten et al., 2006, pp. 725–728). At that time, we celebrated the impact of positive psychology and the PYD movement, along with other work on resilience in youth, that continues to shine light on the competent side of adaptation in general and, in particular, how competence in certain domains at certain times can prevent psychopathology and lead to progressively better outcomes. We also noted the beginnings of complex modeling approaches, such as cascade models, that occupy a more central role in this edition. Although there is much to celebrate in terms of the field's advances in recent years, progress has been (perhaps understandably) slower in integrating mental disorder classification systems such as *DSM-5* with broader research on the nature of competence, disorder, impairment, and disability.

However, there is great hope for continued progress integrating the study of competence and psychopathology in the near future. We have a growing body of work that is exploring key questions around the definition and assessment of mental disorder and how to best separate out symptoms of disorder from impairment; a set of studies using longitudinal cascade models that collectively help to elucidate pathways by which symptoms and competence interact over time; and a robust and growing body of prevention data that has increasingly employed sophisticated tests of mediation and G×E in addition to well-developed conceptual models. We look forward to increasing integration of all three of these broad areas in the near future, with continued attention to more stringent tests of competing theories in each domain.

CHAPTER 10

The Development of Coping: Implications for Psychopathology and Resilience

MELANIE J. ZIMMER-GEMBECK and ELLEN A. SKINNER

It's a characteristic of human nature that the best qualities, called up quickly in a crisis, are very often the hardest to find in prosperous calm. The contours of all our virtues are shaped by adversity.

—GREGORY DAVID ROBERTS, *SHANTARAM*

SUMMARY AND CONCLUSION 532
REFERENCES 533

A primary justification for the study of coping is the notion that, when people are faced with adversity, the ways they react to and deal with its challenges can make a material difference to their subsequent development. If they are overwhelmed, they can become more vulnerable to subsequent psychological problems and disorder; if they rise to the challenge, they can become toughened, strengthened, and more resilient to future threats and difficulties. Akin to the concept of host resistance in the study of whether exposure to germs will lead to illness or to immunity, the concept of coping refers not to the assets and liabilities people bring to their dealings with adversity but instead to how people actually interact with the real problems, setbacks, and difficulties they encounter daily,

right on the ground. These myriad ways of coping, such as problem solving, negotiation, rumination, accommodation, escape, confrontation, and help seeking, describe specific transactions along the arc of episodic encounters with stress and suggest one set of mechanisms through which adversity can erode individual resources to create long-term liabilities or, alternatively, can help individuals accrue lasting competencies for managing stress.

Surprisingly, however, the strands of research that focus on coping have not been well integrated with research on resilience and the development of psychopathology. Despite the potential centrality of coping as a moderator and mediator of exposure to stress, coping is rarely included in programs of study focusing on developmental psychopathology or resilience (cf. Cicchetti & Rogosch, 2009). By the same token, despite the fact that the adversities people face, such as poverty and maltreatment, shape both the array of problems they confront and the resources they can access to deal with them, coping research rarely considers the effects of higher-order contexts (cf. Tolan & Grant, 2009). All of these areas would benefit from a further exploration of their inherent interconnections.

The natural overlaps among coping, developmental psychopathology, and resilience have been expanded over the last several decades by a major shift in conceptualizations guiding the study of coping during childhood and adolescence. This shift was initiated in the 1980s with the publication of the book *Stress, Coping, and Development in Children* (edited by Garmezy & Rutter, 1988) and the seminal article in *Psychological Bulletin* titled "Coping with Stress during Childhood and Adolescence" (Compas, 1987a), and then it accelerated rapidly during the late 1990s (Eisenberg, Fabes, & Guthrie, 1997; Skinner & Edge, 1998; Wolchik & Sandler, 1997). Since that time, conceptualizations of coping during childhood and adolescence have branched off from work on coping during adulthood (Aldwin, 2007), after which it was largely patterned, to focus not only on individual differences but also on the *development* of coping. This "new" way of looking at coping, which takes the concept back to its roots as an adaptive process (Murphy & Moriarity, 1976; White, 1974), has forced a reconsideration of the very definition of coping as well as the meaning of ways of coping, their antecedents and consequences, the role of social partners, and, most important, qualitative shifts with age in how the adaptive processes that comprise coping are organized across infancy, childhood, adolescence, and early adulthood (Skinner & Zimmer-Gembeck, 2007, in press).

GOAL OF THE CHAPTER

The goal of this chapter is to review conceptual and empirical progress in the study of the development of coping and to identify important ways in which this work may be useful to researchers studying the development of psychopathology and resilience. We present our review and ideas in three main sections, each representing a different perspective on coping. An overview of the contributions of each of these perspectives to an understanding of the connections among coping, psychopathology, and resilience is provided in Table 10.1. First we focus on coping as a *transactional process*, basically as constituting individual differences in appraisals and ways of dealing with stressful demands and the emotions they generate. Here we review what is known about the links between different ways of coping, appraisals, and coping resources, on one hand, and different forms of psychopathology and adaptive functioning, on the other hand. We primarily draw from research on children and adolescents, but research with adults is also reviewed when it is important for identifying future directions for research with youth. We also provide conceptual and methodological critiques of this work to date.

Then we describe coping as a *fundamental human adaptive process* that involves the regulation of multiple subsystems (e.g., emotion and attention) that are activated by stress and that also shows regular age-graded developments in how such regulation is accomplished. We explain how a developmental perspective requires a reorientation of the study of coping, including a developmentally friendly definition of coping itself. We review studies of normative age differences and age changes in adaptive and maladaptive ways of coping and knit together research from within and outside the coping area to create a picture of the neurophysiological underpinnings and qualitative shifts in coping as it develops from birth to emerging adulthood. This section highlights the important roles that close relationships with caring adults play in the healthy development of coping and explains how stressful encounters can provide opportunities for the development of coping and regulatory capacities, resources, and efficacy, if demands are manageable, interpersonal supports are sufficient, and parents (and other adults) help children channel setbacks and failures adaptively—by learning and growing from them. We describe how these basic building blocks all work together to contribute to the normative development of appraisals, coping, and personal and social coping resources in order to show how they inherently provide a platform or foundation for more complex theories

TABLE 10.1 Three Perspectives on How the Study of the Development of Coping Can Contribute to Research on Developmental Psychopathology and Resilience

Transactional Perspectives: Coping as Individual Differences in Stress Reactivity and Responses
Coping is a moderator. Ways of coping represent families of adaptive and maladaptive responses to stress and so fundamentally buffer or exacerbate the effects of stress and adversity on psychopathology and resilience.
Coping is a mediator. Adaptive and maladaptive coping are parts of the pathways through which exposure to stress contributes to psychopathology and resilience.
Individual ways of coping are part of a profile of reactions and responses during the course of stressful encounters. Coping can supplement the study of individual ways of coping implicated in psychopathology (such as rumination or social isolation) by considering the repertoire, combination, or sequence of ways of coping that children and adolescents enact over the arc of multiple coping episodes.
Coping is a critical mechanism through which a variety of assets and liabilities, such as self-efficacy, pessimism, and social support, which have long been implicated in psychopathology and resilience, exert their effects.
Normative Developmental Perspectives: Coping as a Fundamental Adaptive Process
Developmentally friendly conceptualizations, which define coping as regulation under stress, integrate research on the development of both stress reactivity and the many kinds of regulation (emotional, attentional, motivational, behavioral, etc.) that are activated by stressful encounters.
Because *core families of coping represent fundamental adaptive and maladaptive processes*, they are tightly linked to other subsystems that serve to detect and deal with threats and danger, such as processes of temperament, attachment, mastery, and self-determination.
Coping influences everyday resilience and marks a site of developmental potential. Coping shapes how children and youth bounce back from daily stressors. Such episodes can be opportunities for the development of regulatory capacities and coping efficacy, if stressors are manageable, personal and interpersonal resources are sufficient, and parents (and other adults) help children channel setbacks and failures adaptively—by learning and growing from them.
Developmental Systems Perspectives: Coping as Part of Developmental Cascades
The stresses of adversity can undermine the healthy development of coping—based on its effects on the neurophysiological, psychological, and social underpinnings of coping. The development of adaptive coping requires years of deep developmentally attuned interpersonal support for dealing with just-manageable demands. Stressful overarching social conditions, such as poverty, oppression, discrimination, harsh families and parenting, maltreatment, and neglect, pose serious risks to the healthy development of coping.
Coping is reciprocally related to psychopathology and resilience. Psychopathology interferes with constructive coping and triggers maladaptive stress reactions. Hence, coping is a key marker and player in the developmental cascades from which psychopathology emerges.
Coping can be a powerful intervention lever in preventing deleterious short- and long-term consequences of stress, risk, and adversity. Upstream interventions that focus on strengthening relationships and promoting core coping resources and coping efficacy should have the biggest impact on the construction of appraisals and coping processes that foster resilience.

and research on the development of psychopathology or resilience.

The section titled "Developmental Systems Perspectives" brings together work on individual differences and normative development to consider coping from a multilevel dynamic developmental systems perspective. According to this approach, coping is always part of developmental cascades that contribute to resilience or psychopathology. Profiles of adaptive and maladaptive coping can be considered both markers and mechanisms for cascades leading in a multitude of directions, and ways of coping are important processes that shuttle individuals back and forth between different pathways. We draw from work on temperament, attachment, and family stress to identify examples of underlying biological and overarching contextual risk and protective factors that shape developmental transitions and dynamics and so likely play a role in developmental cascades that mark and contribute to psychopathology and resilience. We end the chapter with some suggestions about how future research can productively combine work on the development of coping with work on the development of psychopathology and resilience.

TRANSACTIONAL PERSPECTIVES: COPING AS INDIVIDUAL DIFFERENCES IN APPRAISAL AND COPING PROCESSES AND RESOURCES

Early work on coping during childhood and adolescence, inspired by research with adults, focused on coping as a transactional process that unfolds in several recursive steps (Folkman & Moskowitz, 2004; Lazarus & Folkman, 1984). According to this perspective, as pictured in Figure 10.1,

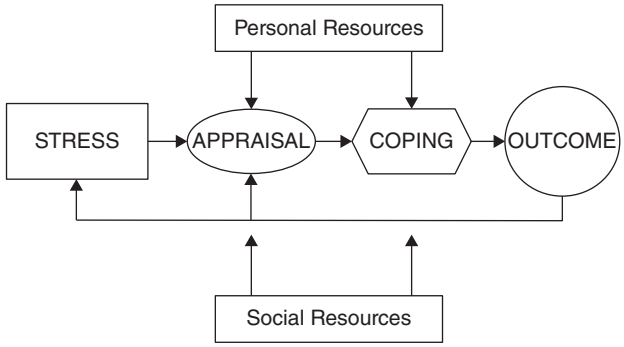

Figure 10.1 Coping Depicted as a Transactional Process of Appraising and Dealing with Demands.

coping transactions are initiated by encounters with *stress*, defined as internal and external events that individuals appraise as important to their well-being and as taxing or exceeding their resources (Lazarus & Folkman, 1986, p. 63). Cognitive appraisals, focusing on the extent to which the stressor is personally relevant and amenable to personal control, result in views of the encounter as constituting a *threat* (i.e., impending harm), a *loss* (i.e., irreversible harm that has already been incurred), or a *challenge* (i.e., a stressor the individual is confident about mastering).

These appraisals trigger bouts of coping, defined as "cognitive and behavioral efforts to master, tolerate, or reduce external and internal demands and conflicts among them" (Folkman & Lazarus, 1980, p. 223), which utilize personal and social resources to solve the stressful problem or manage the individual's negative emotional reactions to it. These efforts produce coping outcomes, which, by feeding back to both the stressful event and individuals' reappraisal processes, can terminate or prolong the stressful transaction. According to this perspective, coping can be seen as a process that involves a wide variety of ways of reacting to and dealing with stressors that are organized sequentially, forming an interconnected action sequence or coping episode (Folkman & Lazarus, 1985).

Stress, Appraisals, and Coping Associated with Adjustment and Psychopathology

A primary focus of research on stress and coping across the life span has been on correlating the many ways of coping with indicators of adjustment, such as internalizing behavior (e.g., depressive and anxiety symptoms or disorders) or externalizing behavior (e.g., behavior problems and aggression or conduct disorder). In fact, in 2000, Coyne and Racioppo reported that the cumulative number of publications with coping as a keyword totaled almost 25,000 articles, with the great majority focused on identifying stress and coping as risks or resources for mental health and adjustment. Literally thousands of additional studies have been published in the past 15 years. The size of the literature makes it difficult to achieve a comprehensive review, but a few trends are apparent. For example, in the most recent decades, contemporary research has focused on stress and coping as correlates of physiological functioning and physical health (Appleton, Buka, Loucks, Gilman, & Kubzansky, 2013; O'Leary, 1990; Penley, Tomaka, & Wiebe, 2002; Walker, Smith, Garber, & Claar, 2007), and even more recently, a small but growing number of studies focus explicitly on stress, coping, and psychopathology (e.g., Boxer, Sloan-Power, Mercado, & Schappell, 2012; Tolan, Gorman-Smith, Henry, Chung, & Hunt, 2002). Multiple reviews summarize much of this research (Bridges, 2003; Clarke, 2006; Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2001; Compas, Orosan, & Grant, 1993; Decker, 2006; Frydenberg, 1997; Nes & Segerstrom, 2006; Penley et al., 2002; Petticrew, Bell, & Hunter, 2002; Seiffge-Krenke, 2011; Taylor & Stanton, 2007; Wolchik & Sandler, 1997).

Stressful Life Events

Across these reviews, it is clear that major life stressors, including the death of a loved one, witnessing a traumatic event, or experiencing abuse by family members or others, are common experiences among children and adolescents, occurring for about 25%. An even greater number of children and adolescents experience repeated, sometimes daily, hassles related to school (e.g., fights or problems with teachers or academic performance) and interpersonal relationships (e.g., conflicts or problems with parents, siblings, and peers; Donaldson, Prinstein, Danovsky, & Spirito, 2000). Both significant life events and daily hassles have been associated with increasing symptoms of psychopathology over time, including depression, anxiety, and delinquent behavior (Compas, 1987a,b; Compas et al., 2001). Although these associations are usually small to moderate in most studies, associations are much stronger when specific stressors are examined, such as peer victimization (Harper, 2012; Kochenderfer-Ladd & Skinner, 2002; Zimmer-Gembeck, Hunter, & Pronk, 2007; Zimmer-Gembeck et al., 2013), friendship and romantic formation or dissolution (Nieder & Seiffge-Krenke, 2001; Seiffge-Krenke, 2011; Zimmer-Gembeck, Siebenbruner, & Collins, 2001); racial discrimination (Berkel et al., 2010; Brittian et al., 2013; Pascoe & Smart Richman, 2009; Umaña-Taylor & Updegraff, 2007), or community violence (Fowler, Tompsett, Braciszewski, Jacques-Tiura, & Baltes, 2009).

Despite clear evidence that the experience of stressful life events is a risk factor for children and adolescents, it has been widely acknowledged that, in order to understand the development of psychopathology, it is important not only to attend to the intensity and chronicity of stressful events but also to take into account individuals' appraisals of stress, their coping responses, their feelings of efficacy in being able to carry out successful coping efforts, and their personal and social resources for coping (Moos & Holohan, 2003; Taylor & Stanton, 2007). In the remainder of this section we summarize and build on previous reviews linking stress and coping with psychopathology

and positive adjustment, emphasizing studies of childhood and adolescence. We begin with what is known about general coping categories and their associations with psychopathology. We then consider how psychopathology and adjustment are related to specific coping strategies, to cognitive appraisals of stressful events, to coping self-efficacy, and, more recently, to profiles or combinations of coping strategies and resources. We end with a summary of transactional models of the connections among stress, coping, adjustment, and psychopathology as well as findings from new and innovative research studies, using intensive repeated measures, which provide evidence of reciprocal linkages between coping and psychopathology.

Challenges to Summarizing Research on Coping

In integrating studies of coping, we faced three challenges that have often been noted in the literature. The first was to figure out how to compare the many ways of coping examined across different studies—which show little consistency and typically employ different or partially overlapping lists of ways of coping. Hundreds of ways of coping have been identified, which have been combined into dozens of instruments to assess them, primarily through standardized self-report questionnaires, written open-ended responses, or open-ended interviews, but also via others' reports of coping (e.g., spouses, parents, teachers, friends) and, less frequently, diary methods and observation (Skinner, Edge, Altman, & Sherwood, 2003). In efforts to manage coping's apparent complexity, many researchers who examine the links between coping and psychopathology have boiled these variegated response options down to two categories, sometimes referred to as problem-focused versus emotion-focused, engagement versus disengagement, approach versus avoidance, or active versus passive (and described in more detail in subsequent sections).

A second challenge, given their potential overlap, was to distinguish between ways of coping and psychopathology, both conceptually and in terms of measurement. Maladaptive ways of coping sometimes are so closely connected to psychopathology that researchers have questioned whether coping assessments tap *symptoms* rather than predictors of disorder (Compas et al., 2001). Moreover, studies sometimes use measures that confound personal or social attributes, stress, and psychopathology, so that, for example, interrelations between coping and psychopathology might be explained by overlapping item content related to levels of stress and emotional distress (Austenfeld & Stanton, 2004; Coyne & Racioppo, 2000; Lazarus, 2000; Park, Armeli, & Tennen, 2004). As a result, in measurement work, researchers have had to carefully remove items from coping inventories that overlap with measures of emotional distress, and internalizing and externalizing behavior (Ayers, Sandler, West, & Roosa, 1996; Connor-Smith, Compas, Wadsworth, Thomsen, & Saltzman, 2000; Treynor, Gonzalez, & Nolen-Hoeksema, 2003).

A third challenge to integrating work on coping stems from the broad array of stressor domains (e.g., medical conditions, victimization, environmental disasters) that are covered in current research on children and adolescents. It is now clear that conclusions about whether certain kinds of coping responses are adaptive versus maladaptive across a range of mental health outcomes (e.g., Kendall & Terry, 2008) depend heavily on the type of stressor with which children and adolescents are dealing, particularly on identifiable features of stressful events, such as their severity or perceived controllability (Skinner & Zimmer-Gembeck, 2011; Zimmer-Gembeck & Skinner, 2011). In fact, in recent years, this conclusion seems to be implicitly acknowledged in the coping literature as research has become even more differentiated and focused—as reflected in the increasing proliferation of special population studies in which researchers often focus on a single specific stressful health condition, chronic situation, or acute event, with the aim of explaining one or many potential adjustment outcomes.

Links between Broad Categories of Coping and Psychopathology

Problem-Focused and Emotion-Focused, and Approach and Avoidance Coping

One of the most commonly known broad categorizations of coping is the differentiation of strategies that are primarily problem-focused from those that are more emotion-focused (Lazarus & Folkman, 1984). Problem-focused coping is usually defined to include strategies enacted in an attempt to modify or directly confront the stressful event, such as problem solving and direct action. Emotion-focused coping is usually defined to include responses that serve the purpose of managing emotional reactions to stress, such as social withdrawal, distraction, and emotional venting. Studies that examine the association of problem-focused and emotion-focused coping categories with psychopathology have considered a wide range of outcomes, most frequently depression, anxiety, loneliness, suicidal ideation, self-esteem, and positive well-being. A smaller number of studies have assessed additional outcomes, such as stress reduction, physiological reactions, or physical health (e.g., Appleton et al., 2013).

In reviewing the literature on problem-focused and emotion-focused coping and adjustment among children

and adolescents, Losoya, Eisenberg, and Fabes (1998) noted two general trends: (1) problem-focused coping strategies are associated with fewer emotional and behavioral problems and greater social competence, whereas emotion-focused coping is generally associated with more internalizing and externalizing symptoms; and (2) these findings are not uniform across studies and generally depend on the type of stressor or features of the stressor. Subsequent research confirms both of these trends. For example, in one recent study, the use of more problem-focused coping responses was correlated with fewer symptoms of mental health disorders (Li, DiGiuseppe, & Froh, 2006), but other studies found no such associations (e.g., Horwitz, Hill, & King, 2011). Findings are slightly more consistent across studies of emotion-focused coping, in that greater use of these strategies is correlated with elevated symptoms of mental health disorders (Horwitz et al., 2011; Rafnsson, Johnson, & Windle, 2006).

However, a recent study by Krattenmacher et al. (2013), which also found that problem-focused coping was associated with better mental health, draws attention to the different forms that emotion-focused coping can take, producing a more differentiated pattern of associations with psychopathology (see Stanton, Danoff-Burg, Cameron, & Ellis, 1994, for similar conclusions in work with adults). In a study of 214 adolescents coping with their parents' cancer, some emotion-focused strategies, specifically those that also had an approach or active component, such as cognitive reappraisal, were associated with better mental health, whereas those strategies that had the function of venting emotions or of avoiding emotions or stressors were associated with worse mental health (see Austenfeld & Stanton, 2004, for more detail on emotion-focused coping subtypes). In summary, the general evidence points to the positive role of problem-focused coping and the negative role of emotion-focused coping in adjustment. Yet such findings are often inconsistent across studies, potentially because the broad categorization of problem-focused versus emotion-focused may not always adequately discriminate the pattern of coping responses that account for increasing mental health problems or effective resolution and adaptation.

Although the broad categorization of problem-focused versus emotion-focused coping is probably better known (Lazarus & Folkman, 1984), the most commonly used categorization of coping in recent studies of children and adolescents refers to general styles of approach (sometimes also called active or engagement coping) and avoidance (sometimes also referred to as disengagement coping; e.g., Causey & Dubow, 1992; Compas et al., 2001; Ebata & Moos, 1991; Jaser et al., 2007; Lengua & Stormshak, 2000). Definitions of approach coping, which often share many of the same responses as problem-focused coping, include cognitive or behavioral efforts to manage the stressor. These are usually measured as problem solving, cognitive reappraisal, information or support seeking, and taking concrete action. Avoidance coping includes both cognitive and behavioral responses that serve the function of avoiding the distressing event or circumstances. Most often this is measured as distraction from the stressor, ignoring the situation, denial or minimization, withdrawal, escape, and/or wishful thinking.

When reviews and the latest research are considered, there is substantial evidence that, among children and adolescents, approach and active forms of coping are associated with positive adjustment as well as with fewer symptoms of mental health problems. Such findings are generally consistent with the findings for problem-focused coping strategies (Compas et al., 2001; Fields & Prinz, 1997; Holahan & Moos, 1991; Lengua & Stormshak, 2000). Evidence is especially strong when measures of approach coping tap the use of these responses relative to avoidant forms of coping. In contrast, avoidant forms of coping are very frequently associated with risks for heightened negative outcomes, such as greater psychological distress and elevated behavior and other externalizing problems (Krattenmacher et al., 2013; Rohde, Lewinsohn, Tilson, & Seeley, 1990; Seiffge-Krenke & Klessinger, 2000).

Three reviews have summarized evidence about the associations of approach and avoidant coping categories with psychological adjustment among children and adolescents. In the first review of 21 such studies (Fields & Prinz, 1997), approach/active strategies, such as seeking social support and direct problem solving, were associated with greater social competence and fewer internalizing and externalizing behavior problems. In a second review, by Compas et al. (2001), two classes of coping—"active" coping (which typically entails problem solving, problem-focused support, and/or information seeking) and "engagement" coping (which includes not only problem solving but also constructive emotional expression and support seeking) were associated with fewer internalizing problems in 29 of 40 studies, fewer externalizing problems in 15 of 18 studies, and greater social and academic competence in 17 of 20 studies. Within the broader factors of problem-focused and engagement coping, the individual ways of coping that have been found to be linked most closely to better functioning include problem solving and positive reappraisal.

The Compas et al. (2001) review also noted that two kinds of coping, "emotion-focused coping" (which usually

includes expression of negative affect, denial, and/or wishful thinking) and "disengagement coping" (which typically entails problem avoidance, cognitive avoidance, and social withdrawal) seem to be detrimental to positive functioning, in that they are linked to elevated internalizing and externalizing problems. The individual ways of coping that have been found to be most consistently associated with poor adjustment include cognitive and behavioral avoidance, social withdrawal, wishful thinking, self-blame, resigned acceptance, emotional discharge, venting, and self-criticism (Compas et al., 2001).

Active Coping

In the third review, Clarke (2006) conducted a meta-analysis to summarize effect sizes from 40 studies of youth age 21 and under focusing on the connections between active/approach coping in response to interpersonal stressors and adjustment. In analyses of externalizing behavior, internalizing behavior, social competence, and academic performance, only the association between active coping and social competence was significant, with a mean effect of .11 (confidence interval .01–.21). The effect of active coping on internalizing was moderated by age, however, with a stronger, and surprisingly positive, effect found in adolescents (.14, 17 studies) compared to preadolescents (–.04, 10 studies). Thus, it appears that, on average, active coping with interpersonal stress may have a small link to more internalizing symptoms among adolescents, but not among preadolescents. It may be helpful, however, to interpret this finding of age moderation in connection with the controllability of the stressor. Clarke found that the type of stressor was a particularly important moderator of the effects of coping: Active coping in response to controllable events was positively associated with healthy functioning (.05 to .22) but negatively associated when used in response to uncontrollable events (–.06 to –.19). In particular, utilization of active coping is especially adaptive in situations that children and adolescents expect to be amenable to personal control, such as school-related tasks. When situations are objectively less controllable, such as the experience of parental conflict or medical procedures, active coping may not be associated with adaptation or positive outcomes and sometimes may actually predict mental health problems. In these situations, some kinds of coping that reduce the experience of stress, such as self-distraction, may be more adaptive.

Primary and Secondary Control Coping

Following up on studies suggesting that the effects of different ways of coping depend on whether target events are amenable to personal control, recent research has focused on the (objective, researcher-defined) controllability of environmental stressors (Forsythe & Compas, 1987). Most coping researchers now agree that the use of active coping is associated with fewer externalizing problems and greater social competence, but only when it is deployed in response to controllable stressors as compared to uncontrollable ones. This finding has been extended to understanding other broad categories of coping and psychopathology, specifically categories like primary and secondary control coping (Rothbaum, Weisz, & Snyder, 1982), in which the term *primary control coping* refers to attempts to change the stressful situation through typical problem-focused, active, and approach ways of coping, whereas *secondary control coping* refers to strategies that allow people to accommodate to events, placing less effort on trying to change them. Secondary control strategies include cognitive reappraisal, focus on the positive, distraction, and willing acceptance (Connor-Smith et al., 2000).

In general, research suggests that it is more adaptive to use primary control coping when dealing with controllable stressors and secondary control coping when dealing with uncontrollable ones. For example, one study found that adolescents were lower in internalizing symptoms when they used more secondary control efforts (i.e., accommodation) to adapt to the stress of having a depressed parent (an uncontrollable event; Langrock, Compas, Keller, Merchant, & Copeland, 2000). Extending this finding, another study reported that adolescents with depressed parents were better adjusted when they used active secondary control, such as positive thinking and cognitive restructuring, in response to situations that were less controllable (e.g., family stress) and used active primary control, such as problem solving and emotional modulation, in response to more controllable situations (such as peer stress; Jaser et al., 2007). Finally, in a third study of 204 children and adolescents and their experiences of uncontrollable stressors (parental depression and interparental conflict), those who used more secondary control coping strategies of acceptance, distraction, cognitive restructuring, and positive thinking were lower in both child and parent reports of anxiety and depressive symptoms as well as lower in aggressive behavior (Fear et al., 2009).

In summary, these reviews and recent empirical evidence illustrate that the fit between the situation and the use of approach or accommodative coping responses is an important indicator of likely adaptive or maladaptive outcomes among children and adolescents (and adults; also see S. M. Miller, 1992). Although it is still rare for studies to examine both the objectively defined controllability of

stressful events and participants' own perceptions of controllability, these findings highlight the crucial importance of the capacity to accurately diagnose the controllability of stressors in order to implement approach or active coping or to draw on accommodative and distraction techniques depending on the needs of the stressful situation. Rather than relying only on approach and active coping attempts, children and youth, when faced with uncontrollable stressors, may benefit from accommodation strategies, such as positive reinterpretation and distraction, in order to deal with emotions, shield themselves from stress, promote acceptance, and allow them to move forward, all of which may be more healthy for concurrent and later mental health (Brandtstädter & Rothermund, 2002; Compas, Banez, Malcarne, & Worsham, 1991; Forsythe & Compas, 1987; Losoya et al., 1998; S. M. Miller & Green, 1985; Roth & Cohen, 1986).

Connections between Specific Coping Strategies and Psychopathology

Although less frequently a focus of research than studies examining broad coping categories, there have also been more fine-grained investigations of specific coping strategies and their links to psychopathology or competence (e.g., Decker, 2006; Khurana & Romer, 2012; Zimmer-Gembeck, Skinner, Morris, & Thomas, 2013). In general, results of studies of specific coping responses and adjustment or psychopathology are consistent with the findings for approach/active/primary, secondary control/accommodative, and avoidance coping and psychopathology. In particular, problem solving, a form of active and approach coping, is one of the most adaptive specific responses for maintaining good mental health in the face of stress. In a review of 12 studies of stress, coping, and personal attributes in adolescents with cancer, two specific coping strategies were consistently related to lower levels of depressive symptoms: problem solving and seeking alternative rewards (Decker, 2006). In other research with adolescents or young adults, help seeking (Gould et al., 2004), planning (Aldridge & Roesch, 2008), and positive reinterpretation (Stewart et al., 1997), as well as problem solving (Khurana & Romer, 2012), were each associated with greater competence or fewer symptoms of mental health problems.

Yet there are also specific strategies that seem to prompt heightened or increasing adjustment problems. In particular, aggressive and ruminative coping are among the strategies that seem most detrimental to child and adolescent mental health. In one study, both were associated with more internalizing symptoms and more peer reports of withdrawal or isolation from others (Sandstrom, 2004). In a second study, however, an even wider range of maladaptive coping strategies was identified (Horwitz et al., 2011). In this study of 140 adolescents seeking pediatric emergency services, five ways of coping and appraisals were measured, including denial, substance use, use of emotional support, behavioral disengagement, and self-blame. All were associated with more heightened depressive symptoms and more frequent suicidal ideation for boys, for girls, or for both. Unique coping and appraisal correlates of elevated depressive symptoms were behavioral disengagement, self-blame, and seeking emotional support. The one unique correlate of suicidal ideation was the greater use of emotional support, suggesting that emotional support seeking may also reflect level of distress.

Other studies have found that behavioral disengagement, often assessed as behaviors that imply giving up or helplessness, is a risk factor for elevated depressive symptoms (e.g., Kaminsky, Robertson, & Dewey, 2006; Nolen-Hoeksema, Girgus, & Seligman, 1992; Wadsworth & Compas, 2002), and the use of distraction as a response to the stressor of discrimination is a risk factor associated with increased internalizing disorders over time (Brittian et al., 2013). Taken together, denial, rumination, aggression, or opposition in response to stress, as well as helplessness or disengagement, blaming the self, and seeking emotional support, are most indicative of greater symptoms of mental health problems among children and adolescents. Moreover, distraction may also be a risk for elevated symptoms, especially if it is used when stressful events are within personal control and active coping might be more productive.

Although most studies have focused on older children or adolescents, there is also evidence that there are specific coping strategies associated with problems or competence in younger children. For example, Eisenberg et al. (1997), in their study of children 2 to 4 years of age who were reassessed again at ages 6 to 8 and 8 to 10, found that the use of destructive coping (more venting and avoidance/distraction, and less cognitive restructuring), especially when reported by teachers rather than parents, was negatively associated with concurrent and future levels of social competence and positively associated with externalizing symptoms and problem behaviors. Simultaneously, constructive coping (the use of instrumental coping and support seeking) was associated with greater social competence. In a study of 153 young children (K. A. Blair, Denham, Kochanoff, & Whipple, 2004), preschoolers higher in parent-reported and teacher-reported passive coping (e.g., avoidance and denial of the problem) showed

more signs of emotional and social maladaptation, and the use of passive coping sometimes exacerbated the effects of irritable or sad-fearful temperaments on externalizing or internalizing symptoms. In contrast, actively facing the problem (e.g., problem solving) was associated with fewer internalizing symptoms. Thus, even in very young children, there is emerging evidence that active coping rather than avoidant coping or passivity in response to stressful demands from the environment may be important for maintaining mental health and building social competence. Moreover, the capacity for adaptive coping may counteract temperamental challenges in the early years of life.

Do Subjective Appraisals of Stressful Encounters also Play a Role in Psychopathology?

According to the transactional perspective, individuals' subjective appraisals of stressful encounters are a key part of the stress and coping process (Lazarus & Folkman, 1984). Appraisals, including perceptions of threat, harm, loss, or controllability, as well as attributions of causality, responsibility, or blame, are important because they are imbued with emotion, prompt other cognitions, and guide subsequent behavior (Lazarus, 1994). In particular, appraisals can be motivating or demoralizing, can calm emotion or amplify distress, and can foster continued engagement with the environment or lead to disengagement and helplessness (Roesch & Weiner, 2001; Weiner, 1985).

One complication within the research on appraisals, coping, and psychopathology, however, is that empirical distinctions between appraisals and coping are not always clear (Folkman, 1984). In some studies, causal attributions have been included as a way of coping (see Folkman, 1984, for a review). For example, self-blame, a form of internal attribution, has been examined as a coping strategy (e.g., Horwitz et al., 2011); and some multidimensional measures consider blaming others, sometimes referred to as projection, as a maladaptive way of coping (Skinner, Pitzer, & Steele, 2013). As Aldwin (2007) concluded, this research remains "muddled" (p. 182), and theories are needed that either clearly differentiate between appraisals and coping or explicitly posit that appraisals and reappraisals are integral parts of coping processes themselves.

Regardless of the challenges facing researchers, it is now widely accepted that, along with children's coping responses, it is also important to consider their perceptions of control and other appraisals of stress in the development of psychopathology (Chorpita & Barlow, 1998; Skinner, 1995; Weems & Silverman, 2006). In general, the impact of stressful events appears to depend not only on the objective stressors themselves but also on subjective appraisals of stress, and these may vary from child to child. As would be expected, appraisals are important correlates of emotional reactions to stress and to mental health (Compas et al. 2001; Zimmer-Gembeck, Lees, Bradley, & Skinner, 2009). For example, the appraisal of a stressful event as more threatening has been associated with children's self-reported symptoms of anxiety, depression, and conduct-related problems following parental divorce (Sandler, Kim-Bae, & MacKinnon, 2000).

One study illustrates the importance of appraisals in understanding how stress and coping are linked to psychopathology among children and adolescents. This study also raises the possibility that appraisals may be as important (or perhaps even more important) than coping for understanding the development of psychopathology. Lengua and Long (2002) examined threat and challenge appraisals, active and avoidant coping, and adjustment problems (depression, mother-reported internalizing and externalizing symptoms, and self-reported internalizing and externalizing symptoms) among 101 children ages 8 to 12 years old. Challenge appraisals were expected to be associated with active coping, as has been found in other research (Santiago-Rivera, Bernstein, & Gard, 1995). In contrast, threat appraisals were expected to be associated with maladaptive outcomes, because previous research had demonstrated that they were associated with depression, anxiety, and conduct problems in children experiencing parental divorce (Sandler, Tein, Mehta, Wolchik, & Ayers, 2000) and were found to be the conduit linking the stressor of interparental conflict to internalizing symptoms (Grych, Fincham, Jouriles, & McDonald, 2000). Although higher stress levels, appraisals of greater threat and use of more avoidant coping were associated with elevated internalizing and externalizing symptoms in simple correlations, coping had no direct effects on internalizing and externalizing symptoms once the significant impacts on symptoms of stress levels, threat appraisals, and temperament were accounted for in a multivariate model.

Other studies have found that the fit between appraisals and coping is important to consider when predicting psychopathology. For example, in a study of 76 adolescents who reported their coping and appraisals of the controllability of their cancer-related stress, the match between coping style and appraisals of controllability was associated with fewer depressive symptoms, less anger, less distress, and less anxiety (Sorgen & Manne, 2002). Thus, using more problem-focused coping when controllability was perceived to be high or using more emotion-focused

coping when controllability was perceived to be low was associated with less distress and fewer symptoms. These findings show that, just as has been found for objectively defined controllability, subjective appraisals of controllability can be important to understanding the implications of coping for adjustment and psychopathology. However, to date, few studies have directly tested this goodness-of-fit hypothesis in children and adolescents (cf. Forsythe & Compas, 1987), and findings remain rather mixed even in studies of adults or university students (e.g., see Park et al., 2004, for a discussion and an example of mixed findings).

Coping Self-Efficacy

An additional set of appraisals that seem to be important to coping and mental health following encounters with stress can be found in global beliefs about one's capacity to cope effectively or successfully, sometimes referred to as coping self-efficacy (Smith, Calkins, & Keane, 2006; see also Galatzer-Levy, Burton, & Bonanno, 2012, for a similar construct referred to as coping flexibility). Building on the view that a sense of efficacy in coping promotes the subsequent use of constructive coping strategies, coping self-efficacy has been defined to include beliefs about one's own ability to manage stressful events themselves as well as perceptions of one's capacity to understand and adaptively regulate one's emotional reactions to stress. Adolescents who report more coping self-efficacy tend to cope more successfully with stressful events and to receive more interpersonal support (Sandler, Kim-Bae, et al., 2000; Sandler, Tein, et al., 2000). It is not yet clear whether coping self-efficacy should be differentiated from the stress and coping process, for example, by considering it to be akin to a personal or a social resource. However, because high coping efficacy also reflects a history of successful coping, it is probably best conceptualized as an indicator of self-perceived coping success, so that it captures not what young people actually do in response to stress but how effectively they feel they have done it. In such instances, coping efficacy might be considered a mediator that links coping to mental health outcomes, and such pathways have been documented. In one study of children (Sandler, Kim-Bae et al., 2000), approach coping was negatively associated with depression and anxiety, and avoidant coping was positively associated with emotional adjustment problems, with coping efficacy fully mediating these associations.

The importance of considering both coping and coping efficacy when trying to understand mental health was also suggested by a comprehensive study of children of alcoholic parents (Smith et al., 2006). In this study, in which all constructs were assessed via multiple reporters (mothers, father, teachers, children), children who had a history of more positive parenting (supportive parenting practices and consistent discipline) used more active and support-seeking coping and were higher in coping efficacy. Moreover, all of these factors were important in explaining why children differed in their levels of externalizing and/or internalizing symptoms. In particular, children's active coping and coping self-efficacy mediated associations between positive parenting and lower symptoms. Yet some findings depended on the reporter, on whether the outcome was internalizing or externalizing symptoms, and whether the child had an alcoholic parent.

Causal Attributions

Appraisals can also involve causal attributions or explanations for why an event occurred. These appraisals and attributions include not only estimations of the controllability of the event itself but also explanations about its cause, such as whether it was caused by the self or by something outside the self (sometimes called locus) or whether the cause was stable (versus unstable) or global (versus specific). Although no review of the role of attributions in coping during childhood and adolescence could be located, one meta-analysis was conducted that included 27 studies of adults who were coping with illness (Roesch & Weiner, 2001). When the results of these studies were quantitatively combined, internal attributions were found to be associated with more approach coping responses. Attributions that stressful events were more unstable and controllable were associated with more coping responses of all kinds, (approach and avoidance, problem and emotion focused). For example, patients who appraised their illnesses as stable and uncontrollable used more avoidance coping and were less well adjusted than those who viewed their illnesses as more unstable and controllable. Moreover, there was evidence that the effects of attributions on psychological adjustment were fully mediated via all coping responses (except for behavioral avoidance). Thus, in adults, at least when they are coping with an often uncontrollable stressor like illness, appraisals are important to understanding coping responses, adaptation, and psychopathology.

The results of these studies raise the possibility that causality and attributional processes may also be critical for understanding coping prior to adulthood, or at least by late childhood or early adolescence. When focusing on these younger age groups, however, such findings should be considered only suggestive, given the cognitive changes that occur between childhood and adulthood. Perhaps the development of causal beliefs and attributions may

explain some of the changes in coping that are found with increasing age (Band & Weisz, 1990; Zimmer-Gembeck & Skinner, 2011). It may also be the case that causal beliefs and attributions become more closely tied to coping processes with increasing age (Skinner & Zimmer-Gembeck, 2011).

Strategies for Emotion Regulation, Coping, and Psychopathology

Coping is often aimed at regulating emotional experiences, either by changing one's own responses or by modifying the stressor that prompted the emotional reaction (Compas et al., 2014; Losoya et al., 1998). Overall, emotion dysregulation, usually assessed via measures originally designed to assess coping, is thought to be a core feature of many forms of psychopathology (e.g., see Aldao & Nolen-Hoeksema, 2010, 2012; Aldao, Nolen-Hoeksema, & Schweizer, 2010; Webb, Miles, & Sheeran, 2012). Because of the clear conceptual and methodological overlaps, research on emotion regulation and the dysregulation of negative affect and their links to psychopathology often seem to be tantamount to studies of stress and coping, allowing some conclusions about coping and psychopathology to be drawn from such work.

Not surprisingly, the basic findings from these two bodies of research are similar: Just as with studies of stress, coping, and psychopathology among children and adolescents (and even adults), complex interrelations have been found in the associations between psychopathology and the multitude of available emotion regulation strategies. At the same time, two general patterns can be discerned. First, three specific emotion regulation (or coping) strategies have been widely theorized to be protective against psychopathology: (1) cognitive reappraisal of the stressful event, defined as generating benign or positive interpretations or perspectives on stressful situations as a means of reducing distress (Aldao et al., 2010; Gross, 1998; John & Gross, 2004); (2) problem solving, which involves conscious attempts to change a stressful situation or contain its consequences; and (3) acceptance, which refers to willingly consenting to emotions as they are without judgment. Second, and also overlapping with research on coping, three emotion regulation strategies have been identified as risk factors for the development of psychopathology: (1) suppression, defined as the control and repression of unwanted thoughts and emotions and their expression; (2) avoidance, which involves evading an array of unwanted psychological experiences, including emotions, sensations, memories, and urges; and (3) rumination, which refers to repetitively focusing on negative and distressing experiences and emotions and their causes and consequences.

Testing these expectations using a range of measures of coping and emotion regulation associated with stress, Aldao and Nolen-Hoeksema (2010) found that university students who relied more often on cognitive reappraisal and problem solving also reported fewer indicators of psychopathology (symptoms of anxiety, depression, and eating disorders), whereas symptoms were more elevated in students who relied more often on suppression and rumination. Moreover, associations were stronger between maladaptive strategies and symptoms than between adaptive strategies and symptoms.

These patterns of findings were also confirmed in a meta-analysis of 114 studies that examined the associations between six forms of emotion regulation and four psychopathologies: Aldao et al. (2010) found that there were large effects of rumination on depression and anxiety; medium to large effects for avoidance, problem solving, and suppression; and small effects for reappraisal and acceptance. Three of these coping strategies—rumination, avoidance, and suppression—were associated with heightened levels of depression, anxiety, and (somewhat less strongly) substance use and eating disorders. The other three responses—problem solving, reappraisal, and acceptance—were associated with lower levels of symptoms. The strongest effect was for rumination, and the weakest effect was for acceptance. John and Gross (2004) also reviewed evidence of the links between adjustment and the emotional regulation strategies of reappraisal and suppression, concluding that research has predominantly supported the positive implications of reappraisal and the negative implications of suppression. Most recently, many, but not all, of these associations were confirmed in a review of 306 experimental studies of emotion regulation and its effects on a range of outcomes including distress and adjustment (Webb et al., 2012).

Much less research has examined the use of these emotion regulation strategies in children and adolescents. It may be that some of these strategies are not as widely used in younger age groups, given their cognitive complexity and the autonomous actions required to execute them. However, some research has been conducted, which has identified multiple emotion regulation deficits among children with internalizing and externalizing psychological difficulties (for a review see Zeman, Cassano, Perry-Parrish, & Stegall, 2006). Across these studies, deficits in emotion regulation and coping have been measured as biased or misguided appraisals of the

threat and challenge of stressful events and excessive emotional reactions and displays. All of these deficits appear to be heightened among children with depression, anxiety, or bulimia nervosa (compared to children without these disorders), but patterns of deficits differ for children with internalizing versus externalizing disorders. In particular, children with elevated depressive and anxiety symptoms have been found to display poorer emotional awareness and emotional understanding, report lower self-efficacy regarding their ability to regulate their emotions and cope with stress, show a less well-developed emotional vocabulary, have difficulties expressing and regulating their anger, and more often display inappropriate expressions of sadness. In contrast, children identified as having elevated externalizing disorders seem to suffer from emotional undercontrol resulting in displays of high emotional intensity, evince poorer inhibition of anger as evidenced by facial and other displays, and respond to distressing events with less sadness than would be typical for other children.

Patterns or Profiles of Coping as Correlates of Psychopathology

Emerging evidence suggests that coping strategies may be deployed in clusters or may interact in ways that heighten their effects on adjustment and psychopathology. Although recent studies have addressed this issue, the notion of coping patterns or clusters is not new. For example, Timko, Moos, and Mickselson (1993) argued for the importance of the relative or combined use of a range of coping strategies for psychopathology more than two decades ago. However, subsequent research has identified a number of important combinations of coping responses or coping resources.

First, generalizing from findings across multiple studies, positive reinterpretation combined with acceptance may be especially beneficial for adjustment in uncontrollable situations, whereas positive reinterpretation combined with active coping may be especially beneficial to adjustment in controllable situations. Second, contrary to the idea that people rely on problem-focused *versus* emotion-focused coping strategies, multiple studies have found that coping strategies such as positive reappraisal, reinterpretation, or distraction (i.e., emotion-focused strategies) actually often occur in combination with or promote or antecede problem-focused coping, suggesting that calming emotion may promote constructive problem solving and that it may be this combination that aids good adjustment when facing stressful events, especially when events are objectively controllable (e.g., Mattlin, Wetherington, & Kessler, 1990; Shimazu & Schaufeli, 2007; see also Folkman, 1984, for a review). Third, the negative effects of internalizing coping strategies, such as isolating oneself and emotional venting, may be weakened if they are used in conjunction with more active strategies, such as problem solving (Kingsbury, Coplan, & Rose-Krasnor, 2013). Fourth, social support may be most beneficial to relieving distress in situations of low personal control. In general, combinations or sequences of different coping strategies, theoretically or empirically derived, may turn out to be particularly helpful in understanding social and emotional adjustment following stressful events, both in the short and the longer term.

At least two studies of adolescents have gone somewhat further in tackling this issue by implementing person-centered approaches (i.e., data clustering techniques) to better understand how the use of particular combinations of coping strategies may contribute to adjustment and mental health problems (Boxer et al., 2012; Tolan et al., 2002). In a first study, focused on youth living in impoverished areas of the inner city (Tolan et al., 2002), 372 adolescents 12 to 16 years old provided information twice over a 1-year period about their use of 12 ways of coping when facing difficulties or feeling tense. Stress (social) was also measured, and the psychopathological outcomes were youth reports of their internalizing and externalizing symptoms as well as teacher reports of the same symptoms. About 50% of the items formed seven coping categories (seeking support, venting emotion, avoidance by substance use, distraction, positive thinking, seeking guidance, and humor), and these were subjected to cluster analysis. Five clusters were accepted as the best representation of differentiation among adolescents in their person-level patterns of coping responses, and these were labeled: (1) support and guidance seekers, (2) minimal copers, (3) emotional substance users, (4) emotion-focused copers, and (5) complex copers. After controlling for demographic differences and stress levels between coping groups, the lowest concurrent internalizing symptom levels were found for support and guidance seekers and minimal copers. Over time, minimal copers showed greater increases in internalizing symptoms when compared to support and guidance seekers. In contrast, the highest concurrent externalizing symptom scores were reported by emotional substance users and emotion-focused copers; emotion-focused copers also had greater increases in externalizing symptoms over time when compared to support and guidance seekers and complex copers. Such findings suggest that reliance on seeking support and guidance, relative to other coping strategies, to manage stressful events during adolescence

may serve to deflect the escalation of both internalizing and externalizing symptoms.

In a second study, the focus was on coping with stress and violence among 131 adolescents living in a distressed metropolitan area (Boxer et al., 2012). Coping included externalizing-internalizing coping (which included such strategies as aggressive responses, emotional venting, and high emotional reactions) and distancing; and mental health was measured as symptoms of posttraumatic stress disorder (PTSD), externalizing, and internalizing. Three coping cluster groups were found: those identified as (1) low in all forms of coping, (2) high in internalizing-externalizing coping but low in distancing, and (3) high in distancing but low in internalizing-externalizing coping. The low coping group showed the highest levels of competence, whereas the high internalizing-externalizing group reported elevated symptoms of all disorders relative to the other two coping groups. At the same time, however, this study illustrates the continuing problem of potential overlap in measures of stress, coping, and psychopathology. The measure of coping responses had obvious overlap with symptoms, and the levels of stress experienced by youth were assumed and not directly assessed, making it likely that the group of adolescents who reported the lowest levels of coping was also exposed to the fewest stressful events related to neighborhood violence. Once these methodological issues are addressed, however, person-centered analyses that identify coping patterns have much potential to inform our understanding of developmental pathways of psychopathology and resilience.

Transactional Models of the Links between Stress, Coping, and Psychopathology

Partly because the direct associations between stress exposure (or adversity) and psychopathology have been rather small, transactional theories often posit complex roles for appraisals, coping, and coping resources in the processes that protect (or harm) children and adolescents at risk for psychopathology (Fields & Prinz, 1997; Lazarus & Folkman, 1994; Moos & Holahan, 2003; Skinner & Zimmer-Gembeck, 2007). At least four kinds of general models depicting the role of coping and its associated processes can be identified (see Figure 10.2): Coping has been conceptualized as a moderator, mediator, mechanism, and reciprocal process in the relations between stress and psychopathology. Because of such theoretical developments, studies of mediators and moderators have become the norm rather than the exception in coping research. As a result, there is research to support or refute all of these more complex views, as described in this section.

Coping as a Moderator, Mediator, and Mechanism

One of the most straightforward models posits that all (or some forms) of coping are moderators that minimize, buffer, or exacerbate the negative effects of stress on adjustment or on the onset or relapse of psychopathology (Aldwin, 2007). Coping can be thought of as a stabilizing or destabilizing factor that helps maintain positive psychological adjustment during stressful periods or may explain why stressors lead to psychopathology. From this perspective, coping efforts should be most helpful when stress is severe and distress is high. Consistent with this notion, Holahan and Moos (1991) found that under high stress, personal and social resources (self-confidence, easy-going disposition, family support) were related to better psychological adjustment indirectly through their link to greater reliance on approach coping responses. Under low stress, only personal and social resources were related to adjustment (directly).

When tested, moderation effects are often found, although not consistently across studies and not for all ways of coping. Nevertheless, some of the differences are consistent with theory and conceptual frameworks. For example, in one study, moderation effects were found for problem-focused coping but only main effects of coping on psychological symptoms were found for emotion-focused coping strategies (Aldwin & Revenson, 1987). To explain this finding, the authors argued that emotion-focused coping may, to a large extent, reflect predispositional characteristics and that such characteristics may be more likely to show main, but not moderating, effects. In contrast, problem-focused strategies may be more situational specific—they are influenced by situational constraints and affordances—and, therefore, may have their effects by interfering or modifying the situation, which, in turn, has implications for adjustment.

A second model (see Figure 10.2) views coping as a mediator or an adaptive process that itself is embedded in or shaped by stress and is the primary (or only) pathway through which stress exerts its proximal effects on adjustment and psychopathology (Aldwin, 2007). According to this model, one of the reasons that adversity has deleterious effects is that stressful life events trigger maladaptive coping in children and adolescents, which then puts them at risk for the development of psychopathology. For example, avoidant coping, often measured as denial or withdrawal, has been found to mediate between stressful circumstances and distress, on one hand, and concurrent or later adjustment, on the other. In one study, avoidant coping mediated the negative effect of living in a homeless shelter on women's depressive symptoms (Rayburn et al.,

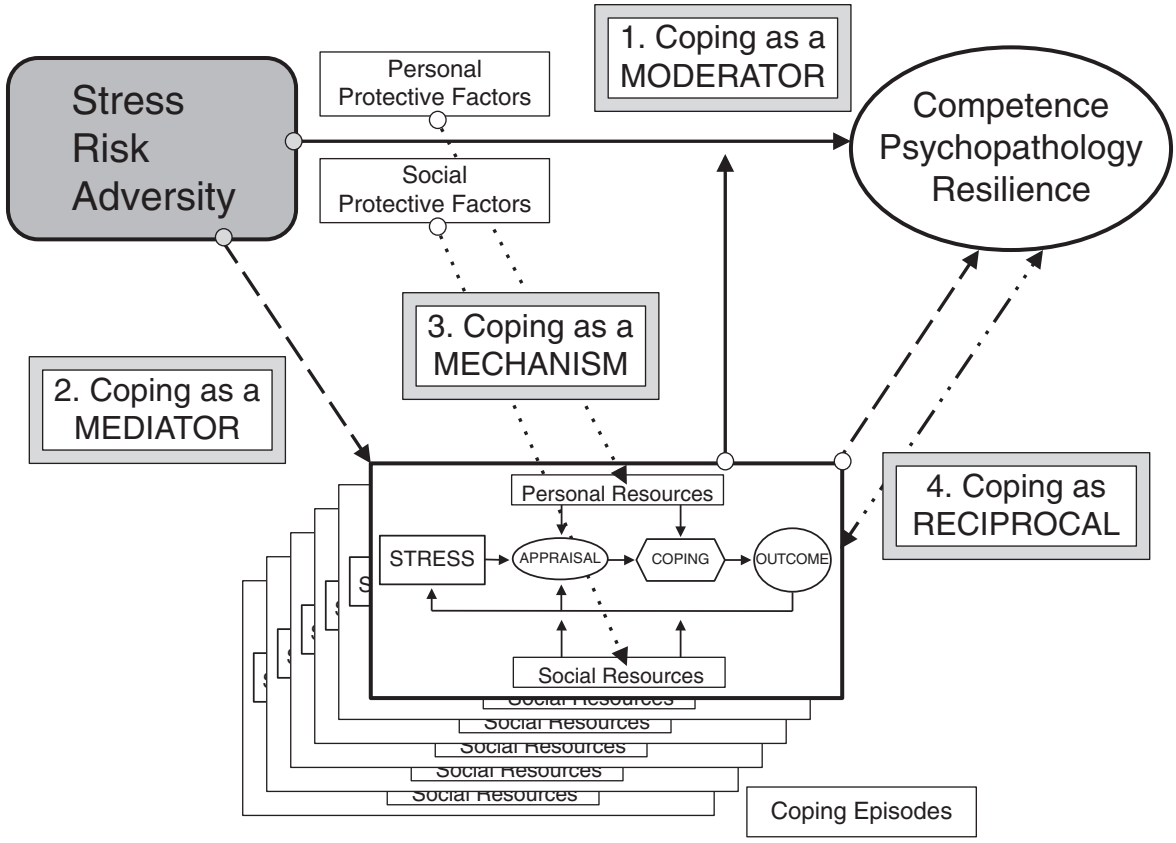

Figure 10.2 Four Models of the Role of Coping in the Processes that Connect Stress to Psychopathology, as a (1) Moderator; (2) Mediator; (3) Mechanism; and (4) Reciprocal Process.

2005). Other studies have also found avoidant coping, particularly behavioral rather than cognitive avoidance, to mediate the impact of stress on adjustment (Barker, 2007; Holahan, Moos, Holahan, Brennan, & Schutte, 2005; Roesch & Weiner, 2001). In a recent study of two samples, one of early adolescents and the other of adults, followed for 7 or 12 months, respectively, rumination mediated the association of more stressful life events with increased anxiety symptoms in adolescents and adults and mediated the association of more stressful life events with increased anxiety and depressive symptoms among adults (Michl, McLaughlin, Sheperd, & Nolen-Hoeksema, 2013). However, other studies have found that other forms of coping do not mediate the effect of stress on adjustment or psychopathology (e.g., Aldwin & Revenson, 1987) and instead may have more direct effects on adjustment in some circumstances (such as the main effect of active coping with controllable events on more positive adjustment; Clarke, 2006).

A third model (see Figure 10.2) posits coping as a mechanism through which protective factors exert their impact. Protective factors would include social resources, like social support, as well as personal resources, like optimism, personal control or mastery, self-esteem, or coping efficacy, which are hypothesized to proffer their protective effects at least in part by promoting constructive coping and discouraging reliance on maladaptive coping responses (Taylor & Stanton, 2007). From this perspective, in order to demonstrate the effects of coping per se, it would be essential to show that coping behaviors have unique effects on psychopathology over and above the effects of the preexisting personality and other characteristics that shape them (Carver & Connor-Smith, 2010).

Complicating matters even further, there is new evidence that some coping responses interact with each other and that coping responses and resources may also interact with each other, suggesting that some personal traits or environmental conditions (i.e., coping resources) may exacerbate or deflect the positive or negative effects of coping on outcomes (Dagan et al., 2011; Shimazu & Schaufeli, 2007; Taylor & Stanton, 2007). For example, Jacobsen et al. (2002) found that posttraumatic stress symptoms were most elevated among cancer patients who reported a combination of low social support and

greater use of avoidant coping. Dagan et al. (2011) found that unsupportive spousal behavior was associated more strongly with distress among adult cancer patients when the patients were also low in personal control.

Coping as Reciprocally Related to Psychopathology

The fourth model (see Figure 10.2) views coping as part of a set of reciprocal processes binding it to psychopathology. According to these models, stress, coping, and psychopathology have bidirectional or reciprocal effects, whereby stress interferes with coping processes and contributes to maladjustment or psychopathological outcomes; at the same time, maladjustment and psychopathology generate later experiences of stress and undermine the development of coping responses and resources (Conway, Hammen, & Brennan, 2012; Hammen, 2005; Lazarus, 2000; Liu, 2013; Roesch & Weiner, 2001; Rudolph & Asher, 2000).

Evidence from longitudinal studies has accumulated that documents both directions of these reciprocal effects. Results from time-lagged studies show that psychopathology can make it increasingly more difficult to cope adaptively with stress, just as multiple studies show that poor coping is associated with increasing adjustment problems and psychopathology. For example, multiple studies have shown that children (Zeman et al., 2006), adolescents (Littleton, Axsom, & Grills-Taquechel, 2011), and adults (Aldao et al., 2010; Roemer, Orsillo, & Salters-Pedneault, 2008) with elevated levels of depression, anxiety, or other forms of distress symptoms find it more difficult to use constructive coping strategies, such as cognitive reappraisal, acceptance, problem solving, and attentional redeployment. Depressed children also report using fewer strategies to regulate their negative emotions than nondepressed children (Garber, Braafladt, & Weiss, 1995), and adolescents with heightened depressive symptoms, relative to their nondepressed peers, report using more cognitive avoidance and resigned acceptance to cope with stressors, and less problem solving and positive reappraisal, all of which have been associated with the development of psychopathological symptoms (Ebata & Moos, 1991; Littleton et al., 2011). Such findings also extend to the flip side of these reciprocal relationships, as seen in the connections between coping and competence, whereby children rated higher in social competence by their parents also make more use of constructive coping strategies, such as problem solving and support seeking, compared to children rated as less competent (Zimmer-Gembeck, Lees, & Skinner, 2011).

Although both directions of effects are not typically examined together in a single study, a few investigations have explicitly targeted and found bidirectional effects. In one such study, adults with more psychological symptoms (measured with the Langner 22-item Screening; Langner, 1962) experienced increasing stress and reported more maladaptive coping over time at the same time that maladaptive coping was found to predict increasing psychological symptoms over time (Aldwin & Revenson, 1987). In another study, reciprocal associations were found between distress related to a university mass shooting, coping responses, and PTSD symptoms, with maladaptive forms of coping (avoidance, social withdrawal, wishful thinking, and self-criticism) related to increased distress over time, at the same time that levels of PTSD symptoms were associated with changes in coping over time (Littleton et al., 2011). As another example, adolescents' peer stress in the form of rejection by classmates has been associated with increasing depressive symptoms over time (Bagwell, Schmidt, Newcomb, & Bukowski, 2001; Garber et al., 1995; Panak & Garber, 1992; Parker, Rubin, Price, & DeRosier, 1995) and multiple, other forms of adolescent stress also have been associated within a chain of events that create increases in depressive symptoms over time (for a review, see Compas et al., 1993).

However, it is important to point out that some longitudinal studies explicitly looking for bidirectional effects have found evidence for one pathway but not the reverse. For example, one study which showed that coping was associated with increasing or decreasing mental health symptoms over time did not find the converse temporal associations between earlier symptoms and changes in coping (Wadsworth & Berger, 2006); and another study revealed that some forms of psychopathology (e.g., PTSD) may prompt increasing maladaptive coping with stress over time, but such coping was not associated with escalation in symptoms over time (Littleton et al., 2011).

In most cases, patterns of reciprocal relations between psychopathology and coping must be pieced together from multiple studies separately documenting complementary directions of effects. For example, studies have shown that adolescents' heightened depressive symptoms predict their reports (and their classmates' reports) of increasing peer stress over time (Zimmer-Gembeck et al., 2009) or other stress (Compas, Howell, Phares, Williams, & Giunta, 1989; Windle, 1992). Moreover, for adolescents, high levels of depressive symptoms can prompt increasing use of coping responses such as social isolation and avoidance (see Hammen, 1999, for a review), and, in turn, higher levels of withdrawal, isolation, or avoidance have been associated with increasing stress and distress among children (Gazelle,

2010; Prinstein & La Greca, 2002), adolescents (Littleton et al., 2011), and adults (Barker, 2007; Holahan et al., 2005; Shah, Gupchup, Berrego, Raisch, & Knapp, 2012). It is important to highlight the key role that avoidance coping seems to play in these bidirectional pathways between stress and depression.

Daily Stress, Coping, and Psychopathology

Stress, coping, and mental health also seem to be reciprocally linked across very short, even daily, temporal episodes. Because such series of interrelations can unfold so rapidly, stress and coping researchers have found the application of diary research designs particularly useful and informative. In these designs, participants often complete an initial assessment and then provide reports of their stress, coping, and other daily experiences for 5 or more days. Such studies tend to replicate the findings from cross-sectional and longitudinal research but also make clear that individuals differ in how rapidly they appraise stressful events, how often they use coping responses, and how necessary coping seem to be for maintaining positive emotion and well-being over time.

For instance, in a study of (mostly female) university students' stress, coping, and appraisal of stressor controllability, individual differences were found in the temporal patterns of controllability appraisals and coping (Park et al., 2004). Some individuals matched their appraisals to coping by using problem-solving coping strategies when events were appraised as controllable and using emotion-focused coping strategies when events were appraised as uncontrollable. However, others did not match appraisals and coping to the same degree. Although matching problem-focused coping to controllable situations was associated with better adjustment, matching emotion-focused strategies to stressors appraised as uncontrollable was associated with better adjustment only for a subset of participants. Moreover, the personality characteristic of neuroticism explained some of the individual differences in associations of controllability and coping with negative and positive mood across the 28 days of the diaries. In children, diary studies have also revealed the ways that coping and coping efficacy are associated with symptoms of mental and physical health problems over short periods of time. In particular, passive coping has been associated with more functional impairment, elevated depressive symptoms, and more somatization over a 5-day diary, whereas reports of coping efficacy have been associated with reduced symptoms of mental health problems, including fewer depressive symptoms and less somatization (Walker et al., 2007).

Summary of Transactional Research

Transactional research, which links reliance on different ways of coping (or emotion regulation) to different indicators of adjustment and psychopathology, is typical of the interindividual difference focus of most coping research with children and adolescents (as well as with adults). Also consistent across age groups is the pattern of findings suggesting that certain kinds of coping are positively linked to adaptive functioning and negatively to problems and disorders. These methods include active approach or engagement strategies like problem solving, positive reappraisal, constructive expression of emotions, and acceptance. In contrast, other ways of coping seem to show the reverse pattern of associations, that is, they are correlated positively to indicators of psychological problems and disorders and negatively to adjustment. These methods include avoidance and disengagement strategies, such as cognitive and behavioral escape, rumination, helplessness, suppression, social withdrawal, wishful thinking, emotional discharge, resigned acceptance, and self- and other-blame.

Several kinds of appraisals and causal attributions also show consistent links with competent functioning and psychopathology through their effects on approach and avoidance coping. Appraisals of challenge, controllability, and attributions of stressful events to internal and controllable causes generally predict higher levels of approach coping and lower levels of helplessness and, through these, higher levels of competent functioning and lower levels of depression and externalizing behaviors. Appraisals of threat, uncontrollability, and attributions of negative events to internal, stable, and global causes generally predict higher levels of avoidance, self-blame, and ruminative coping, which in turn typically are connected with higher levels of disorder and lower levels of competence. Particularly important seem to be appraisals of coping efficacy, or individuals' confidence that they can deal successfully with the problems, setbacks, and negative emotions entailed in stressful experiences.

The study of subjective and objective estimates of the controllability of stressful situations has demonstrated that it is the match between situational demands and ways of coping that both characterizes competent functioning and predicts effective outcomes. As depicted in the Serenity Prayer, individuals need "the courage to change the things I can" because active approach "primary control" ways of coping are a good fit for stressors (or aspects of stressors) that are controllable (like schoolwork); as well as "the serenity to accept the things I cannot change" because accommodative, positive reappraisal, acceptance,

and distraction coping are a better match for stressors (or aspects of stressors) that are not under an individual's personal control (like interparental conflict). Although not studied as often, this pattern of findings also implies that individuals must develop "the wisdom to know the difference" and suggests that children and adolescents would benefit from having parents who are aware of the fine distinctions and differences and can assist them in learning to make these distinctions.

Particular combinations or sequences of coping have proven to be associated with competent functioning: for uncontrollable events, cognitive reinterpretation accompanied by acceptance; and for controllable events, cognitive reinterpretation along with active forms of coping. These combinations seem to blend ways of dealing with distressing emotion with ways of guiding productive behavior, perhaps even sequencing them so that distress does not interfere with constructive action. Other combinations suggest that it is the balance between adaptive and maladaptive forms of coping that is typical of more positive functioning under negative conditions: The deleterious effects of coping strategies such as isolation or emotional discharge can be buffered by the use of problem-focused or engagement coping; and high levels of social support may help compensate for low levels of personal control. Taken together, these findings suggest that it may be most useful to examine interconnected patterns of situational demands, appraisals, and profiles of coping in order to better understand social and emotional adjustment following stressful events in both the short and the long term.

Multiple complex conceptual models have been proposed to account for the role of coping in the connections between exposure to stress, risk, or adversity, on one hand, and the development of psychopathology, competence, or resilience, on the other hand. Coping has been posited to act as a moderator, mediator, mechanism, and reciprocal partner in these connections. Evidence has been found for all these roles, but not consistently. Constructive coping, especially problem-focused coping, does seem to be especially crucial when stress is high (i.e., it seems to act as a moderator), but other forms of coping, such as those captured in typical emotion-focused amalgams, seem to be harmful under most circumstances. Avoidance coping, especially behavioral avoidance, seems to be a key pathway (i.e., mediator), in that high levels of stress and adversity elicit more avoidance and social withdrawal, which in turn is likely to create problems for psychological adjustment and functioning. However, some studies suggest that approach coping may both mediate the effects of stress and exert direct effects, irrespective of stress levels. Coping also seems to be a particularly important mechanism through which a variety of personal and social resources (such as mastery or sense of control, optimism, self-esteem, and social support), which have been found to act as protective factors under conditions of adversity, have been found to exert their beneficial effects on competent functioning and to buffer children and adolescents from symptoms of psychopathology.

Some of the strongest support for complex models comes from accumulating evidence that coping and psychopathology are reciprocally linked. Although not often investigated in the same studies, research increasingly documents the operation of each direction or pathway of influence. In terms of the effects of psychopathology on coping, studies show that emotion dysregulation and poor coping are hallmarks of many kinds of psychological disorders. In terms of the effects of coping on psychopathology, longitudinal, experimental, and intervention research show that when children and adolescents display these out-of-control emotions and maladaptive coping responses, they generate stress for themselves and their families and so initiate or exacerbate psychological problems. When taken together, most findings suggest that associations among stress, coping, and psychopathology are often reciprocal, unfolding in positive and negative developmental cascades across situations and over time.

Critique of Individual Differences Research on Coping and Psychopathology

Over the last several decades, tens of thousands of studies have examined the connections between a variety of ways of coping and a variety of indicators of psychological adjustment and disorder. Studies in this cast have multiple problems, but they can be optimized through the improvement of measurement and design strategies. In terms of measurement, overlap among indicators of stress, coping, and maladjustment continues to be problematic. Maladaptive ways of coping seem so closely connected to expressions of distress and indicators of psychopathology that researchers continue to question whether coping assessments tap symptoms rather than predictors of disorder (Compas et al., 2001). As a result, in measurement work, researchers need to continue to carefully scrutinize and remove items from coping inventories that overlap with measures of stress, emotional distress, and internalizing and externalizing behaviors (Ayers et al., 1996; Connor-Smith et al., 2000; Treynor et al., 2003).

A second set of problems is presented by typical study designs. The vast majority of individual differences

research looks at links between coping and psychopathology at a single time point. As a result, as underscored by Compas et al. (2001) in their review of this work, it is not possible to determine a specific direction of effects from these associations:

> Although it is tempting to infer that the use of engagement or problem-focused coping leads to more successful adaptation to stress, this interpretation is tautological to a certain extent. That is, these findings may simply indicate that children and adolescents that are more socially competent, who are less anxious and depressed, and who exhibit fewer conduct and disruptive behavior problems are better able to generate solutions to problems and to maintain a positive outlook when faced with stress. (p. 118)

This situation can be improved by the use of designs that include multiple times of measurement—either short term, such as daily diary time-series studies, or long term, such as longitudinal studies. These kinds of designs are essential to allow researchers to examine reciprocal effects.

The optimal study designs that allow causal inferences (in either direction) continue to be experimental or intervention studies, in which researchers foster more constructive coping and then examine the effects of these improved coping strategies on subsequent psychological symptoms. Researchers are more limited in their ability to experimentally study the reverse direction. That is, researchers are not ethically able to induce psychopathology, but they can induce dysphoria or negative mood and then examine these effects on how people cope with challenges and setbacks. Most persuasive are programs of research that utilize both experimental and naturalistic longitudinal designs to examine both directions of effects (e.g., Nolen-Hoeksema, Wisco, & Lyubomirsky, 2008).

Despite the many contributions of transactional studies of individual differences in coping processes and psychopathology, even the best of this research suffers from an intractable problem: Any individual differences approach is inherently incomplete with respect to an understanding of psychopathology, which (at least from the perspective of the interdisciplinary field of developmental psychopathology, Cicchetti & Toth, 2009) is by nature a developmental process. This means that key questions can never be completely answered by looking at snapshots of the relations between coping and psychopathology at single time points or even at multiple points in time. Coping, like psychopathology, competence, and resilience, is inherently and reciprocally developmental: Developmental level decisively enables and constrains each of the processes depicted in transactional theories of coping: appraisals, personal and social resources, ways of coping, outcomes, and all the feedforward and feedback loops that connect them. At the same time, episodes of coping contribute to development: Through the repeated process of dealing with problems and difficulties, children and adolescents generate resources and liabilities for dealing with subsequent stressful encounters. To fully realize the value of transactional perspectives and to fully recognize the role of coping in the onset and progression of mental disorder, mental health, or the growth of resilience, an important next step is the creation and use of developmental conceptualizations of coping.

NORMATIVE DEVELOPMENTAL PERSPECTIVES: COPING AS A SET OF BASIC ADAPTIVE PROCESSES THAT ARE REORGANIZED WITH AGE

Normative developmental frameworks are grounded in the proposition that coping is a fundamental adaptive process that has evolutionary value in allowing people to detect, manage, and learn from potentially dangerous encounters (White, 1974). From this perspective, it becomes clear that coping has its roots in many functional systems designed to deal with threats and dangers. Because all these subsystems are likely to be activated by stress, developmental conceptualizations posit that the term *coping* refers to how all of them are coordinated and sequenced during stressful encounters. Hence, in the field of coping during childhood and adolescence, coping has come to be defined as "regulation under stress" (Compas et al., 2014; Eisenberg et al., 1997; Rossman, 1992; Sandler, Wolchik, MacKinnon, Ayers, & Roosa, 1997; Skinner & Wellborn, 1994; Skinner & Zimmer-Gembeck, 2007, 2009).

When coping is seen as the coordination of adaptive processes designed to detect and respond to challenges and threats (see Figure 10.3) or as "reactivity and regulation under stress," it becomes clear that the coping system needs to accomplish four tasks: (1) to detect and interpret information about internal and external demands (threat detection and appraisal); (2) to prepare a response based on internal and external guides and capacities (action readiness); and (3) to execute a response by coordinating action tendencies with internal and external demands and resources (action regulation). Moreover, in order to develop, the coping system also needs (4) to recover and learn from stressful encounters.

From this perspective, it becomes clear that coping represents a complex multilevel system (see Figure 10.4), which extends from (1) the neurophysiological level, including

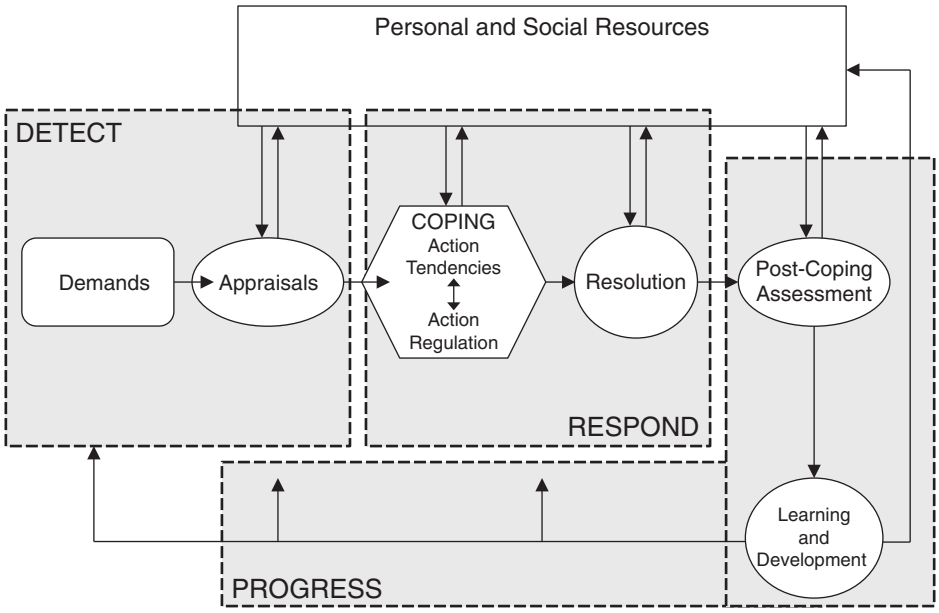

Figure 10.3 Depiction of the Coping System as a Set of Fundamental Adaptive Processes Used to Detect, Respond to, and Learn from Encounters with Potential Challenges, Threats, and Dangers.

psychobiological subsystems involved in detection and reactions to stress and the regulation of stress reactivity, most centrally the hypothalamic-pituitary-adrenocortical axis (HPA), the sympathetic-adrenal medullary (SAM) axis, the amygdala, and the prefrontal cortex (PFC), especially the anterior cingulate cortex (ACC); (2) the psychological level, including processes involved in stress reactivity and regulation, especially the attentional, emotional, and motivational subsystems; (3) the level of action, including subsystems that jointly generate action tendencies and that integrate and regulate them, especially the behavioral, cognitive, and meta-cognitive subsystems; (4) the social level, including participation in coping by social partners as well as interpersonal relationships (such as with caregivers, other family members, teachers, friends, and peers) that scaffold the development of coping's many subsystems; and (5) the societal level, including the stressors that impinge on and the resources that are available to children and adolescents themselves as well as the societal stressors and supports that influence their social partners.

After considering these five levels, the reciprocal connections between coping and development become more apparent. On one hand, development shapes coping: (1) by exerting extensive effects on the bottom-up processes that are coordinated and integrated during stressful transactions, including neurophysiological and psychological (i.e., attentional, emotional, motivational, behavioral, and cognitive) features of reactivity and action tendencies, as well as (2) exerting extensive effects on the top-down regulatory processes used to coordinate and integrate them. Higher-order developmental organizations contribute to coping by determining the nature of the tools children and adolescents have at their disposal to detect, respond to, and learn from threats at different ages as well as the sociocultural scaffolds that they can count on to protect them (or leave them vulnerable) while their own coping capacities are developing.

On the other hand, coping also contributes to development: The actual moment-to-moment transactions between individuals and stressful events can be considered "proximal processes" that act as engines of development (Bronfenbrenner & Morris, 2006). These episodes, in which individuals are trying to optimize the fit between environmental and intrapsychic demands (stress) and their internal and external resources and responses (coping), can be seen as creating a "zone of proximal development," in which strategies for dealing with stress and negotiating emotions can be discovered, practiced, and consolidated (or overwhelmed and discarded). Hence, cumulatively, such transactions can contribute to the development of capacities and resources for improved coping, regulation, and resilience (Carver, 1998; Carver & Scheier, 1998; Luthar, 2006; Tedeschi, Park, & Calhoun, 1998).

A view of coping as a basic adaptive process suggests that, at the most global level, one way of outlining the age-graded progression of coping, as well as its qualitative shifts, is to consider several broad developmental phases that are characterized by different mechanisms of

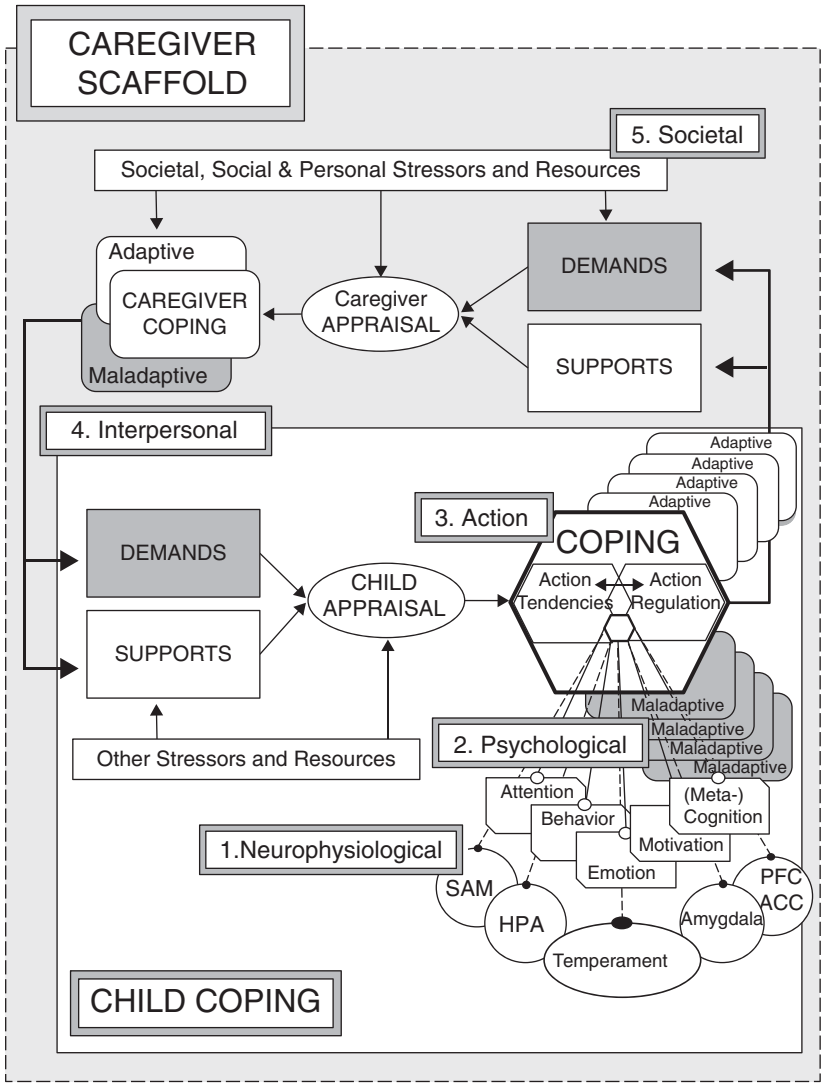

Figure 10.4 Integrative Multilevel Conceptualization of Coping as a Set of Interrelated Processes that Function on the (1) Neurophysiological, (2) Psychological, (3) Action, (4) Interpersonal, and (5) Societal Levels.

detection, appraisal, reactivity, regulation, and learning as well as different kinds of participation by social partners. As we outlined in our earlier work:

> Infancy would begin with stress reactions governed by reflexes, soon to be supplemented by coordinated *action schema*; during this period, caregivers would carry out coping actions based on the expressed intentions of their infants (interpersonal co-regulation). During toddlerhood and preschool age, coping would increasingly be carried out using *direct actions*, including those to enlist the participation of social partners; this would be the age at which voluntary coping actions would first appear (intrapersonal self-regulation). During middle childhood, coping through *cognitive means* would solidify, as described in work on distraction, delay, and problem-solving; children would be increasingly able to coordinate their coping efforts with those of others. By adolescence, coping through *meta-cognitive means* would be added, in which adolescents are capable of regulating their coping actions based on future concerns, including long-term goals and effects on others. (Skinner & Zimmer-Gembeck, 2007, p. 128)

Age-graded shifts in the basic tasks of coping (i.e., detection and appraisal, action tendencies and regulation, and learning) are shaped, on one hand, by the development of neurophysiological subsystems, and, on the other hand, by changes in the demands and resources provided by social partners, and especially caregivers. In this section, we use research on the development of coping itself and of other regulatory subsystems (including attentional, emotional, and behavioral regulation), to trace the course of age-related changes in how these subsystems are triggered

and coordinated in the face of stress. Because social partners are so critical to the development of all these subsystems, we also detail the role of caregivers (and later, other social partners) in the emergence and consolidation of these regulatory resources and capacities. We focus especially on how the caregiver's role in coping changes over development, from one in which caregivers are doing most of the coping for newborns based on their infants' expressed preferences, to one of direct participation, then cooperation, and finally acting as a resource and backup system to the relatively independent coping of which adolescents are capable by the time they reach emerging adulthood. (For more details on the normative development of coping, please see Skinner & Zimmer-Gembeck, in press.)

Normative Development of Coping during Infancy: Implicit Coping

Because systems to detect and deal with threats are essential to survival, newborns come equipped with preadapted responses to carry out these tasks. Sensory, perceptual, and attentional subsystems aid in threat detection; emotional and motivational subsystems aid in threat appraisal and action readiness; and the motor system carries out actions to express distress or respond to danger. The initial systems that coordinate newborns' threat detection and responses are based on reflexes and other automatic processes triggered by the neurophysiological stress reactivity subsystems, including the SAM, the HPA axis, and subcortical neurological subsystems, like the amygdala (Izard, Hembree, & Huebner, 1987; Ohman & Mineka, 2001).

Attachment and "External Coping"

At the level of action, these physiological subsystems initially trigger automatic motor behaviors, such as startling, huddling, crying, and diffuse whole-body reactions to physical discomfort, novelty, constraint, and other sources of psychological displeasure or distress. These expressions of distress are not initially intended as communications, but they can be read and interpreted by sensitive caregivers and so can initiate cycles of contingent and responsive caregiving. As described by decades of work on the attachment system (Ainsworth, 1979; Bowlby, 1969/1982; Carlson & Sroufe, 1995; Kobak, Cassidy, Lyons-Ruth, & Zir, 2006), these call-and-response cycles are part of species-general evolutionarily adaptive mechanisms, in which caregivers are predisposed to respond to a newborn's distress by engaging with and soothing the infant and by figuring out what is wrong and taking action to change the stressful situation, guided by the infant's needs and expressed preferences.

Such soothing and comforting, along with actually meeting newborns' expressed needs, can be considered forms of "external coping" in which the caregiver, using information provided by the infant, appraises the stressor, analyzes the "problem," and responds with emotion regulation or constructive coping actions. For the infant, such interactions cumulatively create the experience of a safe and trustworthy environment, which may be an important foundation for the infant's ability to modulate physiological stress responses (Fuertes, Dos Santos, Beeghly, & Tronick, 2006; Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). From the first days of life, infants are also learning from stressful encounters, using mechanisms described by operant and associative conditioning (Harman, Rothbart, & Posner, 1997), in which habitual responses through their repeated use become embedded in implicit memory.

These mechanisms soon modify infants' stress responses from those of reflexes to those of action schema or habits (Rothbart & Posner, 2006), perhaps regulated by subcortical structures, such as the amygdala, that rely on cumulative experience and learning about the nature of the environment and its relation to the actions of the individual (Lewis & Todd, 2007). Based on repeated experiences in a secure relationship with a sensitive caregiver, these cumulative patterns of learning, perhaps stored in the amygdala as "hot" information, may continuously downregulate the HPA axis and the SAM. This repeated experience with sensitive responding from others may be one of the mechanisms through which infants' stress reactivity subsystems become tuned to their environments (Spangler & Grossmann, 1993; Spangler, Schieche, Ilg, Maier, & Ackerman, 1994). When infants develop in the context of a secure attachment relationship, these neurophysiological systems (especially the HPA axis) go into a period of hyporesponsivity by about 3 months of age (Gunnar & Donzella, 2002; Gunnar & Quevedo, 2007), resulting in a calmer and less stress-reactive state for the infant after the first few months of life (Lewis & Todd, 2007).

Proximity Seeking as an Omnibus Coping Strategy

As described by attachment theory (Kobak et al., 2006; Sroufe, 1996; Sroufe & Waters, 1977), a secure relationship with the caregiver is also accompanied by the development of an omnibus coping strategy over the first few months of life, namely, proximity seeking. This response, to which human infants are biologically predisposed, relies

on biobehavioral systems that are visible first in reflexes and crying and then, based at least partly on sensitive caregiving, in intentional communications and focused actions, such as looking, reaching, and distinctive vocal patterns and differentiated crying. By the end of the first 3 months of life, infants have developed, from a diffuse set of undirected expressions of distress and reflexive reactions, a differentiated set of appreciations and action tendencies that are integrated with caregivers' responses to infants' signals, including caregivers' strategies for repair and comfort (K. C. Barrett & Campos, 1991; Holodynski & Friedlmeier, 2006; Kopp, 1989). Following all of these accomplishments, coping shifts from what has largely been external coping to emotion regulation and problem solving that is coordinated between the active infant and the sensitive caregiver, and so can be more properly labeled interpersonal coping.

Internal Working Models and Coping Appraisals

Infants also construct generalized expectations, which have been referred to as "internal working models" of relationships, and they are considered to be the rudimentary beginnings of successively more complex and differentiated self-systems (Connell & Wellborn, 1990; Deci & Ryan, 1985; Laible & Thompson, 1998). Such self-systems include generalized expectancies of safety and security, or that loving care is available when one is distressed (Lewis, 1997), generalized expectancies for contingency and dependability and a sense of mastery or efficacy in the face of environmental challenges (J. S. Watson & Ramey, 1972), and generalized expectancies that one's preferences will be attended to and respected (Deci & Ryan, 1985). These kinds of generalized expectancies likely continue to downregulate stress reactivity by broadcasting benign (implicit) appraisals of potentially stressful environmental encounters.

Development of Regulation and Rudimentary Coping

Infants and toddlers make momentous early advances in their capacity for regulation, which parallel the maturation of the PFC, which is involved in the processing, intensity, and regulation of emotion during the first years of life (Grimm et al., 2006). At this time, infants exhibit nascent cognitive control, and they can manage working memory and inhibitory control tasks (A. Diamond, Prevor, Callender, & Druin, 1997). They also develop rudimentary skills that they can use to regulate their emotional displays (N. A. Fox & Calkins, 2003; Rothbart, Derryberry, & Posner, 1994; Ruff & Rothbart, 1996) and are better able to direct their attention toward or away from environmental events in order to regulate emotion and action (Kopp, 2002).

By about 18 months, toddlers can engage in effortful self-regulation primarily through self-directed attention and voluntary control of action (Feldman, 2009; Harman, Rothbart, & Posner, 1997; Kochanska, Philibert, & Barry, 2009; Ruff & Rothbart, 1996). Such attentional orienting can serve as a way to guide thinking, feeling, and behaving, and the increasing efficiency of skills in each area builds the capacity of the entire system. Emotion regulation strategies are also improved by the end of the second year of life. All of these improvements parallel what is known about the maturation of the PFC in these early years (A. Diamond, 2002) and are also facilitated by changes in vagal tone (Feldman, 2009). Overall, by the second year of life, there are marked improvements in focused attention, response inhibition, effortful control, and emotion regulation, all of which aid in generating adaptive responses to the novel and discomforting events often encountered by infants. The capacities to inhibit and to attend are adaptive for many reasons, providing a foundation for the capacity to respond to others and to comply with parental requests or other environmental demands.

Goal-Directed Action and Early "Problem-Focused Coping"

In challenging but not overwhelming interactions with social and physical contexts, infants also develop the capacity for problem-focused coping as they flexibly deploy and focus attention on their goal-directed actions (Braungart-Rieker & Stifter, 1996; Bridges & Grolnick, 1995; McCarty, Clifton, & Collard, 1999). Especially interesting are interactions in which infants cannot fully realize their intentions; these can trigger rudimentary "coping" actions—for example, infants may increase their exertions toward the goal, become more energized, and later may try out different action strategies (DeLoache, Sugarman, & Brown, 1985; McCarty et al., 1999). If goals are blocked, infants may direct energy toward removing the obstacle, or they may withdraw their efforts and switch to another goal.

These coping interactions are developmentally useful: The goals created by the stress of not being able to immediately realize their intentions spontaneously coordinates infants' biobehavioral systems, both within the associated neurological subsystems (Lewis & Todd, 2007) and between the neurophysiological subsystems and infants' action subsystems. Such interactions not only exercise or consolidate existing connections but also stretch infants' actions into a zone of proximal development, where new strategies and combinations are generated. In fact, a shifting role of social

partners is to maintain a set of conditions for infants under which they can develop increasing regulatory resources and capacities. In the most general terms, doing this involves helping infants maintain a state of biological integrity and stability while nudging interactions toward the zone of "just manageable challenge," that is, providing opportunities for exploration and focused interaction with intrinsically interesting objects and people, combined with the availability of supports on an as-needed basis.

Social Referencing and the Emergence of Interpersonal Coping

Infants also begin to tune their appraisals of novel or ambiguous events more to their caregivers' signals of distress or interest, in a process known as social referencing, which allows infants to consult their caregivers' "radar" over some distance in order to make decisions about the potential dangers present in new situations and the extent to which they should engage or withdraw from specific encounters (Fonagy, Gergely, & Target, 2007; Lewis & Ramsay, 1999). At the same time, infants become more capable of indirect coping (K. C. Barrett & Campos, 1991) in which they delegate coping actions to caregivers through the use of intentional communications designed to elicit desired outcomes, such as pointing at a desired object.

Caregivers' sensitive responsiveness can be considered a kind of coregulation in which babies and caregivers are in good communication about how to deal with challenging, and potentially threatening, encounters (L. M. Diamond & Aspinwall, 2003; Hornik, Risenhoover, & Gunnar, 1987; Lewis & Ramsay, 1999; Sorce, Emde, Campos, & Klinnert, 1985). These interactions form kinds of coping packages, which infants can initiate using increasingly differentiated intentionally communicated signals of their distress, internal states, preferences, and goals. Such episodes, repeated thousands of times, begin to synchronize infants' internal experiences of distress with their external expressions, acknowledged and mirrored by caregivers through attunement. These appreciations, or appraisals, are in turn coordinated with caregivers' external actions to relieve distress, and infants' subsequent internal experiences of relief from discomfort and satisfaction of goals.

As these packages are differentiated, based on the underlying problem (cause) and its emotional markers, two new developments emerge: (1) infants construct sets of distress appraisals and expressions that are actual representations of their genuine underlying physiological states, emotions, and motives; and (2) they build up a repertoire of constructive interpersonal coping strategies that are targeted at the actual problem and are effective in dealing with the stressor and in bringing comfort, relief, and motive satisfaction (Calkins & Hill, 2007). Using their emerging representational capacities, infants can also begin to form subjective representations of the contingencies between these elements, allowing the packages to be stored in implicit memory for later use, when triggered by similar problems or emotional markers of distress.

Normative Development of Coping during Early Childhood: Voluntary Coping

Early childhood (about age 1 to 4 years) is sometimes referred to as a period of emotional action regulation, because emotional systems seem to be coordinating toddlers' appreciations and action readiness in stressful situations (Holodynski & Friedlmeier, 2006; Kopp, 2009). Detection and responses to challenges and threats are largely carried out by the emotional and intrinsic motivational systems, which generate approach or engagement reactions to objects, people, or events that young children find attractive, and avoidance or withdrawal reactions to ones they find unattractive, frightening, or repulsive (K. C. Barrett & Campos, 1991). Based on a history of experiences with sensitive interpersonal coping and the construction of secure internal working models, toddlers become able to tolerate increasingly higher levels of stress, showing equanimity and patience, perhaps based on benign implicit appraisals of stressful situations and expectations that episodes will be resolved favorably. They are also able to clearly communicate their genuine emotions and desires and are generally ready and willing to cooperate with caregivers in regulating emotions and dealing effectively with action problems.

Caregivers participate directly in appraisals and coping of toddlers at this age, as described by Gottman, Katz, and Hooven (1996, 1997) in their depiction of "emotion-coaching" parenting (see also Calkins & Hill, 2007; Keenan, 2000; Kliewer, Fearnow, & Miller, 1996; Power, 2004; Sroufe, 1996). Caring adults help children identify and discuss differentiated emotions, as well as their causes, and jointly examine strategies for tolerating or alleviating them (aka strategies for emotion regulation or emotion-focused coping) (Dunn, Bretherton, & Munn, 1987; Kopp, 1989; P. J. Miller & Sperry, 1987). Such emotion coaching allows children to integrate their genuine internal experiences of distress with a differentiated vocabulary to accurately recognize and represent a variety of emotions (Denham, 1998; Malatesta, Culver, Tesman, & Shephard, 1989; Saarni, 1997), thus affording children access to the full range of their emotional experience, which

provides crucial information when they are appraising the meaning of a potentially stressful event and when they are coping.

Representational Capacities and Coping, and the Development of Extrinsic Motivation

The development of representational capacities, which were seen in early forms in generalized expectations and action schemes, produces a major shift in emotion regulation and coping with stress during early childhood (Denham, 1998; Derryberry & Tucker, 2006). These capacities make it possible for toddlers to maintain goals over longer periods of time, to "plan" successively more complex action strategies before carrying them out, and to communicate in more differentiated and accurate ways about their goals, desires, and emotions. The joint representation of internal states and preferences along with external affordances and conditions allows these elements to be more effectively coordinated and, with practice, to become linked; these joint representations then lead to more coherent and goal-directed interactions with social and physical partners, even under conditions of greater challenge and demand (Fonagy et al., 2007).

At the same time, the growth of representational capacities and working memory also shape the development of the emotional system, which comes to include the "other-conscious," or socially communicated, emotions of pride, shame, and guilt. These new self-conscious emotions, coupled with close relationships and the desire to please attachment figures, ushers in the development of the "extrinsic" motivation system, which allows toddlers to comply to requests from caregivers to inhibit the expression of prepotent behaviors and emotions or to show behaviors or emotions that they do not spontaneously wish to perform (Kochanska, Coy, & Murray, 2001). The prepotent bottom-up emotional action tendencies generated locally by the intrinsic motivation system and marked by emotions can now begin to defer to top-down cognitively represented goals from the extrinsic motivational system, for which no action readiness is spontaneously available. Toddlers' capacities to comply seem to depend not only on the quality of the relationship with the caregiver but also on the strength and direction of the prepotent action tendencies that are generated (Kopp, 2009).

Caregiving and the Development of Self-Regulation in Coping

To support this transition, caregivers encourage young children's use of language to express their distress and requests ("use your words"), even under increasingly stressful conditions, and begin to regulate young children's action based not only on children's desires but also on cultural norms and moral principles for appropriate behavior (Power, 2004; Tolan & Grant, 2009). The shift from heteronomous regulation (or compliance, guided by caregivers) toward autonomous regulation (or self-regulation, guided by the young child's core self) not only allows children to begin to become the agent of their own coping but also requires children to more actively and intentionally coordinate their coping efforts with the needs and desires of social partners (Eisenberg, Fabes, & Murphy 1996; Eisenberg, Valiente, & Sulik, 2009). This shift has been studied most thoroughly in research on the development of compliance, which focuses on parental demands and norms (Kopp, 2009) and the development of conscience (Kochanska, Forman, Aksan, & Dunbar, 2005), which folds moral principles and priorities into coping.

The kinds of scaffolding that seem to be most effective in promoting compliance, the internalization of conscience, and autonomous regulation more generally, include several elements that create "coping episodes" for young children (Kopp, 2009). First, parents provide consistent demands for appropriate behavior, focusing almost exclusively on insistence about only a very small number of "true moral rules," such as honesty, treating the self and others with kindness and respect, and taking responsibility for one's mistakes and messes. Violations of these principles create "interpersonal problems" for young children with their parents, preschool teachers, or peers. In helping children solve these problems, one key is warm and caring structure provided by trusted adults, who offer alternative appropriate means, both verbal and nonverbal, for children to express their true feelings and desires. Especially important, in promoting both compliance and eventual internalization, are induction strategies that support autonomy by acknowledging children's genuine goals and feelings, combined with explanations of the relevance and importance of prosocial actions to children's own goals (Hoffman, 1994). Such inductions allow children to internalize alternative means of expressing feelings and regulating actions under stressful conditions.

Executive Functions, Problem Solving, and Coping

The study of conscious control, or executive functioning, suggests that the emergence of such voluntary self-regulation is the product of neurological and cognitive developments that increasingly allow children to create and resolve conflicts in action regulation (A. Diamond, 2013; Zelazo, Muller, Frye, & Marcovitch, 2003). Previously, potential conflicts were resolved automatically by prioritizing prepotent habitual responses generated by the intrinsic motivation and emotion subsystems. With

increases in working memory and attention and improved awareness of their own goals and intentions, children are able to represent conflicting sources of regulation—such as two rules for behavior, a bottom-up urge and a top-down goal, or a habit and a current alternative intention (Nigg, 2006; Pennington & Ozonoff, 1996). Executive functions allow young children to internally mediate these conflicts, for example, to begin to inhibit prepotent responses and to show alternative nondominant responses, or to shift the guides for their action regulation from one set of rules or tasks to another (Best & Miller, 2010; A. Diamond, 2013; Nigg, 2006).

The internalization of prosocial strategies, concern for others, and moral rules for use in regulating action are combined with the continued development of the capacity to search for effective means to reach desired goals, or problem solving. Although it has its origins in contingency detection and tertiary circular reactions during infancy, intentional problem solving as a cognitive and social process comes into its own during early childhood (Keen, 2011). If handled sensitively, "stressful" transactions with uncooperative peers and materials (such as blocks, games, sports, or artwork) can become laboratories for developing problem-solving skills—allowing young children, with the help of adults and peers, to identify and generate ideas for new means or strategies, imagine their consequences, select from alternatives, try them out, and note their actual effectiveness (Berg & Strough, 2010).

Individual Coping as a Supplement to Interpersonal Coping

One of the most important reorganizations of the coping system takes place with the emergence of volitional action regulation during early childhood. By lifting regulation off emotions and integrating emotions with volition, coping becomes less reactive—that is, less a product of local conditions and implicit motives, and more flexible:—more open to top-down influences from both social partners and internal sources. The primary shift during this developmental period is from *inter*personal to *intra*personal coping. The coping packages (with their appraisals differentiated by causes and emotions and their action repertoires for satisfying motives and soothing distress) that were coproduced by the child *and* the caregiver are now increasingly handed over to the child, and "independent" coping becomes the young child's developmental task, while scaffolding from adults (e.g., caregivers and preschool teachers) creates a zone of proximal development. For some theorists, who define coping as comprising only conscious and volitional efforts (e.g., Compas et al., 2001), the development of voluntary action regulation marks the beginning of coping proper.

Such a shift requires children to reroute the interpersonal appeals that they previously directed to caregivers (with their emotional expressions of problems and desires), so that they are directed *intra*personally for satisfaction (i.e., at their own newly emerging sense of self), and to use the information contained in emotions and language that was formerly used to guide the actions of caregivers toward meeting the child's needs, so that it is now employed to guide their own actions in meeting their own needs (Holodynski & Friedlmeier, 2007). Hence, the coping repertoire that was previously enacted between children and caregivers eventually comes to be reconstructed in the domain of children's own voluntary actions.

It is important to make clear, however, that intrapersonal or individual coping does not replace interpersonal coping; it supplements it. Young children still have access to interpersonal strategies, which they can initiate through support, proximity, or help seeking, and they are likely to fall back on these strategies when the stressor is severe or the children are highly distressed, tired, or otherwise impaired (Zimmer-Gembeck & Skinner, 2011). At the same time, parents begin to dole out their direct participation, judging for themselves whether children are capable of coping on their own with the particular stressor in the current condition (Eisenberg et al., 2009). Caregivers may encourage a few bouts of independent coping and, if they see that children are intimidated or overwhelmed, may add resources or participate in a round of interpersonal coping to see whether they can tip the children back from a sense of threat and toward the experience of manageable challenge.

Caregivers continue to shape emotion and coping by protecting young children from events that are potentially overwhelming, by coaching via direct instruction, and by more general discussions of problems and emotions (Fabes, Eisenberg, & Bernzweig, 1990; Morales & Bridges, 1996; Thompson, 1990; Valiente, Fabes, Eisenberg, & Spinrad, 2004). It seems likely that the development of all of the constructive ways of coping emerge from interpersonal scaffolding—not only of prosocial ways of coping (such as accommodation and negotiation) but also ones that are not so obviously social, like strategizing and self-soothing, which may emerge from joint problem solving and the coaching of emotion regulation.

Normative Development of Coping during Middle Childhood: Reflective Coping

A major reorganization in the coping system takes place sometime during the 5-to-7 age shift (Sameroff & Haith, 1996), when children begin to internalize the mental means of regulation and slowly become able to regulate

their actions using reflective consciousness. As noted by many coping theorists (e.g., Aldwin, 2007, Aldwin, Skinner, Zimmer-Gembeck, & Taylor, 2011; Compas et al, 2001; Murphy & Moriarity, 1976; Skinner & Edge, 1998a; Skinner & Zimmer-Gembeck, 2007, 2009), this cognitive revolution ushers in a widely expanded repertoire of coping because it allows children to reconstruct and deploy mental forms of all the ways of coping that they have previously used on the plane of direct action. For example, instrumental action is supplemented by cognitive problem solving, behavioral distraction by mental distraction, physical escape by mental withdrawal, physical soothing by cognitive emotion regulation, and so on.

Regulatory Development and Coping, and Construction from Intrapersonal Coping

The capacity for voluntary coping that emerged in toddlerhood and improves up until school entry coincides with advances and increasing efficiencies in attentional skills and shifting of attention, the capacity to inhibit responses, effortful control, and emotion regulation (Fan, Fossella, Sommer, Wu, & Posner, 2003; Rueda & Rothbart, 2009). Children also exhibit great improvements in working memory by age 4, and this continues to improve up until age 7 (Luciana & Nelson, 1998). Children become able to delay gratification for longer and display decreases in impulsivity (L. B. Jones, Rothbart, & Posner, 2003; Prencipe & Zelazo, 2005). Children who are better at response inhibition by the age of 4 are better able to focus and shift their attention and are less impulsive and prone to frustration (Gerardi, Rothbart, Posner, & Kelper, 1996; Zelazo, Reznick, & Pinon, 1995). All of these capacities serve them well when coping with stress.

Thus, children show major advances in coping and self-regulation between the ages of 3 and 6, and all of these advances seem to be occurring at the same time as maturation is progressing in the dorsal ACC network (Geidd et al., 2004; Gogtay et al., 2004). Moreover, the average volume of brain activation is reduced in adults compared to children (Casey, Jones, & Somerville, 2011), which suggests that brain areas involved in executive functions are becoming more focal and efficient, at the same time as children increasingly recruit more sophisticated prefrontal systems of the brain for self-regulation (Casey et al., 2011; Luna et al., 2001; Luna & Sweeney, 2004; Rubia et al., 2000).

The brain seems to be moving toward specialization and reduction in the time needed to process information and respond. Some researchers refer to this as "fractionating" to reflect the differentiated and distributed functioning seen in the adult brain (Baddeley, 1998; Tsujimoto, 2008). Therefore, development may mean an increasing fractionation of brain function from early childhood to early adulthood in which multiple higher-level brain processes draw on common areas of functioning and covary with each other before the age of about 7, but these same processes become fractionated beginning at about age 7 or 8. This change is also apparent in neural organization, in that functions move from diffuse to more focal and fine-tuned for performance (Casey, Tottenham, Liston, & Durston, 2005; Durston et al., 2006).

The reconstruction of the coping repertoire on the mental plane is accomplished through a long process of internalization and transformation of the previously enacted coping system. This process is made easier if earlier bottom-up action tendencies are coherent and genuinely informative about children's authentic feelings, motives, and neurophysiological stress reactions; and if developing top-down self-systems for regulating action tendencies are sturdy and constructive, that is, undergirded by high levels of trust (and so are socially cooperative), mastery (and so are optimistic), and self-determination (and so are agentic).

Because coping, by definition, involves actions in potentially threatening situations of personal relevance, the system of direct coping actions is likely reconstructed on the representational plane as emotion-laden "hot" cognition. The most obvious features to be internalized are language components: of stress reactions (e.g., distress labels), appraisals (e.g., emotion and problem labels), and responses (e.g., sequences of actions). Emotionally expressive signs and emotion experiences are also internalized, which then become capable of triggering emotional reactions in the absence of direct physiological stimulation (Holodynski & Friedlmeier, 2006). Also internalized are attention and motivation—in which children come to represent the priorities and goals that matter to them (Derryberry, Reed, & Pilkenton-Taylor, 2003; Rueda & Rothbart, 2009), which can then serve to direct focused attention as well as to energize engagement and withdrawal action tendencies (Block & Block, 1980; Metcalfe & Mischel, 1999).

Advantages of Mental Means of Coping

The internalization of the coping action system allows the child to reconstruct, in his or her imagination, sequences of potential coping responses and to play out not only their likely success in accomplishing the child's goals during stressful transactions but also their likely motivational, emotional, and social costs and benefits. The capacity

to conduct such mental coping exercises confers many advantages: Children can conserve energetic resources that would be expended (and avoid the risks that would be incurred) if they were to try out these options on the plane of action. Mental constructions also allow for a qualitative shift in flexibility, as a wider variety of possibilities can be considered, including novel sequences that have not yet been directly enacted on the ground.

From the perspective of action regulation, the biggest improvement during this developmental period is the capacity to coordinate all the features of coping on the same level, namely, the cognitive level (see Derryberry & Tucker, 2006, for a similar description of self-regulation and self-organization). Reconstructions of bottom-up physiological reactions, emotions, attentional priorities, and intrinsic motivations, along with top-down recommendations from extrinsic motivations, relationship considerations, cultural and social norms, and moral principles, can now all be brought together to the same table of hot cognitive representations to be coordinated through active and reflective mental "discussion," making explicit the conflicts and trade-offs that were previously dealt with through competing action tendencies or regulation by others. These conflicts, which both create stress and are exacerbated by stress, can be consciously recognized and thoughtfully negotiated.

"Mental" Participation of Social Partners

Such internal negotiations are made easier by caregivers who are sympathetic to the dilemmas children face in stressful situations and are willing to continue coaching and cooperating with their attempts to work them out (Denham, 1998; Eisenberg et al., 1998; Gross & Thompson, 2007; Kliewer et al., 1996; Neitzel & Stright, 2003). Adults' direct participation in coping episodes slowly recedes across middle childhood, as their active participation is successively replaced with "mental participation" through cognitively mediated reflective means, such as discussions, reminders, encouragement, suggestions, and structures (e.g., routines, rules, and rituals).

If parents are able to continue providing high levels of warmth and caring, structure, and autonomy support as children practice dealing with conflicts, dilemmas, obstacles, and problems, out of these stressful situations can emerge the *autonomous* regulation of action, in which children internalize and integrate moral rules and sociocultural demands with their true selves (Mesquita & Albert, 2007; Ryan, 1992) and so become able to use these guides to organize their action even in the absence of external monitors. It is important to note that, even though children are potentially capable of autonomous self-regulation, it can still be difficult to enact under stressful conditions, for example, in conditions of "temptation," when strong prepotent conflicting action tendencies are activated (Metcalfe & Mischel, 1999).

Role of Coping Attempts and Failures

The capacity to mentally coordinate and integrate information from all coping subsystems represents a major shift in the operation of the coping system itself. And it is through repeated attempts to accomplish this mental coordination, with the cooperation of social partners, that these skills emerge, are practiced and consolidated, and eventually can be reliably executed under conditions of increasing stress (i.e., under conditions of increasing internal distress and external pressure). Continuing to be extremely important during this phase are the reactions of adults (e.g., parents, teachers, coaches) to children's failures and breakdowns, which are key experiences in the development of resilient "mindsets" (Dweck, 2008). Children need practice with mistakes and failures in order to learn how to tolerate and benefit from the negative emotions mistakes generate; to view failures constructively; to engage fruitfully despite anxiety, frustration, or shame; to take responsibility for mistakes and repair them; and to figure out how to help negative emotions dissipate.

Mental Means Supplement the Coping Repertoire and Sturdy Coping Systems

These new mental means of emotion regulation and problem solving, although built on direct coping actions, do not replace them. Children still have access to previous behavioral forms of coping, which they are likely to fall back on when stress or distress is high and when mental means are too difficult to execute or are not as effective as action means. During middle childhood, the child's mental coping repertoire is not only expanded and differentiated but also coordinated and integrated with the previous repertoire of action, interpersonal, and automatic strategies. Hence, a major developmental task during middle childhood is to learn how to flexibly deploy this repertoire over the course of a coping episode—based on the severity of the stressor, the changing internal conditions of the child, and the actual effectiveness of the previous sequence of strategies in dealing with the stressor and its emotional concomitants (for reviews see Decker, 2006; Eisenberg et al., 1997; Fields & Prinz, 1997; Losoya et al., 1998; Zimmer-Gembeck & Skinner, 2011).

Middle childhood, with its pragmatic cognition and well-developed self-systems, is a developmental phase

during which coping is often described as "sturdy," especially if coping systems are built on constructive action tendencies, guided by (1) a sense of control and competence that is calibrated to actual performance in different domains and that encourages challenge appraisals and mastery responses to problems and obstacles; (2) feelings of security and relatedness that are calibrated to the prosocial actions of the self and the actual trustworthiness of different social partners—these internal working models encourage both self-reliance in action and emotion regulation along with appropriate support seeking as needed to restabilize independent coping; and (3) feelings of self-determination and autonomy that are calibrated to the true self and that encourage both accommodation to reasonable demands and self-assertive cooperative negotiation when the child's own needs are not met by current conditions. This sturdy coping system may be one reason why middle childhood is seen as a particularly resilient period—a time during which children can withstand and sometimes even flourish under conditions of adversity (Masten, 2001).

Normative Development of Coping during Adolescence: Proactive Coping

By adolescence, much of the brain structure and circuitry that allow for accurate stress appraisals and sophisticated coping responses are in place, but there are developmental changes in both the bottom-up and top-down processes that shape stress and coping during this age period. The hormones of puberty seem to reopen the underlying stress reactivity systems governed by the SAM and HPA axis so that they may become increasingly susceptible to influence from external stressors. The period of hyporesponsivity of these systems, which started in infancy, comes to an end, and a period of more intense emotional and motivational activation of the bottom-up, amygdala-regulated reactivity systems commences (Dahl, 2004; Gunnar & Quevado, 2007; Lewis & Todd, 2007; Spear, 2003).

Some theorists characterize this phase as one of imbalance between strong bottom-up emotionally charged impulses and the still developing PFC which cannot yet effectively regulate these urges (e.g., Casey et al., 2011; Steinberg et al., 2006), making emotion regulation and the focusing of cognition and attention when affect is high quite challenging for youth until later in adolescence or even into the mid-20s. This imbalance may also make adolescents vulnerable, especially under stressful conditions, to the short- and long-term consequences of highly attractive but highly risky behavior in a variety of domains (Fischhoff, 2005; Michel, Kropp, Eyre, & Halpern-Felsher, 2005; Reyna & Farley, 2006; Steinberg & Morris, 2001; Zimmer-Gembeck & Helfand, 2008; Zimmer-Gembeck, Siebenbruner, & Collins, 2004). In terms of coping, these challenges to emotion regulation in highly emotional environments during the earliest years of adolescence provide one explanation for trends suggesting that, after improvements in most ways of coping across early and middle childhood, during early adolescence, some youth seem to use more of a variety of maladaptive coping strategies (e.g., aggression, Pelligrini & Bartini, 2001) and become reluctant to seek help from adults (Newman, Murray, & Lussier, 2001).

Regulatory Developments and Coping

At the same time, increasingly stronger top-down regulatory capacities are slowly added, as can be seen in the growing efficiency of adolescents' executive functioning, involved in skills such as inhibitory control, problem solving, planning, logic, reasoning ability, and understanding consequences (Best & Miller, 2010; Reyna & Farley, 2006) along with other neurological developments (Spear, 2003). The PFC and the dorsal system of the brain, including parts of the ACC, have a prolonged course of development continuing into adolescence, which is consistent with research showing improvements in executive control and inhibitory skill during this time (Dennis, 2010; Luna, Padmanabhan, & O'Hearn, 2010).

Inhibitory control is relevant for stress and coping because it is critical for inhibiting both responses to threatening events and negative emotions. By about 13 to 17 years of age, many adolescents show adultlike performance on inhibitory control tasks, although their performance continues to require more effort than from adults (Flair et al., 2007; Luna et al., 2010). Similar to inhibitory skill, the development of emotional control seems to shows a prolonged pattern of development, but it has not yet been examined as thoroughly as cognitive control and executive functioning. Hence, it is not known, for example, whether it is the generation of emotion that changes with age or the capacity to control or manage it. In the same vein, working memory, a central component of executive function, operates quite well early in life but also improves substantially all throughout adolescence (Luna & Sweeney, 2004).

Nevertheless, adolescents' cognitive capacities have not yet fully matured. Studies of cognitive control using functional magnetic resonance imaging (fMRI) have generally identified two critical differences between adolescents and adults: Adolescents have more difficulties with response inhibition, and their working memory performance may

not yet be as fully developed (Luna et al., 2010). Because voluntary planned behavior depends on advanced cognitive skills, such as retaining goals online via working memory, preparing and planning responses, and suppressing task irrelevant responses (response inhibition), it seems clear that these types of tasks challenge adolescents' coping responses more than adults.

Although development and participation of the PFC may be partial explanations for these improvements in cognitive control and the increasing efficiency of response inhibition and working memory, all of these advances in functioning also are supported by the increasing integration of diverse brain systems outside the PFC as children get older (Luna et al., 2010). As Luna et al. (2010, p. 109) described:

> Overall, these results imply that an important part of development is the process of specializing and segregating circuitries that support task ability, response state, and default processing. The ability to utilize cognitive control to perform a response, the ability to retain a response state, and to suppress internal thoughts improves with development, as the circuits supporting these distinct processes become independent. These suggest age-related improvements in white matter connectivity but also functional integration as seen in spontaneous waves of synchronized activity (Fair et al., 2008; Uhlhaas et al., 2009, p. 109)

Metacognition and Coping

These developing executive functions and the cognitive abilities of formal operations should result in a major reorganization of the coping system, brought about by the emergence during adolescence of metacognitive capacities, that is, the capacity to think about one's own thinking and cognitive activities (see Compas et al., 2001, for a review; also see Frydenberg, 1997; Kuhn & Franklin, 2006; Seiffge-Krenke, 1995). Metacognitive capacities supplement the mental system of coping that was internalized during middle childhood, by integrating it with the adolescents' capacity to reflect on, evaluate, critique, and improve their own coping.

Metacognitive capacities open the way for increasing and intentional self-regulation of all the coping families, such as problem solving (as seen, for example, in increasingly self-regulated learning), reflective emotion regulation, and the exercise of volition through identified self-regulation (Band & Weisz, 1990). All of these capacities combine to enable more proactive coping (Aspinwall & Taylor, 1997), in which regulation under stress comes to include not only a concern for current internal action tendencies and external opportunities but also future, long-term considerations. Coping responses that seem attractive in the short term come to be informed by graphic imaginations of the future, such as the possibility of being physically or psychologically hurt; of getting caught; of losing valued outcomes, relationships; and even one's own self-evaluations.

As with mental means of regulation, these newly developing metacognitive capacities allow adolescents to differentiate and consider any aspect of the coping system, including appraisals, emotions, desires, action tendencies, and regulatory strategies. For example, metacognition allows adolescents to reflect on their interpretations of complex emotional states, their strategies for regulating them, and their potential to enact alternative strategies that might be more constructive. Moreover, "meta-emotions" allow adolescents to have emotional reactions to their emotional reactions, for example, feeling embarrassed about being afraid. Adolescents' increasing capacities for reflection, although generally positive, may also help to explain the increases seen during this age and in ways of coping focused on self-criticism and rumination and in reluctance to seek support (Zimmer-Gembeck & Skinner, 2011): The same capacities that allow adolescents to *reflect* on their emotions allow them to *criticize* their emotions; the same capacities that allow adolescents to *plan* for the future make them more vulnerable to *worrying* about the future; and the same capacities that allow adolescents to *recognize* they need help can also trigger *concern* that others may lose respect for them if they seek help.

Identity Development and Coping

Adolescent metacognitive capacities may also exert an influence on the nature of the self that is participating in regulation, as suggested by the fact that a major task of adolescence and young adulthood is identity development (Kroger, 2007; Meeus, 2011). The facets of the self that were differentiated by domain and calibrated to actual performance during middle childhood can now be thought of as parts of a whole that can be compared to each other and to the criteria of social norms and demands, with evaluative consequences for the self. To the extent that, in the process of identity construction, these disparate parts can be integrated successfully with each other, with the genuine self, and with the reflected regard of trusted others, a positive and coherent sense of self and identity can be achieved (Harter, 2012) that allows identified and autonomous self-regulation to become the dominant mode of coordinating bottom-up action tendencies and top-down considerations, even under increasingly higher levels of temptation and stress.

Coping Flexibility, Attunement, and the Importance of Social Partners

These emerging metacognitive capacities may also help to explain the increases in coping flexibility that are seen during this developmental phase (Babb, Levine, & Arseneault, 2010), which is perhaps most noticeable in adolescent support seeking (Zimmer-Gembeck & Skinner, 2011). Adolescents become more differentiated and flexible about the kinds of support they request and the person to whom they turn for these social resources, seeking out parents, friends, teachers, or other adults or peers, and asking for comfort, distraction, advice, or instrumental help, depending on the local conditions: the domain and specific problem, the social partner's authority over the situation, and the kind of supports they need. With this new level of representation, it seems that the entire repertoire of previous forms of *inter*personal coping can be integrated into the intrapersonal repertoire of support seeking, eventually enabling youth to initiate, access, and guide the deployment of available social resources while coordinating them with their own self-reliance and independent coping.

This same pattern, in which coping strategies become more differentiated and more selectively applied and coordinated with local internal and external conditions, can also be seen in other families of coping—even in those more focused on independent or cognitive coping. For example, youth are increasingly likely to use problem solving in response to stressors which they perceive as controllable (e.g., academic problems) whereas they are more likely to use accommodation or distraction strategies when dealing with problems that are uncontrollable (e.g., medical issues or parental problems) (Compas et al., 1991; Zimmer-Gembeck et al., 2011). This finding suggests that, although the repertoire of coping strategies is still expanding at this age, coping can also become less flexible in its execution during adolescence as youth discern the most effective strategies for dealing with common problems and begin to deploy the strategies more efficiently and with less effort.

Throughout adolescence, social partners continue to be crucial to the development of adaptive coping systems. Close and caring parental, family, and peer relationships along with meaningful cultural roles and activities (e.g., after-school programs, sports teams, youth groups) provide the external regulatory structures needed to keep adolescents safe during this risky period while their own coping capacities are still developing. Judicious support from caring adults (parents, teachers, extended family, etc.) is central, in which these grown-ups carefully monitor adolescents' "adventures in coping" (even when adolescents are not keen on having their activities monitored) while remaining sympathetically available to be called on as a backup system for whatever advice and comfort might be requested. Since adolescents' willingness to reveal their problems and failures to adults is a sensitive proposition at this age, the past dyadic history of communication, comfort, and joint interpersonal coping is critical in determining whether, when feeling overwhelmed, adolescents will bring their current coping concerns to an adult.

Reflection and Reappraisal

Adolescents' growing capacity to reflect on the entire coping system expands their potential to view and utilize coping episodes, whether they are "successes" or "failures," as increasingly valuable opportunities for learning. Reappraisal processes following mistakes and failures, which were practiced in cooperation with adults during middle childhood, now become highly inferential and can be reconstructed on the plane of the adolescents' own reflective coping systems, providing internal metaregulatory and metamotivational "commentary" during each phase. Supportive adults, through caring, coaching, and modeling, can help youth cultivate compassion for the fallibility of the self and others in stressful circumstances while also holding the self and others accountable for their actions, thus allowing adolescents to increasingly take ownership for the ways they deal with challenges and setbacks (i.e., for their own coping). These experiences can lead adolescents to supplement their coping repertoires with proactive or antecedent regulation or coping (Aspinwall & Taylor, 1997; Gross, 1998; Gross & Thompson, 2007), in which they make intentional decisions about the states or situations they let themselves get into, to make sure that their regulatory and coping capacities allow them to create the outcomes that they desire.

Conclusion

At each level, ways of coping are supplemented with new means of reactivity and regulation. Strategies that were initially neurophysiological and external at birth become interpersonal during infancy and toddlerhood, then individual or intrapersonal during early childhood, eventually to be reconstructed at the reflective level during middle childhood and finally transformed into metacognitive proactive strategies during adolescence and emerging adulthood. At each age, previous means of coping are differentiated and integrated with new modes, supplementing them and providing a wider repertoire that can be deployed

more intentionally and flexibly, in concert with changing internal and external conditions and resources.

Taken together, these developmental shifts can be seen as creating a system that gets better and better at detecting and responding to threats and problems, eventually realizing its full developmental potential. As we tried to make clear in our earlier work (Skinner & Zimmer-Gembeck, 2007):

> These developmental potentials depict a system that can increasingly monitor and appropriately appraise more (current and future) demands using its own and other's "radar"; maintain composure under higher levels of appraised threat with more capacity to withstand multiple demands and better "fallbacks"; respond increasingly in measured socially competent ways that reflect integration of ongoing emotional, attentional, and motivational reactions; more flexibly adjust actions to meet changing environmental demands without losing sight of genuine priorities; recover more quickly from setbacks; and at the same time take more away from stressful encounters, learning how to prevent and deal with future challenges and how to deploy coping in line with future goals. (p. 136)

Normative Development of Coping and Developmental Psychopathology

An understanding of the normative reorganizations of the coping system is helpful to researchers interested in developmental psychopathology for multiple interrelated reasons (Cicchetti & Toth, 2009; Egeland, 2007; Rutter, 2005; Sroufe, 2007). Most important, it allows researchers and interventionists to fully appreciate the complexity of the coping system and the many essential elements orchestrated and consolidated within it. From a developmental perspective, appraisals are not simply fleeting perceptions, and ways of coping are not simply lists of strategies; appraisals reflect "apparent reality" (Fridja, 1987), and ways of coping reflect basic configurations that infants, children, and adolescents have adopted as they organize their actions to deal with demands in the environments in which they are developing (Bowlby, 1969/1982; Garmezy & Rutter, 1983; White, 1974).

A normative description provides a basic yardstick for determining whether children and adolescents of all different ages are on track in the development of their coping resources and strategies (i.e., whether they seem to be accomplishing the age-graded developmental tasks that would serve the dual purpose of allowing them to deal effectively with current demands and stressors as well as providing a foundation that prepares them to deal with subsequent challenges successfully). It also allows interventionists to calibrate their prevention and remediation efforts to target the attitudes and skills that are most central to children at their current developmental levels as well as those they will need to be successful at subsequent ages.

Explanatory theories and research depict the many factors that allow the healthy development of the coping system to proceed and so allow researchers and interventionists to identify positive pathways through which children and adolescents can obtain robust tools for dealing constructively with stress. They also allow researchers to identify children and adolescents who may benefit most from interventions, because a range of problems in the subsystems that underlie or scaffold coping may put children at risk for the development of psychological and behavioral difficulties. Prevention and remediation efforts could rely on explanatory research to help locate likely intervention levers that would allow the systems that support the healthy development of coping to be repaired or optimized.

At the broadest level, developmental conceptualizations have created much overlap between the study of coping and the study of the development of psychopathology and resilience. Approaches that frame coping as part of multilevel integrative systems designed to detect and respond to threats and challenges have identified subsystems that extend from neurophysiology to social context and culture. Such perspectives on the development of coping create broad conceptual overlap with the approaches that have guided the study of developmental psychopathology (Cicchetti & Toth, 2009) and resilience (Compas, 2004; Masten, 2007) over the last five decades (Luthar, 2006). All these traditions consider their phenomena to extend from the biological (genetic, neurophysiological) through the behavioral to the psychological, social, and cultural levels of analysis (Cicchetti & Curtis, 2007). Definitions of coping as "reactivity and regulation under stress" link coping to the burgeoning research on regulation of the many processes (e.g., emotion, attention, behavior, motivation) that are activated during stressful encounters and that have been found to be implicated in the development of psychopathology (Cicchetti & Toth, 2009).

To understand coping—and especially its development—it is necessary to understand the multiple systems that give rise to it and how they work together over time. This is a central tenet of an integrative multilevel approach. The assertion that coping actions are diagnostic of the state of the entire "coping system," which includes psychological and social stressors, demands, resources, and their underlying neurophysiological and overarching social contexts, suggests that during transactions with stress, children and adolescents can and do move through successive (re)appraisals of challenge, threat, and loss as well

as through a repertoire of adaptive and maladaptive ways of coping. Hence, when current developmental researchers refer to the "coping system," they typically view coping actions as outward manifestations of an orchestra of biopsychosocial forces, very similar to the ways resilience researchers refer to their phenomena, *mutatis mutandis*. In other words, coping is part of an open and dynamic system and, as such, can be considered part of the same set of (sub)systems that contribute to (and are reciprocally shaped by) developing psychopathology and resilience (Marshall, 2013).

DEVELOPMENTAL SYSTEMS PERSPECTIVES: COPING AS PART OF DEVELOPMENTAL CASCADES TOWARD PSYCHOPATHOLOGY AND RESILIENCE

A description of normative age-graded reorganizations of the coping system provides an outline of a set of broad and healthy pathways that lead toward constructive and cooperative repertoires for detecting, dealing with, and learning from challenges, threats, and losses. The identification of the many subsystems that work together to give rise to coping actions, as depicted in Figure 10.4, makes it clear that optimal development and the avoidance of psychopathology entail a large number of essential ingredients, which typically serve as reciprocally self-righting, in that they work together to assist the organism toward pathways that channel growth in positive directions. For example, the newborn's intact neurophysiological and communication subsystems, the caregiver's sensitive responsiveness, and their emerging joint secure attachment, co-create a calmer and more stable infant stress reactivity subsystem that is easier to soothe and also provides clearer communication to the caregiver, which in turn informs and sustains sensitive responsive caregiving and lays down implicit infant learning that supports benign appraisals of ambiguous interactions and triggers constructive coping through focused exploration and proximity seeking.

At the same time, if any of these essential ingredients is missing or incapacitated, it can pose a risk for children and adolescents, nudging them toward maladaptive coping and psychopathology. In principle, problems can arise from any of the components described in the previous section on normative development, but we focus on three factors that play crucial roles in shaping the architecture of the coping system: (1) differences in the stress and regulatory neurophysiology that underlie coping, especially as captured in work on temperament; (2) differential histories of caregiving relationships involved in scaffolding action tendencies and regulatory processes under stress, especially as examined in work on attachment and parenting; and (3) differential exposure to stressful life events (especially those that originate in the family) that can undermine or overwhelm developing coping systems.

To integrate and extend research that has documented links among these factors, maladaptive coping, and psychopathology, we use several key principles from dynamics systems perspectives, which have been clearly articulated in approaches to developmental psychopathology (Cicchetti & Toth, 2009; Masten, 2007; Sroufe, 2009). First, building out from previous research, we assume that the connections between coping and psychopathology are bidirectional and cascade over time. Second, we explore the idea that one way in which risk factors can exert their effects on psychopathology is by creating perturbations in (neurophysiological, interpersonal, individual, reflective, or proactive) coping systems. These perturbations should create lasting effects to the extent that they not only interfere with the concurrent functioning of the coping system but also damage the foundations that are under construction and upon which subsequent developments of the coping system will be built.

Third, we think it unlikely that any one factor (e.g., difficult temperament or avoidant attachment) would be sufficient by itself to eventuate in a nonnormative pathway of maladaptive coping. In cases where a single factor is a little off, protective and compensatory processes can (and typically do) redirect divergent pathways back toward healthy development. Instead, risk accrues when the functioning of one factor is very seriously compromised or is part of a pattern of cumulative impairment or stress, because these conditions may combine to initiate self-amplifying patterns of maladaptive (neurophysiological, interpersonal, and individual) coping. Fourth, there are likely to be multiple pathways from coping to psychopathology, and different families of coping, rather than being considered global indicators of "good news" or "bad news," might suggest different markers of and routes toward different disorders. Finally, episodes of maladaptive coping may be expected to routinely participate in a wide range of "developmental cascades" (Masten & Cicchetti, 2010), both signaling and igniting problems in multiple domains—problems in individual functioning and in relationships—that cumulatively put children and adolescents at risk for the development of psychopathology.

In this section, we select illustrations of how extremes in the functioning of each of these three subsystems

(i.e., temperament, attachment and parenting, and family stress) can act as risk factors for both coping and psychopathology. Whenever possible, we focus especially on longitudinal studies that directly explore this possibility (for more detailed analyses, see Skinner & Zimmer-Gembeck, in press). In every case, the research base is inconsistent and cannot confirm all the connections that we posit. In fact, consistent with previous descriptions of the coping literature as dominated by correlational studies of individual differences in ways of coping, much of the research connecting coping to temperament, attachment and parenting, and family stress is cast in this mold, making connecting the developmental dots challenging.

At the same time, however, when the findings are considered as a whole, we think they are encouraging and together suggest that it may be useful to further explore the ideas presented in this section. Specifically, we argue that coping is *always* a part of the developmental cascades that lead to psychopathology: The neurophysiological, psychological, and social factors that predispose children to the eventual development of psychopathology typically result in maladaptive forms of stress reactivity and coping, and these forms of stress responses in turn set successive chains of negative events in motion, including the formation of habits, action tendencies, implicit and explicit self-systems, and (perhaps especially) reactions from social partners that are likely to further exacerbate behavioral problems and cumulatively potentiate the onset or escalation of disorders. These ideas are depicted graphically in Figure 10.5, which shows the cascades that start with temperament and attachment, are embedded in family stress, and, along with parenting, lead to different forms of psychopathology or resilience.

Temperament, Differential Pathways of Maladaptive Coping, and Psychopathology

Researchers have suggested multiple ways in which temperament and personality factors contribute both directly and indirectly to the development of problem behaviors and psychopathology (e.g., Calkins, 1994; Carver & Connor-Smith, 2010; Caspi, Roberts, & Shiner, 2003; Connor-Smith & Flachsbart, 2007; Derryberry et al., 2003; Mezulis, Hyde, & Abramson, 2006; Nigg, 2006;

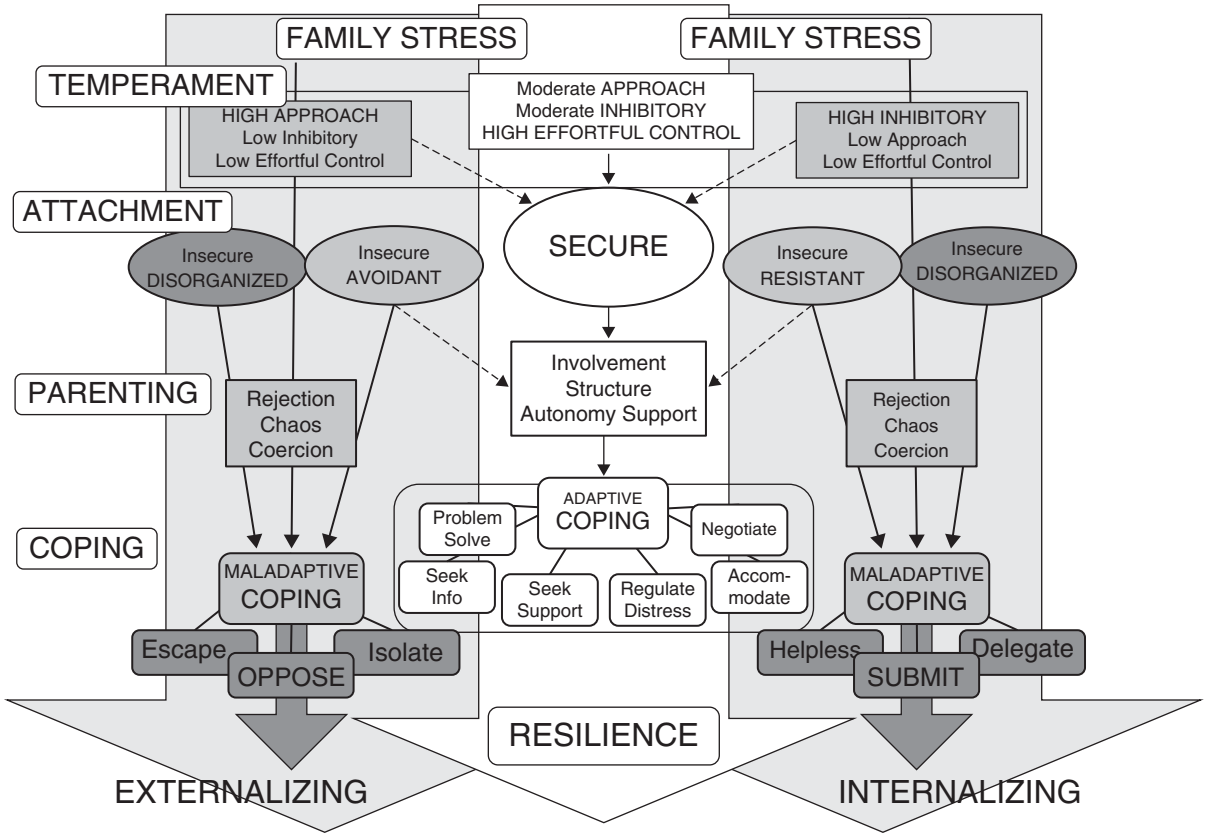

Figure 10.5 Underlying Neurophysiological Factors and Overarching Socialization Factors that Contribute to the Differential Development of Maladaptive Coping and Increase the Risk of Behavior Problems and Psychopathology.

Rothbart, 2011, Table 10.1; Rueda & Rothbart, 2009; D. Watson, Kotov, & Gamez, 2006). For example, research indicates that children who have an easy temperament are less prone to develop both internalizing (e.g., depression and anxiety) and externalizing problems (e.g., behavioral problems; Jaffee, Caspi, Moffitt, Polo-Tom, & Taylor, 2007), and children with temperaments characterized as high in negative reactivity or as very inhibited may be at risk for anxiety and other disorders (Belsky & Pluess, 2009; Eisenberg et al., 1997; McClure & Pine, 2006). This body of research is substantial and complex, and has been very useful for identifying individual differences in the kinds of physiologically based temperamental characteristics that may tip a child toward or away from developmental pathways marked by maladaptation or health and resilience. Yet it may also be useful to supplement this growing body of research by explicitly considering the differential patterns of stress reactivity and coping that stem from such temperamental predispositions in order to understand when, how, and why temperament provokes risk or provides protection from psychopathology.

Temperamental Patterns as Differentially Tuned Primitive Coping Systems

In principle, the coping systems of all newborns are built on their own individual temperaments, which refer to heritably based neurophysiological processes that predispose them to patterns of responding to environmental challenges and stressors (Rothbart, 2011). Most interesting from a coping perspective are temperamental classifications that focus on reactivity and regulation (Derryberry et al., 2003; Rothbart, 2011; Rueda & Rothbart, 2009; Shannon, Beauchaine, Brenner, Neuhaus, & Gatzke-Kopp, 2007). In this context, "reactivity" is closely connected to stress reactivity, in that it refers to how easily the appetitive/approach and the defensive/ inhibitory systems can be triggered by external and internal stimuli; and "regulation" has close ties to action regulation, in that it refers to how effective the executive attention system is in facilitating volitional control of emotional, motor, and attentional reactivity (Rueda & Rothbart, 2009).

As pointed out by Derryberry et al. (2003), "the appetitive and defensive systems can be viewed as relatively primitive 'coping' systems. The defensive system is designed to help the person cope with dangerous situations where it is crucial to recognize the threat, inhibit inappropriate responses, and find a source of safety. In contrast, the appetitive system is designed to help the person attain positive outcomes in appetitive contexts, where it is crucial to avoid or overcome obstacles in order to obtain the reward" (p. 1052). Individual differences in newborns' stress responses and regulation (i.e., coping) are shaped by the balance among these three neurophysiological systems: the appetitive, defensive, and executive attention systems. The appetitive and defensive systems are generally antagonistic in their functioning, so that overactivation of one system can be modulated by the activation of the other. Moreover, over- or underactivation of the appetitive or defensive systems can be compensated for by the executive attention system, which, if capable enough, can modulate the effects of the other two systems.

Research on Temperament and Coping

A growing body of research has focused on direct associations between coping and temperament or personality during childhood and adolescence by examining whether particular coping responses are more or less common in children and adolescents with particular temperamental characteristics or personality traits, such as negative emotionality, neuroticism, effortful control, or introversion (Markovic, Rose-Krasnor, & Coplan, 2013). Several of these studies show, for example, that an "easy" temperament is associated with constructive ways of coping, such as problem solving and support seeking (Zimmer-Gembeck et al., 2011), and with resilience (Luthar, 2006; Werner, 1993). Taken together with research on the links between temperament and psychopathology, such studies provide hints about how temperament might shape coping under conditions of stress.

Most interesting are studies that have begun to more directly investigate these processes by focusing on whether coping serves as a moderator or mediator in the connections between temperament and psychopathology. Moderation has been found in studies testing whether temperamental traits are more relevant to the development of symptoms of depression or anxiety (or other forms of psychopathology) depending on the presence or absence of certain coping responses (Seiffge-Krenke, 2011; Sugimura, Rudolph, & Agoston, 2014). In general, these studies focus almost exclusively on the more risk-producing temperamental traits, such as negative emotionality, and yield patterns of findings suggesting that adaptive forms of coping (such as reliance on primary control strategies when stressors are controllable and on secondary control or accommodative coping when they are not), can reduce the elevated or increasing levels of internalizing and externalizing symptoms that children or adolescents with these temperamental characteristics would otherwise be likely to experience over time. Mediation has been found in studies testing models in which coping acted as a conduit of the

impact of particular temperament or personality traits on symptoms or healthy outcomes (Compas, Connor-Smith, & Jaser, 2004; Mezulis, Simonson, McCauley, & Vander Stoep, 2011; K. S. Miller et al., 2009; Van De Ven & Engels, 2011). For example, in one longitudinal study of preadolescents, avoidant coping mediated the impact of temperamental impulsivity on heightened internalizing problems. Thus, preadolescents who were more impulsive used more avoidant coping, which in turn was related to their increasing internalizing symptoms over 1 year (Thompson et al., 2014). Some studies have examined both moderation and mediation, showing that they are not mutually exclusive; they can co-occur even when the same coping constructs, temperamental traits, and adjustment outcomes are examined (K. S. Miller et al., 2009).

"Easy" and "Difficult" Temperaments

When the research on temperament is filtered through the lens of developmental perspectives on coping, it suggests that temperamental characteristics of newborns can be thought of as neurophysiological set points for the development of their coping systems and so provide early foundations that start to channel infants' coping down differential pathways. The healthy development of coping should be facilitated by an "easy" temperament, which involves moderate responsiveness of the appetitive and defensive systems along with the capacity to flexibly modulate emotion and action using attentional and behavioral processes (Rothbart, 2011). Moderate stress reactivity comprises a threat detection system that is calibrated appropriately to external demands and conditions, in both approach and defense, along with the capacity to flexibly modulate reactions when conditions improve, allowing rapid recovery from stress. From the first days of life, this kind of temperament should make it easier for newborns to participate in effective interpersonal coping: Distress signals are moderate and informative and so more easily converted into directed distress communications, and infants are more easily satisfied and soothed by caregivers' coping efforts on their behalf (Rothbart, 2011).

More "difficult" temperaments, which involve high reactivity and poor regulation, should be a liability in the healthy development of the coping system (see Rothbart, 2011; Rothbart, Posner, & Kieras, 2006). The kinds of problems presented to the developing coping system and their likely effects on subsequent patterns of coping should differ depending on whether overreactivity originates in the defensive/inhibitory or in the appetitive/approach system. In either case, a temperamental profile would be more extreme to the extent that one of the systems is set very high while at the same time the other subsystems that would typically balance it out (namely, the opposing subsystem and the executive attention system) are set very low. Such extreme temperaments create challenges for both infant and caregiver in establishing a calm, well-calibrated and modulated neurophysiological coping system as well as co-constructing a positive interpersonal coping system. Based on their low levels of effortful control, such temperamental patterns may also interfere with the shift toward voluntary self-regulated coping and the subsequent systems that build on this type of coping (i.e., the reflective and proactive coping systems).

Inhibited "Fearful" Temperaments, the Differential Development of Maladaptive Coping, and Internalizing Psychopathology

Most research attention has been paid to infants with inhibited fearful temperaments that likely reflect an overreactive defensive/inhibitory system (N. A. Fox, Henderson, Marshall, Nichols, & Ghera, 2005; Kagan, 1997; Kemen & Block, 1998). By definition, newborns high in neurophysiological stress reactivity consistently overreact to external demands and internal states. In response to novel stimulation, they typically show high and escalating emotional distress, in which attention is captured by the eliciting event (e.g., a noise or sudden movement). It is as if one of the key underlying systems upon which subsequent coping is going to be built has a hair trigger that keeps tripping the alarm of threat detection constantly and unnecessarily, making such infants' harsh distress signals less discriminating and therefore harder for caregivers to read and interpret. Moreover, weak executive attention (or effortful control) makes it more difficult for infants or caregivers to "turn off" the alarm through soothing, distraction, or other means of interpersonal coping. Attention is not easily freed from the distressing stimulus, and recovery from distress is slow and fragile, with increased risk of triggering additional distressed emotional reactions.

High levels of stress reactivity combined with low levels of effortful control may put inhibited/fearful infants and young children at risk for the development of poor coping. An overreactive defensive/inhibitory system provides a more challenging stress neurophysiology, at the same time that it makes sensitive responsive caregiving more difficult, thus interfering with the kind of secure attachment most needed to contribute to the development of a calmer hyporesponsive neurophysiological system (Nachmias et al., 1996). If neither infants nor caregivers are successful in helping recalibrate an overreactive stress neurophysiology, infants and then young children will have

repeated experiences of being overwhelmed by internal and external events.

Such experiences may in turn lead to overreliance on maladaptive forms of coping, in which children either try to avoid contact with stressors and/or with their overpowering emotional and physiological reactions to them or simply become resigned and submit to overwhelming stress. Such coping episodes can cumulatively lead young children to construct internal working models that consolidate the "message" of the overreactive defensive system, namely, that the world is a highly dangerous and uncontrollable place with which the self cannot hope to cope effectively. Over time, such a pattern of maladaptive appraisals and ways of coping might mark one step along the pathway to social avoidance, learned helplessness, rumination, and subsequent internalizing problems of depression and anxiety (Derryberry et al., 2003; Keiley, Lofthouse, Bates, Dodge, & Pettit, 2003; Lengua, Sandler, West, Wolchik, & Curran, 1999; Rothbart, 2011).

Impulsive "Fearless" Temperaments, the Differential Development of Maladaptive Coping, and Externalizing Psychopathology

Although exuberance and "surgency" are typically seen as parts of an "easy" temperament, in some cases, a high appetitive motivational system, unchecked by the defensive system or by effortful control, can still be considered a risk factor for the development of maladaptive coping (Derryberry et al., 2003). An "overactive" appetitive system can lead to forceful and impulsive actions, in which infants and young children fearlessly go after whatever it is they want without attending to dangers or to caregiver attempts to redirect their efforts. Such infants should show a pattern of strong approach tendencies, determined attempts to overcome whatever they perceive as obstacles, persistence in the face of attempts to distract or redirect them, and high levels of frustration and protest if they are thwarted.

It is easy for caregivers to see these children, whose every goal becomes a fervent demand, as strong-willed or stubborn, and they can be difficult social partners with whom to construct adaptive interpersonal coping systems because compromise, accommodation, or distraction are not natural action tendencies for them. The lack of discriminating signals about the infants' priorities can make it difficult for caregivers to remain sensitively responsive, and exhausted caregivers can easily decide to just give in and allow infants to have whatever they want, or become frustrated by infants' demands and refuse to cooperate. Both of these reactions, however, create a less than optimal interpersonal coping system. When caregivers simply give in, this reinforces children for their dogged persistence, making them even more tenacious. However, arbitrarily terminating goal pursuit can also trigger the highly reactive appetitive system, which is focused on overcoming obstacles, thereby escalating protest, frustration, and externalizing problems (Bates, Pettit, Dodge, & Ridge, 1998; Shaw et al., 1998).

Both of these caregiver reactions may also contribute to experiences that reinforce implicit appraisals of the world as one that requires strong and unyielding opposition on the part of infants if they are to reach their goals. Such generalized expectancies can, in the face of even mild stressors, such as being asked to wait or settle for another goal, cumulatively strengthen prepotent bottom-up action tendencies of explosive reactance or resistance. These reactions may then become increasingly difficult for caregivers to modulate in interpersonal coping episodes and can become very problematic for toddlers and young children to manage with their emerging executive functioning skills, as they encounter the developmental task of self-regulation, a task that is a prerequisite for the construction of the intrapersonal coping system. Without these personal and interpersonal buffers, such impulsive and strong-willed temperaments may contribute to the development of maladaptive forms of coping, such as opposition or perseveration, that are precursors or markers of emerging externalizing disorders, such as aggression (Eisenberg et al., 1996, 2001; Rothbart et al., 1994).

Temperament and Differential Pathways of Coping and Psychopathology

Although research on the role of coping in the connection between temperamental characteristics and the development of psychopathology is just beginning, it does seem to suggest at least three important working hypotheses that could be tested in future studies. First, it seems likely that extreme neurophysiological temperamental patterns (which combine high levels of reactivity in the defensive or appetitive subsystem with low levels in both the opposing subsystem and executive attention) should predispose infants and young children to corresponding differential patterns of stress reactivity and coping, and such patterns are likely to be exacerbated by experiences of stress. Second, it seems possible that these strong reactions to stress could be overwhelming to infants and their caregivers and that if caregivers cannot gently curb and compensate for them during infancy, an integrated base of neurophysiological, implicit learning, and relationship problems, as manifest in patterns of maladaptive coping, may emerge as a result. Third, it also seems possible (based on studies

with older children) that adaptive ways of coping, first laid down in interpersonal relationships with caregivers, could be one set of strategies that eventually allow young people to adapt and constructively manage the demands created by their own temperaments. By learning to "listen" compassionately to one's own neurophysiological messages about stress reactivity and to respond to them with caring suggestions about how to "keep calm and carry on," infants and their caregivers may be able to strengthen the (interpersonal and then intrapersonal) coping and regulatory systems that can complement and compensate for the potential neurophysiological liabilities implied by temperamental risk.

Attachment, Differential Pathways of Maladaptive Coping, and Psychopathology

Although most attachment theorists agree that patterns of caregiver-infant interactions and attachment relationships formed in the earliest years of life will set in motion differential patterns of coping with stress, empirical research has been slow to directly substantiate these claims. Very few studies have directly examined secure and insecure attachment relationship classifications as correlates of coping responses, and those that do tend to focus on older children. For example, several studies have shown that parental warmth and support, or attachment quality (as measured, e.g., by the Parent and Peer Attachment measure; Armsden & Greenberg, 1987) are associated with more adaptive coping, such as active problem solving or support seeking, in children and adolescents (e.g., Dusek & Danko, 1994; Gaylord-Harden, Taylor, Campbell, Kesselring, & Grant, 2009; Kliewer et al., 1996). Moreover, in one study of coping and emotion regulation in 87 children ages 10 to 12, attachment security was associated with less difficulty recognizing emotions, but it was not associated with more adaptive coping (Brumariu et al., 2012). Instead, it was disorganized attachment, and not anxious or avoidant attachment, that was associated with less active coping and more catastrophizing, suggesting that children who have experienced some of the most significant caregiver-infant relationship failures will register the greatest impact on their coping (Kobak et al., 2006).

Attachment and the Differential Development of Coping

When viewed through the lens described in the previous section on the normative development of constructive coping, however, it becomes clear that the healthy growth of the coping system is predicated on sensitive responsive caregiving and a secure caregiver-infant attachment relationship. Initially, sensitive responsiveness provides "external" coping on newborns' behalf, and, cumulatively, it shapes interactions that allow caregivers to co-construct a cooperative interpersonal coping system with infants (Contreras & Kerns, 2000; Raby et al., 2012; Sroufe, Egeland, Carlson, & Collins, 2005). If infants' coping systems have to operate without the scaffold of this sensitivity, and insecure attachment relationships form, infants are required to adapt to caregiving that does not always protect them or help to soothe them effectively and to social interactions that are not tuned to their signals, are not responsive to their expressed needs, and may even add to their distress (Cassidy & Berlin, 1994; Mikulincer & Florian, 2003; Thompson & Meyer, 2007). It is as if, when infants' systems are calibrated to insecure or disorganized attachment relationships, the coping system has received the message that the world is stressful and dangerous, or at least cannot be relied on to provide consistent help or comfort when stress and distress occurs (Kobak, Little, Race, & Acosta, 2001).

For infants with highly reactive temperaments, such experiences seem to result in continued stress reactivity, instead of the more normative establishment of equanimity and hyporesponsivity seen in infants who are part of secure attachment relationships (Nachmias et al., 1996). When infants adapt their behavior and coping to these experiences of maladaptive interpersonal coping over the first year, nascent problems can be observed in their physiological and emotional reactivity, communication, and action tendencies, presaging the development of maladaptive patterns of coping with stress (Bosquet & Egeland, 2006; Cicchetti & Rogosch, 2009; L. M. Diamond & Aspinwall, 2003; Mikulincer & Florian, 2003). The particular form that problems with coping will take likely depends on the kinds of responsiveness that is provided, as depicted in different kinds of insecure or disorganized attachments.

Anxious-Resistant Attachment Relationships

When the early caregiving environment is behaviorally inconsistent and emotionally unreliable—when caregivers are sometimes forthcoming but mostly are unresponsive to expressed needs, and when they can be at times neglectful and at other times intrusive and overstimulating—these experiences tend to yield insecure attachment relationships that are referred to as anxious and/or resistant. When considering the effects of a history of these experiences on coping, it is as if infants must adapt their systems to compensate for the lack of a reliable coping partner by trying to amplify their own part in the exchange, essentially ramping up the volume—leading to greater emotional reactivity,

louder and more unrestrained signaling of distress that is harder to turn off, more indiscriminate proximity seeking, and more wary monitoring of the caregivers' whereabouts (Nolte, Guiney, Fonagy, Mayes, & Luyten, 2011).

Moreover, when coping develops within such a shaky interpersonal scaffold, secondary attachment patterns, called hyperactivating regulatory strategies (Mikulincer & Florian, 2003; Wei, Heppner, & Mallinckrodt, 2003), may form and emerge as anxious preoccupation about the availability of support. Thus, the developing organism ends up with little opportunity and energy to devote to learning constructive strategies for exploring the world or dealing with negative emotions or problems. Hence, infants (and later toddlers) are likely to overrely on proximity seeking (which can become dependency), but since the relief that proximity is supposed to provide is available only intermittently, their coping is also laced with irritation, frustration, and opposition, directed toward the caregiver. Because of the lack of contingency between their actions and caregivers' responses, they should also increasingly show coping that is fragile, helpless, and easily derailed. Just as with the overreactive physiologies characteristic of certain temperaments, this history of caregiving would be another pathway to stress reactivity that is so high that it becomes challenging (for anyone) to successfully (co)regulate it.

Insecure Avoidant Attachment Relationships

A different pattern of coping would be likely to result from avoidant attachment relationships, in which infants must adapt their coping to caregivers who reject their expressions of distress, who show some hostility in response to signals indicating discomfort, and generally appear to resent infants' bids for attention and help. In these relationships, infants basically discover that, if they want to maintain proximity with their caregivers, they must learn to overregulate (Martins, Soares, Martins, Tereno, & Osorio, 2012): Their expressions of distress fall away when it becomes clear that they can elicit negative reactions; they restrain their appeals to caregivers for regulating their emotions or for instrumental help; over time, even when they are in situations that elicit physiological stress reactions, they do not seem to be calmed by the caregivers' presence.

Infants who experience a history of rejecting or unavailable caregiving must construct a coping system without the usual reliance on the interpersonal matrix needed to learn adaptive strategies, and so they remain reliant on the primitive actions they can carry out for themselves. The development of such secondary attachment patterns, referred to as deactivating patterns (Mikulincer & Florian, 2003; Wei et al., 2003), results in a coping system that develops within an intrapersonal bubble, unconnected to the wider world of interpersonal resources that could nurture and protect infants locally and that could guide them to more constructive ways of dealing with problems and emotional distress. As a result, toddlers, young children, and adolescents with an avoidant working model of attachment figures may come to rely on social isolation and have difficulty coordinating their coping with other social partners in the future. Such children would be less likely to express (or understand) their distress, less likely to turn to others when they are upset or in trouble, less able to benefit from support offered by others, and less able to cooperate when others try to participate in their coping efforts. Cumulatively, these experiences would be one pathway toward overreliance on maladaptive coping strategies, such as avoidance, escape, and social isolation.

Disorganized Attachment Relationships

The third and more recently identified pattern of insecure attachment has been referred to as disorganized; this form of an attachment relationship is more likely to emerge from a history of maltreatment or other multiproblem family circumstances. In the case of child abuse, caregivers not only fail to protect their infants from danger, they actually augment infants' exposure to stress by neglecting to take care of their basic needs or through abusive interactions (Cicchetti & Rogosch, 2009). Hence, the internal coping systems of these infants, which must try to adapt to a dangerous and maladaptive interpersonal coping system, can become confused, exhausted, and chaotic—in other words disorganized—marked by a fundamental dysregulation of emotion combined with chaotic attempts to regulate it (DeOliveira, Bailey, Moran, & Pederson, 2004); to denote the riskiness inherent in these kinds of attachments, they are sometimes referred to as catastrophizing (Brumariu, Kerns, & Seibert, 2012).

Insecure Attachments and Stress Reactivity

Over time, stress-inducing interactions with caregivers can have a negative effect on the normative development of both neurological and emotional functioning (Cicchetti & Rogosch, 2009; Herbert et al., 2006; McEwen, 1998; 2004; Sapolsky, 1999). Overall, children in dyads with insecure attachment relationships of any kind, but particularly the disorganized form, show greater risk of atypical cortisol responses to threat (Ahnert, Gunnar, Lamb, & Barthel, 2004; Nachmias et al., 1996; Spangler & Schieche, 1998). Although cortisol reactivity to stress is adaptive in the short term, *chronic* activation of the HPA axis (the systems involved in rapid threat appraisal and response, including

parts of the PFC) has been associated with physical and psychological impairment and neuronal death, resulting in a system primed for stress and unable to regulate (recover from) the stress response once it is activated (Gunnar & Cheatham, 2003; Gunnar & Vasquez, 2006).

Additionally, cortisol level has been associated with affective responses and regulation. Children have greater cortisol responses when they have less knowledge of emotion control (Gunnar, Marvinney, Isensee, & Fisch, 1989) and when social support resources are not available (Gunnar, Larson, Hertsgaard, Harris, & Brodersen, 1992). These findings suggest that cortisol is higher when individuals perceive they are unable cope or have few response options when confronted with threat or challenge (Dawson, Hessel, & Frey, 1994; Stansbury & Gunnar, 1994), and this reaction is more likely when there is an insecure attachment history.

Cumulatively, chronic stress reactivity can result in disruptions to the typical pattern of cortisol over a day; in humans, glucocorticoids demonstrate a circadian rhythm with the highest levels in the morning on awakening and the lowest levels in the evening prior to onset of sleep (Sapolsky, 1992). A departure from this typical pattern has been found among children neglected or otherwise maltreated by their caregivers. Children with such a history tend to show low levels of cortisol in the early morning and blunted adrenocorticotropic hormone and cortisol responses to stressors (referred to as hypocortisolism). Children placed in foster care because of maltreatment also have atypical cortisol diurnal rhythms compared to children without such histories (Loman & Gunnar, 2010).

Secondary Attachment Strategies and Coping

Connections between attachment status and ways of coping have been investigated most thoroughly by researchers who have proposed upward theoretical extensions of attachment theory beyond childhood, focusing on attachment as an affect regulation system during adolescence (e.g., Allen & Manning, 2007; Allen & Miga, 2010; Cassidy & Berlin, 1994; Compas, Worsham, & Ey, 1991) or adulthood (Mikulincer & Florian, 2003; Shaver & Mikulincer, 2002). More specifically, current theoretical views highlight the notion of secondary attachment strategies, which depict configurations of emotion regulatory strategies used by older children, adolescents, and adults when dealing with, managing, or confronting stressful life events.

According to this perspective, attachment relationships early in life, sometimes included as one aspect of the overall emotional climate of the family (Morris, Silk, Steinberg, Myers, & Robinson., 2007), result in different patterns of emotion recognition and expression and differential utilization of strategies for dealing with stress that emphasize reliance on others versus self-reliance or social isolation. A few researchers have extended the range of secondary attachment strategies under investigation to consider how attachment could be associated with all the core families of coping—from support seeking and active problem solving to emotion expression, avoidance, distraction, and withdrawal during infancy (Roque, Verissimo, Fernandes, & Rebelo, 2013), adolescence (Gaylord-Harden, Taylor, Campbell, Kesselring, & Grant, 2009), and adulthood (Holmberg, Lomore, Takacs, & Price, 2010; Wei et al., 2003).

It may be the case that attachment emerges as a stronger correlate of coping after interpersonal and intrapersonal forms of coping have been fully internalized, which we argue takes place by early adolescence. This internalization may help to explain why studies of adolescents and adults, compared to studies of children, typically find more consistent associations between attachment categories and patterns of coping. For example, in one study of adults, the two types of insecure attachments (avoidant and anxious) were differentially associated with theoretically specified ways of coping: Attachment avoidance, but not attachment anxiety, was associated with less use of social support; and attachment anxiety, but not attachment avoidance, was associated with more use of emotion-focused coping (Holmberg et al., 2010).

Attachment and Coping with Interpersonal Stressors

Patterns of findings linking attachment to coping during adolescence suggest that the effects of attachment history may be more pronounced when individuals are dealing with *interpersonal* stressors. For example, two studies have shown that secure attachment is related to more active coping with the interpersonal stressors of conflict and relationship dissolution (Creasey & Hesson-McInnis, 2001; Davis, Shaver, & Vernon, 2003). Moreover, one of the few longitudinal studies of these connections from adolescence to early adulthood also found clearer patterns when examining changes in coping with relationship stressors (Seiffge-Krenke, 2006). Researchers followed 64 girls and 48 boys for 7 years through five waves of data, collected at ages 14, 15, 16, 17, and 21 years. Associations between perceptions of the severity of relationship problems (parent, peer, partners) and three kinds of coping (active coping, which combined problem solving and support seeking, internal coping, and withdrawal) were examined as correlates of attachment classification (secure, dismissing,

or preoccupied, as measured via the Adult Attachment Interview at age 21).

As expected, the secure group stood out as utilizing increasingly more active coping responses over time when dealing with stressors in both the parent and the peer domains. Secure group members were more active than the dismissing group in responding to parent stress, more active than the preoccupied group when responding to peer stress, and used less withdrawal in response to all stressors when compared to the preoccupied group. Although not directly examined in this study, the pattern of results for the insecure groups suggests that it is not the level of a particular coping response that may signal problems but rather the combination of different responses. For example, the preoccupied group had an ambivalent style of coping that involved high levels of both active coping and withdrawal, and the dismissing group used internal coping at a level that did not differ from the secure group but, compared to the secure group, also used less problem solving and support seeking (i.e., active coping).

Such patterning may also be important in detecting differences based on attachment status when coping sequences are examined. Although not yet investigated in children and adolescents, a study of 75 adults revealed that attachment classification was related to the point in the coping sequence at which participants reported using specific ways of coping, such as social support, distancing, and emotion-focused coping (Holmberg et al., 2010). When coping with major events, those classified as avoidant-dismissing (via the Experiences in Close Relationship-Revised; Fraley, Waller, & Brennan, 2000) reported using distancing to cope earlier in the stressful encounter and resorted to seeking support from a partner only later in the coping episode. In contrast, those classified as anxious-preoccupied reported the use of emotion-focused coping earlier in the coping sequence.

Coping as a Mediator of the Effects of Attachment on Psychopathology

Many researchers have suggested that coping could be a mediator that links attachment to psychopathology, given evidence that both coping and insecure attachment, particularly disorganized attachment, are associated with the development of multiple forms of psychopathology (Kobak et al., 2006). In piecing this literature together, some longitudinal research has shown that the form of insecure attachment classification (or continuous measures of attachment anxiety and avoidance) partially accounts for different forms of emotion dysregulation, consistent with theory, and emotional dysregulation has been found to mediate associations between attachment and psychopathology (e.g., Kullik & Peterman, 2013; Wei et al., 2003).

However, little research has examined these pathways directly. In one of the few such studies, children's constructive coping was found to mediate the association between maternal attachment and peer competence (Contreras, Kerns, Weimer, Gentzler, & Tomich, 2000). In a second study, 515 undergraduate students completed measures of attachment anxiety, attachment avoidance, a range of symptoms of psychopathology, and perceived ineffective coping, modeled as a latent variable marked by three ways of coping, namely (1) low levels of problem solving, (2) low levels of a reflective style involving planning and systematic responses to stress, and (3) high levels of a suppressive style involving denial and avoidance. Using structural equation modeling, researchers discovered that attachment anxiety and avoidance were each uniquely associated with higher levels of perceived ineffective coping and that perceived ineffective coping and attachment avoidance (but not attachment anxiety) both showed unique concurrent associations with heightened psychological distress. Thus, as had been argued, ineffective coping did mediate, at least partially, the associations between insecure attachment and psychopathology symptoms (see Lopez, Mauricio, Gormley, Simko, & Berger, 2001, for similar findings with attachment orientations and distress in college students).

Although few studies targeting attachment assess the full range of responses that can be used to cope with stressful events, it is possible to draw on research that assesses a narrower set of emotion regulation strategies in order to discover why or how different forms of attachment, even during infancy and toddlerhood, have implications for the ways individuals react to and cope with stress. For example, in one longitudinal study of very young children (Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002), infant boys classified as securely attachment (at age 1.5 years) were shown to possess more effective anger regulation skills (i.e., emotion-focused coping) at 3 years of age.

In a second (cross-sectional) study, all three attachment classifications during infancy (assessed via the Strange Situation) were shown to correspond concurrently to the differential use of theoretically predicted sets of emotion regulation strategies, including positive and negative social engagement, object use, and self-comforting (Crugnola et al., 2011). As would be expected, infants classified as secure, compared to those who were anxious-resistant or avoidant, used more positive social engagement to regulate their distress. Also consistent with theory, anxious-resistant infants displayed more negative social engagement and

less object use to comfort themselves compared to the other two attachment groups. Finally, infants classified as avoidant displayed less use of social engagement strategies (combined positive and negative) compared to both other attachment groups and relied more on use of objects to regulate emotion than did infants in the anxious-resistant group (see also Smith et al., 2006, for another study of infant attachment and emotion regulation).

Perhaps most important, upward extensions of attachment theory provide a foundation for proposing that individuals with different types of insecure attachments are likely to use different predominant models for regulating emotions (Brenning & Braet, 2013; Ein-Dor, Mikulincer, & Shaver, 2011; Shaver & Mikulincer, 2007). In particular, individuals with an insecure-anxious attachment relationship history have been found to rely predominantly on hyperactivating strategies, which entail heightened negative emotions in times of stress combined with overly dependent or energetic reliance on promixity and support from others. In contrast, individuals with an insecure-avoidant relationship attachment history seem to use as their predominant approach the deactivation or suppression of social needs and emotions and the inhibition of proximity seeking. Similar ideas have been proposed in self-determination theory, which identifies emotion dysregulation and suppression as two primary contrasting styles of emotion regulation (Ryan, Deci, Grolnick, & La Guardia, 2006).

The literature remains quite limited, but emerging (mostly cross-sectional) evidence supports theoretical ideas regarding the differences in emotional regulatory approaches that would be expected between those classified as insecure-anxious compared to those classified as insecure-avoidant (see e.g., Cassidy & Berlin, 1994; Thompson & Meyer, 2007). In a series of two cross-sectional studies of Belgian adolescents, youth with insecure-anxious attachments showed greater dysregulation of emotion, whereas youth with insecure-avoidant attachment showed more suppression of emotion (Brenning, Soenens, Braet, & Bosmans, 2012). In a second series of two studies, the type of emotion mattered (Brenning & Braet, 2013): Youth with anxious attachments showed greater dysregulation of sadness and anger, whereas youth with avoidant attachments showed more suppression of sadness but more dysregulation of anger. The authors argued that the type of emotion should shape how it is regulated by insecure-avoidant youth—because expressions of sadness elicit support from others whereas expressions of anger warn others to back off. Thus, it makes sense that insecure-avoidant adolescents, who wish to be left alone, should deactivate sadness but amplify anger.

Attachment and Differential Pathways of Coping and Psychopathology

Taken together, this work suggests that early attachment relationships may set a template for current interpersonal and subsequent intrapersonal strategies for coping and emotion regulation. Research supports the notion that individuals' emotional and behavioral expressions in response to stress, which include emotion regulatory as well as coping responses, are grounded in their attachment relationship history—and so should differ markedly between individuals with a history of secure versus insecure attachment relationships as well as between individuals with the two different insecure types of relationships. This research also suggests three hypotheses that warrant further investigation. First, insecure forms of attachment, which originate in infancy and toddlerhood, likely have quite specific relations with emotional reactions and relate to different coping responses and emotion regulatory processes. These may be adaptive for managing stress in the short term but may limit optimal development and put infants at risk for the development of psychopathology in the longer term. Second, coping seems to be one important mediator of the association between attachment relationships and later resilience or symptoms of psychopathology. Third, it is possible that many of the sequelae of early attachment relationships for the whole range of coping strategies do not emerge until adolescence or later, when the capacities for intrapersonal and reflective coping are fully integrated. Before this time, infants, toddlers, and young children have a more limited range of coping responses (which are often assessed and studied as emotion regulatory strategies) that are carefully scaffolded (and so may be proscribed) by concurrent interpersonal relationships (Zimmer-Gembeck & Skinner, 2011). Although research is still in its infancy, findings point to the role that coping should play in future studies focused on attachment relationships and their links to the development of psychopathology and resilience.

Parenting, Differential Pathways of Maladaptive Coping, and Psychopathology

Reviewers of research on coping and emotion regulation have identified a wide variety of pathways through which parents can shape how their offspring interpret and deal with stressful events (Bradley, 2007, Table 2; Kliewer, Sandler, & Wolchik, 1994; Power, 2004, Tables 1, 2, and 3; as well as Calkins & Hill, 2007; Grant et al., 2006; Kochanska & Kim, 2013; Morris et al., 2007; Schwarz, Stutz, & Ledermann, 2012; Skinner & Edge, 2002a; Thompson &

Meyer, 2007). In fact, when examined through the lens of normative development described in the previous section, it becomes clear that the participation of responsive adults, in successively age-graded roles, is essential to every step in the development of children's own adaptive coping. Hence, one way to consider the role that parenting plays in the differential development of maladaptive pathways of coping is to scrutinize each of these parental practices and to focus on their specific negative contribution, considering a wide spectrum of parenting behavior—which might range from allowing children to be exposed to overwhelming stress, to modeling self-blame, to suggesting coping strategies that are ineffective (see Skinner & Zimmer-Gembeck, in press, for a more detailed analysis).

A second strategy, more consistent with developmental systems perspectives and upward extensions of attachment theory, would be to consider the interpersonal support systems provided by parents as a whole and to try to consider, when these systems are not adequate, what happens to children's own coping systems when they must adapt to these nonoptimal contexts. Particularly useful in such an endeavor are theories of parenting that identify a relatively small set of umbrella dimensions that describe the basic functions of parenting in meeting children's psychological needs (Bradley, 2007, Table 1; Connell & Wellborn, 1990; Deci & Ryan, 1985; Grolnick, 2002; Skinner, Johnson, & Snyder, 2005). The dimensions that theories converge on, depicted in Table 10.2, include parental provision of warmth, structure, and autonomy support. By the same token, parental interactions that undermine children's basic needs, also presented in Table 10.2, include rejection, chaos, and coercion. Although they are referred to using a variety of labels, the study of each of these dimensions has a long history in work on parenting (see Skinner et al., 2005, for a review over the last five decades).

From this broad perspective, there are two primary ways in which parents can undermine the development of healthy coping: through errors of omission (i.e., by *not* creating an adaptive interpersonal coping system within which children's coping can develop) and through errors of commission (i.e., by dealing with their offspring in times of stress in ways that are actively unproductive or harmful). These pathways, as described in more detail in the remainder of this section, can potentially provide a rudimentary map to a line of next studies that would add to the growing literature on the role of parents in children's coping (Bradley, 2007; Power, 2004), perhaps extending its investigation to consider children's maladaptive coping as a mediator between risky parenting and the development of psychopathology and resilience (Barber & Harmon, 2002; Compas et al., 2010; Cummings & Davies, 1999; Kobak et al., 2006; Repetti, Taylor, & Seeman, 2002; Rutter, 2013).

TABLE 10.2 Six Dimensions of Parenting

Dimension	Description
1	**Warmth:** Through caring and affectionate interactions, parents communicate their emotional availability, unconditional love, and positive regard for the child.
2	**Structure:** Through dependable, reliable, and contingent interactions and routines, parents create a sturdy durable context that children can count on as being organized, predictable, responsive, and available to provide instrumental help when it is required or requested.
3	**Autonomy support:** Through interactions that are attuned to the child's own genuine desires and best interests, parents express respect, encouragement, deference, and trust in the child's authentic self.
4	**Rejection:** Parents overtly or covertly express their aversion, repugnance, or dislike for the child through interactions that are hostile, dismissive, derisive, sarcastic, callous, uncaring, or cruel.
5	**Chaos:** Parents create a context that is unstable, disorganized, and tumultuous through interactions that are erratic, unpredictable, inconsistent, and noncontingent.
6	**Coercion:** Parents behave in ways that are controlling, pressuring, and disrespectful, either through intimidation, force, demands for obedience, and threats of punishment or through guilt-inducing criticism and threats of love withdrawal.

These dimensions of parenting behavior can be seen as interpersonal resources and pressures that parents can either add or subtract during stressful interactions (Skinner & Edge, 2002a) and that create interpersonal coping systems to which children's own coping must adapt (Grant et al., 2006; McCarthy, Lambert, & Seraphine, 2004; Seiffge-Krenke, 2011; Skinner & Edge, 2002a; Valiente, Lemery-Chalfant, & Reiser, 2007). Negative dimensions of parenting permeate the development of coping systems because they increase objective demands, intensify the experience of threat, escalate distress, interfere with the detection and identification of the actual nature and source of negative emotions and action problems, trigger action tendencies that are compelling yet destructive, divert personal regulatory resources, lead to over- or underregulation of emotion and action, undermine constructive action regulation, and interfere with learning.

For example, when a child is dealing with a demanding situation, parental rejection, such as negative responses to emotional displays (Eisenberg, Fabes, Carlo, & Karbon, 1992; S. Jones, Eisenberg, Fabes, & Mackinnon, 2002) or harsh discipline (Grant et al., 2006) generally makes things worse: It adds the stress of parental disapproval and

criticism; it communicates that the parental relationship may be at stake, increasing distress and the probability of threat appraisals; it can trigger action tendencies that propel the child away from the parent (e.g., social withdrawal or escape), shutting down communication of feelings and concerns and thus making it more difficult for the parent to diagnose the problem and be supportive (further subtracting social resources); because the child must also regulate his or her distress about the parent's reaction, it reduces the regulatory resources available for dealing with the stressful situation, making maladaptive coping strategies more likely; and it focuses the child on the conditionality of parental regard rather than on what can be learned from the stressful episode (Assor, Roth, & Deci, 2004).

Over time, the interpersonal coping systems created by the general absence of parental warmth, structure, or autonomy support as well as the presence of rejection, chaos, or coercion can be problematic, even when such bouts of parenting are intermittent but especially when they are more chronic, pervasive, and severe, as in cases of parental child abuse and neglect (Cicchetti & Rogosch, 2009; Maughan & Cichetti, 2002; Shipman et al., 2007). They are likely to exert a downward pressure on children's own functioning, cumulatively leading to increasingly consolidated appraisals of implicit threat, maladaptive action tendencies, and poor regulation (Eisenberg et al., 1998; Valiente et al., 2007). The effects of children's attempts to adapt to the interpersonal coping systems created by negative interactions with parents should be visible in their own developing coping systems, as expressed through high emotional reactivity and distress, powerful but ultimately unconstructive action tendencies of different stripes (e.g., reactions to parental coercion that are submissive or oppositional), nonautonomous systems for action regulation that may be weak or rigidly overcontrolled, and a profile of coping that is low in adaptive and high in maladaptive strategies, including a noxious admixture of coping, such as helplessness, escape, social isolation, delegation, submission, and opposition.

Cumulatively, these experiences (along with social partners' widespread negative reactions to such maladaptive coping actions) should contribute to children's construction of self-systems that confirm a negative view of the self (as unlovable, incompetent, or inauthentic) or the world (as untrustworthy, uncontrollable, or coercive). These stressful parent-child interactions are also likely to further undermine the quality of the dyadic relationship and so contribute to the development of both personal and interpersonal vulnerabilities for coping. Such maladaptive patterns of appraising and dealing with stress, along with the reactions they provoke from social partners (not just from parents, but also from other family members, teachers, and peers), should put children at risk for escalating cycles of stress and ineffectual coping, not only in the family but also in school and with their age mates, perhaps cumulatively contributing to forms of internalizing and externalizing psychopathologies.

Family Stress, Differential Pathways of Maladaptive Coping, and Psychopathology

The family represents a primary source of comfort and support and can serve as a basis for protection during times of stress. For this reason, stressors that occur in the family, and which threaten its connectedness, can have detrimental effects on health and reduce the likelihood of resilient outcomes (Lynch & Cicchetti, 1998; Repetti et al., 2002; Schwarz et al., 2012). Researchers have identified a long list of family-level factors that put children at risk for the development of behavior problems; these include marital discord, conflict or violence, divorce, family turmoil, death of a parent or sibling, parental problems (substance abuse, physical or mental illness, incarceration), high rates of mobility, crowding and noise, and generally living in conditions of poverty and oppression, in a dangerous neighborhood, or in communities exposed to environmental pollution, war, or natural disasters. These circumstances can all be considered "developmentally challenging" because of their effects on children: They "pose direct harm, have the potential to seriously undermine emotional security, dislodge productive coping strategies, and impede the use of existing assets or the formation of new ones" (Bradley, 2007, p. 102).

At the same time, these situations are challenging to parents: To offset the potential harm posed by these circumstances, children require more from their parents, while, at the same time, because these conditions have an impact on everyone in the family, parents have fewer resources to employ in the service of supportive parenting. Hence, researchers who study the ways that children cope with family stressors point out that events like divorce or death of a parent or sibling are doubly dangerous to children, because they stress children directly (creating neurophysiological, psychological, and social problems) and because they stress parents—and so disrupt the family system just when children need its support the most (Sandler et al., 2000).

Although full coverage of this topic is beyond the scope of this review, researchers also point out that these

developmentally challenging circumstances are not randomly distributed throughout the population (Luther, 2006). Instead, they represent profiles of cumulative risk (Sameroff, 2010) that are common to particular societal niches, such as those created by poverty and oppression, which disproportionately contain environmental risk and dangers and lack supportive resources (Evans, 2004; Evans & Kim, 2012). Hence, parents with potentially limited caregiving resources, such as adolescent single parents, are often asked to parent in conditions that are high in demands (e.g., multiple young high-needs children) and stressors (e.g., poverty, violent relationships, dangerous neighborhood) and low in supports (e.g., neglectful extended family, limited social services, few high-quality child care facilities).

These niches can be considered high in cumulative risk, or allostatic load, which is a term that refers to the total concentration or aggregate of stressors to which a person (or dyad or family unit) is subjected or exposed (McEwen, 2010). Concepts of cumulative risk and allostatic load draw researchers' attention to the larger context of stressors and supports within which children and their families function and can help to explain the vulnerabilities in family systems created by living in niches that attract a high allostatic load (C. Blair & Raver, 2012; Seeman, Epel, Gruenewald, Karlamangla, & McEwen, 2010; Tolan & Grant, 2009). Perhaps most important, as outlined in models of how contexts shape stress and coping responses (Tolan & Grant, 2009) and in models of how coping and coping resources influence psychopathology and health (Taylor & Stanton, 2007), these kinds of stressful contexts are one source of the kinds of stressors children experience, the resources that are available to cope with stress, the coping patterns that emerge, and the development of psychopathology or resilience in the face of adversity.

Higher-order contexts, such as culture, neighborhood, or society, will contribute to parent-child coping episodes that, over time, enhance or reduce both personal and social regulatory resources. The accumulation of these episodes should play a significant role in the development of self-system processes that consolidate negative views of each other and prevent both parties from learning how to deal constructively and cooperatively with problems and obstacles. In that sense, family stress can cumulatively contribute to the development of adaptive or maladaptive coping in both children and their parents, and coping responses then becomes some of the core foundations for the development of resilience and psychopathology (Cicchetti & Rogosch, 2009; Tolan & Grant, 2009).

FUTURE RESEARCH AND TRANSLATION OF RESEARCH INTO ACTION

Consistent with many researchers who study risk and resilience, we view the factors discussed in this chapter as part of developmental cascades (Curtis & Cicchetti, 2003; Masten & Cicchetti, 2010), in which early conditions (both neurophysiological and social) contribute to subsequent difficulties. These difficulties then snowball through the accumulation of risk factors, to eventually potentiate behavioral problems and psychological disorders. According to this perspective, each of the factors discussed in this chapter can be seen as a series of steps along pathways that become more difficult to reverse the longer they are followed.

For example, when infants have temperaments that are high in stress reactivity, it is more difficult for caregivers to be sensitive and responsive to them; as a result, parents and children are more likely to form insecure or disorganized attachment relationships. The parent-infant interactions characteristic of these kinds of attachment patterns shape the developing neurophysiological processes underlying reactivity, sensitizing infants and young children to the effects of stress, perhaps even at the epigenetic level (C. Blair & Raver, 2012). Moreover, with highly stress reactive children, it can become increasingly difficult for parents to remain warm, involved, structured, and autonomy supportive, and so early patterns contribute to (or are the beginnings of) more general styles of problematic parenting. The discordant parent-child interactions characteristic of these styles of parenting contribute to an atmosphere of tension and turmoil in the larger family system. This higher-order family stress permeates caregiving and has its biggest effects on children who are biologically more susceptible to environmental effects (Cicchetti & Curtis, 2006; Cicchetti & Rogosch, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van IJzendoorn, 2011).

The Role of Coping in Developmental Cascades toward Psychopathology and Resilience

These general dynamics have been noted by researchers from many areas, and in fact, temperament, attachment, parenting, and family stress can be considered the usual suspects in creating developmental cascades that lead to almost any kind of problem behavior or form of psychopathology (e.g., Dodge, Greenberg, & Malone, 2008). What this chapter has to add to such discussions is the idea that, during infancy, childhood, and adolescence, patterns of maladaptive stress reactivity and coping are important

parts of these cascades—both as symptoms and as players. For example, temperamental vulnerabilities, almost by definition, are most apparent under conditions of stress and are typically held to be vulnerabilities precisely because they trigger maladaptive reactions to external stressors (such as changes, novelty, and social or attentional demands). One of the primary things that makes children with "difficult temperaments" so difficult is their poor coping—their overreactions and their difficulties in accommodating to demands and recovering from stress.

By the same token, poor coping is a key marker of insecure, especially disorganized, caregiver-child attachments—the term *coping* could be used to describe the outward behaviors of infants and young children under the stress of separation and especially during recovery from that stress. For young children with a history of insecure attachments, these patterns of emotional reactivity and maladaptive coping, as carried forward into preschool, are one of the main reasons they find it more difficult to form optimally safe, supportive, and stable relationships with other adults (e.g., teachers) and peers (e.g., Contreras et al., 2000; Kobak et al., 2006). The same point can be made for problematic parenting and family stress: These conditions are risk factors for developmental outcomes for many reasons (Repetti et al., 2002), and parenting problems and family stress are conditions that can have deleterious effects on children's and adolescents' coping, including their neurophysiological and psychological stress reactivity and the development of their regulatory capacities for dealing constructively with stress (Bradley, 2007).

In future studies, researchers who specialize in either coping or psychopathology may wish to examine these processes explicitly, by focusing on the multiple ways that maladaptive coping directly participates in these kinds of developmental cascades. Investigations can explore whether the emotional reactivity and action tendencies underlying maladaptive coping (e.g., opposition, submission, delegation, helplessness, escape, social isolation) can get children and adolescents in trouble in social contexts that expect mature forms of coping, whether those contexts are organized by teachers, peers, coaches, or friends' families. It is possible that children's maladaptive coping can have the direct effect of repelling positive supports, generating stress, or provoking reactions that are intrusive, retaliatory, or rejecting (Conway et al., 2012; Liu, 2013). Difficult temperaments, high stress reactivity, and insecure attachments all shape development—and these effects may accrue partly because the poor coping they engender itself elicits negative reactions from adult and peer interaction partners.

Researchers who study profiles or patterns of coping may also wish to consider whether maladaptive coping participates in developmental cascades through the downward pressure it exerts on adaptive functioning. Chronically activated threat appraisals and poor coping may interfere with children's access to their own better natures and competencies, such as their compassion and regulatory resources, making it more difficult for them to enact adaptive strategies and potentially leading them to feel powerless in the face of their own urges. Moreover, the emotional and action impulses characteristic of maladaptive coping may be so compelling that they lead children and adolescents to feel that their negative behaviors are fully justified to defend against imminent threat (Lansford, Malone, Dodge, Pettit, & Bates, 2010). As a whole, the recursive components of maladaptive coping systems, with their high stress reactivity, threat appraisals colored by fear or resentment, experiences of ineffectiveness in dealing with problems and emotions, and the negative social reactions they elicit, together may create an integrated biopsychosocial "apparent reality" that should intensify actual and subjective stress and cumulatively channel development toward heightened reactivity, regulatory vulnerabilities, behavior problems, and psychopathology.

A comprehensive picture of the developmental cascades that lead to maladaptive coping, and through maladaptive coping to psychopathology, will clearly include more contexts and social partners than we have been able to describe here. Like all other developmental cascades depicted thus far, they will undoubtedly travel through the worlds of school and peers, where children's and adolescents' maladaptive coping will likely put them at risk for academic disaffection and underperformance, peer rejection and membership in deviant peer groups, evasion of supervision by competent adults, and eventual participation in a host of risky activities during adolescence, such as truancy, delinquency, substance abuse, and unprotected sexual activity, that further constrict life paths during emerging adulthood.

The researchers who study these phenomena do not label them all as coping or consider the problems they depict as partly the result of maladaptive coping (cf. Spencer, 2006). Nevertheless, coping researchers can profit from what has been learned about the functioning of temperament, attachment, academic progress, peer relationships, teaching, and parenting under stress. And work on coping may also be useful to researchers from these largely disparate traditions by providing some common ground where they can meet to figure out how all these components work together during stressful encounters to

shape children's short-term coping and their long-term development, including pathways toward competence and disorder.

Translation of Basic Research on Coping into Action

If indeed, as we have argued, coping is both a key marker and a central player in the development of psychopathology and resilience, it follows that work on coping and its development has the potential to provide a platform for building out preventive interventions designed to avert the onset of mental health (or other) problems as well as for creating targeted interventions designed to promote the construction of coping resources, strategies, and efficacy once problems have been identified. Evidence for the utility of coping as an intervention lever can be found in the substantial portion of the larger stress and coping research agenda that has been dedicated to translating such research into direct action—by developing and evaluating prevention programs implemented in locations with almost universal access to families and/or children (e.g., the schools). Such interventions often rely on psychoeducation to teach coping strategies with the aim of preventing the development of a range of internalizing and externalizing symptoms or of reducing the likelihood of symptom escalation (e.g., P. M. Barrett, Lock, & Farrell, 2005; Eassau, Conradt, Sasgawa, & Ollendick, 2012; J. K. Fox et al., 2012; Frydenberg & Lewis, 2000; Ginsburg, 2009). Other applied stress/coping research has tested programs designed to improve coping resources and reduce distress and symptoms of mental health disorders among select groups who are at risk due to major life stressors, such as parental divorce or serious illness (e.g., Compas et al., 2010; Conrod, Castellanos-Ryan, & Strang, 2010; Sansom-Daly, Peate, Wakefield, Bryant, & Cohn, 2012; Soper, Wolchik, Tein, & Sandler, 2010; Vélez, Wolchik, Tein, & Sandler, 2011).

As a whole, these studies have demonstrated the feasibility and efficacy of providing children and adolescents with guided practice in using coping resources or emotion regulation strategies that can be effective in dealing with many stressors or helpful in alleviating distress (Compas et al., 2009, 2010, 2014; Fresco, Mennin, Heimberg, & Ritter, 2013; Kovacs et al., 2006; Suveg, Sood, Comer, & Kendall, 2009; Tein, Sandler, Ayers, & Wolchik, 2006; Weisz, Hawley, & Jensen Doss, 200; Weisz, Thurber, Sweeney, Proffitt, & LeGagnoux, 1997). Other interventions have shown success in increasing coping efficacy (Gonzales et al., 2012; Wolchik et al., 2000). Some of the most interesting studies have examined coping as a mediator between treatment and outcome, documenting that improvement in coping capacity as a result of interventions is an important factor that accounts for whether children will show reduced symptoms of mental health disorders (or other adjustment problems) following treatment (e.g., Compas et al., 2010; Essau, Conradt, Sasgawa, & Ollendick, 2012; Tein, Sandler, MacKinnon, & Wolchik, 2004).

Yet despite the growing body of research that examines efforts to directly intervene to improve coping or coping resources or that examines coping as an outcome or as a part of the recovery process, it is surprising to discover just how few studies of this kind have been conducted and that most of them have been completed quite recently. What is equally noteworthy in this literature, however, is the number of studies that have been carried out to examine the efficacy or effectiveness of implementing enhancement programs for youth that include the aim of improving coping but never actually assess it. Nevertheless, these commonly used clinical treatments spotlight the possibility that minimizing the use of maladaptive coping strategies and identifying new adaptive strategies to use instead, through therapeutic conversation, psychoeducation, role play, direct practice, or other techniques, may be effective components of such programs. Programs implementing these methods have been shown to reduce symptoms of mental health disorders, whether the programs are directed toward youth who are experiencing family problems (Garber et al., 2009; Silverman, Kurtines, Jaccard, & Pina, 2009), chronic physical or health conditions (Sansom-Daly et al., 2011), or general and other forms of anxiety and fear (P. M. Barrett et al., 2005; P. M. Barrett, Farrell, Ollendick, & Dadds, 2006; J. K. Fox et al., 2012).

When these efforts are examined in light of research and theory on the development of coping, however, three primary ways are revealed in which the current research agenda on child and adolescent stress and coping could be broadened in order to better integrate basic research with application to clinical and educational practice. First, as can be imagined from our overall emphasis on the development of coping, we would argue that the entire agenda could benefit from more careful and systematic attention to child age as a marker of developmental level. Second, a greater consideration of the roles of child temperament and family relationship history in contributing to coping strengths and vulnerabilities might allow researchers to design more successful intervention strategies by tailoring approaches to match children's specific underlying issues. Third, there could be better integration of measures of coping in translational research, both to identify children and youth who could benefit from interventions and to

assess the mechanisms of effects in interventions—via typical questionnaires and via in-the-moment techniques.

Child Age and Developmental Level

As described in this chapter, the coping system and the multiple individual and interpersonal subsystems that support and influence it show developmental patterns that are linked with age and experience. This fact is recognized implicitly or explicitly in much of the basic research on stress and coping in children and adolescents, as can be seen in age-graded choices about the coping strategies selected for study or, more rarely, in decisions to examine age directly (Zimmer-Gembeck & Skinner, 2011). Such developmental changes can be viewed as obstacles and challenges to treatment research as well, and most interventions have not yet been tested to determine whether they are effective across the age ranges of children who receive the services (Eyberg, Schumann, & Rey, 1998).

At the same time, we now have an increasingly rich body of developmental ideas about coping, which have yet to be fully incorporated into the design of prevention and intervention programs to enhance children's coping resources, capacity, and efficacy, to reduce the fallout from stressful experiences, or to otherwise optimize children's functioning in the face of adversity. A lack of integration of research on coping into program development is partly because reviews of basic research (and basic research itself) have not often directly addressed the development of coping with an eye toward guiding intervention. We also suspect that it is partly because few studies that focus on enhancing coping explicitly attend to age either by examining whether age matters to program effectiveness or by using theory and research to intentionally adapt the program to better serve different age groups (and reporting these modifications) (see P. M. Barrett et al., 2005, for an exception; Eyberg et al., 1998). In one recent study (Farrell, Waters, & Zimmer-Gembeck, 2012), when researchers did examine age differences in the cognitive beliefs theoretically linked with anxiety symptoms, such beliefs were found only among adolescents (ages 12–17) and not among children (ages 7–11), consistent with developmental research that reveals age-graded changes in the ability to consider inner thoughts and beliefs during early adolescence and the greater use of cognitive coping responses in adolescents compared to children (see also Essau et al., 2012).

Moreover, basic researchers can help interventionists more thoroughly integrate developmental dimensions in their programs if they themselves attend more closely to developmental theory when designing studies of coping. They should more closely align their selection of age groups with the stressors and coping responses that should be most relevant. For example, enhancing active coping (problem solving or positive cognitive reappraisal) may not be appropriate for all ages or situations. The kind of accommodative coping that is most effective when dealing with uncontrollable stressors likely differs with age—only during later childhood and early adolescence do cognitive reappraisal strategies become accessible, and even then they may require practice if they are to become durable enough to utilize under stress; during middle childhood, distraction may be more effective, and behavioral distraction may be the only option for younger children, who may also need to rely on support and active distraction by others. Similarly, the kinds of coping that is effective with controllable stressors may also require different intervention responses at different ages.

Research scrutinizing the kinds of interpersonal relationships that provide developmentally graded support as children begin to enact more self-reliant forms of coping with stress would be helpful for planning interventions directed to children between ages 5 and 7. Research examining how children use different forms of social support, how they balance this with individual efforts, and how this balancing act changes from early to middle childhood would be particularly useful for identifying entry points for ameliorating deficits and bolstering strengths at these ages. And studies focusing on how the range and flexibility of adolescents' strategy use changes as they get older would also be useful for guiding practical work to help young people more intentionally match their coping efforts to situational demands during these age periods.

Finally, research using cluster analysis or person-centered approaches (Boxer et al., 2012; Tolan et al., 2002) also suggests that patterns of coping or patterns of other regulatory responses and coping need to be considered as targets for interventions. We know about the "complex ways that coping strategies are interrelated" (Gaylord-Harden et al., 2010, p. 852), and we are beginning to find out that these interrelations may change with age (Zimmer-Gembeck & Skinner, 2011). As research progresses toward identifying optimal profiles of ways of coping for different developmental periods and the type of stress under consideration (Skinner & Wellborn, 1997), this information would be invaluable for informing practice. If research is carefully designed with clinical implications in mind, future developmental research findings should be much more easily translated into the creation of practical supports, and treatment or prevention programs for young people of all ages. Perhaps coping researchers will be more

motivated to explore important developmental issues, such as what kinds of coping are and are not adaptive in particular situations and at particular ages, if they see how important such findings could be to the creation of more effective prevention and intervention practices (see also Gaylord-Harden et al., 2010; Tolan et al., 2002, for further discussions of these issues).

Coping, Temperament, and Family Relationship History

Universal intervention to assist children when dealing with stress can be beneficial by teaching a range of cognitive or behavioral strategies to put in place and practice before stress occurs (P. M. Barrett et al., 2006). Nevertheless, selected approaches have the advantage of tailoring intervention techniques—with the goals of compensating for deficits and building on strengths among individual or groups of children identified for inclusion in programs based on history (e.g., parental divorce or maternal depression; Compas et al., 2009, 2010; Soper et al., 2010; Vélez et al., 2011) or personal symptoms, such as anxiety disorders (Kovacs et al., 2006; Waters, Donaldson, & Zimmer-Gembeck, 2008).

Such focused tailoring could be guided even more explicitly by studies documenting the different patterns of maladaptive appraisals, stress reactions, and coping strategies children are likely to exhibit, given developmental differences in temperamental status, attachment history, and parenting experiences. This knowledge might also be useful in assisting children to cope more effectively and compassionately with their own temperamental tendencies and to modify their own behaviors with the goal of reducing "dependent" stress events, which are stressful experiences that are partly self-generated (Conway et al., 2012; Liu, 2013). The study of children's differential histories could also be useful in order to identify potential appraisal biases that will prompt inappropriate coping responses (Kochenderfer-Ladd & Skinner, 2002; Zimmer-Gembeck & Nesdale, 2013; Zimmer-Gembeck et al., 2013), including reliance on coping strategies that are not well matched to the situation. Not only could such studies guide interventions as they directly tackle biased appraisals and maladaptive coping, but they could also identify the kinds of promotive opportunities children are likely to have missed, given their temperamental and attachment histories; some children may never have participated in constructive interpersonal coping or experienced practical success in coping, suggesting that interventions could be enriched by providing new opportunities for such children to acquire these skills as well as to build feelings of trust, cooperation, efficacy, and agency (Larson, 2011), which might all feed back into increasingly more beneficial coping patterns over time.

Integrating Coping Measures More Fully into Prevention and Intervention Research

Better translation of basic coping research into practice also depends on expanding present intervention research to more frequently consider ways of coping, as well as closely related regulatory processes, as "active ingredients in the prevention [or escalation] of mental health problems in children and adolescents" (Compas et al., 2010, p. 623). Coping measures can serve as screening devices to identify children and youth who could benefit from services. Coping also represents a valid and important measure of the goals, aims, and outcomes of treatment (or other types of prevention/intervention programs) for young people and should be assessed more routinely.

Given the challenges of measuring coping, doing so will require careful thinking on interventionists' parts. Current multidimensional measures of coping (e.g., Ayers et al., 1996; Connor-Smith et al., 2000), as reported by children, youth, and their adults, provide a valuable menu from which researchers can select the range of ways of coping that are most appropriate to the developmental level of their target population (Zimmer-Gembeck & Skinner, 2011) and best suited to the situation and treatment approach (Eyberg et al., 1998). Measurement development work is needed in order to assess coping in a way that is sensitive to developmental age, situation, and prior history but is also sensitive enough to detect changes when comparing assessments at pre- and posttreatment or later. Perhaps daily diary assessments of distress and coping (e.g., Walker et al., 2007) will turn out to be especially useful for these purposes. As assessment becomes more sophisticated, such translational research incorporating coping measures will help to locate the particular components of interventions that yield positive and lasting treatment outcomes (Kazdin, 2008).

SUMMARY AND CONCLUSION

We hope that some of the ideas outlined in this chapter (such as those summarized in Table 10.1) may provide grist for thought about how future research can productively combine research on the development of coping with work on the development of psychopathology. These are two rich empirical traditions that attempt to understand how adversity and stressful events in the lives of children and adolescents can shape their developmental pathways, for

better and for worse. We have suggested that coping—with its strategies, resources, and efficacy—should always be considered a part of these developmental cascades and also a part of intervention and prevention efforts to optimize them. Both developmental psychopathology and the development of coping have much to contribute to our understanding of how children and adolescents, when faced with stressful life events, whether they are woven into lives of privilege or derived from chronic adverse circumstances, can (with or without our help) nevertheless create pathways that lead to the development of enduring competence and resilience.

INTRODUCTION

The field of developmental psychopathology has relied extensively on the study of normal development in order to understand psychological maladjustment (Cicchetti & Cohen, 2006; Sroufe, 2009). Along with current models of development that consider multiple determinants of developmental outcomes, developmental psychopathology is concerned with understanding how both child and environmental factors predict the development of problem behavior in children. And, consistent with research in adult psychopathology, research in developmental psychopathology has examined how individual differences in emotionality, attention/regulation and activity, better known as temperament, have contributed both directly and indirectly to behavioral disorders.

Although there is a long tradition behind the concept of temperament and its role in psychopathology, it was not until the twentieth century that individual variation in child behavior became the focus of study. And it was not until the early 1960s that such variation became the focus of child psychologists and psychiatrists interested in understanding the origins of children's behavioral problems (Thomas & Chess, 1977). Since that time, various developmental models of temperament have been proposed leading to a vast array of instruments and observational methods for assessing temperament in children, all in the service of understanding the defining characteristics and structure of temperament as well as its impact on other developmental outcomes, including psychopathology.

In this chapter we review the current literature linking infant and child temperament to developmental psychopathology. Our review is an update to the reviews found

This chapter was written with support from grants funded by the NIDDK (DK081512) and the John Templeton Foundation (#43177) awarded to the first author.

in previous editions of this volume provided by Rothbart and colleagues in 1995 and in 2006 (Rothbart & Posner, 2006; Rothbart, Posner, & Hershey, 1995). We concentrate on studies published after 2000, a period of increased study in this area (Zentner & Shiner, 2012). Paralleling this wave of new research was a growing understanding of the biological systems underlying both temperament and psychopathology (Fox, Henderson, Pérez-Edgar, & White, 2008). Likewise, temperament theory and research was going through a renaissance of sorts with an update of the definition of temperament and introduction of new approaches to the study of temperament. Hence, another goal of this chapter is to review these exciting changes. Before the review of the most current research in temperament and developmental psychopathology, we introduce the concept of temperament and consider a number of agreed-on principles. We follow this with a discussion of the structure of temperament, including a review of the contemporary theoretical models, as well an examination of the more traditional dimensional approach and the more recent (resurgent) categorical approach to the structure of temperament. We then consider the measurement of temperament by questionnaire, laboratory/home observation, and other methods. We conclude our introduction by discussing the proposed links between temperament and developmental psychopathology. Following our review of the current research on temperament and developmental psychopathology, we provide a brief overview of the biological underpinnings of temperament and their links to developmental psychopathology. Based on our review of the research literature, we conclude the chapter with directions for future research.

WHAT IS TEMPERAMENT?

In 1987, several prominent and active researchers in the field of temperament gathered for a roundtable sponsored by the Society for Research in Child Development (Goldsmith et al., 1987) to discuss the current state of the field. Although there was significant consensus, the participants' conceptualizations differed in several ways depending on what they chose to emphasize in their models. For example, A. Buss and Plomin (1984) emphasized the genetic basis of temperament while Goldsmith and Campos's framework (1982) was emotion based. In his commentary on the roundtable, McCall attempted a definition that integrated the agreed-on concepts: "temperament consists of relatively consistent, basic, dispositions that underlie and modulate the expression of activity, reactivity, emotionality and sociability" (Goldsmith et al., 1987, p. 524). More recently, researchers who were affiliated with each of the original roundtable participants met in the same format 25 years later to review what was learned about temperament in the interim (Shiner et al., 2012). Based on their own research and knowledge of the current literature on child temperament, the progeny of the original roundtable participants updated the definition of temperament as "early emerging basic dispositions in the domains of activity, affectivity, attention, and self-regulation, and these dispositions are the product of complex interactions among genetic, biological, and environmental factors across time" (Shiner et al., 2012, p. 437). As can be seen, this definition was expanded to illustrate that temperament is not a static construct but one that develops.

This definition of temperament is consistent with the six key criteria for temperament identified by Zentner and Bates (2008). (Zentner & Bates, 2008). Several of the criteria overlap with the preceding definitions of temperament (domains of affect, activity and attention; early appearance; linked to biological mechanisms; relatively enduring). Additional criteria included: (1) variations in expression as reflected in response intensities, latencies, durations, thresholds, and recovery times; (2) comparability with individual differences observed in other social mammals; and (3) predictions to "conceptually coherent outcomes," such as internalizing and externalizing problem behaviors. These current definitions/criteria of temperament are important as they provide a consensual framework to guide future research and allow for the comparison across studies on child temperament.

The Principles of Temperament

The contemporary definitions of temperament strive to include the many principles of temperament on which the different models agree (Goldsmith et al., 1987). It is worth discussing a few of these principles in light of the following review of the literature linking temperament to developmental psychopathology. The first principle is that *temperament reflects individual differences that are relatively stable*. Stability, which comes in many forms (e.g., homotypic, heterotypic; Caspi, 1998), applies theoretically to temperament, given the characteristics used to define temperament such as "basic," "disposition," and "enduring." That temperament is stable also increases its predictability. That is, parents may expect their child to respond similarly across situations. Likewise, when asked to describe their children, parents use descriptions that reflect stable characteristics, such as "She is outgoing" and "He is shy," which

are easily understood by others (Kohnstamm, Mervielde, Besevegis, & Halverson, 1995). Despite this notion that temperament is stable, the qualifier "relatively" has been added in current definitions of infant and child temperament, reflecting an understanding that temperament traits may change over time, given biological maturation and environmental input. Evidential support for relative stability of temperament is found in studies that show the consistency of temperament to be low to moderate with stability coefficients ranging from zero (0) to around .50, depending on how temperament is measured as well as the ages over which stability was calculated (Durbin, Hayden, Klein, & Olino, 2007; Lemery, Goldsmith, Klinnert, & Mrazek, 1999; Roberts & DelVecchio, 2000). Greater consistency is usually found for parent ratings, older children (>3 years of age), and across shorter lengths of time while lower stability coefficients are typically found for laboratory/observational measures, infants and toddlers, and across longer periods of time. Further evidence is provided by quantitative behavior genetic studies. High heritability of a temperament trait would indicate excellent stability, and for many traits, heritability effects are robust. However, genetic effects across studies range from .20 to .60, and there is little consistency across studies examining the same dimension. Taken together, these data suggest the possibility of environmental effects as well as error in measurement (Saudino & Wang, 2012). Recent research examining the genetic influences on continuity and change in temperament from infancy to preschool revealed that the modest continuity of several observed traits was due to genetic factors, but other dimensions, such as shyness, were influenced by genetic and environmental factors (Saudino & Cherny, 2001). Although these studies indicate the genetic bases for stability of temperament, it is important to note that the average age-to-age correlation was .24, confirming that stability of temperament is modest, particularly in early childhood.

A second principle of temperament is that *temperament develops*. This is an often-neglected principle given the folk theories about the endogenous nature and stability of temperament. However, the modest correlations of temperament across age suggest that change in temperament is more likely to occur; this may be due to maturation of biological systems, the emergence of other temperament dimensions, as well as input from the environment, particularly parents. Many of the dimensions found within contemporary temperament models can be said to develop. Consider Rothbart and Derryberry's (1981) definition of temperament; they define temperament as individual differences in reactivity and regulation. Although several forms of reactivity are observable at birth, its expression is undifferentiated in terms of emotion (e.g., distress) and diffuse with relation to motor activity. With development, different emotions emerge and consequently reactivity becomes more specific. For example, anger reactivity and social smiling emerge around 3 months of age while fear emerges after 6 months of age and is dependent on the start of self-locomotion (Barrett & Campos, 1987). Studies examining the emergence of fear-based inhibition support this later emergence of temperamental fear, demonstrating that prior to 6 months, infants approach low-intensity (e.g., plate, saucer) and high-intensity toys (e.g., flashing light) with similar latencies but by 12 months of age, latencies to approach lengthen to high-intensity toys, and individual differences in latencies to approach are predictive of later inhibited/uninhibited temperament (Putnam & Stifter, 2002; Rothbart, 1988).

Regulation, in contrast, begins to develop at the end of the first year, although attentional behaviors, such as focusing and sustained attention that form the foundation of self-regulation (Garon, Bryson, & Smith, 2008), can be observed earlier. By the end of the first year, infants are demonstrating rudimentary self-regulation or effortful control, as demonstrated by their ability to initiate, maintain, and cease activities and their awareness of rules (Kopp, 1982). Throughout the next 2 years, the ability to control emotions, behavior, and cognition develops rapidly, moving from voluntary inhibition of behavior to the ability to suppress a dominant response in favor of a nondominant response (Kochanska, Coy, & Murray, 2001). Likewise, executive control of attention, which is linked to activation of the anterior cingulate cortex (ACC) (Rudea, 2012) emerges during this period. The emergence of temperamentally based self-regulation or effortful control overlaps significantly with the development of executive functions, a rubric that subsumes cognitive processes that control thought and action including planning, working memory, set shifting, error detection, and inhibitory control of prepotent responses (Blair, Zelazo, & Greenberg, 2005; Welsh, Pennington, & Groisser, 1991).

Thus, both temperamental reactivity and regulation develop across infancy and early childhood. Indeed, while specific forms of reactivity emerge within the first year, development continues across childhood such that levels of reactivity typically decrease due to increases in self-regulation. Whether these changes are due to the structure of temperament or its expression continues to be debated. What is known is that the inability to regulate emotional reactivity is related to risk for behavior problems and is symptomatic of child clinical disorders.

It is important to note that *self-regulation* refers to voluntary, executive control, which is contrasted with what Rothbart (Rothbart & Bates, 2006) calls "passive control" and Eisenberg (Eisenberg & Morris, 2002; Eisenberg et al., 2004) calls "reactive control." Although these terms appear to be opposing, they are quite similar in that both terms define nonvoluntary or automatic control that is driven by approach/withdrawal processes. Rothbart's term is focused exclusively on fear-based behavioral control, such as when inhibited children withdraw from an object/person they perceive as a potential threat. Thus, their fear constrains or regulates their behavior. Interestingly, passive control is related to later effortful control such that fearful children exhibit better effortful control than fearless children (Kochanska & Knaack, 2003). Eisenberg extended Rothbart's term to include impulsive approach as a form of reactive control in that impulsive children are fueled by their approach system without any voluntary regulation. Importantly, both forms of reactive control have been related to problem behaviors (see below).

Acknowledging that temperament develops may be particularly important for understanding how temperament influences developmental psychopathology. The central tenet of developmental psychopathology is that behavioral and emotional disorders are the result of a complex developmental process (Sroufe & Rutter, 1984). Research on this process requires prospective longitudinal study that starts in infancy and includes genetic, physiological, contextual, and experiential components and their development over time (Sroufe, 2009). Assessing the development of the emotional and regulatory components of temperament is essential to identifying the pathways to and away from psychopathology. For example, understanding when children develop regulatory strategies in light of their temperamental reactivity and how effective these strategies are developmentally will assist in the assessment of anger reactivity as a symptom of psychological maladjustment rather than the extreme end of a temperamental characteristic.

A third principle to which all contemporary temperament models subscribe is that *temperament interacts with the environment to affect the child's development*. This principle is consonant with the premise that interactions between children and their parents are bidirectional (Bell, 1968) and transactional (Sameroff, 2009) such that the characteristics of children, including temperament, contribute to their own development through interactions with the parenting environment across time. Children's temperament can, for example, evoke certain responses from parents, which can, in turn, affect how children consequently respond. Studies have shown how specific parenting behaviors interact with temperament either to attenuate or exacerbate later reactivity as well as to support or undermine the development of self-regulation, which has been shown to have implications for the development of psychopathology (Kiff, Lengua, & Zalewski, 2011).

Several theoretical approaches attempt to explain how temperament by environment interactions impact developmental outcomes, including psychopathology. The organismic specificity hypothesis (Gandour, 1989; Wachs, 1991) proposes that similar environments will affect children differently due to inherent individual differences in each child. Thus, a highly negative infant will respond to parental soothing differently from an infant who is low in negativity. This differential response may impact the development of the child, depending on how the parent adjusts his or her behavior accordingly. This model of development parallels the diathesis-stress or dual-risk model utilized to describe the development of psychopathology (Ingram & Luxton, 2005). More specifically, the diathesis-stress model views individuals who possess certain vulnerabilities that serve as a diathesis to increase their risk for negative outcomes (e.g., psychopathology) when combined with adverse environments while those who are not characterized by vulnerabilities are unaffected by the same environments and thus considered resilient (Luthar, 2006). In other words, some children are more strongly affected by poor environmental conditions, whereas other children appear to be more resilient to difficult environmental situations; this resilience frequently is believed to be a result of the child's temperament. A child who is temperamentally fearful, for example, and who has multiple nonparental caregivers with little predictability may develop general anxiety disorder while a less fearful child in the same circumstance would be a low risk for such a disorder (Degnan, Almas, & Fox, 2010). An important aspect of this model is that all children, including both those who are resilient and those who are vulnerable, thrive similarly in supportive or nonmaladaptive environments.

Some researchers have recently argued that most research in developmental psychopathology has not considered the full range of environments or outcomes, ranging from positive to negative (van IJzendoorn & Bakermans-Kranenburg, 2012a). Two very similar developmental models have been put forward to address this gap: the differential susceptibility hypothesis (Belsky & Pluess, 2009) and the biological sensitivity to context theory (Boyce & Ellis, 2005). These models propose that certain individuals are susceptible to both "risk-promoting and development-enhancing environmental conditions"

and that this susceptibility is found within the individual's biology (B. J. Ellis, Boyce, Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2011). In other words, susceptible individuals are not only more affected by adverse environments than less susceptible individuals but are also more open to positive, enriching environments that will affect outcomes for these individuals above and beyond those individuals who are less susceptible (Belsky, 1997; Belsky & Pluess, 2009).

Temperament, particularly difficult temperament or high levels of negative emotionality, and the biological systems and genetics that underlie temperament, have been used as examples of a susceptibility factor. Van Zeijl and colleagues (2007), for example, found that children with difficult temperaments were more susceptible to both negative and positive discipline than were children with easy temperaments in predicting the highest and lowest levels of externalizing problems, respectively. In another study, Kim and Kochanska (2012) demonstrated that infants with high negative emotionality exhibited the lowest self-regulation when their mothers were not mutually responsive and the highest levels of self-regulation when their mothers were very responsive. Biological sensitivity might be exemplified by activity in the parasympathetic nervous system (PNS) as measured by respiratory sinus arrhythmia (RSA). Findings from a study on marital conflict showed that when children with low RSA live in a household high in marital conflict, they are most anxious; when children with low RSA live in households with low marital conflict, they are least anxious (El-Sheikh, Hager, & Whitson, 2001). It is important to note that fearful children are characterized by low RSA, suggesting that their propensity for anxiety disorder would not only be lowered under positive conditions but buffered to the extent that they are the least anxious among other fearful and nonfearful children.

As many of the proposed pathways to developmental psychopathology include the role of the environment, these developmental models become increasingly important in understanding the relationship between temperament and psychopathology as well as in guiding future research. Moreover, the differential susceptibility and biological sensitivity models of person by environment interactions have only recently been fully tested because they are relatively new. However, several studies show the pattern suggested by these models. In the Temperament and Psychopathology: A Review of the Literature section we note which studies are supportive of temperament as a differential susceptibility in the development of child psychopathology.

THE STRUCTURE OF TEMPERAMENT

Conceptually and empirically, the structure and measurement of temperament in childhood has traditionally been dimensional. This is likely because the predominant conceptualization of adult personality/temperament that influenced the consideration of temperament earlier in life was dimensional, and that measurement of personality in adults and temperament in children was and is based primarily on questionnaires.

In this chapter, we focus on the four contemporary models of temperament that dominate the field: Thomas and Chess's (1968) behavioral-style model, A. Buss and Plomin's (1975) genetic criteria model, Rothbart and colleagues' (1981) psychobiological model, and Goldsmith and Campos's (1982) emotion-based model. Drawn from the dimensions that emerged from the interviews of Thomas and Chess and subsequent theory-driven and factor analytic work on child temperament, researchers converged around defining temperament as individual differences in three major areas: emotions, activity, and attention/regulatory behaviors (see Mervielde & De Pauw, 2012; Zentner & Bates, 2008, for a more expanded list of converging traits). Table 11.1 lists the specific dimensions of the four child temperament approaches that correspond with these three broad temperament factors as well as those dimensions that are specific to the temperament model. As noted, each theory emphasizes different aspects or criteria for temperament as well as the different developmental ages that each model covers. Both of these factors influenced the type and number of dimensions proposed by each theory. Here we describe briefly the dimensions from each temperament model that fall within these broad factors. In addition, these broad temperament factors are used later in the chapter to guide the organization of our review of the current research on the links between temperament and developmental psychopathology.

The broad factor of *emotionality*, which describes intensive and temporal variations in emotion expression, is defined either generally or specifically, depending on the theoretical framework. For example, Thomas and Chess (1968) include children's quality of mood, which ranges from positive to negative, while A. Buss and Plomin's (1975) emotionality dimension focuses broadly on negative emotions and does not include consideration of positive emotions. Other researchers view individual differences in discrete emotions, such as happiness, anger, and fear. Rothbart's (1981) positive emotion dimension includes smiling/laughter and high-/low-intensity pleasure. Smiling, as a reflection of joy, is also included in Goldsmith and

TABLE 11.1 Dimensions of contemporary developmental models of temperament

Thomas & Chess (1968)	A. Buss & Plomin (1975)	Goldsmith & Campos (1982)	Rothbart et al. (1981)	
			Infant	*Child*
Emotionality				
Intensity of reaction; Threshold of response; Quality of mood	Emotionality	Anger Fear Smiling	Distress to limitations; Fear; Sadness; Low/high intensity pleasure; Smiling and laughter	Anger/frustration; Fear; Sadness; Low/high intensity pleasure; Smiling and laughter; Discomfort
Activity Level				
Activity level	Activity level	Activity level	Activity level	Activity level
Attention Behaviors				
Attention span		Interest	Duration of orienting	Attentional focusing
Regulation				
Approach/ withdrawal	Sociabilty		Approach	Approach; Shyness
			Falling reactivity; Soothability	Falling reactivity and soothability
				Inhibitory control
Distractibility	Impulsivity			Impulsivity
Other dimensions				
Rhythmicity; Adaptability			Cuddliness; Perceptual sensitivity; Vocal reactivity	Perceptual sensitivity

Campos's (1982) framework. Similarly, individual differences in anger and fear are described in both theories. However, these are termed distress to limitations (anger) and distress to novelty (fear) in the infant version of Rothbart's model (1981). The attention to discrete emotions in these models emphasizes the understanding that the functions of these emotions are different (Barrett & Campos, 1987) and thus individual differences in their expression may lead to different outcomes (Putnam & Stifter, 2005). Indeed, among negative emotions, some may be positively related, as was found between anger and sadness (Dyson, Olino, Durbin, Goldsmith, & Klein, 2012), while others may be unrelated, as in the case of anger and fear (Goldsmith, 1996). Interestingly, factor analytic data (Rothbart, Ahadi, Hershey, & Fisher, 2001) on parent ratings of child temperament and observational studies (Gagne, Van Hulle, Aksan, Essex, & Goldsmith, 2011) indicated that in some cases, happiness and anger are positively linked. This is consistent with Carver's (2004; Carver & Sheier, 1998) theoretical model of affect, which proposes that positive and negative emotions are generated in response to the effectiveness of approaching incentives (happiness and anger) or withdrawing from threat (relief, fear).

Activity level, which reflects an individual's level and intensity of motor activity, is included in all modern theories of child temperament (A. Buss & Plomin, 1975, 1984; Rothbart & Derryberry, 1981; Thomas & Chess, 1968, 1977). Activity level is commonly viewed as such a critical aspect of temperament that it is even considered in Goldsmith and Campos's (1982) emotion-focused temperament framework. They proposed that motor activity is tied to each emotion and thus represents the child's emotional arousal (Goldsmith & Campos, 1982; Goldsmith & Campos, 1990). Its inclusion in A. Buss and Plomin's (1984) genetic criteria model is due to its moderate to high heritability in children, which has been found in both parent ratings of activity (Saudino & Eaton, 1991) as well as objective measurements, such as actigraphs (A. Wood, Saudino, Rogers, Asherson, & Kuntsi, 2007). Activity level is often associated with other temperament dimensions. For example, it is positively associated with anger and negatively associated with fear (Rothbart, Ahadi, & Evans, 2000). This finding confirms Goldsmith and Campos's (1982) proposal that activity level, at least in very young children, reflects emotional arousal. High levels of activity are also linked to high levels of approach. As we discuss later, these traits along with high-intensity pleasure and impulsivity, to name a few, make up the superfactor "surgency" identified by Rothbart (Rothbart, Ahadi, & Hershey, 1994).

The third broad factor of temperament that emerges from these four theories is *attention/regulatory behaviors*. Regulation is the process that modulates (e.g., increases, decreases, or maintains) emotional and behavioral reactivity, and attention is foundational to this ability (Posner & Rothbart, 2000). Thomas and Chess's (1977) attention span dimension and Rothbart's (Rothbart & Derryberry, 1981) duration of orientation and attention focusing dimensions

reflect individual differences in attention. Goldsmith and Campos's (1982) model includes the construct of interest, which is conceptualized as an emotion resulting from attention to stimuli and thus is included under this factor. Approach/withdrawal behaviors found in the Thomas and Chess and Rothbart models are listed under regulation because they increase positive affect by approaching or moving toward novel stimuli while withdrawal from novel stimuli decreases negative affect. Of course, who is more likely to use approach or withdrawal behaviors will depend on their reactivity to novel stimuli. A. Buss and Plomin's (1984) sociability and Rothbart's shyness dimensions represent approach/withdrawal in social situations. As regulation is central to Rothbart's definition of temperament, this model has several dimensions not seen in the other models. Falling reactivity and soothability reflect the child's ability to recover from the height of reactivity and to be regulated by others. Inhibitory control, which is defined as the child's ability to plan activities and suppress reactivity when instructed, develops in early childhood and thus is not seen in measures of infant temperament. Finally, as can be seen in Table 11.1, distractibility and impulsivity were included under this broad factor. Although these dimensions represent the speed with which a child responds to stimuli, we conceptualize them here as reflecting the lack of regulation. Impulsivity was initially included in Buss and Plomin's framework and then removed upon findings of lower than criteria heritability. Recent findings, however, suggest that there is a significant genetic influence on impulsivity (Gagne & Saudino, 2010).

Higher-Order Temperament Factors

As with the development of the Three-Factor (Eysenck, 1970) and Five-Factor (Costa & McCrae, 1976) models of personality and their numerous variations, temperament researchers have also examined how dimensions of temperament might relate in a coherent fashion. Examining the presence of higher-order factors is theoretically consistent with the proposal that temperament, like adult personality, is organized hierarchically (Zentner& Shiner, 2012). The use of higher-order temperament factors also has both methodological and interpretative advantages. As it is expected that many of the dimensions covary (e.g., activity level and high intensity pleasure) creating broad traits increases the power to predict relationships with other nontemperament factors (Putnam, Ellis, & Rothbart, 2001). Higher-order temperament factors also align quite well with the Three- and Five-Factor models of personality such that investigations of the links between temperament and personality are better executed and interpreted (Rothbart, Ahadi, et al., 2000). Likewise, since there is no unifying model of temperament, higher-order factors are useful for comparing across studies of temperament using different theoretical and methodological approaches.

Rothbart and colleagues (Putnam et al., 2001; Rothbart, Ahadi, et al., 2001) have done the most extensive quantitative analysis of temperament dimensions across childhood. Using factor analysis on the 15 dimensions (see Table 11.1) measured with the Child Behavior Questionnaire (Rothbart et al., 2001), three superfactors were identified: Negativity, Surgency, and Effortful Control. Negativity reflects a general tendency toward negative affect and is composed of anger/frustration, fear, sadness and low soothability. The surgency factor, which defines an approach orientation that generates positive affect and activity, is comprised of positive loadings of high-intensity pleasure, activity level, impulsivity and approach, and a negative loading of shyness. Effortful control, which results from positive loadings of inhibitory control, attention focusing, low intensity pleasure, smiling/laughter, and perceptual sensitivity, represents the child's regulatory capacity. These factor structures were similar across ages 3 years to 7 years and replicated in a Chinese sample (Ahadi, Rothbart, & Ye, 1993; Rothbart, Ahadi, et al., 2001) and a Dutch sample (Mervielde & De Pauw, 2012). The three superfactors subsequently emerged from questionnaires aimed at infants (Gartstein & Rothbart, 2003) and toddlers (Putnam, Gartstein, & Rothbart, 2006), demonstrating considerable coherence of these broad factors across childhood. Interestingly, these broad temperament factors map well onto adult personality factors, supporting the proposed link between temperament and personality traits (Shiner & Caspi, 2012).

The three factors identified by Rothbart were all derived from parent ratings of their children's temperament. Recently researchers have attempted to identify higher-order factors using observational methodology. Using procedures from the Laboratory Assessment Battery (Lab-TAB; see the section on Observational Measures of Temperament for further details, Goldsmith, Reilly, Lemery, Longley, & Prescott, 1993), which was designed to measure a number of lower-order traits, such as anger, sadness, fear, activity, and inhibitory control, Dyson and colleagues (2012) took a two-stage factor analytic approach. Exploratory factor analysis identified five factors, which were confirmed with a second sample: Sociability, Positive affect/interest, Dysphoria, Fear/inhibition, and Constraint versus impulsivity. In another study,

examiner ratings of child behavior across a number of cognitive and motor tasks were used to assess such temperamental characteristics as fearfulness, emotional lability, and impulsiveness (Caspi, Henry, McGee, Moffit, & Silva, 1995). Three factors emerged from the factor analysis: Lack of control, Approach, and Sluggishness, which described children who were passive, quiet, and withdrawing from novelty. When examining the relationship among these temperament factors and child behavior problems, lack of control was the most robust predictor. Similar results have been found with parent-reported effortful control. Taken together, the factors that emerged from studies using observations overlap (e.g., positive affect/interest, approach and surgency; constraint, lack of control, and effortful control) but are not identical to those that emerged from analysis of parent questionnaires.

Higher-Order versus Lower-Order Traits

Although there are several advantages to using higher-order factors in temperament research, this does not diminish the benefits of a fine-grained approach examining lower-order traits. Consideration of specific temperament traits may reveal more definite relations with outcomes such as behavioral and emotional disorders in childhood. So while there is evidence that the higher-order factor of Negativity, which includes variations in fear, anger, sadness, and general distress, is related to child behavior problems, an examination of the lower-order traits of anger and fear reactivity show that they are differentially related to the broad-band dimensions of problem behavior. For example, anger is positively associated with externalizing while fear reactivity is associated with internalizing (see the Review of Literature section). This finding should not be surprising, as these emotions have very different adaptive goals and action patterns (Barrett & Campos, 1987). It is interesting to note that in the factor analysis that derived the three higher-order factors of Surgency, Negativity, and Effortful control, anger reactivity loaded equally across the Surgency and Negativity factors (Rothbart, Ahadi, et al., 2001). Surgency includes high approach and activity level, characteristics that, when restrained, may lead to frustration and anger. Indeed, anger is often referred to as an approach emotion (Carver & Harmon-Jones, 2009; He et al., 2010). The use of higher-order temperament factors, therefore, may obscure important individual differences reflected in lower-order traits. Finally, it is important to note that the higher-order factors were derived from factor analysis of parent-rated temperament. As we discuss later, this method of assessing temperament is highly subjective, which may account for the associations found among the different types of infant and child negative emotions. Researchers interested in the links between temperament and developmental psychopathology, therefore, should be guided by the underlying emotions or behaviors defining the disorder. Researchers interested in oppositional defiant disorder (ODD), for example, which is characterized by ease of frustration, might consider focusing on anger reactivity, while those examining anxiety disorders would benefit from a more focused examination of fear reactivity.

A Categorical Approach to Temperament

Although the dimensional approach to temperament is the predominant method by which this construct is described, the categorical approach to understanding individual differences in reactivity and regulation has recently come to the forefront. The emergence of advanced statistical techniques, such as latent profile analysis, has allowed researchers to more fully examine how patterns of temperament characteristics define homogeneous groups of individuals.

The categorical approach to the study of temperament, however, is not new. In the second century, Galen described temperament categorically (e.g., sanguine, melancholic) based on the balance of the four humors of yellow bile, black bile, phlegm, and blood (Kagan, 1994). Interestingly, these types persisted across a number of cultures until the nineteenth century, when empiricism and later behaviorism emerged to explain individual differences. In the second half of the twentieth century, Thomas, Chess, and Birch (1968), the first developmentalists to consider temperament as important to understanding developmental psychopathology, created nine dimensions (see Table 11.1) based on interviews with parents which were then collapsed into three child temperament types. The easy type, which made up 40% of the sample, was more approaching of unfamiliar objects and persons, more positive in mood and adaptive. The difficult type described a child who withdrew from the unfamiliar, had an irritable, negative mood, and exhibited poor adaptation and comprised 10% of the sample. Children of this type were most likely to be rated as high in behavior problems. The third type, slow to warm up, comprised 15% of the sample and was most likely to exhibit withdrawal from novelty with some emotional distress and moderate adaptation. These categories were developed through qualitative analyses followed by factor analyses.

The recent resurgence of research examining categories or types of temperament resulted in part from

the person-oriented approach to individual functioning discussed by Block (1971) and further developed conceptually and methodologically by Magnusson and colleagues (Bergman & Magnusson, 1997). The theoretical basis of the person-oriented approach is holistic in that the person is viewed as integrated and hierarchically organized, and individual differences are investigated for patterns among the behaviors of interest (Magnusson, 1998) rather than a summation of the variables. Person-centered or typological methods aim to create subgroups of individuals with similar patterns of behaviors or traits (Kagan & Fox, 2006; Zentner & Bates, 2008) based on the premise that members of a specific subgroup are more similar to each other than to members of a different subgroup (Bergman & Magnusson, 1997). This approach provides increased statistical power to identify complex interactional associations among multiple temperament traits (Laursen & Hoff, 2006; Magnusson & Bergman, 1990).

It is important to note that temperament typologies were based on observations of behaviors rather than questionnaires, the predominant method of studies using the dimensional approach (cf. Dyson et al., 2012; Gagne, Van Hulle, et al., 2011). This contrast in methodology raises the issue of comparability across the dimensional and categorical approaches to temperament. However, the variable-centered and person-centered methods of studying temperament might be considered complementary to one another, not competing (Laursen & Hoff, 2006; Magnusson, 1998). Both approaches have utility in temperament research, are aimed at answering different research questions, and offer different methods of examining the data. The variable-oriented, dimensional approach might ask what the implications are of being high or low on a temperament characteristic for behavioral problems. For example, are high levels of anger reactivity related to aggressive behaviors? Research taking a person-oriented, typological approach, however, would consider the developmental outcomes of distinct subgroups of children with patterns of temperamental reactivity and regulation, such as how behaviorally inhibited children might develop anxiety disorders.

There are several ways in which personality and temperament types might be identified (Robins, John, & Caspi, 1998): (1) typologies based on extreme groups; (2) typologies based on a bimodal distribution; (3) bivariate or two-dimensional typologies where two independent dimensions are crossed to form four groups of individuals; and (4) a multivariate approach to creating groups. At least two of these methods have been used to create temperament types. Using the extreme groups approach, Kagan (1995) and others (Fox, Henderson, Rubin, Calkins, & Schmidt, 2001) identified behaviorally inhibited children and uninhibited children based on a number of characteristics that reflected their approach/withdrawal tendencies that fell into the top 10% and bottom 10% of these behaviors. Research from these labs has shown that the two temperament types are distinct behaviorally, physiologically, and physically. Behaviorally inhibited children, for example, are characterized by low verbal and emotional spontaneity with unfamiliar adults, long latency to relax in new situations, a reluctance to take risks, blue eyes, and a narrow face (Kagan, 1994). As we discuss later in this chapter, they have a distinct physiological profile. In addition, several studies have shown strong associations between extreme behavioral inhibition, particularly if it is stable across childhood, and later internalizing disorders. It is important to note that the groups used by these researchers were not exhaustive, and similar to the Thomas and Chess's (1977) creation of temperament types, several children were left unclassified.

A number of studies have employed a variety of multivariate approaches to derive temperament types. Using multivariate methods allows for the identification of types based on a configuration of a number of traits/dimensions. Cluster analysis is one such multivariate method and has been used to classify all children in a sample. For example, Caspi and Silva (1995) found five replicable types based on examiner ratings of several emotional, approach/withdrawal, and regulatory characteristics of 3-year-olds: well adjusted, inhibited, undercontrolled, confident, and reserved. Using coded behaviors of children observed during a number of laboratory tasks designed to elicit approach/withdrawal and emotional reactivity, Putnam and Stifter (2005) identified three temperament types in toddlers using cluster analysis: exuberant, inhibited, and low reactive. The exuberant type was high on approach and showed high levels of positive affect whereas the inhibited children showed the lowest levels of approach and the highest levels of negative affect. The low reactive type was so labeled as they showed lower levels of both positive and negative affect as well as moderate levels of approach. One of the goals of this study was to distinguish among low approach that was due to high levels of fear to novelty and low approach due to low interest in novelty.

Another multivariate method for identifying groups of children based on their temperament is to use a latent variable approach (e.g., latent class analysis, latent profile analysis) which classifies individuals based on probabilities of membership for each class. Using latent profile analysis based on variables coded from a risk-room procedure,

Dollar, (2011) identified three temperament types similar to those of Putnam and Stifter (2005): exuberant, inhibited, and average. Importantly, this replication was conducted with a slightly older preschool sample using a different statistical technique. In another study, Loken (2004) replicated the infant reactivity groups first identified by Kagan (1994) using latent class analysis. Latent variable analyses have also been used to identify longitudinal profiles. For example, stable high versus stable low profiles across infancy and early childhood emerged for behavioral inhibition (Chronis-Tuscano et al., 2009) and exuberance (Degnan et al., 2010). These longitudinal profiles have been successful in predicting later behavioral disorders.

Summary

Contemporary temperament research has viewed the structure of temperament as dimensional. The dimensions identified by the four most popular models of temperament converge somewhat and coalesce around three general domains: emotionality, activity level, and attention/regulatory behaviors. Higher-order factors or superfactors have emerged through factor analysis of these temperament dimensions demonstrating some distinct associations among temperament traits. A resurgence of the categorical approach to temperament has produced a number of temperament types. The inhibited/shy type and the exuberant/social type have emerged rather consistently from studies using varied methodologies and samples. Both the dimensional and categorical approaches to the structure of temperament have their advantages, which should be considered when investigating the link between temperament and developmental psychopathology.

TEMPERAMENT AND PERSONALITY

When discussing the definition or criteria for temperament, it is important to consider how temperament is related to personality. Personality in children of school and adolescent age has recently been studied, and the evidence suggests that children's personality is structured very similarly to adult personality. Although the approach to child temperament is considered bottom up in that Thomas and Chess (1977) interviewed parents about their children's enduring characteristics, contemporary temperament theorists have said that they were influenced by adult personality research at the time (Goldsmith et al., 1987). A number of scholars focused on understanding the distinction between temperament and personality, and several models have emerged (McCrae et al., 2000; Rothbart, Ahadi, et al., 2000; Shiner & Caspi, 2012); however, very little empirical study has been conducted to test the conceptual link between temperament and personality (De Pauw, Mervielde, & Van Leeuwen, 2009). As a result, the boundaries between what is temperament and what is personality still are fuzzy. In general, the term *personality* describes individual differences that are the product of early emerging constitutionally based temperament traits in interaction with the social and physical environment and development in cognitions, self-concept, and more complex emotions, such as guilt and pride. Thus, personality incorporates traits that may be the continuation of temperament traits, though labeled differently, as well as attitudes, values, and coping mechanisms, all of which are proposed to be influenced by temperament (Rothbart, 2011; Shiner & Caspi, 2012). Importantly, these characteristics may be specific to a particular time or place (McAdams & Pals, 2006).

Thus, the most direct link between temperament and personality is hypothesized to be through dispositions or traits: behaviors, thoughts, and emotions that are consistent across time and situation. In personality, these traits are referred most often as the Big Five and include Neuroticism, Extraversion, Agreeableness, Conscientiousness, and Openness to New Experiences (McCrae et al., 2000). These personality traits, which are composed of a number of lower-order dimensions, have been conceptually linked to both higher-order factors and lower-order temperament traits. Extraversion is similar to the higher-order factor of surgency, and both extraversion and surgency include components of approach and positive emotionality. Neuroticism, which reflects individual differences in anxiety, fearfulness, moodiness, and low frustration tolerance, overlaps with the temperament trait of negative emotionality. Conscientiousness, which reflects general self-control, is very similar to temperamental effortful control. The two remaining personality factors, agreeableness and openness to experience, do not have direct conceptual overlap with any temperament higher-order factor, but some of the characteristics of each of these personality factors can be found in lower-order temperament traits. For example, agreeableness, which reflects individual differences in the capacity to form and maintain positive relationships, is negatively related to anger reactivity and positively related to early attention (Caspi & Shiner, 2006).

Much of the recent research on the links between temperament and personality has been conducted with the goal of demonstrating that personality can be measured in children (Halverson et al., 2003; Shiner & Masten, 2008). Studies on the structure of child personality have found

personality in children to be structurally similarly to adult personality, increasing in similarity with age (Soto, John, Gosling, & Potter, 2011). Likewise, several studies have measured personality in children as young as preschool (e.g., Halverson et al., 2003) and suggest a significant overlap with temperament at the trait level of personality. Using principal components analysis on three temperament questionnaires and one personality instrument, De Pauw and colleagues (2009) recently demonstrated that many of the temperament dimensions factored with the personality items to produce a six-factor model distinguishing sociability, activity, conscientiousness, disagreeableness, emotionality, and sensitivity. Interestingly, these new factors were more differentially predictive of internalizing and externalizing problem behaviors than the individual temperament and personality measures.

Shiner and Caspi (2012) have argued that temperament traits develop into personality traits through four developmental processes that emerge at different times in childhood. Learning processes, which include positive and negative reinforcement, are proposed to begin early in life and be influenced by temperament traits. Likewise, environmental elicitation processes operate early in infancy and describe how the child's temperament elicits specific responses from others that may influence their behaviors over time. For example, infants who are high in positive emotionality elicit positive responses from parents, which may in turn affect their developing relationship. The third process, environmental construal, which is proposed to emerge after significant cognitive maturation, describes how temperament shapes the way children think about their environment and experiences. Fearful children, for instance, construe novel situations as stressful and overwhelming while fearless children interpret the same situation as exciting and stimulating. Environmental selection and manipulation, the fourth developmental process by which temperament traits influence personality, defines the ways in which temperament guides or shapes children's selection of which environments to engage. With age, children are given more opportunities to choose their environments, and it is proposed that temperament affects this choice. Thus, children who are more shy and withdrawn may be more cautious in their choice of friends.

In sum, strong arguments have been put forward that temperament and personality are linked. However, empirical evidence is still needed to clarify the processes by which temperament influences or "is" personality. Although some studies indicate that temperament develops into the traits of personality, there is little data on how child temperament influences the other aspects of personality, such as self-concept and attitudes. This information will be important toward understanding whether temperament influences the development of psychopathology through its relation to personality (Clark, 2005).

THE MEASUREMENT OF TEMPERAMENT

The measurement of any construct should follow closely the theoretical assumptions of that construct. As temperament is defined broadly as individual differences in the intensive and temporal parameters of emotion, activity, and attention/regulation, temperament researchers must be able to assess the subtle variations of child behavior, subtleties that cannot be reported by the children themselves. Consequently, the measurement of temperament has relied almost entirely on questionnaires aimed at parents' ratings of their children's behavior, particularly in infancy and childhood. Contemporary temperament researchers rarely interview parents about their children's behavior, but such interviews had a critical role in the development of questionnaires in use today (Thomas et al., 1968). Another method for assessing temperament is to observe children either in a natural situation, such as their home or school, or in a laboratory setting where target behaviors are elicited. Finally, with technological advances in electrophysiology, neural imaging, gene identification, and neuroendocrine assessment, researchers are now able to assess biological activity proposed by some theoretical models to underlie temperament. Next we describe each of these methods and discuss their advantages and disadvantages. We review the research on the neurobiology of temperament in a separate section later in this chapter.

Questionnaire-Based Assessments of Temperament

Likely because of the ease of their administration, a number of questionnaires have been developed, most of which are based on the four contemporary models of temperament. These instruments differ, quite obviously, on the dimensions they assess but also on several other factors, including: (1) the number of items comprising the dimension of interest, (2) the specificity of the behavior and its context, (3) the reference group (e.g., comparison to other children), and (4) attention to developmental period and changes across development. One of the earliest parent-report temperament instruments developed were those based on Thomas and Chess's (1977) New York Longitudinal Study including the Infant Temperament Questionnaire (Carey, 1970), the Behavioral Style

Questionnaire (McDevitt & Carey, 1978), and the Middle Childhood Questionnaire (Hegvik, McDevitt, & Carey, 1982). These questionnaires assess the nine dimensions proposed by Thomas and Chess as well as the broad factor of "difficultness." Although used quite extensively across a number of studies, these instruments have demonstrated marginally acceptable psychometrics (Rothbart, Chew, & Gartstein, 2001; Vaughn, Bradley, Joffe, Seifer, & Barglow, 1987).

Designed to assess temperament dimensions that are heritable, A. Buss and Plomin (1975) developed the EASI Questionnaire as well as the Colorado Childhood Temperament Inventory (Rowe & Plomin, 1977). Due to the low number of items (30–50), these measures have been popular with researchers interested in assessing temperament; however, many of the items are decontextualized (e.g., "child gets upset easily"), and the instruments do not take into account developmental changes in behaviors.

Perhaps the most thoughtfully constructed and researched set of questionnaires are those developed by Rothbart and colleagues. Based on their psychobiological approach, these questionnaires are tailored to ask specific questions about the child's behavior within different contexts. On the Infant Behavior Questionnaire–Revised (IBQ-R; Gartstein & Rothbart, 2003), caregivers are asked questions about the child's emotional and motor reactions to, for example, being bathed within the last 2 weeks. Importantly, Rothbart has designed questionnaires for each developmental level. Aside from the IBQ-R, caregiver reports on toddlers (Early Childhood Behavior Questionnaire; Putnam et al., 2006), preschool/school-age children (Child Behavior Questionnaire; Rothbart, Ahadi, et al., 2001), and a self-report instrument in adolescence (Early Adolescent Temperament Questionnaire; Capaldi & Rothbart, 1992) have been tested and found to have good to excellent reliability and validity (Putnam et al., 2001). Factor analysis of each questionnaire has produced surprisingly consistent superfactors of surgency, negative affectivity, and orienting/effortful control with interesting shifts of some of the dimensions from one factor to another with development (Putnam et al., 2001). These changes reflect a more mature, organized system that is less reactive and more self-regulatory over time.

The advantages of questionnaire measures are numerous and include the ease of administration, the low cost in terms of time and money, and the ability to tap into infrequent behaviors that are descriptive of a child's temperament. And because parents observe their infants across a number of contexts, parent reports also provide a fuller, more ecologically valid description of their child's behavior than other methods. Indeed, although some instruments do not consider context in their questions, we can assume, for example, that parents are able to judge the likelihood that their child will respond negatively to novel persons because they view them across many different settings.

Despite the advantages of temperament questionnaires, the accuracy of parent reports has been the topic of much debate (see Kagan & Fox, 2006; Rothbart & Bates, 2006). Parents may be biased in their view of their children, have differing interpretations of the questions posed, and have varying experience with other children for comparison purposes (Kagan, Snidman, McManis, Woodward, & Hardway, 2002). Studies on parental bias have convincingly demonstrated that many factors influence how parents rate their children's temperament, a fact that has led some researchers to advocate either disregarding parent report all together (Kagan, 1998; Seifer, Sameroff, Barrett, & Krafchuk, 1994) or using them in conjunction with other measures, such as laboratory observations (Rothbart & Bates, 2006; Stifter, Willoughby, & Towe-Goodman, 2008).

The question of validity of parent report is largely due to the small to insignificant association between parent ratings and laboratory observations of child temperament. Although several studies have reported significant correspondence, the correlations are in the weak to modest range (rs < .30). Moreover, a similar number of studies have reported no such association (Mangelsdorf, Schoppe, & Buur, 2000). These findings have prompted many researchers to examine the source of disparity between what parents observe and what is observed in the laboratory. As mothers are typically the parent who reports on the child's behavior, the preponderance of these studies have focused on the characteristics of the mother. For example, maternal depression (Leerkes & Crockenberg, 2003; McGrath, Records, & Rice, 2008), anxiety (Vaughn et al., 1987; Voegtline & Stifter, 2010), and personality (Bates & Bayles, 1984; Hayden, Durbin, Klein, & Olino, 2010) have been related to mothers' reports of their children's temperament. Such factors may alter parent perceptions of their children's behavior, thus impacting their ability to objectively report on their children's emotional reactions and regulatory behavior. Indeed, in some studies, maternal characteristics were more strongly related to the mother's ratings of the child than with observed child behavior (e.g., Sameroff, Seifer, & Elias, 1982).

Another reason for this disagreement between parents and observers is that the contexts in which they observe the child are vastly different. As noted, mothers have access to a variety of different settings while observers may see the child only in the laboratory or over a few hours in

the home. In an attempt to control the conditions under which parents and observers rate a child's temperament, researchers compared parent and observer ratings under the same conditions. Seifer and colleagues (1994) had both parents and observers rate infant reactions to the same tasks using the same rating system. The findings demonstrated that even after aggregating multiple observations, parents and observers did not agree. In a second study, Seifer (Seifer, Sameroff, Dickstein, Schiller, & Hayden, 2004) had mothers and observers rate the mother's own child and another child. Observers' and mothers' ratings of temperament showed strong convergence when rating another child but poor agreement when rating the mother's own child. Expanding on this methodology, Durbin and Wilson (2012) had mothers and naive observers rate children during the same tasks and compared both to objective coding of the behavior. Mothers and observers had weak agreement, and observers agreed with objective coding more than mothers. To explain this weak convergence, the researchers examined the effect of maternal mental health on mothers' ratings and found that mothers higher in depression and anxiety were more biased toward viewing their children more negatively than both naive observers and objective coders. Thus, even under conditions that are designed to maximize agreement, maternal characteristics operate to bias mothers' views of their children's temperament. Researchers should be aware of these biases when designing studies and consider using multiple informants and measures. We discuss this issue later in this chapter.

Observational Measures of Temperament

A second method by which researchers assess the temperament of young children is through observation, in a laboratory setting or the more naturalistic settings of the child's home, daycare, or school. Typically, child behavior is elicited through a series of tasks designed to provoke a temperament dimension. To illustrate, children's approach/withdrawal tendencies and their accompanying emotional responses might be assessed by having an unfamiliar person interact with children or putting children in uncertain situations, such as the "risk room" (K. Buss & Goldsmith, 2000; Rothbart & Goldsmith, 1985), which contains structures/objects that may be unusual or "threatening" (large black box, tunnel). Variations in children's behavior, such as proximity to the black box, willingness go through the tunnel, and the number of spontaneous vocalizations exhibited during the interaction with the unfamiliar person, are then coded, usually from a video recording.

There are many advantages to using observations to measure temperament. For one, observations that are conducted in the laboratory standardize the procedures, tasks, and setting across subjects, which cannot be expected from parent reports. That is, the contexts even with questionnaires such as the IBQ-R are not identical across families and thus introduce error into the assessment. A second advantage is that laboratory assessments target specific temperament behaviors that may not be as frequently observed by parents. Indeed, some parents may limit, for example, the number or type of novel situations their child is exposed to, which in turn can alter the expression of their fear reactivity. Laboratory measures, in contrast, may specifically create such situations to examine the range of reactions to novelty. A third advantage is that laboratory observations are usually recorded, which allows the researcher to examine the temporal and intensive qualities of behaviors that are related to temperament. Additionally, researchers can code different modalities of expression (facial, vocal) that may be less accessible to parents. It may be more difficult for a parent to recall the latency with which their children become facially and vocally angry, for example.

Despite the many advantages, observations are not the gold standard, as suggested by studies that examine the relationship between parent-rated questionnaires and laboratory measures. The lack of agreement might be due to problems in both measurement approaches or to differences in what is being measured by each approach (Goldsmith & Gagne, 2012). So, while data drawn from observations are less biased than that drawn from questionnaires, observational methods have their own issues. For one, observational measures do not capture temperament behaviors across a wide range of contexts. If we accept that temperament reflects cross-situational responses, then assessing behavior across more than one situation is essential. Observations provide a snapshot of children and thus may not be truly representative of their temperament. Second, the ecological validity of the laboratory setting is questionable. The unfamiliar laboratory and experimenters, no matter how friendly, can influence children's reactions to many of the tasks designed to evoke temperament, especially in more fearful, inhibited children. Unless one is interested in measuring behavioral inhibition, researchers must be aware of the degree to which the laboratory setting may affect behavior. Often researchers will have a warm-up period and allow children access to the parent at all times to alleviate this concern. A third disadvantage is the cost of conducting laboratory assessments of temperament, especially in terms of

time. Parents must travel to the lab, observations must be video-recorded, and behaviors must be coded before data are available for analysis. Even if researchers decide to code online, which is not standard practice, the time it takes to train coders to become reliable on these coding schemes is substantial.

Naturalistic observations are more ecologically valid, but they have similar disadvantages in that researchers are unfamiliar and the introduction of a person and/or camera in the setting may change aspects of the home or school. In addition, the setting is less controlled, which may affect the ability to administer standardized measures. Despite these disadvantages, observational measures of temperament have provided exceptional insights into the temporal and intensive features of individual differences in emotionality, activity, and regulation, particularly as it relates to behavioral adjustment.

Many studies have employed observations to assess temperament, particularly if children's temperament is the primary construct. Because of the time and effort required to collect and code observational data, temperament researchers usually focus on one or two temperament dimensions. Kagan (1994), Fox et al. (2001), and others have used observational measures to examine behavioral inhibition, while Stifter (Dollar, 2011); Putnam & Stifter, 2005; Stifter, Putnam, & Jahromi, 2008), and others (Degnan et al., 2010; Pfeifer, Goldsmith, Davidson, & Rickman, 2002) have used tasks to elicit exuberance. Observational measures have also been used to measure anger reactivity/frustration (Braungart-Reiker & Stifter, 1996; Calkins, Dedmon, Gill, Lomax, & Johnson, 2002) and positive affect (Aksan & Kochanska, 2004; Goldsmith & Campos, 1990; Kochanska, Aksan, Penney, & Doobay, 2007). Effortful control has also been observed in a laboratory setting and presents an interesting contrast to measures of approach/withdrawal, emotionality, and activity level. As effortful control overlaps with the construct of executive function (Zhou, Chen, & Main, 2012), its assessment involves standardized tasks, such as the delay of gratification task or the Day/Night Stroop (see Other Objective Measures of Temperament section).

In an effort to provide standardized behavioral tasks that tap a list of temperament dimensions, Goldsmith and colleagues created the Lab-TAB (K. Buss & Goldsmith, 2000; Goldsmith & Rothbart, 1996; Goldsmith et al., 1993; Kertes et al., 2009) for premotor (infants), locomotor (toddlers), and preschool children. Not only are tasks provided for each dimension, but coding schemes for the parameters of latency, duration, and intensity of the behaviors are included. As an example, for assessing anger reactivity in toddlers, the Lab-TAB offers several frustrating tasks, such as the gentle arm restraint, confinement to a car seat, and a toy behind a barrier, which can then be coded from video recordings for the latency, duration, and intensity with which toddlers display the facial, vocal, and bodily expressions of anger. As the Lab-TAB is developmentally sensitive, the preschool version assesses anger reactivity with different tasks but uses the same parameters of emotional reactivity. Other dimensions that can be assessed using the Lab-TAB include positive affect, fear, sadness, shyness, approach, activity, persistence, and inhibitory control.

Just as they have used questionnaires, researchers have been using observational measures to derive temperament dimensions or factors. Because of the difficulty and cost of conducting multidimensional longitudinal studies using observational methods, few studies have addressed the psychometrics of this approach. In one of the few existing studies examining the psychometrics of observed temperament measures, Durbin and colleagues (2007) examined positive and negative emotionality and their lower-order traits (e.g., sociability, interest, sadness, anger, fear) assessing behaviors from 12 tasks designed to elicit these traits at 3, 5, and 7 years of age. Results from this study indicated good to excellent stability as well as discriminant validity. Similar levels of short-term stability were reported in another study using Lab-TAB episodes to measure the dimensions of anger, fear, sadness, exuberance, and activity level (Majdandzić & van den Boom, 2007). Consistency across situations, as well as moderate convergence with parent ratings (both mother and father), was found for the observational measures. Using 12 episodes of the Lab-TAB during home visits, Gagne and colleagues (Gagne, Van Hulle, et al., 2011) created nine higher-level temperament composites mirroring those derived from questionnaire-based assessments. Cross-method convergence was found for most measures and parent-rated temperament, although postvisit ratings by observers were more closely related to the micro-coded measures. Predictive validity to a number of socioemotional outcomes has also been demonstrated by observational studies, many of which examined behavioral problems. These studies are reviewed later in this chapter.

An alternative to the more microanalytic observational approach is to have experimenters observe behaviors across a laboratory or home visit and then globally rate specific aspects of the child's temperament (Braungart, Plomin, DeFries, & Fulker, 1992; Matheny, 1983; Saudino, 2009; Voegtline & Stifter, 2010). The majority of these measures are based on the Infant Behavior Record/Behavior Rating

Scales, a behavioral assessment of the child while being administered the Bayley Scales of Motor and Mental Development (Bayley, 1969, 1993). Such items as social responsiveness, affect, activity level, irritability, reactivity, and task orientation are rated using a 9-point scale. Because these measures use global ratings and are based on behaviors across tasks and during transitions between tasks, they are proposed to mimic parent ratings of temperament (Stifter et al., 2008). However, in one study, when compared to parent ratings, only measures of positivity, not negativity, converged (Stifter et al., 2008). In another study that compared observers' ratings with parent ratings and coded behaviors, observer ratings converged more strongly with coded behaviors than did parent ratings of child temperament (Gagne, Van Hulle, et al., 2011). That observer ratings across the lab/home visits were correlated with microcoding of behavior suggests that this method might be substituted for the more time-consuming coding approach to observing temperament.

Although temperament observed in the laboratory/home and rated or coded by observers unrelated to the child may more closely reflect the true nature of the child than parent ratings, it does not necessarily present as the best alternative to parent ratings. Aside from being costly and limited in context and the types of behaviors that can be elicited, observational data may be influenced by other factors related to the raters/coders, such as experience with variations in child behavior and less sensitivity to the nuances of the temporal and intensive aspects of temperament. Training and inter-rater reliability calculated regularly can increase the accuracy of the ratings/coding systems. Likewise, reducing behaviors to observable parts that do not require significant judgment can also eliminate error. Researchers interested in observational studies should consider these limitations when designing studies on temperament and developmental psychopathology and when interpreting results from studies using this methodology.

Other Objective Measures of Temperament

The most objective measure of a temperament dimension is one that does not use individuals close to the children to rate their behavior or observers to code behavior elicited in the laboratory, home, or school. One temperament dimension amenable to such a method is activity level. Using actigraphs, a device designed to detect frequency and intensity of motion within the range of normal human movement, researchers have examined the heritability of activity level as well as its relation to hyperactivity–attention-deficit disorder (Ilott, Saudino, Wood, & Asherson, 2010). The only requirement for actigraphs is that the more actigraphs used (one per limb) and the longer they are used, the more reliable the data (A. Wood, Rijsdijk, Saudino, Asherson, & Kuntsi, 2008). In a study of twin toddlers, actigraphy was related to parent ratings and observations of activity level, but the degree of agreement was different, with parents being less accurate than observers (rs = .25 versus .67), even when assessments were done within the same context (Saudino, 2009). In addition, the overlap in genetic effects between parent and mechanical measures of activity level was modest compared to the robust shared genetic effect between observers and the actigraph data.

With advances in technology, automated methods have been developed and applied to facial expressions of emotion, which are central to the emotionality component of temperament. Using computer vision software that codes the action units of facial expressions of emotion automatically (Cohn & Kanade, 2007), researchers have successfully coded dynamic expressions of emotion in adults. More recently, automated facial coding has been applied to infants during a mother-infant interaction, and the data demonstrated concurrent validity with a manual anatomically based facial coding system and construct validity with naive raters (Messinger, Mahoor, Chow, & Cohn, 2009). Importantly, these systems can measure the intensive quality of a facial expression of emotion (Messinger, Mattson, Mahoor, & Cohn, 2012), a temperament parameter identified in several temperament models (e.g., Rothbart's [Rothbart, Ahadi, et al., 2001] high- and low-intensity pleasure dimensions and Thomas and Chess's, 1977, intensity of mood dimension).

Finally, standardized tests can also be used to tap certain temperament dimensions, specifically inhibitory control and the superfactor effortful control. Although this method involves an experimenter, the standardized administration and scoring (e.g., number correct; errors of commission/omission) decreases the subjectivity that is found in both parent ratings and observations. Standardized tests from other research domains, specifically the area of executive function, have been used by temperament researchers to measure effortful control. This is because the concept of effortful control overlaps significantly with several core components of executive function (Zhou et al., 2012). Effortful control is defined by Rothbart and Bates (2006) as the ability to inhibit a dominant response in favor of a subdominant response, to plan, and to detect errors. Executive function, like temperament, is an umbrella term that describes top-down goal-directed processes that

operate to control attention, cognition, and behavior (Blair et al., 2005). Thus, both effortful control and executive function describe voluntary control in the face of challenging or competing demands. Unlike most measures of temperament, developmental researchers interested in executive function have developed a battery of tests that have been accepted by the research community as reliable and valid measures of these cognitive processes. Consequently, temperament researchers have adopted these measures, including the Day/Night Stroop, Go/No Go, and the Delay of Gratification task, to measure effortful control (Cipriano & Stifter, 2010; Kochanska & Knaack, 2003; Kochanska, Murray, & Harlan, 2000).

Multimethod Approach to Measuring Temperament

As can be seen from the previous discussion, the two most utilized methods of assessing temperament, parent ratings obtained by questionnaires and laboratory/home observational measures, have their advantages and disadvantages. Although parent ratings are easy to administer, cost less, and provide an assessment of children's temperamental disposition across a wide range of contexts, studies suggest that parents are biased in their assessments, and researchers should be cautious about these biases when using parent reports of temperament in their studies. This advice is well heeded by researchers who are interested in the association between child temperament and problem behaviors since many studies rely on parent report of behavior problems as well.

Despite this caveat, temperament questionnaires can be useful, depending on the focus of the study. If one is interested in mother-child interactions, how a mother views her child may be important toward understanding how she interacts with him or her. In a study of preterm infants (Voegtline & Stifter, 2010), mothers who were anxious rated their preterm infants as more negatively reactive than mothers of full-term infants, even though these infants were not observed to be more negative during home observations. Knowing this bias may improve our understanding of how the transactions between mothers and their preterm infants may lead to poorer socioemotional outcomes. If due to time and money constraints researchers need to employ parent ratings of children's temperaments, it is advised that they obtain information from multiple sources, such as daycare providers/teachers, as they may be less biased and base their ratings on child behavior in different contexts than parents might (Bishop, Spence, & McDonald, 2003; Goldsmith, Rieser-Danner, & Briggs, 1991). In addition, using questionnaires that ask about specific behaviors within a reasonable time frame that are tied to a context and do not require parents to compare their child to other children of the same developmental age are highly recommended. Rothbart's infant, toddler, childhood and adolescent questionnaires attempt to reduce parent bias through these means (Putnam et al., 2001).

Likewise, the decision to use observational measures should be driven by the theoretical approach and the questions researchers are attempting to address. Although costly, observation of children's reactions in tasks designed to elicit the behaviors of interest are likely to be more accurate than asking parents about specific parameters of behavior that characterize the temperament trait and to recall those situations that elicited these reactions. Observational measures have been criticized for the lack of validity (Rothbart & Bates, 2006); however, more recent reports indicate that observations of behaviors reflecting temperament dimensions, particularly if they aggregate across a number of tasks, are indeed valid (Goldsmith & Gagne, 2012).

Ideally, research in temperament should consider multiple methods for assessing this construct. As Rothbart and Bates (2006) suggested, these measures represent components of variance in child temperament; each method contributes to a shared (parents and observers agree) and individual (that which is unique to the method) assessment of the child (Rowe & Kandel, 1997). A recent study on the quantitative genetics of temperament, specifically activity level, supports this conceptualization. Saudino (2009) found only modest overlap for the genetic effects of activity level measured mechanically and by parent report in the same situation. These findings suggest that different measures may be engaging different processes.

Following this call for multiple methods, a handful of studies have combined laboratory/home observations and parent report of child temperament. Using principal components analysis, studies examining behavioral inhibition (Kertes et al., 2009) and social withdrawal (Kiel & Buss, 2011) have combined laboratory observations with questionnaire data. In one case, parent ratings, observer ratings, and coded behavior during parent-child interaction were combined to assess task persistence; the resulting composite measure correlated well with age, cognitive performance and behavior problems (Deater-Deckard, Petrill, Thompson, & DeThorne, 2005). Most studies have combined parent and child report (Lengua, 2006) and mother and father ratings (e.g., Leve, Kim, & Pears, 2005). Even home and laboratory observations (Dougherty, Klein, Durbin, Hayden, & Olino, 2010) have been combined

to measure temperament. The availability of statistical techniques amenable to quantifying shared and independent variance across methods, such as structural equation modeling, should allow for a more reliable measure of child temperament and thus more confidence in understanding the role of temperament in adaptive and maladaptive behavior.

Summary

A number of methods for assessing child temperament exist. The most widely used and affordable method is parent ratings of child temperament. Due to reporter bias, however, findings based on parent report alone should be interpreted with caution. Although observational methods avoid reporter bias, they also have their limitations. Automated measures and standardized tests appear to avoid many of the pitfalls of both parent ratings and observations of temperament, but they do not assess every temperament dimension. Perhaps with the advancement in digital and mobile technologies, innovations in the measurement of temperament will emerge. For now, researchers, guided by their research questions, should carefully weigh the advantages and disadvantages of each method and consider utilizing multiple measures of temperament. It is also important for researchers to keep in mind that these measures are tapping into different components of child temperament and are not interchangeable, as each method may be assessing different processes (Saudino & Wang, 2012).

TEMPERAMENT AND DEVELOPMENTAL PSYCHOPATHOLOGY

There is a long tradition linking temperament to psychopathology. Galen, in adopting the ancient Greek and Roman belief in the four humors (blood, yellow bile, black bile, phlegm), proposed that an imbalance of humors led to the temperaments of the sanguine, choleric, melancholic, and phlegmatic types. The idea that temperament influenced one's vulnerability to develop emotional and behavioral disorders carried through to the nineteenth-century psychoanalytic theories of Freud and Jung (Kagan, 1994). Importantly, contemporary models of temperament were instigated by a search for how child characteristics affected the development of child behavior problems. The primary aim of Thomas and Chess (1977) was to understand how the children they saw in their clinical practice with similar behavior problems came from both dysfunctional and "good" families prompting them to consider the child's contribution to his or her development of these problems.

Many scholars have hypothesized the means through which temperament and psychopathology are linked. Rothbart, Posner, and Hershey (1995), in the first edition of *Developmental Psychopathology* (Cicchetti & Cohen, 1995), proposed several ways in which temperament might contribute to psychopathology, developmentally and with regard to treatment. Here we review seven of the hypothetical pathways from temperament that would most affect the development of behavioral/mental disorders in children.

1. Extremes in temperament may constitute a behavioral problem, such as extreme shyness or attention deficits.
2. Relatedly, extremes in temperament may predispose a child to develop a related disorder, such as when a highly fearful child develops general anxiety disorder or when the lack of attention regulation leads to conduct disorder (CD).
3. Temperament may affect others to act in ways that put the child at risk for developing problem behaviors. High levels of infant irritability, for example, may frustrate a vulnerable parent, who in turn may treat a child harshly, leading to the development of conduct problems.
4. Another pathway may be through self-regulation, such that deficits in self-regulation would allow the expression of a temperamental extreme, as in the case of an easily frustrated child who develops ODD.
5. Alternatively, overregulation of attention or behavior may lead to clinical levels of inhibition or anxiety.
6. A temperamental characteristic may heighten a child's response to a given event, for example, when a child's high negativity heightens his or her stress levels, leading to depression.
7. Another possible pathway is that a certain temperamental disposition may protect a child from developing psychopathology, such as when some level of fear protects against CD or when positive affect protects against trauma.

Thus, there are a variety of ways in which temperament contributes to developmental psychopathology, and recent research in this area supports many of these pathways.

The means through which temperament influences the development of psychopathology proposed by Rothbart and colleagues (Rothbart & Posner, 2006; Rothbart et al., 1995) are aligned with the models linking adult personality to psychopathology (Krueger & Tackett, 2003), which were recently applied to the developmental

literature (Tackett, 2006). These include the scar model, the pathoplasty/exacerbation model, the spectrum model, and the vulnerability/predisposition model. The scar model proposes that the development of psychopathology changes the individual's personality such that multiple occurrences of depression can increase neuroticism. According to the pathoplasty/exacerbation model, personality will affect the course, severity, and presentation of a disorder. In a review of research linking child personality to developmental psychopathology, Tackett (2006) concluded that empirical tests of these two models are rare, likely due to the methodological challenges of measuring personality before the emergence of a disorder and continuing to measure personality and psychopathology longitudinally. The remaining two models, however, have been supported by recent studies examining child temperament/personality and psychopathology.

The spectrum model hypothesizes that personality traits and characteristics of psychopathology lie on a continuum, thus sharing a similar etiology. For example, attention-deficit/hyperactivity disorder (ADHD) may lie on the extreme end of inhibitory control/impulsivity. This model maps onto the first two pathways proposed by Rothbart (Rothbart et al., 1995) just reviewed. Studies that have investigated the spectrum model have found shared genetic links between such temperament traits as negative emotionality and effortful control with externalizing problems and CD (Tackett, Martel, & Kushner, 2012). The spectrum perspective is similar to that of Clark (2005), who proposed that the temperamental dimensions of negative affectivity, positive affectivity, and disinhibition are the shared factors that underlie the link between personality and psychopathology. This hierarchical model hypothesizes that these temperament dimensions differentiate through biological and environmental developmental processes into personality traits and that, at their extremes, they put the individual at risk for psychopathology. Clark's conceptualization of the link between temperament and psychopathology also aligns with the precursor model, a more specific spectrum model, which assumes a developmental sequence in that temperament is evidenced before the onset of a disorder. The temperament trait of negative emotionality, for example, would be an early manifestation of internalizing disorder (Klein, Kotov, & Bufferd, 2011).

The vulnerability/predisposition model incorporates many of the proposed temperament-developmental psychopathology links of Rothbart (Rothbart et al., 1995). In this model, certain personality traits are proposed to place an individual at greater risk for developing certain clinical disorders, such as when impulsivity, a characteristic of low conscientiousness (and temperamental surgency), is related to antisocial behaviors. This model assumes a distinction between temperament/personality and psychopathological disorders and includes the potential for the interaction between temperament/personality and environmental factors to increase risk for psychopathology. The vulnerability model is analogous to the diathesis-stress model discussed earlier. One of the challenges in testing the vulnerability model is that the measures of temperament, personality, and psychopathology overlap. We consider this issue later in this section.

Internalizing and Externalizing Problem Behaviors

The most prevalent outcomes examined by research on the link between temperament and developmental psychopathology are the broad dimensions of externalizing and internalizing problem behaviors. Based on Achenbach's (Achenbach, Edelbrock, & Howell, 1987) conceptualization and empirical work assessing childhood behavioral problems, externalizing and internalizing problem behaviors form a hierarchical model that accounts for the systematic covariation among behavioral and emotional symptoms commonly observed in childhood. Externalizing behaviors, so called because they represent outward behaviors that are uncontrolled, include aggressive and rule-breaking behaviors (Achenbach & Edelbrock, 1978). Several subscales of the externalizing dimension can be derived from the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983), one of the most commonly used instruments assessing childhood behavior problems. Importantly, the CBCL overlaps with constructs defined in the *Diagnostic and Statistical Manual of Mental Disorders* (Tackett, 2006). ODD is characterized by negativistic, noncompliant, and argumentative behavior and is considered an earlier and less intense form of CD. CD is primarily characterized by rule violations, such as aggression, destruction of property, and theft. The third subscale, ADHD, is not included in Achenbach's externalizing broad band but can be derived from items measuring inattention, impulsivity, and hyperactivity.

Internalizing behaviors are those that are directed inward and subsume the disorders of anxiety and mood (depression). These problem behaviors are less studied in early childhood due to the inability of children to report on their internal states and the reliance on parent or teacher observations of behaviors reflecting anxiety and depression (Achenbach, McConaughy, & Howell, 1987; Edelbrock, Costello, Dulcan, Conover, & Kala, 1986; Kolko & Kazdin, 1993). Several studies have examined

internalizing behaviors in children younger than 5 years, but there is some question as to whether they constitute problematic behavior or just more extreme temperamental distress or inhibition (Goldsmith & Lemery, 2000). In addition, the reliance on parent report also raises questions as to parents' interpretation of child behavior, particularly given what is known about the accuracy of parent report. However, by middle childhood, self-reports of internalizing problems are relatively valid and reliable (Ebesutani, Bernstein, Chorpita, & Weisz, 2011; J. Goodman, Meltzer, & Bailey, 1998) but should be considered along with other informants' observations (Achenbach, 2006). Symptoms of anxiety include excessive worry and irritability whereas depressive symptoms can include sad mood, loss of interest, and sleep and eating disturbances.

Perhaps because of their disruptive nature, externalizing behaviors are reported more often and earlier than internalizing behaviors. Research indicates that children as young as 3 years of age are at high risk of developing clinical levels of externalizing disorders if a constellation of noncompliance, overactivity, poor regulation, and aggression occurs frequently beyond the age-appropriate period, increases in intensity, and cuts across several contexts and domains. Moreover, children who exhibit externalizing behaviors early and persistently are more likely to develop antisocial behaviors in adolescence and adulthood (Odgers et al., 2008). A six-site, cross-national study of physical aggression in childhood, for example, demonstrated that boys with developmental trajectories of consistently high levels of physical aggression were associated with both violent and nonviolent delinquency in adolescence (Broidy et al., 2003). It is important to note that those behaviors that put the child at risk for the development of externalizing behaviors (e.g., overactivity, poor regulation) are temperament traits which is consistent with the spectrum model of developmental psychopathology that proposes extremes in temperament to be pathological.

The developmental trajectories for internalizing disorders mirror that of externalizing disorders in children, although they are more transient. Children who exhibit high and increasing levels of internalizing behaviors are more likely to be anxious later in childhood or adolescence (Feng, Shaw, & Silk, 2008; Ollendick & King, 1994). Likewise, adolescent anxiety or depression is a risk factor for the same difficulties in early and even late adulthood (Coleman, Wadsworth, Croudace, & Jones, 2007; Glied & Pine, 2002; Pine, Cohen, Gurley, Brook, & Ma, 1998), particularly if it is persistent in adolescence. One source of internalizing disorders is the presence and rapid increase in externalizing problems. Externalizing and internalizing disorders co-occur at greater than chance levels (Angold, Costello, & Erkanli, 1999). When examining the developmental trajectories of both externalizing and internalizing behaviors across development, the data suggest that externalizing disorders may lead to increased internalizing problems in early childhood (Gilliom & Shaw, 2004) and anxiety and/or depression in adolescence (Copeland, Shanahan, Costello, & Angold, 2009; Loeber & Burke, 2011). Some have argued that this progression from externalizing to internalizing problems may be the result of the accumulation of negative interactions arising out of the child's dysregulation that makes him or her vulnerable to anxiety or depression (Wolff & Ollendick, 2006).

Many of the studies investigating the developmental emergence and course of externalizing and internalizing problem behaviors have considered child, parent, and demographic markers of risk. Child temperament has been identified as one of those factors. However, a problem unique to the examination of the link between temperament and developmental psychopathology is the method used to assess both constructs: parent ratings. Not only are both assessments based on the same reporter, but the instruments may be confounded.

Measurement Confounding

Identified as a significant issue in research on personality and psychopathology, the confounding of measures of temperament and symptoms of psychopathology in children takes on more methodological importance because of the reliance on parent report. As with child temperament measures, the assessment of problem behaviors in children, such as the broad bands of externalizing and internalizing disorders and the more specific subtypes of ODD, CD, ADHD, anxiety, and depression, is typically accomplished through parent ratings of the child's behavior. Consequently, many of the studies examining the link between child temperament and developmental psychopathology utilize the same informant, typically the mother, which can artificially inflate the relationship between the two constructs. To address this issue, the removal of overlapping items has been recommended, but this may decrease the validity and reliability of the measures.

Lengua, West, and Sandler (1998) proposed two reasons for this overlap in measures, one theoretical and the other methodological. The spectrum model of the temperament-psychopathology association discussed earlier reflects the potential for similarity in items measuring temperament and symptoms of developmental psychopathological disorders. As many of the externalizing

and internalizing disorders constitute emotional and behavioral reactivity at the extreme, overlap among measures might be expected. The dispositional/vulnerability model proposes that temperament and behavior problems are distinct but related; thus, any overlap in measures would be an issue for testing this model as well (Lemery, Essex, & Smider, 2002). In addition, overlap might be expected because the development of each temperament and problem behavior measure was done independently without consideration of the items tapping the other construct. Consideration of overlap in items would increase discriminant validity (Lengua et al., 1998).

At least three studies have directly examined the measurement confounding issue using similar techniques (Lemery et al., 2002; Lengua et al., 1998; Sanson, Prior, & Kyrios, 1990). Using both expert ratings and factor analysis, several items in the temperament measures and symptomology measures were confounded. In one study, 38% of the symptom items and 10% of the temperament items were rated by experts as confounded; factor analysis of caregiver reports revealed overlap in 23% of symptoms and up to 14% of temperament items (Lemery et al., 2002). After eliminating confounding items, each of these studies reanalyzed the correlation between the "purified" measures of temperament and symptoms and found reduced but still significant association, even when tested longitudinally (Lemery et al., 2002).

Taken together, the findings from these studies (Lengua et al., 1998; Lemery et al., 2003; Sanson et al., 1990) suggest that the overlap in items measuring temperament and behavioral problems does not affect their relationship. Many of the studies to be reviewed utilized parent reports of both child temperament and problem behaviors, concurrently and longitudinally. However, although simple correlations indicate some association, as predicted, the results should continue to be viewed with caution as the reporter of temperament and symptomology is typically the same, usually the mother. Current research has, and future research should, continue to consider multiple informants as well as observational measures.

TEMPERAMENT AND PSYCHOPATHOLOGY: REVIEW OF THE RESEARCH LITERATURE

In this section, we discuss research that has addressed the link between various temperament traits and styles and the development of behavior problems and early psychopathology. Most research considering the association between temperament and different forms or precursors of psychopathology has measured direct, linear effects. In such studies, the research questions address how a single temperament trait contributes to the development of behavior problems or psychopathology. Additive effects are also possible in which multiple temperament traits linearly increase the child's risk of developing a problem behavior, such as when fearfulness or negative emotionality predict children's internalizing behavior problems (Gilliom & Shaw, 2004)

There are also indirect processes by which temperament is associated with psychopathology. We discuss two forms of these indirect pathways: mediation and moderation. Research on mediated associations largely has focused on the manner in which temperament affects a child's interactions with the environment, which, in turn, shape the child's development of psychopathology. For example, Eisenberg and colleagues (Eisenberg, Zhou, et al., 2005) found support for the role of effortful control in mediating the relation between parental warmth/positive affect and children's later externalizing behavior problems. The second indirect process widely used in temperament studies involves investigating the conditions by which certain temperament traits are associated with behavior problems and psychopathology; specifically, these investigations consider moderating factors on the relation between temperament traits/styles and psychopathology. There are two central types of moderation that we consider in this review due to their large presence and influence: temperament × environment interactions and temperament × temperament interactions. It should be noted that studies on temperament × environment interactions hypothesize the moderating effects differently; some research investigates the moderating effects of the environment (i.e., parenting behaviors) and others measure the moderating effects of temperament. Although these views are complementary, we largely focus on studies investigating the moderating role of the environment on the relation between temperament and developmental psychopathology.

It is important to note two fundamental issues when reviewing the research literature linking temperament to psychopathology. First, as previously discussed, it is critical to keep in mind that there is potential confounding of measurements of temperament and behavior problems in much of the existing literature (Lemery et al., 2002; Lengua et al., 1998). This is especially true with research solely using parental reports of children's temperament and behavior problems. Thus, it is essential to take into account that the association between temperament and behavior problems may be overly inflated in some existing research. Another point to consider is the difficulty

determining the direction of influence in a large majority of this research. More recent temperament studies have used statistical and methodological techniques to provide information regarding the direction of effects from temperament to psychopathology; however, this point warrants attention when reviewing the literature. Finally, it is critical that the reader consider the sample employed within each study. Overall, most research is best generalized to community-based samples rather than clinically referred populations since most studies include only a few children who meet the cutoffs for clinically significant behavior problems. Indeed, the reader should keep in mind that the number of investigations focused on clinically significant levels of psychopathology in children is quite small in most of the research reviewed. With that said, the basis of a developmental psychopathology perspective is to consider both normal and abnormal, adaptive and maladaptive developmental processes (Cicchetti, 1984, 1990, 1993; Cicchetti & Toth, 2009; Rutter, 1986; Sroufe, 1990), and, thus, the examination of the role of temperament in the development of psychopathology in both normative and at-risk populations is important.

We organized our review of the research on the links between temperament traits/styles and the development of behavior problems and early psychopathology around the three broad temperament factors of negative emotionality, surgency, and effortful control (Rothbart & Bates, 2006). Within those broad categories, we also included research examining temperament types, specifically the exuberant and behavioral inhibited temperamental types, which have been extensively researched in the last 20 years. We also organized the review to include studies that focus on the specific temperament traits included in the superfactors that have also been theoretically and empirically related to developmental psychopathology. Thus, after reviewing the research on negative emotionality, we review the research on fear reactivity and anger reactivity. Likewise, we review the temperament traits of positive emotionality and activity level after reviewing the surgency research literature. Within each section, we first provide a broad description of the temperament factor/trait and then review the literature outlining direct linkages between the temperament trait and behavior problems/psychopathology. Next, we review relevant studies examining temperament × environment interactions in predicting behavior problems/psychopathology. Each section concludes with a summary and brief discussion of future directions. We end with an overview of temperament × temperament interactions that have been the topic of some of the most recent research in this area.

Negative Emotionality

Negative emotionality is a temperament factor that includes the emotions of frustration/anger, fear, anticipatory anxiety, sadness, guilt, and discomfort. Children high in negative emotionality are prone to cry, fuss, and show more negative emotions overall, as well as display more intense emotional reactions in a variety of situations (Rothbart & Bates, 2006). Historically, research has linked temperamental negative emotionality to various aspects of later development, including psychopathology (Rothbart & Bates, 2006). Indeed, this temperament factor has been shown repeatedly as an important predictor of both externalizing and internalizing behaviors across development, beginning in infancy (Bates, Bayles, Bennett, Ridge, & Brown, 1991; Eisenberg, Sadovsky, et al., 2005; Hagekull, 1994; McClowry et al., 1994; Rothbart, 2011; Rothbart & Bates, 2006). Although the direct relations between negative emotionality in the first years of life and internalizing and externalizing behaviors are modest, replication of these findings across various studies provides support that these are reliable associations.

Garstein Gartstein, Putnam, and Rothbart)2012) found that children's externalizing problems in preschool were predicted by high negative emotionality in infancy, toddlerhood, and preschool, providing evidence for the influential role of negative emotionality across early development. Indication of the importance of negative emotionality across early childhood in predicting internalizing behavior problems has also been provided. In the Uppsala Longitudinal Study, for example, parent-reported negative emotionality when the children were 10 to 15 months old predicted children's self-reports of internalizing and externalizing behaviors when they were 4 and 8 to 9 years old (Bohlin & Hagekull, 2009). Although negative emotionality predicted both internalizing and externalizing behaviors in this study, there was a much stronger relationship between negative emotionality and internalizing behaviors. Of note, negative emotionality was not a significant direct predictor of anxiety or depression when these individuals were 21 years old, although there were other direct and indirect temperament effects.

In addition, some research has examined negative emotionality as it relates to trajectories of behavior problems. This line of research is based on evidence that early behavioral and emotional difficulties often precede psychopathology later in development (e.g., Caspi, Moffitt, Newman, & Silva, 1998; Hofstra, Van der Ende, & Verhulst, 2002; Mesman & Koot, 2001) and are critical for our understanding of the stability, growth, and continuity

of behavior problems across development. Gilliom and Shaw (2004) found in a study of disadvantaged boys that children's expression of negative emotionality predicted their levels of externalizing behaviors at the first time point (2 years of age), but it was not associated with children's changes in externalizing behaviors from age 2 to age 6. Importantly, this study employed multiple methods of observed and maternal report of children's negative emotionality, maternal report of behavior problems at age 2, and maternal and teacher report of behavior problems at age 6, which, as previously discussed, adds to the validity of this study. Findings from this study suggest that children's negative emotionality may contribute to the onset of their early externalizing behaviors but perhaps not its continuity.

Even though there has been extensive research outlining the association between negative emotionality and later psychopathology, more recent research has acknowledged the importance of examining the specific negative emotions of anger, sadness, and fear that are commonly combined in measures of negative emotionality. Indeed, researchers have pointed to the differential roles of these specific negative emotions in children's developmental trajectories toward behavior problems and later psychopathology; thus, the importance of these specific negative emotions will be reviewed.

In addition to studies investigating the direct association between negative emotionality and psychopathology, researchers have also considered the interaction between negative emotionality and aspects of the child's environment in predicting children's development of behavior problems. Within this literature, there is a strong emphasis on parental personality and parenting behaviors as the measure of "environment." For example, mother's internalizing affect moderated the relation between toddler's negative emotionality and depression concurrently, such that children high in negative emotionality who had mothers with higher levels of internalizing symptoms were rated as showing greater depressive symptoms than highly negative children whose mothers were not high on internalizing symptoms. Interestingly, this association was not found for children's anxiety (Marakovitz, Wagmiller, Mian, Briggs-Gowan, & Carter, 2011). Research has also indicated moderating effects on the relation between negative emotionality and externalizing behavior problems. Infant males high in negative emotionality, according to both parent report and laboratory observations, were more likely than boys low in negative emotionality to be rated as high in externalizing behaviors at age 3 if their parents also showed high intrusiveness and negative affect (Belsky, Hsieh, & Crnic, 1998). Importantly, results from this study incorporated both parent report and laboratory observations of children's negative emotionality. Additional research examining this topic area has been conducted with a similar, yet distinct, temperament construct, difficultness, which is reviewed in the next subsection.

Examination of trajectories of externalizing behaviors, not just measures of externalizing behaviors at one point in time, has provided support for the interaction between negative emotionality and parenting in predicting behavior problems, as well. Owens and Shaw (2003) reported that children low in negative emotionality at 18 months of age with mothers high in depression had a faster decline in externalizing behaviors from age 2 to age 6 than children high in negative emotionality. This finding suggests that low negative emotionality could be a protective factor when children are at risk for developing externalizing behaviors due to their mothers' high depressive symptoms. Also of interest, results from this study showed that when mothers were low in depressive symptoms, the opposite finding was revealed. Children high in negative emotionality who had mothers low in depressive symptoms showed greater improvement in externalizing behavior over time so that by the time the children were 6 years old, highly negative children were comparable in externalizing behaviors to children low in negative emotionality. Drawing from the same study but examining different maternal behaviors, Gilliom and Shaw (2004) showed that the combination of negative emotionality, fearlessness, and negative maternal control was related to a high, nondecreasing trajectory of externalizing behaviors from age 2 to age 6.

In general, this literature supports the widespread perspective that environmental risk, such as negative parenting behaviors, exacerbates the potentially deleterious effects of negative emotionality in the development of behavior problems (Bates & Pettit, 2007). However, the potentially maladaptive outcomes that are associated with negative emotionality can be tempered by positive, supportive, and warm parenting behaviors. It is noteworthy that a recent meta-analysis (Paulussen-Hoogeboom, Stams, Hermanns, & Peetsma, 2007) suggested that the relations between negative emotionality and parenting characteristics/behaviors in predicting children's behavior problems are dependent on other factors, such as context (high-risk and low-risk samples) and the methodology employed in the study (e.g., micro- or macro-level approaches, modeling trajectories of behavior) and thus should be considered in future research. Further, as argued previously, the measurement employed in studies of temperament should be taken into

account. Specifically related to the negative emotionality × parenting literature, Paulussen-Hoogeboom and colleagues (2007) found in their meta-analysis that forms of negative parenting behaviors were associated with children's negative emotionality only when parental reports were employed. This finding again highlights the importance of multiple methods and informants, such as using observational measures in conjunction with parent reports of child behavior.

"Difficult" Temperament

Temperamental "difficulty" is a construct that is closely related to negative emotionality. As previously discussed, Thomas and Chess (1977; Thomas et al., 1968) identified a group of children, labeled "difficult," who were defined as high in withdrawal, negative mood, unadaptable to change, intense, and irregular (Thomas, Chess, Birch, Hertzig, & Korn, 1963). Historically, difficultness has received considerable attention by researchers interested in the relationship between temperament and maladaptive developmental outcomes, and the results support this association concurrently and longitudinally (e.g., Bates et al., 1991; Keenan, Shaw, Delliquadri, Giovannelli, & Walsh, 1998). However, this construct has been widely criticized (e.g., Plomin, 1982; Rothbart, 1982) and more recently put aside in temperament research in favor of more reliable measures of negative emotionality or more discrete temperament traits. One central issue with the use of the "difficult" label is that it identifies children as a problem early in life. The ramifications of attaching this negative characterization on children so early may cause unnecessary issues for them. For example, parental expectations that a child is difficult may influence their behavior toward the child, thereby worsening the child's behavior while reinforcing parental perceptions. This label may also influence the child's developmental trajectories in many ways, such that the difficult label may restrict the contexts the child is exposed to, thereby potentially affecting his or her experiences and opportunities. Further, the difficult label may also be inaccurate, as "difficult" behavior may cause problems in some contexts but be beneficial in others. Yet such behavior is less likely to be viewed as beneficial because of the negative connotation associated with the term *difficult*. Another issue with the use of the "difficult" label to describe child temperament is the inconsistencies in its operationalizations. In particular, there have been problems replicating the difficult temperament cluster, which has led to various forms of this construct. For example, algorithm-based perspectives (Fullard, McDevitt, & Carey, 1984; McDevitt & Carey, 1978) include rhythmicity, whereas Bates (1980, 1989) does not include rhythmicity and instead argues that the central aspect of temperamental difficulty is negative emotionality (Rothbart, 2004). Because of this issue, comparisons across studies can be problematic, and caution should be used when interpreting results from studies that examine "difficult" temperament since studies may be tapping into different aspects of a child's temperament (Rothbart, 2012).

Although there are issues with the use of the difficult temperament construct, a wide body of literature has examined its relationship with problem behavior. Because of this fact, we provide a brief review of some prominent studies that have measured a form of "difficult" temperament as well as more recent studies that have incorporated the differential susceptibility perspective using this construct. As mentioned, children labeled "difficult" are more likely to develop a variety of maladaptive developmental outcomes. For example, temperamental difficultness, measured by the Infant Characteristics Questionnaire as frequent and intense negative affect and attention demanding, has been shown repeatedly to predict children's later internalizing and externalizing behaviors (Bates, Maslin, & Frankel, 1985; Bates et al., 1991). Indeed, difficult temperament, as rated by the mother when the infant was 6 months of age, was predictive of conduct problems at age 3 (Bates et al., 1985), and a similar relation was found for report of children's externalizing behaviors at ages 7 to 8 (Bates et al., 1991). Further, infants rated as difficult and fussy at 6 months were rated as showing high levels of hyperactivity and aggression at age 17 (Olson, Bates, Sandy, & Lanthier, 2000). Other studies have found that temperamental difficultness, as measured by the Infant Characteristics Questionnaire, was predominantly associated with internalizing behavior problems, not externalizing behaviors (e.g., Keenan et al., 1998). As mentioned, many of these studies should be interpreted with caution, not only because they examined difficult temperament but also because both temperamental difficultness and behavior problems were both measured via maternal report.

Similar to the negative emotionality × environment interactions, many studies have examined the interactive effects of difficult temperament and parenting and have shown that children with difficult temperaments are much more likely to develop behavior problems when their parents behave in a punitive, negative manner (Bates & Pettit, 2007; Kochanska & Kim, 2013; Rothbart & Bates, 2006). Recently the model of differential susceptibility has been utilized to provide greater understanding of the relation between difficult temperament and parenting in

predicting children's developmental outcomes. Several studies support the hypothesis that difficult children are more susceptible to a range of parenting qualities, both positive and negative, than are easy children (Belsky, 1997; Belsky, Bakermans-Kranenburg, & van IJzendoorn, 2007; van IJzendoorn & Bakermans-Kranenburg, 2012b). For example, difficult children have been found to be more susceptible to negative parental discipline by showing more externalizing behavior problems as well as more susceptible to parental positive discipline by showing less physical aggression and fewer externalizing behavior problems than children with easy temperaments (van Zeijl et al., 2007). Additional support shows that children with difficult temperaments whose mothers were high in maternal sensitivity had the strongest decrease of externalizing problems from ages 2 to 5 (Mesman et al., 2009). More recently, Kochanska and Kim (2013) found that children's observed difficult temperament, as measured by poor effortful control and high anger proneness, moderated the relation between mothers' responsiveness at 30 to 33 months and children's externalizing behaviors at 40 months of age. For difficult toddlers, maternal unresponsive behaviors was related to higher levels of children's externalizing behaviors, whereas high levels of maternal responsive behavior with difficult children was related to low levels of externalizing behaviors. It is worth noting that the results from this study did not find that difficult children who received responsive parenting were statistically lower in externalizing behaviors than were the easy children, thereby providing support for a diathesis-stress model, not differential susceptibility.

Anger Reactivity

It has been suggested by many that anger, sadness, and fear reactivity, encompassed in negative emotionality, might better be treated separately. Specifically, high levels of anger/frustration are hypothesized to underlie externalizing behaviors whereas greater sadness and fear reactivity are consistent with symptoms of internalizing problems (Rothbart & Bates, 2006). For example, in a sample of preadolescents, higher fear reactivity was associated with internalizing problems and higher anger reactivity was related to externalizing problems (Oldehinkel, Hartman, De Winter, Veenstra, & Ormel, 2004). It is important to note that this association is not perfect, as outlined next (i.e., anger sometimes is associated with internalizing behaviors).

The association between anger and externalizing and aggressive behaviors has been found repeatedly across decades of research, providing considerable support for their relation (Eisenberg et al., 2009; Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; Lemery et al., 2002; Lengua, 2006; Rothbart, Ahadi, et al., 1994; Rothbart, Derryberry, & Hershey, 2000; Rydell, Berlin, & Bohlin, 2003). For example, infant frustration observed in the laboratory was related to parent-rated aggression when children were 7 years old (Rothbart, Derryberry, et al., 2000), and 5-year-olds high in parent-rated anger were more likely to be rated as high in externalizing behavior problems by teachers in preschool and elementary school and by parents at home (Rydell et al., 2003). Unfortunately, it is still unclear how the relation between anger and externalizing behaviors emerge developmentally. In particular, it is unknown if anger motivates externalizing types of behavior and/or if children who exhibit aggressive behavior become more angry and volatile across development because their aggressive behavior leads to peer rejection (Rubin, Bukowski, & Parker, 2006). Indeed, even though a functionalist view of emotions proposes that anger motivates goal-oriented behavior and therefore can serve an adaptive purpose (Saarni, Mumme, & Campos, 1998), inappropriate levels and/or expression of anger may generate aggressive behaviors that negatively affect peer interactions and prevent socially adaptive problem-solving abilities.

Some research finds that children prone to high levels of anger early in development are at a higher risk of developing externalizing *and* internalizing problems later in childhood and adolescence than children low in anger (Eisenberg et al., 2009; Frick & Morris, 2004; Gartstein et al., 2012; Rothbart & Bates, 2006). However, these associations tend to be stronger for externalizing behaviors than for internalizing behaviors (Eisenberg et al., 2001; Oldehinkel et al., 2004). Although the link between anger reactivity and internalizing behavior is somewhat counterintuitive, the approach/withdrawal model of emotions proposed by Carver and Scheier (1998) suggests that sadness and depression can result from an individual repeatedly failing to approach a goal. Thus, children might initially experience anger when progress toward a goal is blocked, but after continued efforts to obtain this goal are hindered and presumed lost, the internalizing emotion of sadness may develop. An additional explanation for this association comes from research indicating that increases in externalizing behavior problems coincide with increases in internalizing behavior problems across the preschool period (Gilliom & Shaw, 2004). Thus, there may be multiple pathways from anger reactivity to the development of both internalizing and externalizing behaviors.

As outlined by Patterson (1976, 1982) in his coercion theory, interactions between parents and children that are negative and/or coercive in style are likely to persist

and accumulate over time, thereby increasing children's likelihood of developing externalizing, aggressive behaviors. This could be especially true for children prone toward experiencing negative emotions, specifically anger. In addition, within hostile, harsh environments, it is likely that children prone to experiencing and expressing anger will not learn appropriate methods of regulating their emotions, thereby exacerbating their risk of developing behavior problems and later psychopathology.

There is much correlational support for the notion that children's anger is negatively associated with supportive parenting. For example, anger is concurrently associated with lower levels of parental warmth in infancy (Kochanska, Friesenborg, Lange, & Martel, 2004) and increased levels of harsh parenting (Rhoades et al., 2011). Further, it is hypothesized that for anger-prone children, the effects of negative parenting behaviors, such as hostility, rejection, inconsistent discipline, and the like, might engender greater anger and aggressive behavior, characteristics of both internalizing and externalizing behavior problems. Thus, the effects of poor environmental conditions, such as negative parenting behaviors, might be especially detrimental to children temperamentally high in anger, given that low-quality and negative parenting seem to amplify behaviors already at risk (Calkins & Fox, 2002; Morris et al., 2002). In support of this position, Morris and colleagues (2002) found that first- and second-grade children high in temperamental anger were rated as higher in teacher-reported externalizing behavior problems if children viewed their mothers as high in overt hostility. Interestingly, anger-prone children were also high in teacher-rated internalizing behavior problems when these children rated their mothers as high in intrusive control. Lengua (2008) reported similar results when examining change in problem behaviors. Children high in frustration had greater increases in externalizing behaviors across 1 year during middle childhood (average age at Time 1 was 8.5 years old) within the context of child-reported maternal rejection. Interestingly, inconsistent maternal discipline predicted increases in internalizing behaviors for children high in frustration.

Person-centered methodological approaches also have been employed in research linking anger and the development of behavior problems. For example, Degnan, Calkins, Keane, and Hill-Soderlund (2008) created longitudinal profiles from age 2 to age 5 of children's disruptive behavior, which can lead to antisocial behaviors later in life (Broidy et al., 2003). The findings showed that children high in observed anger were more likely to be members of the high disruptive profile (high levels of disruptive behavior across time) when they had mothers who were high in control (adult-oriented goals and strictness/punitiveness). However, results from this study provided support that high physiological regulation, as indexed by vagal withdrawal, served as a protective factor for anger-prone children by leading toward a greater likelihood of being a member of the normative profile than the high disruptive profile. Thus, similar to findings on negative emotionality × parenting interactions, parenting behaviors high in control and hostility seem to intensify the relation between children's anger and later behavior problems. It is important to note that the developmental process by which parenting moderates children's anger reactivity in predicting behavior problems is still unknown. It could be that children temperamentally prone to anger/frustration have difficulty internalizing rules of conduct, which elicits harsh parenting, increasing the likelihood of behavior problems. Or it is possible that children high in anger might respond with increased frustration and irritability to negative parenting behaviors, leading to a greater likelihood of developing behavior problems. The developmental transactional process for anger reactive children warrants additional research.

Fear Reactivity

Additional support for the importance of considering the specific components (fear, anger, sadness) of negative emotionality comes from researchers linking individual differences in fear, measured as early as infancy, and the development of internalizing behavior problems (Biederman, Rosenbaum, Bolduc-Murphy, & Faraone, 1993; Biederman et al., 2001; Chronis-Tuscano et al., 2009; Hirshfeld-Becker et al., 2008). For example, Gartstein and colleagues (2012) reported that fear in toddlerhood and childhood, as reported by mothers, predicted children's internalizing scores both cross-sectionally and longitudinally. In another study (Rydell et al., 2003), parent-rated temperamental fear was positively associated with internalizing behavior problems longitudinally, although it is important to note that both were parent-rated. Further, children's low regulation of fear was related to higher internalizing behavior problems, both at home when the children were 6.5 years old (parent-reported) and in elementary school when the children were 8 years old (teacher-reported).

A more recent perspective on the relation between temperamental fear and the development of internalizing behavior problems proposes the importance of examining context. K. Buss (2011) found that 2-year-old children's observed expression of fear in a highly threatening context was not associated with anxiety symptoms when

the children were in kindergarten. Instead, dysregulated fear, characterized by high fear across all contexts including low-threat contexts, was related to higher maternal-reported anxiety when children were in preschool as well as social withdrawal when they were in kindergarten. Importantly, although children's inhibition (i.e., shyness, withdrawal) was related to maternal reports of social withdrawal during kindergarten, dysregulated fear predicted variance in social withdrawal over and above inhibition. As an extension of these findings, K. Buss and colleagues (2013) found that children with greater dysregulated fear at age 2 consistently predicted social wariness and social anxiety disorder symptoms throughout the child's kindergarten year.

Although predominantly discussed as a strong predictor of internalizing behavior problems, temperamental fear is also reported as negatively associated with externalizing problems and is hypothesized to protect children from developing aggressive behaviors (Rothbart & Bates, 2006). For example, infants' expression of fear in the laboratory has been shown to predict lower maternal reports of aggression when the children were 7 years of age (Rothbart, Ahadi, et al., 2000). One explanatory mechanism through which fear reactivity early in life is believed to counteract the development of externalizing behavior problems is through the development of conscience, which is negatively related to children's externalizing and aggressive behaviors (Eisenberg, Fabes, & Spinrad, 2006; Kerr, Lopez, Olson, & Sameroff, 2004). Indeed, children high in temperamental fear have been found to demonstrate better internalization of rules and standards (Kochanska, 1995; Kochanska et al., 2001) as well as show more empathy/guilt (Kochanska, Gross, Lin, & Nicholas, 2002; Rothbart, Ahadi, et al., 1994). It is worth mentioning that although temperamental traits, such as fear reactivity, are believed to contribute substantially in the development of conscience, which may lower the risk of externalizing behaviors, there are multiple factors involved in this development. One in particular, parenting behaviors, is discussed next as a moderator of the relation between fear reactivity and children's conscience.

Various parental behaviors have been examined for their moderating role on the relation between temperamental fear and the development of internalizing behavior problems. It has been suggested that fearful temperament encourages warm, supportive parenting behaviors (Lengua, 2006); however, there is also evidence that temperamental fear is not associated with either more or less parental support (Paulussen-Hoogeboom et al., 2007). Although it is not clear if infant and childhood fear reactivity is more likely to elicit a certain type of parenting, there is evidence that negative parenting behaviors increases the relation between temperamental fear and internalizing behavior problems. Gilliom and Shaw (2004) found that children high in observed and parent-rated negative emotionality and fearfulness with mothers high in observed negative control were more likely to develop increasing internalizing behavior problems from the ages of 2 to 6. Moderated mediation analyses have also been conducted in investigations regarding the association between temperamental fear and later anxiety. Kiel and Buss (2010) found that maternal protectiveness mediated the relation between fearful temperament and later anxiety, but only for mothers who were able to accurately predict when their child would be fearful.

Another central line of research on temperamental fear has been conducted by Kochanska (1991, 1995, 1997; Kochanska, Aksan, & Joy, 2007). In this research, she looked at the interaction between parenting behaviors and children's fear and fearless behaviors in predicting the development of moral and behavioral self-regulation, an important component of behavioral adjustment and predictor of fewer problem behaviors (Calkins & Keane, 2004; Keenan & Shaw, 2003). Kochanska (1991, 1995) hypothesized that since fearful children have a low threshold for fear arousal, parenting behaviors that are gentle, positive, and cooperative in nature will promote children's internalization of rules and morals in fearful children. In support of this hypothesis, she found that when mothers of temperamentally fearful children showed higher levels of gentle, low-power discipline and guidance, their children displayed more committed compliance and internalization than fearful children of mothers who did not show these behaviors. Therefore, it was concluded that an optimal level of anxiety arousal is elicited in fearful children when mothers use gentle discipline, thereby promoting compliance and internalization (Kochanska, 1997).

It is important to note that temperamental fear is proposed to underlie a number of behaviors that are included in temperament models, such as withdrawal, behavioral inhibition, and shyness, all of which have been studied in relation to the development of internalizing behaviors, specifically anxiety and social withdrawal. Fear reactivity, for example, is a major component, along with other behavioral and physiological traits, of the behavioral inhibited temperamental type or category, which we consider next.

Behavioral Inhibition

As mentioned, the construct of behavioral inhibition is closely related to other temperamental traits, such as negative emotionality, fear, and shyness. In general, behavioral

inhibition reflects the inability to appropriately handle uncertainty rather than a predisposition to fear (Kagan & Snidman, 2004). In the 1980s, Kagan and colleagues (e.g., García Coll, Kagan, & Reznick, 1984; Kagan, Reznick, & Snidman, 1987b) introduced the construct of behavioral inhibition to the developmental community. Since then a number of studies have examined its development, physiological bases, and relation to developmental psychopathology. Taking an extreme groups/categorical approach, Kagan defined behaviorally inhibited children as those who tend to withdraw and show negative affect in response to novelty. Research has shown that when presented with unfamiliarity, children who are behaviorally inhibited display high levels of negative affect, distress, wariness, and anxiety (Calkins, Fox, & Marshall, 1996; García Coll et al., 1984; Kagan, 1997) and are likely to exhibit social withdrawal or reticence in early childhood (Fox et al., 2001; Rubin, Burgess, & Hastings, 2002). Individual differences in emotional and behavioral reactivity to novelty, according to Kagan (Kagan et al., 1987b), are functions of excitability in the amygdala and proximate areas of the brain. This excitability is thought to generate heightened fear responses to unfamiliar and novel situations, people, and things. For example, adults who had been identified as inhibited in toddlerhood, compared to those individuals who had been identified as uninhibited, had a greater amygdala response to novel versus familiar faces (Schwartz, Wright, Shin, Kagan, & Rauch, 2003). Behaviorally inhibited children also evidence greater autonomic reactivity than uninhibited children (Perez-Edgar & Fox, 2005a; Schmidt, Fox, Schulkin, & Gold, 1999). The results of multiple longitudinal studies have demonstrated moderate stability of behavioral inhibition across childhood (Kagan, Reznick, Snidman, Gibbons, & Johnson, 1988; Pfeifer et al., 2002; Rimm-Kaufman & Kagan, 2005). Approximately 15% to 20% of children are likely to show high levels of behavioral inhibition (Fox, Henderson, Marshall, Nichols, & Ghera, 2005), and about half of these children continue to show indicators of behavioral inhibition across childhood (Degnan & Fox, 2007).

Understanding the developmental course of children categorized as behaviorally inhibited in early childhood has been important to developmental psychopathology. In general, research has found behavioral inhibition to predict later social behaviors and behavior problems (Kagan, 1994; Kagan, Reznick, & Snidman, 1987a; Rubin et al., 2002; Schwartz, Snidman, & Kagan, 1999). But more specifically, children who were consistently labeled as inhibited developed social anxiety disorders (e.g., Biederman et al., 1990, 2001; Hirshfeld et al., 1992; Schwartz et al., 1999). Interestingly, children identified as having anxiety disorders as early as 3 years of age displayed higher levels of behavioral inhibition as well as lower levels of positive affect (Dougherty et al., 2013).

As with other studies on the moderating role of the environment on the relation between temperament and psychopathology, research focused on behavioral inhibition has examined the role of parenting behaviors in the development of psychopathology. Overall, this literature suggests that intrusive, controlling, and/or oversolicitous parent behaviors increase inhibited toddlers' risk of developing social reticence and children's wary, anxious behavior in social situations (Rubin, Cheah, & Fox, 2001; Rubin, Hastings, Stewart, Henderson, & Chen, 1997; Rubin et al., 2002; Van Leeuwen, Mervielde, Braet, & Bosmans, 2004), whereas maternal warmth, sensitivity, and responsiveness are related to lower levels of behavioral inhibition and more socially acceptable behavior (Hane, Cheah, Rubin, & Fox, 2008; Park, Belsky, Putnam, & Crnic, 1997). Conversely, there are also findings from studies on behaviorally inhibited children showing that sensitive, overly responsive parenting behaviors, sometimes discussed as overly solicitous, maintain children's behavioral inhibition. It may be that by catering to the child's proclivity to avoid unfamiliarity, over-solicitous parents may be fostering the continuity of inhibited behaviors (Kagan, Arcus, & Snidman, 1993; Putnam, Sanson, & Rothbart, 2002). Moreover, oversolicitous parents may be reinforcing children's behavioral inhibition by rewarding their children's initial signs of distress with parental warmth and precluding any opportunity for children to develop and use self-regulatory skills (Fox et al., 2005). Although the research is mixed depending on how the parenting behaviors are defined (i.e., sensitive versus intrusive), the findings indicate that parenting behaviors aimed at encouraging children to engage socially may protect behaviorally inhibited children from developing social anxiety by lowering their attention bias to threat and promoting exploration and engagement with other children (Fox et al., 2005; J. Wood, McLeod, Sigman, Hwang, & Chu, 2003). In turn, this mastery of the environment will assist in the development of self-regulatory behaviors. Similarly, Kagan (1994) has posited that if fearful children are forced to face and deal with situations that cause them discomfort (e.g., fear or frustration) within the context of responsive parenting, they will be more likely to learn to regulate these emotions and therefore show fewer fearful behaviors with time.

It is worth noting that a few studies have examined the moderating effect of other nonparenting environmental influences. For example, Essex Armstrong, Burk,

Goldsmith, and Boyce (2011) examined the effect of teacher-child relationships in the first grade on mental health outcomes at grade 7 for behaviorally inhibited children. Behaviorally inhibited children developed worse mental health symptoms under conditions of high teacher-child conflict but the lowest levels of symptoms when there was low teacher-child conflict. Therefore, this study provided support for the differential susceptibility hypothesis for inhibited children. Another nonparental environmental context that is associated with behaviorally inhibited children's development of anxiety is that of the child care context (e.g., Fox et al., 2001). In this study, highly negative infants at 4 months of age were less likely to become inhibited later in development when they were placed in nonparental child care for 10 or more hours per week. As stability of behavioral inhibition is a risk factor for internalizing behaviors, the effects of child care in lessening this risk is achieved by exposing behaviorally inhibited children to other children and adults, encouraging social interaction, and requiring the use of regulatory strategies. However, it is important to consider that these effects may differ depending on the level of positivity and supportiveness within the child care environment (Clarke-Stewart & Allhusen, 2002; Gazelle, 2006). For example, Morrissey (2009) reported that preschoolers who experienced a greater number of child care environments, such as in-home care, center care, and care by grandparents, were rated by their parents as higher in internalizing behavior problems. Thus, the amount of child stress created by nonparental care should also be considered when examining the effects of child care on children varying on their levels of behavioral inhibition.

Summary

In sum, negative emotionality, a temperament factor that includes the emotions of frustration/anger, fear, anticipatory anxiety, sadness, guilt, and discomfort, has been shown repeatedly to be a reliable predictor of both externalizing and internalizing behaviors across development. Direct links between negative emotionality and behavior problems at one time point exist as well as the association between negative emotionality and trajectories of behavior problems. Although there has been extensive research outlining the association between negative emotionality and later psychopathology, recent work acknowledges the importance of examining the lower-order traits that make up the negative emotionality factor; indeed, evidence of the differential roles of these specific negative emotions in children's developmental trajectories toward behavior problems and later psychopathology has emerged. For example, there is considerable support for the association between anger reactivity and externalizing behavior problems. Although temperamental anger is more strongly related to externalizing behaviors than to internalizing behaviors, growing empirical evidence indicates that children prone to high levels of anger early in development are at a greater risk of developing both internalizing and externalizing problems later in childhood and adolescence than are children low in anger reactivity.

Temperamental fear has been shown to be a good predictor of internalizing behavior problems. However, it is also important to note that fear is negatively associated to externalizing problems, which suggests that it may operate as a protective factor for aggressive behaviors. Behavioral inhibition, a temperamental type characterized by high levels of fear/uncertainty along with other behavioral and physiological traits, has also been linked to internalizing behaviors, such as social withdrawal and reticence as well as anxiety.

The moderating role of the environment on the association between negative emotionality and later behavior problems has also been investigated. The findings support the widespread perspective that negative parenting behaviors exacerbates the maladaptive effects of negative emotionality in the development of behavior problems, whereas positive parenting behaviors can temper this relationship. The effects of parenting behaviors are thought to be especially detrimental to children temperamentally high in anger within the context of low-quality and negative parenting. These findings support the transactional nature of the parent-child relationship such that highly negative children are likely to evoke more negative responses from their parents, which may develop into a pattern of maladaptive interactions that decrease the children's opportunities for meeting developmental milestones, such as learning appropriate regulatory behaviors. Fewer studies have examined parenting and temperamental fear in predicting behavior problems. Parenting behaviors that are intrusive, controlling, and/or oversolicitous are related to temperamental fear, behavioral inhibition, and social reticence, whereas maternal warmth, sensitivity, and responsiveness are related to lower levels of behavioral inhibition and more socially acceptable behavior. However, there is also research supporting the notion that sensitive, overly responsive parenting behaviors maintains children's behavioral inhibition, a risk factor for internalizing, by catering to children's proclivity to avoid unfamiliarity. Important research questions remain regarding the specific types of parenting behaviors that lower fearful children's risk of developing internalizing behavior problems.

Overall, researchers have begun to address important questions related to the trajectories of negative emotionality as well as models of differential susceptibility, both of which are important areas of future research. Although the role of negative emotionality in the development of psychopathology is well established, we encourage future research to focus on individual differences in the expression and experience of the more specific emotions of fear, anger, and sadness rather than the broad constructs of negative emotionality and difficult temperament. In addition, despite these consistent and promising findings, it is still unclear how the relation between anger reactivity and externalizing behaviors and fear reactivity and internalizing behaviors emerges developmentally. For example, some studies suggest that anger and aggression share similar neural circuits (Coccaro, McCloskey, Fitzgerald, & Phan, 2007), adding to the complexity of our understanding of the association between anger and the development of behavior problems and psychopathology. Moreover, the existing research literature largely does not acknowledge the direction of effects. Thus, we urge researchers to continue to investigate anger reactivity as influencing the development of behavior problems across multiple levels of analysis (e.g., molecular, neural, emotional, behavioral, environmental) transactionally in an effort to address this important area of developmental psychopathology research.

Surgency

Whereas inhibited children are biologically predisposed to experience high negative affect in response to novelty (García Coll et al., 1984; Kagan, 1997), another temperamental superfactor, surgency, and associated temperament type, exuberant, that is characterized by approach, rather than withdrawal, to novelty, and the high levels of positive affect, activity, and impulsivity that accompany approach has been identified. Historically, temperament research focused largely on negative emotionality, including fear and anger reactivity, difficult temperament, and behavioral inhibition. More recently, temperament constructs including positive reactivity and approach have become of interest to more researchers. This growing interest has been attributed at least in part to an understanding that some children are not simply low in behavioral inhibition but instead take pleasure encountering novelty (Polak-Toste & Gunnar, 2006). As noted earlier, varying research approaches have examined and defined the characteristics of these children. Rothbart's surgency superfactor has been used to label variations in approach to novelty (Gartstein & Rothbart, 2003; Rothbart, Ahadi, et al., 2001). Categories of children with these characteristics may also be labeled uninhibited or exuberant, depending on the methodology and/or perspective employed (Calkins et al., 1996; García Coll et al., 1984; Putnam & Stifter, 2005; Rothbart, Ahadi, et al., 2001). For the purposes of this literature review, we use the terms that were used in the studies reviewed but consider them very similar in conceptualization.

The growing area of research on surgent, uninhibited, and exuberant children has indicated that although these children display high levels of positive affect, which is typically thought to be an adaptive quality, they are at risk for developing later behavior problems, within the realms of both externalizing and internalizing behaviors (Putnam & Stifter, 2005; Rubin, Coplan, Fox, & Calkins, 1995; Schwartz, Snidman, & Kagan, 1996; Stifter et al., 2008). Concurrent associations between exuberance/surgency and externalizing behavior problems have been found in toddlers (Gartstein et al., 2012; Putnam & Stifter, 2005), elementary school children (Oldehinkel et al., 2004; Rothbart, Ahadi, et al., 1994), and adolescents (Muris, van der Pennen, Sigmond, & Mayer, 2008). There is also evidence for a longitudinal association between exuberance and externalizing behavior problems (Rothbart, Ahadi, et al., 2000). Stifter, Putnam, & Jahromi (2008) found that children identified as exuberant at age 2 were more likely to be rated as higher in externalizing behavior problems at age 4 than other children. Dollar and Stifter (2012) found that highly surgent children were more likely to show negative peer behaviors observed in the laboratory as well as higher parent-rated aggression than children lower in surgency longitudinally. In addition, Degnan and colleagues (2011) reported that a high stable exuberance profile over toddlerhood and early childhood was associated with higher ratings of 5-year externalizing behavior and disruptive behavior. This association was especially strong for exuberant children who showed left frontal electroencephalographic (EEG) asymmetry.

Exuberant children may also be at risk for developing internalizing behavior problems; however, this evidence is mixed. In one study (Stifter et al., 2008), exuberant children were not only more likely to be rated as high in externalizing behavior problems but also higher in internalizing behaviors than inhibited children. Some studies, however, suggest that exuberance may offset the risk for internalizing behavior problems. For example, low exuberance has been linked to depressive and anxiety disorders in toddlerhood (Dougherty et al., 2011). There are theoretical explanations for each of these associations, and the mixed findings could be the result of differences in measurement. As this area

of research is relatively new, additional research examining the associations between exuberance the development of internalizing and externalizing behavior problems is warranted. In addition, research examining specific types of externalizing behaviors that exuberant children are at risk for developing is greatly needed.

There has been a recent surge of interest in the developmental trajectories of surgent/exuberant children; yet there still is a dearth of research examining the moderating role of environmental factors, such as parenting behaviors, in affecting children's later psychopathology. The limited research that exists has largely examined the development of behaviors and deficits in skills associated with psychopathology. Root and Stifter (2010) found that high-approach children (similar to children high in surgency) showed higher levels of teacher-rated disruptive behavior in the classroom when they had mothers who reported high levels of punitive, dismissive responses to their children's negative emotions. Also, as previously mentioned, Kochanska and colleagues (Kochanska, 1991, 1995, 1997; Kochanska, Aksan, & Joy, 2007) have extensively examined the interaction between parenting behaviors and fearless children's (similar to exuberant children) behaviors in predicting the development moral and behavioral self-regulation, factors related to problem behavior (Calkins & Keane, 2004; Keenan & Shaw, 2003). Kochanska (1991, 1995) hypothesized that because the fear threshold is higher in fearless children, as compared to fearful children, gentle discipline would not induce enough fear arousal to foster self-regulated compliant behavior. However, simply increasing the applied pressure with these children, termed *power assertiveness*, was not associated with internalization of rules and standards for fearless children. Rather, Kochanska (1997) found that a mutually positive orientation reflected in shared positive affect or a secure attachment that optimizes positive motivation was more effective at promoting internalization and compliance with fearless children. Additional support has been found for the important role of parental warmth in promoting exuberant children's self-regulatory abilities in research showing that exuberant children whose mothers used commands and prohibitive statements coupled with a positive tone were more likely to show effortful control later in childhood (Cipriano & Stifter, 2010). Similarly, the development of self-regulation in exuberant children may depend on maternal attention-directing behaviors. Conway and Stifter (2012) found that exuberant children of mothers who helped themmaintain their attention during a problem-solving task developed better inhibitory control than exuberant children whose mothers did not use this attention strategy. Thus, early parenting behaviors appear to moderate child exuberance to predict important regulatory behaviors that protect against the development of problem behavior. Although this research is an excellent start in identifying important developmental processes in exuberant/surgent children, more research is needed to examine how these processes work together to affect development of behavior problems in these children.

Positive Emotionality

Despite the focus on negative emotions historically, interest in temperamental positive emotionality has grown and appears to be a promising link toward a greater understanding of children's trajectories toward mental health or alternatively dysfunction. In general, a predisposition toward childhood positive emotions, generally measured in terms of happy, cheerful mood, is thought to be adaptive, as it has been found to be related to peer competence and prosocial behavior (Denham, McKinley, Couchoud, & Holt, 1990; Eisenberg et al., 1996). Indeed, there is considerable research linking positive emotionality to adaptive developmental outcomes and lowered risk for psychopathology. For example, one study found that low-intensity positive emotionality exhibited during quiet and interpersonal situations was related to the ability to self-regulate emotion and behavior (Kochanska, Aksan, Penney, et al., 2007) while another study showed parent ratings of low-intensity pleasure to be negatively associated with both internalizing and externalizing behavior problems (Gartstein et al., 2012).

Additional support for the importance of positive emotionality in lowering risk of psychopathology comes from an expanding literature showing that *low* positive emotionality, as early as toddlerhood, is a risk factor in the development of depression. For example, low levels of positive emotionality in children have been linked with EEG asymmetries believed to characterize depressed adolescents and adults as well as to a history of depressive disorders in their mothers (Durbin, Klein, Hayden, Buckley, & Moerk, 2005; Shankman et al., 2005). Further, Dougherty and colleagues (2010) found that low positive emotionality at age 3 predicted depressive symptoms at age 10, after controlling for negative emotionality and depressive behaviors at age 3. Interestingly, these authors also reported that negative emotionality predicted depression only when children were also low in positive emotionality.

Although there is theoretical and empirical work outlining how positive emotionality in children promotes them as attractive social partners and serves as a protective

factor for children in the development of depression, positive emotionality also has been linked to maladaptive social and psychological outcomes (Putnam, 2012). For example, high-intensity pleasure has been linked to expression of anger/frustration from infancy through childhood (Putnam, Rothbart, & Gartstein, 2008; Rothbart, Ahadi, et al., 1994; Rothbart, Derryberry, et al., 2000). Further, empirical work has shown that children who show more intense joy and are quicker to show joy score lower on effortful control measures (Kochanska et al., 2000); laboratory observations of smiling and laughter predict later impulsivity and lower inhibitory control (Rothbart, Derryberry, & Posner, 1994). More specific to problem behaviors, Rothbart and colleagues (1994) found that infant smiling and laughter was related to parent-reported aggression at age 7. Rydell and colleagues (2003) reported that 5- to 8-year old children's positive emotionality/exuberance was related to maternal reports of children's externalizing behavior problems, whereas children's ability to regulate positive emotionality/exuberance was associated with lower externalizing behavior problems. It is important to note that positive emotionality, particularly at high levels of intensity, is a central defining characteristic of temperamental exuberance and surgency which has been linked repeatedly to the development of aggressive, externalizing behavior problems (Degnan et al., 2011; Stifter et al., 2008). It may be that the other characteristics of exuberance, such as approach to novelty, impulsivity, and activity level, together with high-intensity positive affect, contribute toward this risk for problem behavior rather than positive affect alone.

Although the area of inquiry regarding the developmental role of positive emotionality in children's later behavior problems is still in its early stages, there is some support for the role of environmental factors as moderating the association between positive emotionality and later behavior problems. For example, there is some evidence that low positive emotionality may be related to risk of depression and other behavior problems through environmental factors such as lower parental support, acceptance, and involvement (Branje, van Lieshout, & van Aken, 2005; Lengua & Kovacs, 2005). Further, maternal rejection has been shown to be more strongly associated with children's depression and conduct problems for children who were low in positive emotionality as compared to those who were moderate and high in positive emotionality (Lengua, Wolchik, Sandler, & West, 2000). Considered conversely, these results suggest that positive emotionality may be a protective factor for children in negative environmental contexts by buffering the harmful effects of less-than-optimal parenting (Lengua & Wachs, 2012).

Activity Level

Activity level has consistently been considered an important temperament trait (A. Buss & Plomin, 1975; Henderson & Wachs, 2007; Thomas & Chess, 1977). There are two central components to activity level, tempo and vigor, and it is commonly measured as the duration of energetic behavior, displacement of body movements, and rate and amplitude of speech and movement (A. Buss & Plomin, 1975). Generally, high activity is associated with externalizing behavior problems generally, as well as ADHD difficulties (De Pauw et al., 2009). Indeed, the relationship between temperamental activity level and ADHD is well established (J. White, 1999). For example, children with ADHD are rated significantly higher on activity than community children (De Pauw & Mervielde, 2010; Foley, McClowry, & Castellanos, 2008). Foley, McClowry, and Castellanos (2008) examined the associations between ADHD and child temperament dimensions in two groups of 6- to 11-year-old children: one group of children showing symptoms of ADHD and another group of children exhibiting no symptoms of ADHD. Children exhibiting high levels of ADHD symptoms (hyperactivity, impulsivity, and inattention) were rated as significantly higher in activity level than those with no ADHD symptoms. More specifically, temperamental activity was found to be related to the hyperactive-impulsive and combined types of ADHD but not the inattentive type (Stringaris, Maughan, & Goodman, 2010).

Activity level has also been considered as a core component of the surgency superfactor (e.g., Rothbart, Ahadi, et al., 2001). Indeed, activity level may underlie the link between surgency and externalizing behaviors. And, while high levels of activity characterize children with hyperactivity problems, it also characterizes children with disruptive behaviors (Nigg, 2006). However, children with high levels of activity are also likely to be more impulsive and distractible, which might blur the relation between activity and the development of ADHD and/or externalizing behavior problems.

Summary

Historically, temperament research focused largely on negative emotionality, including fear and anger reactivity, difficult temperament, and behavioral inhibition. More recently, temperament constructs, including positive reactivity and approach, have been of interest to more

researchers. Although still a relatively new phenomenon, it is now acknowledged that exuberance is not simply the "opposite" of behavioral inhibition, and research is needed to identify the unique behavioral and neurobiological qualities of these children. Children who are more likely to approach novelty, frequently labeled uninhibited, exuberant, or surgent, are characterized as high in positive affect, activity level, and impulsivity and low in shyness and withdrawal. Although these children display high levels of positive affect, which is typically thought to be an adaptive quality, they are at risk for developing later behavior problems.

Positive emotionality has also been considered as a separate temperament trait, not only as a component of temperamental surgency or exuberance. Indeed, multiple lines of research have shown the adaptive role of positive emotionality, including the development of self-regulation and lowering risk of depression. Yet the role of positive emotionality in children's developmental trajectories is not entirely clear as there is additional research linking this construct with maladaptive behaviors, such as externalizing behaviors and low self-regulation Low positive emotionality appears to be a risk factor for depression and other behavior problems, particularly when combined with negative parenting behaviors, such as low acceptance, and low involvement and negative parenting behavior may exacerbate the risk for psychopathology for children low in positive emotionality.

Investigations on the role of surgency, exuberance, positive emotionality, and activity level in relation to emotional and behavioral disorders are just now emerging, and the results are promising. Additional research examining the associations between exuberance/surgency and the development of specific types of externalizing behaviors, however, is greatly needed, as well as identification of which children are at risk for developing comorbid internalizing and externalizing behavior problems. Although there has been a surge of interest in the developmental trajectories of exuberant children, there is still a lack of understanding regarding the mechanisms involved in risk or protective factors for these children, including both environmental and innate factors of the child. Further, there has been a dearth of research examining the interaction between children's exuberance and their environment in the development of behavior problems. Finally, although there is some support for factors associated with lowering risk of developing behavior problems for exuberant children such as effortful control), research in temperamental exuberance is still very much in its infancy, and many questions still remain.

In addition, there is still much work needed regarding the role of positive emotionality as a protective or risk factor in children's development of behavior problems. Recent reviews of the research literature on temperamental positive emotionality have highlighted the importance of considering the type and/or intensity of positive emotion in understanding its relation in children's adjustment. Specifically, positive emotionality that is associated with strong approach behavior and/or is experienced in high-intensity contexts is hypothesized to be associated with problematic behaviors in the externalizing realm, whereas low-intensity positive emotions, such as contentment and affiliation, are more likely to be associated with the development of self-regulation and desirable social behaviors. More research to support this position, however, is needed before the risk and protective qualities of positive emotionality are fully understood.

Effortful Control

The construct of effortful control was introduced by Rothbart and colleagues (Rothbart, 1989; Rothbart & Ahadi, 1994; Rothbart & Bates, 2006) to describe the self-regulatory components of temperament. *Effortful control* is defined as the ability to inhibit a dominant response in order to perform a subdominant response, to detect errors, and to engage in planning (Rothbart & Bates, 2006; Rudea, 2012) and includes the dimensions of inhibitory control and attentional focusing/control. Because effortful control is voluntary and active, this temperament construct is differentiated from more reactive forms of regulation, fear reactivity and impulsivity (Derryberry & Rothbart, 1997). Effortful control is hypothesized to affect children's developmental trajectories by contributing to their ability to process information and modulate emotion and behavior. Whereas negative emotionality and surgency are associated with behavior problems, effortful control as a temperament factor is largely considered to protect children against maladaptive outcomes, including the development of psychopathology. Indeed, a high level of effortful control is the one temperament trait that has been most often linked to behavior problems by lowering risk (e.g., Eisenberg, Spinrad, & Eggum, 2010), and the evidence is quite strong and consistent (Eisenberg, Sadovsky, et al., 2005; Lengua, 2006; Lengua et al., 1998; Oldehinkel, Hartman, Ferdinand, Verhulst, & Ormel, 2007; Olson, Sameroff, Kerr, Lopez, & Wellman, 2005; Spinrad et al., 2007; Valiente et al., 2003). There is also evidence that the role of effortful control as a protective factor persists into childhood (Muris et al., 2008) and adolescence (L. Ellis,

Rothbart, & Posner, 2004) by being negatively associated with anxiety, depression, and aggression.

Although low levels of effortful control are related to a host of problematic behaviors, empirical evidence suggests that it is most strongly related to the development of externalizing behavior problems, even after controlling for other cognitive and social risk factors (Olson et al., 2005; Valiente et al., 2003). For example, children with externalizing behavior problems were reported to have deficits in attentional and effortful control, in addition to high impulsivity, as compared to children with internalizing behaviors and control children (Eisenberg et al., 2009). Deficiencies in effortful control have also been observed in children with ADHD (see Barkley, 1997; Nigg, 2001; van der Meere 2002), a clinical disorder often associated with externalizing behavior problems. In a large-scale study of preadolescent temperament and problem behaviors, Oldehinkel et al. (2004) reported that low effortful control was the central temperament predictor of externalizing behavior problems, reporting an effect size greater than .50. Importantly, although this study used parent ratings for both temperament and behavior problems, confounding items were removed, and the strength of the relationship between effortful control and externalizing problems was not diminished, nor did it change when the researchers examined adolescents self-ratings of externalizing behavior.

The relationship between low effortful control and externalizing behavior problems has been found across time with the stability of relations also taken into account, indicating that change in effortful control is related to change in children's externalizing behavior problems (Belsky, Pasco Fearon, & Bell, 2007; Valiente et al., 2006). For example, attentional dysregulation predicted externalizing behavior problems at the next assessment for children at 54 months, first grade, and fifth grade, while controlling for previous levels of these constructs (Belsky, Pasco Fearon, et al., 2007). However, at ages 18, 30, and 42 months, researchers found no evidence for a causal relation between effortful control at one time point and externalizing behavior problems at a later time point. Instead, externalizing behavior problems preceded lower levels of effortful control, suggesting that externalizing behaviors may counteract any growth in regulatory abilities (Eisenberg, Spinrad, Eggum, et al., 2010).

Effortful control has also been linked to internalizing behavior problems; however, the association between these two constructs is not always clear. Some researchers have found that effortful control is negatively related to internalizing behavior problems (Eisenberg et al., 2001; Lengua, 2006; Martel et al., 2007; Oldehinkel et al., 2007). For example, parent report of low effortful control and observed attentional control during middle childhood was found to be related to greater internalizing behavior problems (Lemery-Chalfant, Doelger, & Goldsmith, 2008) whereas increases in effortful control over a 2-year period was associated with fewer internalizing behavior problems in preadolescence (Lengua, 2006). In contrast, others have found a positive relation between effortful control and internalizing behavior problems (Murray & Kochanska, 2002; Rydell et al., 2003), suggesting issues of overcontrol. Adding to the complexity of the relation between effortful control and internalizing problems are findings of a quadratic relation between effortful control and internalizing behavior problems (Murray & Kochanska, 2002). Specifically, in a normative sample, a quadratic relation was revealed between preschoolers' observed effortful control and parent-rated total problem behaviors (combined internalizing and externalizing behaviors). Follow-up analyses suggested that this association was because children with higher effortful control were rated by their mothers as higher in internalizing behavior problems than children with moderate levels of effortful control.

Some researchers have hypothesized that the more specific behaviors that make up effortful control (i.e., attention shifting/control, inhibitory control) might account for the mixed findings (Eisenberg et al., 2009; Klein, Dyson, Kujawa, & Kotov, 2012). As with the other temperament superfactors (e.g., negative emotionality, surgency), effortful control is heterogeneous, and the association between it and internalizing behaviors may depend on how effortful control is measured as well as the other innate aspects of the child. A study by Gartstein and colleagues (2012) found that attentional control was primarily responsible for the negative association between effortful control and internalizing behavior problems, especially given the lack of significant associations between inhibitory control and internalizing behavior problems. Interestingly, low attentional *and* inhibitory control have been associated with externalizing behavior problems in the toddler and preschool years (Gartstein et al., 2012; Hill, Degnan, Calkins, & Keane, 2006; Lemery et al., 2002; Spinrad et al., 2007) as well as later in childhood and preadolescence (Belsky, Bakermans-Kranenburg, et al., 2007; Eisenberg, Sadovsky, et al., 2005; Eisenberg et al., 2009). Thus, it appears that it is necessary to take a more fine-grained approach to examining the link between effortful control and developmental psychopathology.

The development of effortful control is very likely to be susceptible to environmental influences and parenting, especially during the preschool years, when children's

development of these abilities is growing rapidly (Lengua, Honorado, & Bush, 2007; Rothbart & Rueda, 2005). Further, effortful control may serve as a protective factor against maladaptive environmental influences, where children low in effortful control who also experience less-than-optimal environments may be at a greater risk of developing behavior problems than children with high levels of effortful control. Morris and colleagues (2002) found that there was an especially strong relation between mother hostility and children's externalizing behavior problems for children rated as low in effortful control. For children low in effortful control, positive parental control appears to buffer this risk (Karreman, van Tuijl, van Aken, & Deković, 2009).

Eisenberg, Cumberland, and Spinrad (1998) hypothesized that parents who are sensitive, warm, and express appropriate emotions are more likely to raise children with higher levels of effortful control, thereby lowering their chances of developing behavior problems. Empirical evidence has been found for this proposal by showing that children's effortful control mediates the relation between parenting behaviors and children's development of behavior problems. For example, the relation between maternal expressivity and later internalizing and externalizing behavior problems was mediated by children's effortful control (Valiente et al., 2006). In addition, Spinrad and colleagues (2007) found that concurrently at both 18 and 30 months, children's effortful control mediated the association between supportive parenting and externalizing problems. Evidence supporting the mediating role of effortful control in the association between various environmental factors and later behavior problems has also emerged. For example, chaos in the home when children were 3 years old was indirectly related to externalizing behavior problems 2.5 years later through children's inhibitory control at age 4 (Hardaway, Wilson, Shaw, & Dishion, 2012).

Summary

Effortful control, the self-regulatory aspect of temperament, defined as the ability to inhibit a dominant response in order to perform a subdominant response, to detect errors, and to engage in planning, is comprised of inhibitory control and attentional control. Effortful control is hypothesized to affect children's developmental trajectories by contributing to their ability to process information and modulate emotion and behavior. Whereas many other temperament traits are positively associated with behavior problems and psychopathology, effortful control is largely considered a protective factor against maladaptive outcomes. Indeed, there is extensive evidence to suggest that effortful control is negatively related to children's development of behavior problems, and this association is especially strong for externalizing problems. Effortful control has also been linked to internalizing behavior problems, but this association is not always clear. The research also indicates that effortful control may serve as a protective factor against maladaptive environmental influences, where children high in effortful control who experience less-than-optimal environmental experiences may be buffered against developing behavior problems and psychopathology. Although the research indicates that effortful control has a central role in maintaining a positive developmental trajectory, how this ability develops in light of the child's level and type of temperamental reactivity and what supports are needed for its development are still unclear. Several studies have indicated that parents are especially important to the child's developing self-regulation when these parenting behaviors vary according to the child's temperament. Research linking these processes to indices of behavioral adjustment and maladjustment are needed.

TEMPERAMENT × TEMPERAMENT INTERACTIONS

There are numerous possible patterns by which one temperament trait moderates the association between another temperament trait and children's psychopathology; however, although the amount of research is growing, relatively little has been conducted on this area of inquiry. Here we provide an overview of existing research on temperament × temperament interactions in predicting children's behavior problems.

Effortful Control × Temperament

Although research examining temperament × temperament interactions is still limited, there are a number of studies examining the moderating role of effortful control on the association between other temperament traits and developmental psychopathology (Rothbart & Bates, 2006). Indeed, effortful control commonly interacts with other temperament dimensions, such as negative emotionality and impulsivity, to predict behavior problems, especially within the externalizing realm (Eisenberg et al., 1996, 2004; Valiente et al., 2003). This association is to be expected since it is widely hypothesized that the purpose of the regulatory aspects of temperament is to modulate the

reactive aspects of temperament—especially because, as outlined earlier, unregulated reactivity frequently leads to maladjustment (Rothbart & Bates, 2006). This position is supported by a number of studies. For example, Muris, Meesters, and Blijlevens (2007) found that effortful control weakened the positive relation between negative emotionality and both internalizing and externalizing behavior problems. Likewise, Lonigan, Vasey, Phillips, and Hazen (2004) reported that highly negative children were at risk for developing anxiety difficulties only when they were also low in self-regulation. Researchers have also found that a negative association between effortful control and externalizing behavior problems was strongest for children with high levels of negative emotionality (Valiente et al., 2003); temperamentally negative children who exhibited better effortful control were less likely to develop behavior problems 4 years later. The moderating role of effortful control on the relation between negative emotionality and externalizing behavior problems has also been found with pre- and early adolescents (Oldehinkel et al., 2007).

Studies examining more specific forms of temperamental reactivity found that infants and toddlers high in anger and activity level and low in effortful control (measured with executive function tasks) were more likely to develop ADHD (Auerbach et al., 2008; Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). Additional support for interactive effect of anger and effortful control has come from a short-term longitudinal study of preschoolers (Diener & Kim, 2004). Results from this study indicated that children whose mothers rated them as easily frustrated and low on self-regulation (composite of low inhibitory control and high impulsivity) were rated by their teachers as being high in externalizing behaviors. Components of effortful control have also been investigated for their role in mediating or moderating the association between other temperament traits and the development of behavior problems. Sustained attentive behavior was found to moderate the association between temperamental anger and aggressive behavior problems in children (Kim & Deater-Deckard, 2011). Evidence for this association has also been found in adolescence (Oldehinkel et al., 2004), 2004). Deater-Deckard, Petrill, and Thompson (2007) found that the link between temperamental anger and later aggressive behavior was mediated by children's regulation of sustained attentive behavior, indicating a lack of effortful regulation. As can be seen, there is good evidence supporting the importance of effortful control in altering the association between anger/negative emotionality and externalizing behaviors; however, it is important to note that other researchers have failed to find evidence of these effects (Belsky, Friedman, & Hsieh, 2001; Rydell et al., 2003).

The moderating role of effortful control is also believed to be important for children at risk for developing internalizing behavior problems, although the association is not as strong as with externalizing behavior problems. Even though there are significant associations between these variables, the role of effortful control in moderating the association between fear/behavioral inhibition and internalizing behavior problems is mixed. Some research has indicated the protective role of high effortful control in lowering risk of developing internalizing behaviors. Oldehinkel and colleagues (2004) showed that adolescents displaying high fear and shyness and moderately low effortful control were high in internalizing behavior problems. Additional support for the moderating role of effortful control has come from Eisenberg, Shepard, Fabes, Murphy, and Gutherie (1998), who found that shy children who were low in attention shifting had greater internalizing symptoms, whereas children who were better at attention shifting showed discontinuity in these behaviors over time.

However, other studies suggest that inhibitory control, defined as the ability to effortfully inhibit behavior when necessary (Rothbart & Bates, 2006), is not always adaptive, particularly for behaviorally inhibited children. Children high in behavioral inhibition who also showed greater inhibitory control were more likely to be rated higher in social anxiety by their teachers (Thorell, Bohlin, & Rydell, 2004) and were more socially withdrawn (Fox & Henderson, 1999) than behaviorally inhibited children low in inhibitory control. More recently though, greater use of attention shifting was associated with a reduced risk of anxiety for behaviorally inhibited children whereas high levels of inhibitory control were associated with increased risk of anxiety (L. White, McDermott, Degnan, Henderson, & Fox, 2011). The authors and others have proposed that it may be critical for behaviorally inhibited children to be able to flexibly shift their attention to help regulate the negative emotions they experience in certain situations. Whereas inhibitory control may serve as an important regulatory ability for most children, heightened inhibitory control may be detrimental for behaviorally inhibited children. Behaving in a rigid, inflexible, and overly cautious manner in many situations may heighten their risk for anxious behaviors and hinder their chances of developing socially appropriate behaviors.

In sum, effortful control may serve a different role for behaviorally inhibited children in increasing or lowering risk of developing internalizing behavior problems, depending on how and which subcomponent of

effortful control (attentional control, inhibitory control) is measured in the study. This is an interesting and important avenue for future research. Research identifying the mechanisms underlying the relation among attention shifting, inhibitory control, and internalizing behavior problems, particularly in behaviorally inhibited children, is needed. The work of Perez-Edgar (Perez-Edgar et al., 2010; Perez-Edgar et al., 2010; Perez-Edgar et al., 2007) on the neural and genetic underpinnings of attention bias in behaviorally inhibited children who develop anxiety highlights a promising area for further study. Likewise, examining the developmental trajectories of both attentional control and inhibitory control in behaviorally inhibited children may increase our understanding of when and how these behaviors develop into anxiety.

Surgency × Temperament

Until recently, we knew very little about the explanatory mechanisms involved in exuberant children's development of aggressive and externalizing behaviors. Although few studies exist in this area, one leading hypothesis points to the role of exuberant children's predisposition toward anger reactivity. Because limits are frequently placed on attempts to approach aspects of their environment, exuberant children are more likely to experience intense reactions of anger when their goals are blocked (Derryberry & Reed, 1994; Rothbart & Bates, 2006; Rothbart, Derryberry, et al., 2000). Indeed, past research has shown that the greater the interest or positive affect experienced when engaging with the environment (e.g., toy, mobile, prize), the more anger expressed when the stimulus was not obtainable (Dennis, 2006; Lewis, Wolan-Sullivan, & Ramsay, 1992). Consequently, early confrontations in which rules of behavior are required may provide important opportunities for exuberant children to learn emotion regulation, a form of self-regulation. If they have not acquired this ability by childhood, exuberant children may be at risk for negative outcomes, such as externalizing behavior problems, as their inability to regulate emotions may cause them to act inappropriately in certain situations, even though at other times they are highly sociable and outgoing (Polak-Toste & Gunnar, 2006).

In support of this position, Stifter and colleagues (2008) found that exuberant children who displayed higher levels of negative emotion and lower levels of positive/neutral emotion to a disappointing situation were rated by their parents as having higher levels of externalizing and total problem behaviors than exuberant children who could regulate their emotional expression. Additional research has found that although highly surgent children are at risk for developing aggressive behaviors, the ability to use specific emotion regulation behaviors in a frustrating situation lowered this risk (Dollar & Stifter, 2012). In another study, children rated as high in surgency and low in self-regulation have been found to display higher levels of aggressive behaviors, which in turn was associated with peer rejection (Gunnar, Sebanc, Tout, Donzella, & van Dulmen, 2003). Taken together, these findings indicate that the development of emotion regulation, especially the ability to regulate anger, is a critical developmental task for exuberant children.

Neurobiological models of approach (e.g., Depue & Collins, 1999; Eysenck, 1967; Gray, 1987) suggest that high levels of approach behavior, such as that exhibited by exuberant children, must be offset by appropriate inhibitory mechanisms. Based on these models, exuberant children are hypothesized to require the ability to regulate their behavior as well as their emotions. Recent evidence suggests that aspects of developing effortful control processes are critical for exuberant children. Lahat and colleagues (2013) found that exuberant children were significantly more likely to show an increased risk-taking propensity, which is associated with various aspects of psychopathology, when they were low in attention-shifting abilities.

Finally, we have found initial evidence that although positive affect, even at intense levels, can be an adaptive trait for exuberant children, the combination of intense positive affect and high activity level in an engaging task put these children at risk for developing conduct problems (Dollar, 2011). These findings suggest that for exuberant children, intense positive affect when accompanied by other "disruptive" behaviors may be a marker for developing externalizing behaviors, likely because their intense excitement becomes too active and impulsive to control. Thus, in addition to learning to regulate anger, it is adaptive for exuberant children to develop the ability to regulate their often impulsive, active behavior.

Positive Emotionality × Temperament

The growth in research examining the role of positive emotionality in the development of psychopathology has produced several studies focused on the interaction between positive emotionality and other temperament traits. One study has shown that for toddlers low in negative emotionality, low positive emotionality was associated with higher rates of parental depression, a known risk factor for childhood depression (Olino, Klein, Dyson, Rose,

& Durbin, 2010). Additional support for the interactive role of positive emotionality and negative emotionality in predicting later depression has been found in research on asymmetry in resting EEG activity in frontal and posterior regions, which are putative biomarkers for depression. Specifically, results from this study found that children with low positive emotionality or high negative emotionality were at risk for depression (EEG asymmetry was used as a marker for depression) and that children low in positive emotionality and high in negative emotionality were not at a greater risk than those children with only one of these traits (Shankman et al., 2011). It is noteworthy that although low positive emotionality has been linked to the development of depression, more recent research has found a temperament × temperament interaction for anxiety. Behaviorally inhibited children who exhibited low positive emotionality were more likely to be diagnosed with anxiety (Dougherty et al., 2013).

More recently, we have been interested in the moderating role of activity level on the relation between individual differences in positive emotionality and the development of behavior problems (Dollar, 2011). Children who showed low activity and low positive affect when playing a game with their mothers were rated as high in social withdrawal; higher levels of positive affect for children low in activity significantly reduced the likelihood of being socially withdrawn. Although corresponding with much extant research showing that children low in approach and activity but high in negative affect and withdrawal are at risk for being socially withdrawn (García Coll et al., 1984), our findings considered positive as well as negative affect. Because much research has focused on the importance of children at risk for developing internalizing behaviors and social withdrawal to learn to regulate their fear (K. Buss, 2011; Fox, 1994), it is important that additional research substantiate these findings that increasing positive affect may protect children, particularly behaviorally inhibited children, from developing these problem behaviors.

Summary

An important area of temperament research that is slowly accumulating empirical evidence is that examining the association between temperament and psychopathology within the context of other temperament traits, or temperament × temperament interactions. Although there are numerous possible patterns by which one temperament trait moderates the association between another temperament trait and children's psychopathology, few studies have examined this area of inquiry. One exception is a fairly extensive literature outlining the importance of effortful control in lowering highly negative children's risk of developing behavior problems; this association is especially true within the externalizing realm. Further, there is much support for the interactive and additive effects of anger with other temperament traits, especially low levels of self-regulatory abilities, in predicting behavior problems. Additional research has considered how effortful control lowers the risk of developing anxiety problems for behavioral inhibited children. However, the findings indicate that different components of effortful control, attentional shifting and inhibitory control, are differentially associated with increasing or lowering the risk of developing anxious behaviors.

Another growing area of temperament × temperament research considers the developmental trajectories of children varying on their levels of surgency. Although this research is still in its infancy, one leading hypothesis points to the importance of anger regulation for highly surgent children in lowering their risk of developing aggressive, externalizing behaviors. Other recent research has presented support for attentional regulation as a critical developmental ability for surgent children to offset their risky behaviors. Another critical ability for exuberant children that has received recent empirical support is the capacity to regulate highly active, impulsive behavior when excited while preserving the positive affect, even at intense levels. Finally, although there has been limited research examining the role of positive emotionality, recent research points to the importance of considering it within the context of the related temperamental constructs of negative emotionality, behavioral inhibition, and activity level.

NEUROBIOLOGY LINKING TEMPERAMENT AND DEVELOPMENTAL PSYCHOPATHOLOGY

Contemporary theories of temperament emphasize a biological or genetic basis for temperament and often include it as part of the definition (Rothbart & Derryberry, 1981). The central tenet of A. Buss and Plomin's (1975, 1984) theory, for example, is that temperament is largely heritable, and behaviors must be present early in life to be considered a temperament trait. The work of Goldsmith and Campos (e.g., Goldsmith & Campos, 1982; Goldsmith, Campos & Lemery, 1997; Lemery et al., 2002) also considers early-appearing individual differences primarily in emotions and emotion regulation and provides empirical support from behavioral genetics research on temperament. Likewise, the research of Kagan and colleagues (e.g., Kagan, 2002; Kagan, Reznick, Clarke,

& Snidman, 1984; Kagan et al., 1988) on behavioral inhibition is strongly rooted in the premise that a child's heritable neurochemistry affects arousal in the amygdala and/or the bed nucleus of the stria terminalis and their projections, which is reflected in the child's withdrawal from novelty. Finally, Rothbart (Rothbart, 1981; Rothbart & Ahadi, 1994; Rothbart & Derryberry, 1981) has long argued that an integrated view of temperament requires temperament research to be conducted at the genetic, neural, endocrine, autonomic, and central nervous systems levels. Rothbart's model emphasizes the autonomic basis of both reactivity and regulation, in addition to the maturation of neutral pathways and brain structures associated with the development of children's regulatory behaviors.

The theoretical links between temperament and psychopathology, particularly the spectrum model, are strengthened by studies examining their shared neurobiological bases (Goldsmith & Lemery, 2000; Nigg, 2006). Alternatively, variations in biological functioning associated with temperament may make children more vulnerable to negative or aversive environments resulting in behavioral and emotional disorders which would support the vulnerability/predisposition model linking temperament to psychopathology (McCrory, DeBrito, & Viding, 2010). Studies testing the differential susceptibility hypothesis, for example, have shown that candidate genes associated with temperament, such as DRD4), interacts with various forms of parenting to predict maladaptive behavior (Bakermans-Kranenburg & van IJzensoorn, 2006). Unfortunately, to date, studies such as these are rare.

Although theories of temperament are based on the notion that individual differences in temperament are biologically based, it is critical that the environment is also acknowledged as serving an important role in the expression of temperament (Goldsmith et al., 1987). Recent perspectives have acknowledged that there is a transaction between biological processes and the environment beginning prior to birth and occurring throughout development, suggesting that temperament is a complex process of development (e.g., Shiner et al., 2012). For example, temperament is not only heritable but is affected by genetics later in development (Saudino & Wang, 2012). This review highlights the various levels of biological functioning that underlie temperament and its link to developmental psychopathology, but as outlined throughout, we encourage the reader to consider the joint workings of biology and the environment in affecting children's development.

Cardiac Measures

Assessments of cardiac functioning have a long history of serving as central biological measures applied to the study of temperament, and the research to date indicates that cardiac measures account for some of the variation in children's observed temperament. The most popular cardiac measures of heart rate, heart rate variability, RSA, and pre-ejection period (PEP), reflect to varying degrees activity in the autonomic nervous system (ANS). The ANS, primarily responsible for the physiological arousal related to emotions, is broken down into two branches: the PNS and the sympathetic nervous system (SNS), which function synergistically. The PNS is predominantly active during moments of relative calm and functions to sustain homeostasis for the individual. The SNS, however, is active during times of stress and produces elevated physiological arousal to assist the individual to respond to physical, psychological, and social challenges.

Research on cardiac measures and temperament has focused primarily on measures of the PNS, specifically RSA (sometimes called vagal tone). Porges (2001, 2003; Porges, Doussard-Roosevelt, & Maiti, 1994) has put forth the polyvagal theory, which posits that the development of children's ability to regulate their states, motor activity, and emotion is supported by the maturation of the PNS. More specifically, this theory proposes that parasympathetic influence on the heart by way of the vagus nerve enables flexible responses to varying demands of the environment and is therefore considered a marker of physiological regulation (Porges, 2007). Effective vagal functioning is thought to assist in maintaining homeostasis when the individual is faced with situational change or challenges by allowing attention to move from internal processes to environmental demands, thereby supporting social engagement and facilitating the ability to use coping strategies (Porges, 1992, 2007). Studies have demonstrated rather consistently that PNS functioning, as reflected in RSA, is associated with the regulation of attention, emotion, and motor behavior across development (e.g., Beauchaine, 2001; Beauchaine, Gatzke-Kopp, & Mead, 2007; Calkins et al., 2002; Porges, 2001, 2007; Porges et al., 1994; Stifter & Corey, 2001; Stifter & Jain, 1996). Two RSA measures are primarily used: baseline RSA and RSA change.

Baseline RSA is measured when a person is at rest and denotes the individual's characteristic level of arousal. As such, this measure may reflect temperamental reactivity since it is considered an individual's traitlike ability to engage with the environment. Several studies have demonstrated this relationship (Blandon, Calkins, Keane, &

O'Brien, 2010; Calkins, 1997). Higher baseline RSA has been found to be associated with parent and observer reports of greater negative reactivity to anger-eliciting stimuli and positive reactivity to joy-eliciting situations (Calkins, 1997; Calkins et al., 2002; Fox, 1989; Stifter, Fox, & Porges, 1989). Many studies also report high baseline RSA to be associated with other reactive as well as regulatory behaviors, such as approach toward a stranger, activity level, regulated distress in frustrating situations, and lower levels of aggression (Calkins, 1997; Calkins & Dedmon, 2000; Calkins & Fox, 2002; Porges, Doussard-Roosevelt, Portales, & Greenspan, 1996; Stifter & Fox, 1990; Stifter & Jain, 1996). Interestingly, these temperament behaviors are consistent with the surgent/exuberant temperament profile. Also, not surprisingly, several studies have found a link between baseline RSA and behavior problems. Beauchaine and colleagues (2007), for example, found that children diagnosed with clinically high levels of externalizing behavior problems had lower baseline RSA than matched controls. Other researchers have reported low baseline RSA to be related to greater symptoms of anxiety and depression (e.g., Cole, Zahn-Waxler, Fox, Usher, & Welsh, 1996). It is important to note that some studies do not find a relation between baseline RSA and internalizing and externalizing behavior problems (Calkins, Graziano, & Keane, 2007; Fortunato, Gatzke-Kopp, & Ram, 2013; Gentzler, Santucci, Kovacs, & Fox, 2009), suggesting that this relationship may be more complex and likely involves consideration of the context in which these problem behaviors develop.

Change in RSA, specifically decreases in RSA in response to a stimulus (vagal withdrawal), is proposed to be a physiological strategy to support regulatory behaviors because it assists the individual to transition from maintaining homeostasis to increasing cardiac output for the purposes of controlling emotional or behavioral responses without engaging the SNS (Calkins, Graziano, et al., 2007; Porges, 2007; Porges et al., 1996; Propper & Moore, 2006). Research examining the relationship between RSA change, temperament, and the development of behavior problems indicates that greater vagal withdrawal is most beneficial for children (Calkins & Dedmon, 2000; Calkins & Keane, 2004; Porges et al., 1996). For example, vagal (RSA) withdrawal during a challenging situation was associated with better regulation (Degangi, Dipietro, Greenspan, & Porges, 1991; Huffman et al., 1998; Stifter & Corey, 2001) and fewer childhood behavior problems (Calkins, 1997; Calkins, Blandon, Williford, & Keane, 2007; Calkins & Keane, 2004; Porges et al., 1996). This may be due in part to the relationship between greater vagal withdrawal and children's effortful control of attention and sustained attention (Calkins, Blandon, et al., 2007; Suess, Porges, & Plude, 1994). However, more recent research has shown that moderate levels of vagal withdrawal and vagal augmentation (increases in RSA from baseline) in some contexts are associated with more adaptive outcomes, such as better executive functioning (Marcovitch et al., 2010), better academic performance (Graziano & Derefinko, 2013), and social competence (Blair & Peters, 2003).

While there has been much research examining the role of PNS functioning in temperament and children's behavioral adjustment, much less work has been conducted regarding the association among various temperament traits, problem behaviors, and cardiac measures of SNS activity. The SNS is associated with the fight-or-flight response to stress (Cannon, 1929). Historically, SNS activity was largely measured by changes in heart rate or heart period (García Coll et al., 1984; Kagan et al., 1984, 1987a), but such measures are influenced by both the PNS and the SNS. For example, increases in heart rate may be due to parasympathetic withdrawal, sympathetic activation, or both. More recently, researchers have focused on PEP. PEP is the sympathetically mediated time between the beat of the heart and ejection of blood into the aorta and has been validated as a measure of sympathetic activity in adults (Berntson et al., 1994) and children and adolescents (Matthews, Salomon, Kenyon, & Allen, 2002; McGrath & O'Brien, 2001; Quigley & Stifter, 2006). Low SNS reactivity, as indexed by longer PEP in response to laboratory challenges, is associated with externalizing behavior problems in childhood (Beauchaine et al., 2007; Boyce et al., 2001; Crowell et al., 2006). Beauchaine, Katkin, Strassberg, and Snarr (2001) also found that decreased PEP reactivity distinguished adolescents comorbid for ADHD and CD from those with ADHD only and from controls. Low SNS activity is hypothesized to be a marker of externalizing disorders because children who are unable to mount a physiological response necessary to experience fear may have deficits in the development of conscience while generating autonomic arousal may protect at-risk children from developing behavioral disorders (Fowles, Kochanska, & Murray, 2000; Frick, Ray, Thornton, & Kahn, 2014; Raine, 1993). Supporting this contention are findings from a study we conducted examining the association between PEP and temperament. Highly surgent children who exhibited both higher sympathetic tone and greater sympathetic reactivity scored lower in problem behavior than those who were less sympathetically reactive (Stifter, Dollar, & Cipriano, 2011). Likewise, PEP measures of increased sympathetic reactivity have been associated

with toddler freezing behavior during interactions with a stranger (K. Buss, Davidson, Kalin, & Goldsmith, 2004).

As the PNS and the SNS operate together in supporting physiological arousal and responses to stress, models outlining the dynamic between these two systems have been proposed (Berntson, Cacioppo, & Quigley, 1991) and applied to psychopathology (Beauchaine et al., 2001; Berntson & Cacioppo, 2004). To date, only a few studies have examined activity in both the PNS and the ANS in children. For example, children with externalizing problems were found to have low reactivity in both branches (Boyce et al., 2001). Another study that used skin conductance as a measure of SNS activity (El-Sheikh et al., 2009), found that within the context of parental marital conflict children who exhibited co-activation (both PNS and SNS are reactive) or coinhibition (both branches are nonreactive) were more likely to develop externalizing behaviors. One possible mechanism for these findings is the ability to regulate emotion. For example, coinhibition was related to children's inability to regulate their emotion during a disappointment task (Stifter et al., 2011). Although promising, none of the current research has considered temperament and its association with childhood behavior problems. Following Beauchaine (2001), future research interested in the relationship between temperament and developmental psychopathology would benefit from examining the dynamic between both branches of the ANS.

Electrical Brain Activity

Another biological construct relevant to temperament is neural activation. Historically, most of this research has focused on the EEG of infants (e.g., Davidson & Fox, 1982; Fox & Davidson, 1988) and children (Schmidt et al., 1999). Davidson (2000) and Fox (1994) were among the first to investigate how frontal hemispheric asymmetries in EEG were associated with individual differences in temperament and emotional development. Contrary to the notion that left/right-hemispheric activation was related to positive and negative emotions, Davidson and Fox determined that early in development, left activation was associated with approach to novelty while right activation was associated with withdrawal (Davidson, 1992; Davidson & Fox, 1982; Henderson, Fox, & Rubin, 2001). Accordingly, much research has focused on EEG frontal asymmetries in inhibited and exuberant children. Researchers have repeatedly found inhibited children to have greater relative right frontal EEG activity (Fox et al., 1995; Fox, Schmidt, Calkins, Rubin, & Coplan, 1996; L. Schmidt & Fox, 1994). Interestingly, Henderson and colleagues (2001) found that negative reactivity predicted later behavioral wariness only when children also showed right frontal EEG asymmetry in infancy. There is also evidence that left frontal EEG asymmetry lowers inhibited children's risk of continued behavioral inhibition and social wariness (Degnan & Fox, 2007), which in turn may buffer the development of anxiety disorders. Even though most of this research has examined frontal EEG activity for behaviorally inhibited children, there is also some indication that exuberant children show greater relative left frontal activation (Calkins et al., 1996; Fox et al., 2001; Hane, Fox, Henderson, & Marshall, 2008) and that the association between temperamental exuberance and the development of externalizing behaviors may be especially strong for exuberant children who show left frontal asymmetry (Degnan et al., 2011).

Event-related potential (ERP), which is computed from ongoing EEG activity, assesses dynamic changes in brain activity by time-locking brain electrical activity when individuals are presented with specific stimuli. As with EEG research, ERP research has examined the association between various ERPs and temperamental fearfulness/inhibition. For example, fearful children of mothers with anxiety disorders showed smaller error-related negativity, a possible biomarker for anxiety, than other children (Torpey et al., 2013). McDermott and colleagues (2009) reported that children who were behaviorally inhibited showed enhanced error-related negativity responses as adolescents, and those behaviorally inhibited children with enhanced error-related negativity responses were at a greater risk of being clinically anxious. It is important to note that other ERP components, such as the N2, also have been shown to be associated with temperamental fearfulness/inhibition (e.g., Perez-Edgar & Fox, 2005b).

Functional Neuroimaging

Recent technical advances in neuroimaging have led to a number of studies examining neural structures and functioning underlying temperamental reactivity and regulation. The majority of these studies were performed with adult subjects, but some have been conducted with adolescents and have provided insight into the specific brain areas associated with temperament. Motivating much of this research is the relationship between temperament and psychopathology and the hypothesis of their shared neurobiological bases.

A growing body of empirical work linking temperament and neural functioning has focused on two main areas of the brain: the prefrontal cortex (PFC), including

the dorsolateral PFC, the ACC, and the orbitofrontal cortice, and the limbic structures, including the amygdala, hippocampus, and nucleus accumbens (Cloninger, 2000; Kagan, 2002; Posner & Rothbart, 2007; Whittle, Allen, Lubman, & Yucel, 2006). Negative affectivity, specifically fear and anxiety, is associated with activity in the amygdala and the hippocampus while the right dorsolateral PFC and the ACC are involved in the regulation of negative emotions (Whittle et al., 2006). The nucleus accumbens and ACC appear to be involved in positive affectivity. Effortful control/executive function and the attention system are consistently related to activity in the PFC (Posner & Rothbart, 2007). Although most of this research has been done linking adult personality with neural activation, promising new research has been conducted with adolescents and adults identified in childhood as belonging to a particular temperament type. A study of older children and adolescents with aggression (Stadler et al., 2007), for example, showed low activation in the ACC in response to expressions of negative affect compared to controls. Novelty seeking, which characterized the aggressive children, was also related to reduced activity in the ACC.

Increased activation of the amygdala to emotion faces in individuals with a history of childhood behavioral inhibition also has received significant attention and empirical support (Perez-Edgar et al., 2007; Schwartz et al., 2003). More specific to developmental psychopathology, a study linking amygdala function, behavioral inhibition, and internalizing disorders (Hardee et al., 2013) revealed amygdala-prefrontal (dorsolateral PFC and anterior insula) connectivity to be negative for angry faces (greater threat) in adolescents previously identified as behaviorally inhibited, which, in turn, was also related to more self-reported internalizing problems. In addition, negative fronto-amygdala connectivity moderated the relation between behavioral inhibition and internalizing disorders. Interestingly, older children and adolescents with callous-unemotional traits (including fearlessness) had reduced amygdala response to fearful faces and lower to negative fronto-amyglada connectivity (Marsh et al., 2008).

In summary, research in brain electrical activity and functional neuroimaging has provided some insight into the biology underlying individual differences in reactivity and regulation. However, the bulk of the research has come from studies on behaviorally inhibited children and their risk for anxiety disorders. As exuberant/surgent children are at risk for externalizing problems, more research on the neural correlates of this temperament type, such as the mesolimbic dopamine system, which is involved in reward processing, may give insight to the origins of this risk.

Psychobiological Measures of Stress

Individual differences in stress-related biological measures have also been associated with temperament. The hypothalamus is the neural center for stress responses. When a stress response is triggered, the hypothalamus sends signals to the pituitary gland and the adrenal medulla. Short-term responses are produced via the sympathomedullary pathway (SAM) while long-term stress is regulated by the hypothalamic-pituitary-adrenocortical (HPA) axis. Much of the research linking temperament to behavior problems have investigated the end product of the HPA system—cortisol. Whereas baseline levels of cortisol support the individual's ability to organize and complete fight/flight responses to threatening situations, the regulation of behavioral and sympathetic reactivity is facilitated by smaller elevations of cortisol (Gunnar, Kryzer, Van Ryzin, & Phillips, 2011). Thus, cortisol responses to stressor/challenges serve an important role in challenging situations, and individual differences in reactivity and regulation are believed to prompt variations in these biological responses.

Many researchers have hypothesized that behaviorally inhibited children have a lower threshold for distress and therefore produce more cortisol in response to challenge (Kagan, 1994; Rosen & Schulkin, 1998). In support of this hypothesis, higher levels of cortisol were found to be associated with greater shyness/fearful behavior in children (de Haan, Gunnar, Tout, Hart, & Stansbury, 1998; Kagan et al., 1987a; Watamura, Donzella, Alwin, & Gunnar, 2003). Researchers have also examined changes in children's cortisol over time while also considering the child's temperament. For example, Blair, Peters, and Granger (2004) reported that inhibited preschool-age children showed increases in cortisol across a laboratory visit, while exuberant children showed a drop in cortisol across this time period. Temperamental differences in changes in cortisol also appear across a longer period of time. Tarullo, Mliner, and Gunnar (2011) found that cortisol decreased from fall assessments to spring assessments for highly exuberant and average children but not for inhibited children.

However, the association between cortisol and temperament traits appears to depend on other factors, both internal and external. External contexts, such as parenting (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996) and day care (de Haan et al., 1998) can affect the degree to which temperament and cortisol responsivity is linked. Indeed, individual characteristics, such as social competence, peer rejection, and emotion dysregulation,

are related to cortisol levels when measured in child care contexts (Dettling, Parker, Lane, Sebanc, & Gunnar, 2000; Gunnar, Tout, de Haan, Pierce, & Stansbury, 1997; Gunnar et al., 2003). The association between temperament and cortisol may also depend on other behaviors of the child. Gunnar and colleagues (2003) reported that exuberant children who were more aggressive and experienced greater peer rejection had higher cortisol levels, whereas exuberant children who did not show these maladaptive social behaviors had lower cortisol levels than children lower in exuberance. Tarullo and colleagues (2011) also found evidence that the social experiences predictive of changes in children's cortisol over time (across an academic year) was different for inhibited and exuberant children.

Links between HPA activity and problem behaviors have also been well established such that high levels of cortisol have been found in children with either type of internalizing behavior, anxiety or depression (Gunnar, 2001; Hastings, Fortier, Utendale, Simard, & Robaey, 2009; Lopez-Duran, Kovacs, & George, 2009), whereas children with externalizing problems or disruptive behavior disorders have lower cortisol levels before and after challenging events (Fairchild, Van Goozen, Stollery, & Goodyer, 2008; Hastings et al., 2009; van Goozen, Fairchild, Snoek, & Harold, 2007). A few studies have examined the role that both temperament and cortisol reactivity have in predicting problem behaviors; the findings suggest that gender plays a significant role in this developmental process. Hastings and colleagues (2011) found that inhibition and prolonged elevations of cortisol were linked to internalizing behaviors, but only for girls. In another study, chronic inhibition, which was associated with adolescent anxiety disorder, was predicted by both earlier behavioral inhibition and high levels of cortisol, but only for girls (Essex, Klein, Slattery, Goldsmith, & Kalin, 2010). Interestingly, Perez-Edgar, Schmidt, Henderson, Schulkin, and Fox (2008) found a similar relationship for boys in that high levels of cortisol and high negativity in infancy were related to internalizing behaviors and social reticence in 4-year-old boys.

One end product of stimulation of the SAM is salivary alpha-amylase (sAA), a digestive protein found in saliva and responsive to psychological and physical stress. Similar to cortisol, sAA levels change in response to challenges and stressors presented to the individual but occur in less time because of its short-term flight/fight function. As such, sAA has been used as a surrogate marker of SNS activation. However, only recently have studies examined the link between sAA and children's temperament and problem behavior. Spinrad and colleagues (2009) reported that parent ratings of temperamental anger, impulsivity, and externalizing behaviors were negatively associated with sAA reactivity, whereas regulation was positively associated with sAA, especially for girls. In another study on toddlers, high levels of baseline sAA were related to observed positive affect and approach, and the highest levels were found in toddlers rated high in both positivity and approach (Fortunato, Dribin, Granger, & Buss, 2008).

Because both sAA and cortisol are used to assess stress, researchers have turned to examining how they interact to affect individual differences in behavior (El-Sheikh, Erath, Buckhalt, Granger, & Mize, 2008; Gordis, Granger, Susman, & Trickett, 2006; Keller, El-Sheikh, Granger, & Buckhalt, 2012; Kivlighan & Granger, 2006). For instance, high sAA and low levels of cortisol predicted higher aggression in young adolescents, whereas high sAA and high cortisol predicted internalizing behavior problems (Gordis et al., 2006). El-Sheikh and colleagues (2008) also found that school-age children had increased risk of internalizing behavior problems when they had high levels of cortisol and high sAA. Although promising, research that has examined sAA, temperament, and developmental psychopathology is not conclusive, and we await further findings.

Genetic Measures

The heritability of temperament traits is an important part of most temperament models and research. Indeed, at least one temperament model rests on evidence that temperament traits are sufficiently heritable to be included in the model (A. Buss & Plomin, 1975, 1984). Quantitative behavioral genetics research, which uses twin and adoption study designs to decompose the observed variance of a temperament trait into genetic and environmental variance, has provided strong support that many temperament traits have a genetic basis. Temperament traits such as activity level (Saudino & Eaton, 1991; A. Wood et al., 2007), anger/frustration (Goldsmith, Buss, & Lemery, 1997; Goldsmith & Gottesman, 1981), behavioral inhibition/shyness (Eley et al., 2003; Emde et al., 1992; Smith et al., 2012), and effortful control (Gagne & Saudino, 2010; H. Goldsmith, Pollak, & Davidson, 2008) have been investigated for the genetic effects, and evidence has been found across development. Based on eight twin studies, Goldsmith et al. (2008) suggest that individual differences in children's effortful control are at least moderately heritable. Although estimates of heritability vary across studies and traits, the evidence indicates that genetic differences account for approximately 20% to 60% of the variability in temperament within the population (Saudino & Wang, 2012).

Several studies have shown shared genetic influence between temperament and measures of problem behavior (Goldsmith & Lemery, 2000; Saudino & Wang, 2012). For example, observed inhibitory control is genetically linked to externalizing problems (Gagne, Saudino, & Asherson, 2011) while genetic influence explained about 94% of the association between emotionality and internalizing problems (Schmitz et al., 1999). As noted, these findings lend support to the spectrum model linking temperament to the development of psychopathology (Tackett, 2006).

Quantitative genetic research also focuses on how the environment influences the expression of temperament traits. Although much of the research shows that shared genes, not shared environments, account for similarity in temperaments (e.g., Gagne, Saudino, & Cherry, 2003; Lemery-Chalfant et al., 2008; Mullineaux, Deater-Deckard, Petrill, Thompson, & DeThorne, 2009), findings indicate that shared and nonshared environmental effects may influence the expression of temperament. For example, differential treatment by parents may affect differences in siblings' expression of shyness and activity level (Saudino, Wertz, Gagne, & Chawla, 2004). Further, although rare in temperament research, evidence of shared environmental effects for temperamental positive affect (Gagne, Vendlinski, & Goldsmith, 2009; Goldsmith, Lemery, Buss, & Campos, 1999; Goldsmith et al., 1997;) has emerged. Thus, environmental differences within and between families are important in understanding the genetic bases of temperament (Saudino & Wang, 2012).

Recent developments in molecular genetic techniques now make it possible to identify specific genes associated with various temperament traits with the understanding that no one gene is responsible for individual differences in reactivity and regulation. Thus far, molecular genetics research has identified several candidate genes related to temperament with the genes regulating dopamine and serotonin the most commonly studied genes. The dopamine genes, DRD2, DRD4, and DAT1, for example, have been implicated in reward sensitivity and novelty seeking. Genes regulating serotonergic functioning, such as the 5-HTT gene, are involved in the regulation of emotion and mood. A number of studies examining these candidate genes in samples of infants, toddlers, and children have found support for these functions; however, an equal number found null or opposing associations (see Saudino & Wang, 2012, for a review). Importantly, some of the genes associated with temperament are often those associated with clinical disorders, such as the relationship between DRD4 and ADHD (Faraone et al., 2005).

As noted, the relationship between these candidate genes and temperament is not monotonic; other genes likely work together to explain variations in temperament. Further, environmental or experiential influences appear to affect the expression of temperament for children possessing certain genes. For example, Sheese, Voelker, Rothbart, and Posner (2007) found that quality of parenting interacted with the 7-repeat allele of the DRD4 gene to affect children's activity level, sensation seeking, and impulsivity. In another study, the short 5-HTT allele was associated with behavioral inhibition, but only for those who experienced low maternal support (Fox et al., 2005). Along these same lines, Moffitt, Caspi, and Rutter (2006) have skillfully proposed that gene × environment effects are a major determinant of psychopathology and suggest a number of strategies to test this hypothesis.

Summary

Noninvasive electrophysiological and neuroimaging procedures such as electrocardiography, EEG, ERP, functional magnetic resonance imaging, and cortisol/alpha amylase assays with infants, children, and adolescents have provided insight into the biological link between temperament and psychopathology. Notably, when taken together, the findings appear to coalesce around physiological changes that characterize fearfulness, behavioral inhibition, and anxiety. High heart rate, low resting RSA, greater cortisol reactivity (particularly when paired with higher levels of sAA), right frontal hemispheric asymmetry, and enhanced amygdala activation have been consistently found in fearful children, supporting Kagan's (1994; Kagan & Fox, 2006; Kagan et al., 1984) long-held hypothesis that a low threshold for physiological arousal is a central characteristic of behavioral inhibition. Although less studied, fearless, more approach-oriented, and reward-sensitive children have been found to exhibit low heart rate, less sympathetic reactivity, and greater left frontal activation. Recently, Miskovic and Schmidt (2012) proposed a lateralized brain-body emotion model to integrate these findings and apply them to temperament, specifically fearfulness. Central to this model is the lateralization of central and autonomic function underlying approach-withdrawal whereby the right hemisphere has an excitatory role whereas the role of the left hemisphere is to generate inhibitory responses. Support for this model comes from studies in adults examining at least two biological systems, such as EEG and RSA. Few studies have been done with children, but with the availability of child-friendly, noninvasive techniques and models to test, research in

temperament and psychopathology needs to advance toward considering genetic and multiple physiological levels of analysis.

FINAL REMARKS: SUMMARY AND FUTURE DIRECTIONS

Currently there is little doubt that temperament makes up a considerable part of what the children bring to bear on their own development, including the emergence of emotional and behavioral disorders (Zentner & Shiner, 2012). Whether through extremes in temperamental reactivity or in interaction with proximal and distal contexts that increase the risk of psychological maladjustment, the influence of temperament on the development of psychopathology has been grounded in strong theoretical models and supported by empirical investigations. The recent surge in studies investigating the developmental pathways from temperament to psychopathology using sophisticated methods, multiple levels of analyses, and diverse samples has significantly improved our understanding of the processes by which a child's individual differences in reactivity and regulation directly and indirectly impacts his or her mental health outcomes. Despite this progress, there still remain methodological issues and knowledge gaps that need to be addressed. Next we summarize the findings, highlight the issues, and propose directions for future research.

Existing research has revealed relatively consistent, moderate associations between children's behavior problems and a variety of temperament factors, styles, and traits; yet there is evidence that the association between some temperament traits and behavior problems is stronger than others, such as with effortful control. Further, and as might be expected, some temperament factors/styles/traits are more strongly associated with behavior problems within the externalizing realm than the internalizing realm or vice versa. For example, high levels of anger/frustration are more likely to be related to externalizing behaviors whereas greater sadness and fear reactivity are more consistently related to internalizing problems. There are, however, several caveats to this conclusion that warrant caution and indicate the need for more research.

The temperament factor of negative emotionality has been shown to have a relatively strong association with both internalizing and externalizing behaviors. However, negative emotionality is composed of different forms of negative reactivity, each of which differs by underlying motivations and emotions (Barrett & Campos, 1987). Indeed, the finding that negative emotionality predicts both broad bands of behavior problems highlights this issue. The same could be said about difficult temperament, which has already been deemed a questionable construct. Taking a more fine-grained approach that examines specific temperament traits is recommended. By examining the link between lower-order traits and behavioral and emotional disorders, we can focus on the processes by which children develop psychopathology and achieve more precision and better predictability. We know, for example, that parents can distinguish their children's emotions in early infancy (Source & Emde, 1982). Thus, we might expect fear and anger reactivity to evoke differential parent responses, some of which may not be sensitive to the emotional reactivity of the child (e.g., ignoring fear, disciplining anger harshly). Overtime these interactions may lead to diagnosable emotional and behavioral disorders. We encourage researchers in developmental psychopathology to consider lower-order temperament traits and use theoretical models and supportive research to guide their choice of trait for inclusion in their models.

It is well understood that the environment within which children develop has a significant and long-lasting impact on their cognitive, social, and emotional outcomes even before birth. Thus, when investigating the role of temperament in the development of psychopathology, researchers have considered carefully the conditions and contexts within which the child's temperament operates and its effect on adjustment. Not surprisingly, the majority of studies reviewed focused on the parenting environment. Overall, the research indicates that negative parenting behaviors, such as intrusiveness and harsh discipline, seem to exacerbate the maladaptive effects of some temperament traits (i.e., negative emotionality) in the development of behavior problems. However, potentially poor outcomes can be tempered by positive parenting behaviors, such as warmth and sensitivity, in some cases to the point of developing the fewest problem behaviors among comparable children.

Despite the accumulating evidence that the parenting environment in interaction with a child's temperament increases or decreases the risk for the development of psychopathology, there are a number of gaps in the research. Few studies, for example, have examined the transactional process that exists between children's temperament and aspects of the environment across early development despite the strong theoretical frameworks and statistical applications to guide and support such work. Research on other aspects of the environment is also needed. Other proximal processes, such as family stress or

child maltreatment, that may be mediated or moderated by temperament to increase risk of psychopathology should be examined. Likewise, investigations of adverse contexts, such as poverty and neighborhood risk, are likely to demonstrate both the risk and resilience of temperament traits (Lengua & Wachs, 2012). Indeed, if a researcher is considering broad risk factors such as socioecomonic status, parent mental health, or trauma as they relate to the development of psychopathology, taking into account the child's temperament will determine to some degree whether these factors lead to either emotional and behavioral disorders or normal adjustment by way of the child's perceptions and responses to these environmental conditions.

A review of the current research indicates that certain temperament traits/factors appear to also serve a protective role. Although there is still limited research examining this area of inquiry, one important exception is the number of studies that have demonstrated the role of effortful control in lowering highly negative children's risk of developing behavior problems, especially within the externalizing realm. This protective role is not surprising, given the central role of self-regulation in all developmental domains. Likewise, recent research on the temperament trait of positive emotionality suggests that under certain conditions (e.g., without accompanying disruptive behaviors or when paired with low negative emotionality), greater positive emotionality can protect against both internalizing and externalizing behavior. Although these data may be seem obvious, given the number of social, cognitive, and physical outcomes associated with this trait, a growing number of studies have linked high-intensity positive affect with problem behaviors, particularly as part of the exuberant type.

Continued study of temperament × temperament interactions with effortful control and positive emotionality may elucidate what combinations of characteristics put a child at risk for problem behaviors. For example, in exuberant children, do high levels of positive emotionality combined with impulsivity in particular contexts increase risk of behavior problems, such as when presented with highly novel, exciting stimuli? Or do high levels of effortful control counteract the risk conferred on children characterized by high-intensity pleasure? There is some indication that emotion regulation is important for exuberant children's behavioral adjustment (Stifter et al., 2008), but more research is needed to examine the regulation of positive affect. The work of Klein and colleagues (Dougherty et al., 2010; Klein et al., 2011) has also implicated low levels of positive emotionality in childhood depression. All children have the capacity to feel positive emotions. Future studies might examine the conditions under which these children feel and express positive affect and whether, for example, parent up-regulation of the child's positive emotion reduces the risk of depression. Given that the examination of the link between positive emotionality and developmental psychopathology is a relatively new area of research and the findings are mixed, more studies are needed to investigate how variations in positive affect intensity, the contexts in which positive emotions are elicited, and the underlying motivations for the experience of positive emotions contribute to developmental psychopathology.

More advanced statistical modeling supports new innovative methods for examining the association between temperament and the development of psychopathology, which we have highlighted in our review of the literature. For example, studies taking a person-oriented approach have used latent profile analysis to create children's temperamental styles. This technique has advanced the grouping of children based on similar characteristics from the more simplistic extreme group approach and the somewhat problematic cluster analysis, which relies on more arbitrary criteria for classification (Vermunt & Magidson, 2002). Latent growth curve modeling has been applied to longitudinal data to examine how temperament affects trajectories of behavior problems over time. This method may be useful in testing the *pathoplasty/exacerbation* model which proposes that personality will affect the course, severity, and presentation of a disorder. According to Tacket (2006), this model has not been tested due to the methodological challenges of measuring personality before the emergence of a disorder. If we accept that temperament forms the basis of personality (Caspi & Shiner, 2012) and that a number of clinical disorders presented in adolescence are predictive of adult psychopathology, then the field of developmental psychopathology is prepared conceptually and methodologically to take up this challenge.

Researchers are increasingly implementing multiple measures in their studies of temperament. Importantly, observational and biological measures are becoming more widely incorporated into studies investigating the association between temperament and developmental psychopathology. Yet there is still room for advancement. We strongly encourage future research to consider multiple indicators of temperament across multiple levels of measurement (biological, parent report, behavioral) in single studies. A number of advanced multivariate statistics, such as structural equation modeling, can be used to address the use of multilevel, multi-informant designs.

Although improved statistical analyses encourage the use of multiple methods, much of the current research continues to rely on parent ratings of both children's temperament as well as their problem behavior. The reliance on parent report for both measures of temperament and behavioral problems introduces error into the results by way of parental bias. Although there are many advantages to using parent report, research has clearly demonstrated that other factors, particularly related to the reporter, influence parent ratings of temperament. Controlling for these variables is important but not considered in a number of the studies reviewed. Future research needs to counteract the biases in parent ratings by obtaining reports from others close to the child, such as another parent or child care worker, by including observational measures of temperament, or by obtaining ratings of problem behavior from a number of informants.

Further, several studies have examined the overlap among the instruments measuring both temperament and behavior problems and found that after removing similar items, the relationship between the two constructs was attenuated but remained significant. Research following this discovery, however, has not followed suit, with the majority of studies neglecting to remove the confounding items, thus inflating the relationship between temperament and problem behaviors. For researchers who rely solely on parent report of both temperament and behavior problems, such as in studies using large community samples, removing the confounding items is highly recommended as it is essential to the integrity of the findings.

Another methodological issue that limits interpretation is that the majority of the studies reviewed were conducted with community samples. In many cases, the results linking temperament with problem behavior did not have sufficient numbers of children meeting the criteria for diagnosable externalizing or internalizing clinical disorders. Thus, it is not clear to what extent temperament, even at extreme levels, influences the development of psychopathology. Future research needs to take the next step toward conducting studies that either target children at risk, such as children of depressed mothers (e.g., S. Goodman et al., 2011), or children living in violent homes (e.g., Towe-Goodman, Stifter, Coccia, & Cox, 2011), to increase the chances of finding children with clinical disorders, or use large and diverse community samples that produce sufficient numbers of children with diagnosable levels of behavioral or emotional problems to ensure power to test hypotheses linking temperament to psychopathology.

TRANSLATIONAL IMPLICATIONS

We end this chapter with a brief discussion of the translational implications of temperament for the field of developmental psychopathology. Temperament research emerged out of a clinical tradition; however, the application of what we have come to learn about temperament and behavioral adjustment to practice has not advanced. Only a handful of interventions focused on temperament have been conducted with the aim of reducing behavioral and emotional disorders. However, many of the methodological issues found in the studies reviewed in this chapter are also evident in these programs (McClowry, Snow, Tamis-Lemonda, & Rodrigues, 2010; Rapee, Kennedy, Ingram, Edwards, & Sweeney, 2010). Nonetheless, the research findings from the studies we reviewed in this chapter are informative in terms of understanding the developmental pathways toward clinical disorders as well as informing preventive interventions.

One way to conceive of the role of child temperament in the development of psychopathology is as a risk or protective factor. Risk is a probabilistic concept that defines the likelihood that certain individual or contextual characteristics will contribute to the development of a negative outcome. Protective factors are those characteristics that reduce the impact of risk (Lengua & Wachs, 2012). The developmental impact of a risk factor will depend on a number of circumstances, including whether the child is exposed to other risks, the context within which the risk occurs, and whether there are protections against the risk. Thus, certain temperament traits can be either a risk (e.g., negative emotionality) or a protective factor (e.g., effortful control), as the current review has highlighted. In addition, a temperament trait or style may be a risk factor in some contexts or during some developmental periods but not others. For example, anger reactivity, particularly during the preschool period, is associated with externalizing behaviors, but anger in infancy is adaptive in that it communicates the child's emotional state and elicits caregivers to change the situation (Stifter & Fox, 1990). Treating temperament traits or styles as risk or protective factors implies that it has a translational function.

The findings of the most current research in temperament and psychopathology indicate that extremes in the temperament traits that define behavioral inhibition may be a risk factor for internalizing problems generally and anxiety specifically, supporting the spectrum model. Importantly, the data suggest that it is not just the presence of extreme behavioral inhibition in early childhood that denotes risk likely because many behaviorally

inhibited children tend to move out of that class due to the development of regulatory strategies or other moderating influences. Rather, if a child remains behaviorally inhibited across early childhood, he or she will most likely develop internalizing problems or anxiety. This conclusion is supported by research on the biological indices underlying behavioral inhibition and anxiety, such as right hemispheric activation, as well as the processes through which such children may develop anxiety disorders (e.g., attention to threat). If stable behavioral inhibition is a risk factor, then mental health programs aimed at preventing the development of internalizing disorders in children might select those characterized by high behavioral inhibition over time and focus their interventions on processes that decrease the risk of psychopathology, such as parenting or self-regulation. A handful of interventions with behaviorally inhibited children have been conducted aiming the intervention on parenting behaviors hypothesized to attenuate the risk for anxiety (LaFreniere & Capuano, 1997; Rapee et al., 2010). Although somewhat successful in the short term, the children were classified based on a one-time assessment of behavioral inhibition as preschoolers. Drawing from the research reviewed, the interventions may have been more successful if the researchers had further limited their intervention group to those children who were stable in behavioral inhibition from earlier in childhood.

Taking an extreme group approach to understanding risk for developmental psychopathology may be especially informative for practice with the behaviorally inhibited type; however, most research on other temperament traits and styles supports the vulnerability model's proposed pathways to developmental psychopathology. The vulnerability model differs from the spectrum model in that it makes a distinction between temperament and psychopathology. And while it proposes that individual differences that make up temperament and personality are risk factors for particular clinical disorders, it includes the potential for the interaction with environmental factors to increase risk. We would also add that based on the research reviewed here, combinations of temperament traits found in temperament × temperament interactions increase the risk of or provide protection against the development of psychopathology.

Understandably, parent behavior, personality, and mental health have been the focus on much of the research testing the vulnerability model. Parents are particularly important in providing the context within which developmental tasks are accomplished. Likewise, depending on the type of behavior they exhibit in response to their child's emotions and behaviors, parents may influence whether the child's developmental trajectories are positive or negative. Negative parent behaviors, such as harsh discipline or poor parent mental health, are risk factors for child behavior problems, but when those behaviors are combined with children who are high on negative emotionality and more specifically anger reactivity, which are also risk factors, then the likelihood of the child being viewed as problematic increases. Many preventive interventions aimed at reducing externalizing problems select parents and children who are identified as "at risk" due to such factors as parent psychopathology, income level, or abusive history. Understanding that temperament may add to such risks via how children perceive, react to, and subsequently evoke parental responses could be helpful in creating more selective interventions. For example, low-income parents who are easily frustrated may respond to their highly active, impulsive, surgent child with negative control. Such parenting behavior has been shown to be ineffective with surgent children, increasing their risk of developing externalizing behaviors. Selective interventions that target high-risk parents (low income, easily frustrated) with surgent children may be more effective than an intervention program that targets just the family/parent characteristics.

Finally, we consider the implications of temperament × temperament interactions in the development of psychopathology. The research has clearly demonstrated that effortful control which emerges at the end of the first year of life through the preschool years is important to the regulation of temperamental reactivity. Thus, children who have poor effortful control will exhibit high levels of negative or even positive reactivity that can lead to behavior problems. These findings support current preventive interventions that focus on improving self-regulation or effortful control. However, the evidence also suggests that effortful control may not be a protective factor for the behaviorally inhibited child, demonstrating the importance of considering the child's temperament when designing preventive interventions.

Positive emotionality may also act as a protective factor for other temperament traits. The findings indicate that high positive affect may attenuate the risk of negative emotionality and high activity level. For example, exuberant children, perhaps through their high active, impulsive behavior, may be at risk for problem behaviors, but the negative effects of these behaviors may be counteracted by their positive emotionality and approach orientation. According to Fredrickson's (2001) Broaden and Build theory, positive affect builds social, cognitive, and physical resources that individuals can draw on to cope with aversive situations. Exuberant children, therefore, may have

protective factors within their own group of characteristics. Positive emotionality has a significant impact on all developmental domains, making it an excellent target for interventions, in particular universal interventions that are geared toward all families regardless of risk. Up-regulating positive emotions and learning to use them to cope with aversive events (positive reappraisal) may prove to be very effective in preventing the development of behavior problems.

CONCLUSION

Historically, temperament has been proposed to have a significant influence on the development of psychopathology. Recent improvements in the conceptualization and measurement of temperament and the progress made by studies examining the biological and genetic underpinnings of temperament have enabled researchers to test several proposed models of psychopathology. Overall, the findings are promising and support the notion that, through their individual differences in reactivity and regulation, children contribute to their own development, including their risk for emotional and behavioral disorders. Although the role of temperament in child development is no longer debatable, the degree to which temperament negatively and positively affects maladaptive outcomes and the explanatory mechanisms through which it makes its impact still requires further study.

INTRODUCTION AND HISTORY

Scientists and practitioners have long acknowledged that the quality of the parents' marital relationship affects children's development. For example, at the 1929 meeting of the American Orthopsychiatric Association, Towle (1931) discussed the importance of evaluating the marital relationship of potential foster parents, arguing "since a well-integrated marital situation affords the maximum possibility for well-adjusted children, it is essential that one understands the emotional life of the parents" (p. 281). A few years later, Hubbard and Adams (1936) concluded from an examination of case records from a child guidance clinic that parents' relationship to each other is among a handful of factors frequently found to have a bearing on the development of child problems. However, it was not until the 1970s that efforts to understand the link between marital functioning and child adjustment sharpened.

This shift toward the systematic study of effects of marital functioning on children's development was prompted by several factors. Chief among these was the rising divorce rate in the United States, which stimulated research to better understand how parental divorce affects children. One conclusion that emerged from this research was that children's adjustment was determined more by the parents' conflict with one another than by the divorce itself (R. E. Emery, 1982). The burgeoning family therapy movement during the 1960s and 1970s also prompted interest in the link between marital and child functioning. A primary tenet of family systems theories is that individual family members are inextricably rooted in a larger family context that influences their thoughts and actions, and it was explicitly asserted that parents' marital dissatisfaction could stimulate and maintain adjustment problems in their children (Satir, 1964). Some speculation about this was quite bold. For example, published articles referenced the

assertion that "whenever you have a disturbed child, you have a disturbed marriage" (Framo, 1965, p. 154), and this tenet was commonly accepted by adherents to family systems theory.

There was also growing recognition among researchers outside of the family therapy movement (e.g., behavior therapists) that marital discord could adversely affect child adjustment and that clinicians might be able to enhance the effects of behavior therapy for children by attending to the parents' marital relationship (Oltmanns, Broderick, & O'Leary, 1977; Patterson, Cobb, & Ray, 1973). In addition, during this time, well-designed empirical studies were also beginning to identify marital discord as a potentially important determinant of child adjustment problems. For example, in a large community sample, Rutter (1971) found an unhappy marriage to increase risk for child conduct problems, even after controlling for other potential risk factors.

During the latter part of the 1970s and the 1980s, research on marital functioning and child adjustment expanded considerably. Much of this research focused on answering some variation of the general question of whether there was a reliable association between parents' marital functioning and children's adjustment. Collectively, these early studies helped document the strength, robustness, and generalizability of the relation. It became clear that marital discord was indeed associated with child adjustment problems, in clinical as well as in nonclinical samples, across a very wide age range of children and across a variety of indices of marital functioning and child adjustment. Although the magnitude of the association between parents' marital functioning and child adjustment varied across studies, statistically significant associations, which were typically of small to medium effect size, emerged fairly regularly. It also started to become clear that certain dimensions of interparental conflict were more important than others in predicting child adjustment.

These early studies laid the foundation for the development of two influential theories on the nature of the link between marital and child functioning: the cognitive-contextual framework (Grych & Fincham, 1990) and the emotional security hypothesis/theory (EST) (Davies & Cummings, 1994). Prior to the 1990s, much of the research on interparental conflict and child adjustment was guided by concepts from broad theories of family functioning or social behavior or only loosely tied to theory. These two theories were unique in that they specifically described processes by which parents' marital functioning might influence children's development and, in doing so, laid the groundwork for a new generation of research. They pushed the field to move beyond simply examining the extent to which marital and child functioning are related and to begin considering factors that help explain why this is so. In addition, because studies from the 1970s and 1980s also indicated that many children in maritally discordant families did not have significant adjustment difficulties, investigators also tried to identify those factors that seemed to shield children from the adverse effects of parental marital discord. Over two decades of research following the introduction of these two theories has now been amassed, and quite a bit of progress has been made toward understanding reasons why interparental conflict can lead to child problems and the conditions under which it might not.

The next section of this chapter deconstructs the concept of interparental conflict, describing the dimensions of such conflict that, over time, can adversely affect children's social, behavioral, and emotional development. We then use these dimensions as a framework for reviewing the current state of knowledge on the association between interparental conflict and child adjustment problems. We follow the literature review with a presentation of several noteworthy explanations for the link between interparental conflict and child problems. In addition, we highlight key variables and processes implicated by this work and discuss how specific circumstances surrounding incidents of interparental conflict might influence the way it relates to child adjustment problems. We follow this with a discussion of translational implications of this research and review examples of how the research has informed practice. In the final part of the chapter, we make suggestions for future directions for this research area. Throughout this chapter, we illustrate how different methodologies have been employed and how principles of developmental psychopathology have guided and should continue to guide research on this topic.

INTERPARENTAL CONFLICT AND CHILD ADJUSTMENT PROBLEMS

Interparental conflict can be defined as opposition, disagreement, or a difference of opinion between parents; it is a normal part of adult relationships, and practically all children who have contact with their parents will be exposed to it (Papp, Cummings, & Goeke-Morey, 2002). Despite the simplicity of this definition, the phenomenon itself is complex, and the sources and manifestations of interparental conflict are many and varied. For example, a conflict may center around any number of topics, and the behaviors and emotions expressed during a single conflict

incident can range widely in type and intensity. There is also variability in conflict resolution; some conflicts may be resolved quite easily with no untoward aftereffects, whereas others linger, fester, or seem to have been put to rest, only to arise again.

These particular dimensions of conflict—topic, behavioral tactics, emotions, and resolution—provide the framework for our review. It is important to acknowledge at the outset that certain manifestations of these four dimensions are negative, but others may be benign or even positive and beneficial to children (Cummings & Davies, 2010). For example, parents whose disagreements are calm and respectful, and who come to a reasonable resolution of their differences, might provide their children with healthy models of conflict management and adaptive relationships. We make reference to some of the research that has examined positive aspects of interparental conflict in our review. Unfortunately, relatively little research has examined this side of the coin; more often the focus has been on understanding how conflict undermines child adjustment. In light of this fact, the bulk of our review focuses on the link between interparental conflict and problematic child adjustment.

In most of the research on this topic, child adjustment problems are operationalized along the broad dimensions of externalizing problems, such as aggressive, oppositional, and delinquent behavior, or internalizing problems, such as symptoms of depression or anxiety. It should be acknowledged, however, that interparental conflict has also been linked to child adjustment problems that do not fit neatly into the categories of internalizing or externalizing problems. For example, exposure to interparental conflict has been linked to various aspects of child physical health (Nicolotti, El-Sheikh, & Whitson, 2003; Wood, Klebba, & Miller, 2000), cognitive and academic abilities (Ghazarian & Buehler, 2010; Harold, Aitken, & Shelton, 2007; Jouriles et al., 2008), and behavior in romantic relationships (Jouriles, Mueller, Rosenfield, McDonald, & Dodson, 2012; Kinsfogel & Grych, 2004). These findings are consistent with the developmental psychopathology principle of multifinality, which holds that a given risk factor (i.e., exposure to interparental conflict) may give rise to a variety of possible child outcomes. Although the focus in this chapter is on externalizing and internalizing problems, other aspects of child adjustment are considered, as appropriate.

Externalizing and internalizing problems typically are conceptualized as occurring along a continuum. It is not clear in many of the studies on this topic how many children in the samples were experiencing clinically significant levels of problems or outright psychological disorders, as defined by commonly used classification systems of mental disorders (e.g., *Diagnostic and Statistical Manual of Mental Disorders*). In fact, in many studies, it appears that most of the children in the samples were not experiencing clinically significant problems (as indexed by the standard measures that were used). In other words, it should be recognized that the variation in child adjustment problems accounted for in many studies appears to be primarily within the range of normal child adjustment.

It is also noteworthy that many studies on this topic have evaluated children's immediate responses to specific incidents of adult conflict. In these studies, the investigators are measuring children's emotions (e.g., anger, sadness, fear) and behaviors (e.g., aggression) that occur immediately after a conflict incident. These are arguably symptoms of child distress, and not adjustment problems per se. However, there is evidence that children's immediate emotional and behavioral responses to interparental conflict, when collected across a number of incidents and aggregated, are associated with standard measures of child adjustment problems (Cummings, Goeke-Morey, & Papp, 2004; Goeke-Morey, Cummings, & Papp, 2007). Thus, this research is viewed as pertinent to the question of how interparental conflict influences children's adjustment.

Topic of the Conflict

Compared to other dimensions of interparental conflict, research regarding the effect on children of the topic of the conflict is limited. However, results from studies using a variety of methods converge to suggest that conflict about child-related topics can be deleterious for children. For example, studies that make use of parents' reports on questionnaire measures of child-related interparental conflict indicate that such measures are associated with child externalizing and internalizing problems (e.g., Jouriles et al., 1991; Lee, Beauregard, & Bax, 2005; O'Leary & Vidair, 2005; Snyder, Klein, Gdowski, Faulstich, & LaCombe, 1988), and these associations emerge even after accounting for other dimensions of marital functioning, such as general marital adjustment.

There is also experimental evidence that children are more likely to be immediately affected by interparental conflict that centers on a child-related topic as opposed to other topics. For example, in an analog study, Grych and Fincham (1993) had children listen to audio-recorded vignettes of conflict between a man and a woman. They asked the children to imagine that the conflict was between their parents and afterward had the children answer

questions about their own affect, cognition, and potential coping strategies. Some of the conflicts focused on child-related topics (homework time, who would take the child to an activity), whereas others focused on matters theoretically less related to the child (work, finances). Findings indicated that children reported more shame and fear of being drawn into the conflict when the conflict concerned the child. In another analog study, in which children watched videotaped vignettes depicting conflict between a man and a woman (and were asked to imagine that the conflict was between their father and mother), unresolved child-related conflict resulted in more immediate anger and sadness than unresolved and resolved conflict focusing on non–child-related topics (Koss et al., 2011).

Other evidence for the immediate effects of child-related conflict on child behavior comes from a daily diary study conducted by Cummings and colleagues (2004). Mothers and fathers kept a home diary about incidents of marital conflict and children's aggressive responses to conflict over a 15-day period. Parents recorded different aspects of the conflict, including the topics discussed (child, marital, social, or work) as well as conflict tactics (behaviors exhibited to address the conflict) and emotions around the conflict. Findings indicated that interparental conflict about child and marital (e.g., intimacy, communication) topics related positively to child aggression in response to the conflict, whereas conflict about social and work topics did not. Moreover, the link between conflict about child-related topics and child aggression emerged even after accounting for conflict tactics and emotions surrounding the conflict.

Behavioral Tactics

Research is accumulating to suggest that certain behavioral tactics used during parental disagreements are especially harmful to children. For example, studies in which intimate partner physical violence (IPV) is assessed indicate that children in families in which there has been a recent incident of IPV—common examples include pushes, grabs, and hits—are at greater risk for adjustment problems than children in families in which IPV has not occurred (see Kitzmann, Gaylord, Holt, & Kenny, 2003; Wolfe, Crooks, Lee, McIntyre-Smith, & Jaffe, 2003, for meta-analytic reviews of this literature). Moreover, this increased risk emerges for a variety of different types of adjustment problems (e.g., conduct-disordered behavior, emotional/personality problems), even after accounting for other aspects of the parents' marital relationship, such as general marital discord (Jouriles, Murphy, & O'Leary, 1989). In addition, children's exposure to particular types of IPV, such as violence that carries a high risk for physical injury (violence involving knives and guns), even further elevates the risk for child adjustment problems (Jouriles et al., 1998; Spaccarelli, Coatsworth, & Bowden, 1995). There is also experimental evidence indicating that children react more negatively to conflict involving IPV than to conflict involving other behavioral tactics. Specifically, evidence from studies employing vignette methods similar to those of the Grych and Fincham (1993) study described in the "Topic of the Conflict" section indicates that conflict involving physical aggression between adults elicits more distress and negative emotion from children than does verbal conflict (e.g., Cummings, Vogel, Cummings, & El-Sheikh, 1989; Cummings, Zahn-Waxler, & Radke-Yarrow, 1981).

In addition to physical violence, psychologically and emotionally abusive behaviors, such as insults, verbal threats, and aggression toward objects, are also associated with child adjustment problems. For example, Jouriles, Norwood, McDonald, Vincent, and Mahoney (1996) found that parents' reports of psychological aggression relate to child adjustment problems, even after accounting for acts of physical IPV. Other investigators have documented similar associations, highlighting the potentially unique contribution of these tactics in understanding the link between interparental discord and child adjustment problems (Clarke et al., 2007). Experimental evidence also suggests that interparental psychological and emotional abuse can cause immediate distress in children that is sometimes just as distressing as physical violence (Laumakis, Margolin, & John, 1998).

The two behavioral tactics just discussed (physical violence and psychologically or emotionally abusive behavior) are overt forms of conflict expression. Such behavior appears to be harmful to children, regardless of which parent engages in it (see Sturge-Apple, Skibo, & Davies, 2012, for a review that addresses this issue), and it is most harmful if both parents engage in it, as compared to only one parent (McDonald, Jouriles, Tart, & Minze, 2009). There also is some indication that more subtle forms of conflict expression, such as withdrawal or detachment (e.g., one parent ceasing to attend to what the other parent is saying), particularly in combination with overt forms of conflict expression, are harmful to children. For example, Katz and Woodin (2002) classified couples on the basis of their conflict interactions and found that child adjustment problems were most likely when the parents engaged in both attacking and withdrawing tactics during conflict. Goeke-Morey, Cummings, and Papp (2007) found that interparental conflicts that ended with one of the

parents withdrawing from the interaction were associated with greater child behavioral dysregulation (misbehavior, aggression) in response to the conflict. Related to these findings, results from experimental analog studies indicate that children are sensitive to adult withdrawal and nonverbal expressions of anger (e.g., angry glares) during adult conflicts, and they respond to these behaviors with negative emotions (Cummings et al., 1989; Goeke-Morey et al., 2007).

Although relatively little research has evaluated effects of behavioral tactics that might be conceptualized as positive, the results of several studies suggest that this might be a fruitful avenue for future research. For example, Davies, Martin, and Cicchetti (2012) created a latent variable of constructive marital conflict, which included parents' reports of responding positively toward one another during challenging/stressful times, as well as cooperation and satisfactory conflict resolution. This latent variable was negatively associated with later child adjustment problems, even after accounting for destructive interparental conflict. McCoy, Cummings, and Davies (2009) created a similar latent variable, which included data derived from observations of parents during a conflict interaction (e.g., problem solving, displays of affection) as well as parents' reports of cooperation and satisfactory resolution of their conflicts in general. Although constructive marital conflict was not directly related to later prosocial child behavior, indirect relations emerged in intervening variable models. Frosch and Mangelsdorf (2001) created a composite code, labeled positive engagement, for the coding of a nonconflictual marital interaction task. This code included behaviors such as initiating conversation and demonstrating involvement in the task, cooperation, and the extent to which spouses affirmed each others' contributions. In this study, positive engagement was negatively associated with observer ratings of child externalizing problems during a home visit. Moreover, positive engagement was negatively associated with child externalizing problems even after controlling for marital conflict.

It is important to highlight that in the few studies considering both positive and negative conflict tactics (or constructive and destructive interparental conflict), there was evidence that both contribute uniquely to child adjustment problems (Davies et al., 2012; Frosch & Mangelsdorf, 2001). In other words, it appears that it is not just the presence of destructive interparental conflict that increases risk for child adjustment problems, but also the absence of constructive or positive interparental interactions. Although some investigators have explored whether positive conflict tactics can mitigate the effects of negative conflict tactics on child adjustment problems, the results from a couple of well-designed studies suggest that positive and negative conflict tactics do not interact with one another in the prediction of child adjustment problems (Davies et al., 2012; Frosch & Mangelsdorf, 2001). We revisit this issue again in the section on conflict resolution.

Emotions

The emotions experienced and the behaviors expressed during conflict may be inextricably linked, although they are arguably separate phenomena. This link, however, may partly be an artifact of the methods used to assess interparental conflict. Specifically, some questionnaire items used in studies linking interparental conflict with child adjustment problems combine angry and hostile emotions with violent and abusive behaviors; the same could be said for the conflict vignettes that are used in experimental studies. Studies attempting to isolate or disentangle negative affect (hostility, anger) from destructive tactics during conflict suggest that both contribute independently to children's aggressive behavior (Cummings et al., 2004).

Very little research has evaluated the role of positive emotion expressed during interparental conflict. In one of the few studies on this topic, Goeke-Morey, Cummings, and Papp (2007) found that parental positive emotions expressed during conflict endings were positively associated with child positive emotions and negatively associated with child negative emotions (anger, sadness, fear) immediately following the conflicts. Similarly, Cummings and colleagues (2004) found that positive emotions expressed by either parent during conflict were associated with a lower likelihood of child aggression in response to the conflict. However, there was an important caveat to this latter finding. Conflicts about child-related topics were still positively associated with aggressive child responses, regardless of the nature of the emotions expressed during the conflict.

Resolution of Conflict

Results from a series of experimental analog studies indicate that poorly resolved conflicts, such as those that end with continued hostility or "the silent treatment," elicit negative immediate reactions from children (e.g., Cummings, Vogel, Cummings, & El-Sheikh, 1989; Cummings, Ballard, El-Sheikh, & Lake, 1991). By comparison, resolved conflicts are associated with more positive immediate reactions from children, and there is some evidence that certain tactics and emotions displayed during the resolution period can even ameliorate some of the immediate negative effects of hostile conflicts on children. Specifically, children seem to respond positively to resolution that involves

positive affect and compromise (Goeke-Morey et al., 2007; Koss et al., 2011; Shifflett-Simpson & Cummings, 1996). Apology appears beneficial when coupled with positive affect, but not when coupled with sadness or anger (Goeke-Morey et al., 2007). Interestingly, the effects of resolution are robust, emerging across many different types of conflict scenarios, including those that include physical aggression (Cummings et al., 1991; El-Sheikh, Cummings, & Reiter, 1996). In one of the few field studies examining couples' resolution of interparental conflict and child adjustment problems, Goeke-Morey and colleagues (2007) found that parent ratings of the degree to which the problem had been resolved were negatively associated with child negative emotions (anger, sadness, fear) and problematic behaviors (misbehavior, aggression) immediately following the conflicts. Similarly, Kerig (1996) found that a questionnaire measure reflecting the degree to which positive or negative affect dominates the resolution of conflict correlated in the expected direction with several indices of child adjustment.

Summary on Dimensions of Interparental Conflict

In sum, empirical evidence derived from correlational and experimental research converges to suggest that certain aspects of interparental conflict are more destructive to children than others. In particular, conflict about child-related topics and conflict that includes physical violence or psychologically abusive behavior appears to be especially detrimental to children. There is also some evidence suggesting that parental withdrawal and detachment during conflict episodes is harmful. Heightened negative emotions during conflict interactions contribute to the adverse effects of interparental discord on children. Positive approaches to interparental conflict, such as parents cooperating with one another, contribute to positive child adjustment. In addition, the outcome and immediate aftermath of conflict situations are important, with conflicts that are resolved in a positive manner (this might include compromise, apology, and the expression of positive emotions) being less harmful to children.

A Note about Frequency

Conceptually, research on interparental conflict and child adjustment is concerned with the effects of interparental conflict writ large. Only in extreme instances would one or two isolated incidents of conflict be expected to have marked and lasting effects on a child's development. Thus, in addition to considering the dimensions of conflict just reviewed (topic, behavioral tactics, emotions, and resolution), understanding how interparental conflict affects children's adjustment also demands considering the frequency of the conflict. Generally speaking, a child's history of exposure to destructive forms of interparental conflict influences how that child will respond to a specific conflict incident, and the *frequency* of children's exposure to destructive forms of interparental conflict correlates positively with the degree to which children experience adjustment problems. That is, the more frequently parents have disagreements with child-related content, the more likely the children will experience adjustment problems. Similarly, the more frequently physical IPV occurs, the more likely the children will experience adjustment problems, or the more frequently psychologically and emotionally abusive behaviors occur, the more likely there will be child problems. In other words, this frequency dimension cuts across each of the individual aspects of interparental conflict already reviewed.

Over time, however, the frequency of interparental conflict is likely to vary. There may be some periods in which interparental conflict is relatively frequent and some in which it is not. Although studies addressing this issue are sparse, there is evidence that child problems change with changes in frequency. For example, in a three-wave longitudinal study, elevations in interparental conflict over time corresponded to elevations in child externalizing problems during this same time period (Kouros, Cummings, & Davies, 2010). Similarly, changes in marital distress were positively correlated with changes in adolescents' adjustment (anxiety, depression, delinquency and hostility) over a 5-year period (Cui, Conger, & Lorenz, 2005). A related consideration pertains to the trajectories of specific types of interparental conflict over the course of time, and there is some indication that the trajectory of children's exposure to interparental conflict is important. For example, within a sample of school-age children who had recently been exposed to IPV, increases in children's exposure to IPV over time were related to increases in childhood depression (Kennedy, Bybee, Sullivan, & Greeson, 2010). Similarly, more consistent or chronic exposure to IPV predicts the development of child internalizing and externalizing problems, more so than more sporadic exposure (e.g., C. R. Emery, 2009; Martinez-Torteya, Bogat, von Eye, & Levendosky, 2009).

Developmental Considerations

The bulk of the research linking interparental conflict and child adjustment problems has been conducted with families of preschoolers, school-age children, and adolescents rather than with infants. Among the studies with infants, however, positive associations have been demonstrated between interparental conflict and general emotional

and behavioral distress displayed by infants, insecure/disorganized attachment behaviors, and temperament characteristics associated with poor adjustment outcomes (e.g., Du Rocher Schudlich, White, Fleischhauer, & Fitzgerald, 2011; Owen & Cox, 1997; Pauli-Pott & Beckmann, 2007). For example, Du Rocher Schudlich and colleagues (2011) had parents discuss an area of disagreement in the presence of their infant (ages 6–14.5 months). Destructive conflict—a composite variable that included contempt, defensiveness, demand, and anger—was related to infant distress, dysregulation, and physical frustration. Infants appear to be sensitive to positive aspects of interparental conflict as well. In this same study, constructive conflict tactics, which included problem solving, support, and positive emotion, were associated with less infant physical and emotional frustration and dysregulation.

Thus, interparental conflict is associated with indicators of child adjustment for children of all ages. It might also be argued that certain forms of interparental conflict influence child functioning, even prior to the birth of the child. For example, although empirical data are limited, women who experience IPV during pregnancy, compared to those who do not, are at increased risk for giving birth to a low-birthweight infant (Murphy, Schei, Myhr, & DuMont, 2001). Similarly, IPV during pregnancy has been linked to a weaker maternal-fetal bond and less secure maternal representations of caregiving (Huth-Bocks, Levendosky, Bogat, & von Eye, 2004; Zeitlin, Dhanjal, & Colmsee, 1999); there is also speculation that IPV during pregnancy can have lasting effects on child stress-regulatory systems (Graham, Kim, & Fisher, 2012; Levendosky, Leahy, Bogat, Davidson, von Eye, 2006). Consistent with these findings, IPV during pregnancy has been linked with child adjustment problems during the preschool years (Flach et al., 2011; Levendosky et al., 2006). Moreover, investigators have documented associations between mothers' lifetime experiences of IPV and both fetal loss and infant death (Ahmed, Koenig, & Stephenson, 2006).

It is not clear yet if there is a "sensitive period" over the course of development, during which exposure to interparental conflict is more strongly associated with child adjustment problems, as compared to other time periods. In fact, this question has received surprisingly little attention in the research literature. Yates and colleagues (2003) hypothesized that early exposures to IPV might have an especially strong and enduring effect on subsequent child development, as compared to later exposures. This is because it is during these early years that children are developing the ability to regulate their emotions and behaviors. In other words, children are developing the foundation for adapting to their environment, both in the present and in the future. In addition, during these early years, the child's foundation is believed to be especially sensitive to extreme environmental influences, such as IPV. This is not to say that later exposures to IPV are unimportant. Rather, later exposures are not expected to compromise a child's core self-regulation and adaptive stress-response capacities in the same way that early exposures might.

Yates and colleagues (2003) tested their hypothesis through the use of a longitudinal data set that followed children from preschool to 16 years. These investigators estimated the degree of male-to-female partner violence (referred to as IPV) based on interview data collected from mothers and items from Life Events Scales. These estimates were provided for two time periods in the children's lives: preschool years: 18–64 months; middle childhood: grades 1–3. Children's exposure to IPV during the preschool years made a unique contribution to adolescent (age 16) externalizing problems, above and beyond a number of control variables (e.g., socioeconomic status [SES], life stress) as well as exposure to IPV during the middle childhood years. In fact, IPV during the middle childhood years was not a predictor of externalizing problems at age 16. Similar findings emerged for IPV during the preschool years and child internalizing problems when the sample was limited to girls.

Conclusions drawn from reviews of the literature suggest the magnitude of the relations between interparental conflict and child adjustment problems are fairly consistent across age groups. For example, Buehler and colleagues (1997) found that the effect size for the relation between interparental conflict and child adjustment (.32) did not differ based on the age or age range of children included in studies. Similarly, Evans, Davies, and DiLillo (2008) found medium effect sizes for IPV and child internalizing (effect size range: .47–.51) and externalizing (effect size range: .40–.49) problems, which did not differ based on whether children in the studies were zero to 5, 6 to 12, or 13 to 19 years old. These reviews, however, examined primarily cross-sectional studies on the relation between interparental conflict and child adjustment problems. In sum, it seems clear that children's exposure to interparental conflict, at any age, can influence child adjustment problems. It is not yet clear, however, if there are specific age periods in which children's exposure to interparental conflict is especially detrimental to children (i.e., more detrimental than other age periods).

Another developmental question pertains to how enduring or long-lasting the link is between interparental

conflict and child adjustment problems. It is clear from experimental research that interparental conflict can cause immediate distress among witnessing children. It is also clear from the extant correlational and longitudinal research that this is not just an immediate, short-term effect. Specifically, prospective relations between exposure to interparental conflict and adjustment difficulties have been documented over time periods extending in excess of 10 years (Linder & Collins, 2005; Yates, Dodds, Sroufe, & Egeland, 2003). Yet there is also evidence that some of the adverse effects of witnessing IPV dissipate during the adult years. Specifically, longitudinal studies on the relation between adolescents' exposure to IPV and their involvement in violent romantic relationships suggests a relatively strong association during adolescence and even early adulthood; however, this association appears to dissipate over the course of adulthood (Smith, Ireland, Park, Elwyn, & Thornberry, 2011).

One approach to this question about the enduring effects of interparental conflict, which acknowledges the complexity in which such conflict might exert an influence on development over time, is the construction and evaluation of developmental cascade models, which propose how interparental conflict might interfere with stage-salient tasks, thereby increasing the risk for future adjustment problems (Cicchetti, 1993). Kouros, Cummings, and Davies (2010) tested a developmental cascade model and found that increasing interparental conflict in early childhood (kindergarten to second grade) was related to poor social competence in preadolescence (age 12) via externalizing problems in early childhood. The results suggested that interparental conflict may interfere with children's stage-salient tasks in early childhood, resulting in increased externalizing problems. Externalizing problems in early childhood, in turn, interfere with stage-salient tasks needed to promote optimal social competence and prosocial behavior. Similarly, Davies, Manning, and Cicchetti (2013) found evidence for a developmental cascade model in which preschoolers' exposure to interparental conflict is related to behavior problems 2 years later by interfering with the stage-salient tasks of regulating emotions, establishing autonomy, and problem solving. Additional developmental cascade models are reviewed in the section titled "Theory Explaining the Link between Interparental Conflict and Child Adjustment." Developmental cascade models that select stage-salient tasks specific to the developmental period studied offer promise for understanding developmental pathways that lead to different child adjustment outcomes across individuals and across time.

Prevalence and Degree of Children's Exposure to Interparental Conflict

It is impossible to say with certainty exactly how many children are exposed to destructive forms of interparental conflict. However, one might get a sense of this from statistics on the prevalence of children's exposure to IPV, parental divorce, and marital distress. Epidemiological data suggest that a large number of children in the United States are exposed to IPV and psychological abuse. Although annual prevalence estimates of children's exposure to IPV (e.g., pushing, grabbing, slapping) vary widely from study to study (e.g., Bair-Merritt et al., 2008; Hamby, Finkelhor, Turner, & Ormrod, 2011; C. G. Moore, Probst, Tompkins, Cuffe, & Martin, 2007), IPV has been estimated to occur in as many as 30% of dual-parent households with children in the United States (McDonald, Jouriles, Ramisetty-Mikler, Caetano, & Green, 2006), with severe physical IPV (kicks, punches, threat or use of weapons) estimated to occur in as many as 13% of dual-parent households with children (McDonald, Jouriles, Ramisetty-Mikler et al., 2006). Psychological abuse between parents or caregivers (e.g., threatening, insulting, or attempting to control a partner) appears to be even more common; a population-based survey of mothers in North and South Carolina indicated that psychological abuse occurs in the homes of nearly 50% of children over the course of a year (Chang, Theodore, Martin, & Runyan, 2008).

General marital distress and divorce are more indirect markers of children's exposure to interparental conflict, as compared to the statistics regarding children's exposure to IPV. Nevertheless, statistics about their prevalence offer a general sense of the degree to which children are exposed to potentially harmful forms of interparental conflict. Among intact couples, close to one-third report having distressed marital relationships at any given stage of the relationship (Whisman, Beach, & Snyder, 2008). Moreover, there is some indication that marital distress might be slightly more prevalent during the years in which couples are raising young children. Approximately 40% of American children experience divorce during childhood, with an estimated 5% to 25% of divorces involving high levels of interparental conflict (Lamb, Sternberg, & Thompson, 1997; Maccoby & Mnookin, 1992). Thus, it is safe to conclude from existing studies that, each year, parents of millions of American children engage in forms of interparental conflict that have been found to be harmful to children.

Yet the data just reported provide only an idea of how many children live in families in which destructive

interparental conflict occurs. At a micro-model level, a key contextual variable is the extent to which children are actually exposed to the conflict. For example, are children present when the conflict occurs, and do they directly witness it? This is in contrast to other forms of exposure to interparental conflict, which include living in a household in which it occurs but being unaware of it, or hearing about it from siblings or the parents themselves. Results from a handful of studies suggest that children are present during over a third of their parents' destructive interparental conflict episodes. Specifically, in a study examining police-reported incidents of IPV, Fantuzzo and Fusco (2007) found that children were present during 43% of the violent incidents, and when they were present, they directly observed the violence 80% of the time. Moreover, the authors also found that children were disproportionately exposed to what they described as the most unstable and dangerous types of IPV, which included weapon use and mutual assault. Papp, Cummings, and Goeke-Morey (2002) trained parents to keep diaries of their conflicts over a 15-day period and found that approximately one-third of the conflicts occurred in the children's presence. Interestingly, conflicts in which children were present, compared to those in which they were absent, were more often about child-related issues and more likely to include negative emotions and destructive conflict tactics.

THEORY EXPLAINING THE LINK BETWEEN INTERPARENTAL CONFLICT AND CHILD ADJUSTMENT

Before the 1980s, much of the research on interparental conflict and child adjustment was guided only loosely by theory and was designed simply to examine whether indicators of a troubled marriage (e.g., parent reports of poor marital adjustment) were associated with various kinds of child adjustment problems. In the late 1970s and 1980s, researchers began to apply broad theories of social behavior, such as Bandura's (1973; 1986) social cognitive theory (earlier versions known as social learning theory), to the topic of interparental conflict and child adjustment. Social cognitive theory pointed to a troubled marriage as a risk factor for child adjustment problems, and, more important, it highlighted processes by which a troubled marriage might increase risk (via children observing and modeling/learning from particular expressions of interparental conflict). This theory sparked some of the research on different manifestations of interparental conflict and their relation to child adjustment problems. For example, some of the studies in the late 1970s and 1980s were designed to evaluate whether the particular types or dimensions of interparental conflict that social cognitive theory suggested ought to be important (e.g., physical aggression, overt hostility) contributed to child adjustment problems after accounting for more diffuse measures of marital problems, such as poor global marital adjustment (e.g., Jouriles, Murphy, & O'Leary, 1989; Porter & O'Leary, 1980).

Although there was recognition during the late 1970s and 1980s that social cognitive theory might help explain the link between interparental conflict and child adjustment problems, researchers were also invoking other theories and ideas to help explicate documented relations. For example, in the 1980s, E. Mark Cummings and his colleagues conducted a number of studies focusing on very young children's (e.g., toddler-aged) immediate reactions to inter-adult anger and aggression. In this research, it was noted that the children did not appear to be *learning* aggression from these adult interactions, because their responses did not seem to precisely mimic or imitate what the adults did. Rather, the children seemed to be experiencing heightened arousal and negative emotions from these adult interactions, which transferred to other interactions that the children were having subsequent to the conflict incident. In short, children's emotional reactivity to the adult conflict was thought to be key (in contrast to learning per se), and contagion of emotion and excitation transfer theories were being used to help explain empirical observations from this early research (Cummings, Iannotti, & Zahn-Waxler, 1985).

Theory may have played a role in guiding some of the early research on interparental conflict and child adjustment, but theoretical *processes* invoked to explain why interparental conflict might lead to child problems were rarely tested in these early studies. Rather, the focus was on developing a better understanding of the parameters of the relation between interparental conflict and child adjustment problems. In the 1990s, theories specific to the link between interparental conflict and child adjustment began to appear in the scientific literature. Two of the more prominent theories were Grych and Fincham's (1990) cognitive-contextual framework and Davies and Cummings's (1994) EST. These two theories helped prompt and guide the development of more process-oriented studies designed specifically to explain how interparental conflict might lead to child adjustment problems. Many of the studies conducted during the 1990s and afterward were direct tests of components of the cognitive-contextual framework or EST. In addition, new theoretical explanations for the

link between interparental conflict and child adjustment problems began to arise and other preexisting ones were revisited during these years.

In this section of the chapter, we describe some of the theories and explanations for the link between interparental conflict and child adjustment problems in more detail. Following the lead of other investigators (Davies & Cummings, 2006), we organize this section by distinguishing between direct and indirect theorized effects of interparental conflict on the child. The "direct-pathway" or "direct-effects" models suggest that children's exposure to destructive interparental conflict triggers processes *within the child* (e.g., cognitions, emotions, biological factors) that increase their risk for adjustment problems. In contrast, the "indirect-pathway" or "indirect-effects" models suggest that interparental conflict influences variables *outside of the child* (parenting behavior) that lead to child adjustment problems.

It is important to acknowledge several points before proceeding. First, many explanations of the link between interparental conflict and child adjustment have been advanced. Our review is not intended to be exhaustive. Rather, we cover what we believe to be the most influential theories on this topic as well as several other interesting theories that have received relatively little research attention but that help give a sense of the breadth of explanations that have been offered to explain this link. Second, several of the theories on the link between interparental conflict and child adjustment are quite elaborate; some have had entire books devoted to them (e.g., EST; Cummings & Davies, 2010). We review what we believe are the key ideas and concepts of these theories because a comprehensive review of each theory is beyond the scope of this chapter. Also, several of the more comprehensive theories include both direct and indirect pathways by which interparental conflict influences child adjustment problems. For example, EST (Davies & Cummings, 1994) proposes that children's exposure to destructive interparental conflict triggers processes within the child that can lead to child adjustment problems; in addition, EST accepts the notion that interparental conflict influences whether, and how, children use their parents as a source of support and protection, which can also lead to child adjustment problems. By organizing our review into direct and indirect pathways, some of the complexity and nuance of the more comprehensive theoretical explanations is unfortunately lost.

Third, the vast majority of the research on the topic of interparental conflict and child adjustment problems has been conducted from the perspective that interparental conflict influences child behavior. Child-effect hypotheses are rarely examined in this research literature. Yet early studies offered some acknowledgment that child behavior problems influence the nature of the interparental conflict. For example, interparental conflict on child-related topics has been suggested to be more common in families in which the children are exhibiting problematic behaviors, because these behaviors might prompt parents to discuss, and perhaps disagree about, how to address them (Jouriles et al., 1991). More recently, investigators have begun to examine how certain child responses to interparental conflict (e.g., helping behavior performed by the child with the intent to diminish interparental conflict) might influence subsequent interparental interactions (e.g., Schermerhorn, Cummings, DeCarlo, & Davies, 2007). In addition, investigators have also begun to examine how child problems themselves might lead to more severe forms of marital discord and dissolution (e.g., Wymbs et al., 2008). Our review is limited to theories and ideas on how interparental conflict influences children, but we acknowledge that the effects likely go both ways.

Fourth, it is now generally accepted that "any single theory is inadequate in capturing the reality of children's lives" in highly conflictual or violent families (Jaffe, Wolfe, & Campbell, 2012, p. 17). Researchers recognize that certain aspects of the various theories on the link between interparental conflict and child adjustment are complementary, or at least not in opposition to one another (e.g., Davies & Cummings, 1998). Indeed, many possess similar concepts or ideas but label and/or package them differently. For example, children's "internal representations" (e.g., EST) and "cognitive scripts" (e.g., social cognitive theories) of interparental conflict essentially refer to the same general concept: structures/processes within children that probabilistically govern what they anticipate will happen once a parental conflict has started.

Direct-Effects Models

Social Learning and Social Cognitive Theory

Social learning and social cognitive theories suggest that children learn from observing others, and parents are powerful models for children's observational learning (e.g., Bandura, 1973; 1986). In the case of interparental conflict, parents model ways of addressing and handling interpersonal conflict. Some parents model angry and hostile conflict behaviors, failing to provide their children with respectful and productive models (Margolin, 1981). Through observing their parents' conflicts over time, children learn or acquire, among other things: (1) a

repertoire of behavioral tactics to use in conflict situations, (2) cognitions about the effectiveness of those tactics in achieving desired outcomes, (3) cognitive scripts for how conflict situations play out, and (4) general beliefs about the acceptability and justifiability of certain types of behavioral tactics, including which are condoned or considered permissible. Children who repeatedly observe destructive conflict (e.g., angry and hostile parental interactions) presumably acquire behavioral tactics and cognitions that contribute to the development of angry and hostile social interaction patterns.

Social cognitive theories on the development and perpetration of aggressive and violent behavior sometimes distinguish between the development of explicit and implicit cognitions (e.g., C. A. Anderson & Bushman, 2002; Crick & Dodge, 1994; Jouriles, McDonald, Mueller, & Grych, 2012). Explicit cognitions are the articulated ideas of conscious and effortful thought. An example is the belief that aggressive behavior is justified under certain circumstances or that it facilitates the achievement of desired outcomes. Implicit cognitions, in contrast, can be unarticulated, automatic, and outside of awareness. Knowledge structures that increase access to aggressive thoughts are an example of an implicit cognitive mechanism that heightens the likelihood of aggressive behavior. More precisely, increased access to aggressive thoughts is hypothesized to increase the likelihood that ambiguous situations will be interpreted in a hostile manner. Social cognitive theories posit that explicit and implicit cognitions that facilitate the likelihood of aggressive behavior develop as a result of social experiences, including the observation of destructive interparental conflict, and, once developed, these two different types of cognitions operate jointly to shape future behavior.

Dodge and colleagues' social information processing model has been especially influential in enhancing the understanding of child and adolescent aggressive behavior (Crick & Dodge, 1994; Dodge, 1986). It has also been applied to the topic of interparental conflict and child adjustment. This model proposes four sequential processes that culminate in a response to a social situation: (1) encoding, which is attending to the external and internal cues in the situation; (2) interpretation, which involves formulating attributions regarding others' intent; (3) response generation, which is generating possible responses to the situation; and (4) response evaluation, which is evaluating the possible responses based on the child's goals, anticipated results, and self-efficacy for enacting the response. Similar to other social cognitive theories, a child or adolescent's information-processing style is hypothesized to develop as a result of their social experiences, including the observation of interparental conflict. Dodge's model suggests that by observing how their parents' conflicts emerge and are handled, children may note and internalize situational cues that bear on conflict, make inferences about motives pertaining to conflict, gain a specific repertoire of possible responses to conflict, and evaluate the effectiveness and consequences of those responses. Once developed and integrated, this information-processing style is hypothesized to influence children's future social interactions.

Quite a bit of research examining the link between interparental conflict and child adjustment, especially child externalizing problems or aggressive behavior, is consistent with tenets of social cognitive theory. Most studies directly evaluating processes derived from social cognitive theories find that children exposed to destructive forms of interparental conflict are more likely to have cognitions that facilitate aggressive behavior, such as attitudes more accepting of violence or a hostile attribution bias (Calvete & Orue, 2011; Marcus, Lindahl, & Malik, 2001). These cognitions, in turn, have been found to mediate the association between interparental conflict and various types of child adjustment problems, especially those that involve aggressive behavior. For example, a number of researchers have found key social cognitive processes to mediate associations between different forms of interparental conflict (especially IPV) and violence in romantic relationships (Fite et al., 2008; Kinsfogel & Grych, 2004; Riggs & O'Leary, 1996). It should be noted, however, that most of the research evaluating associations between interparental conflict and the cognitive processes proposed by social cognitive theory focuses on older school-age children and adolescents.

Before concluding this section, it is important to acknowledge the role of reinforcement in social learning theories. Both positive (providing a positive stimulus) and negative (removing a negative stimulus) reinforcement of behaviors increase the likelihood that those behaviors will be repeated. Through observing their parents' conflicts and experiencing their own conflicts with others, children learn what is likely to be reinforced, thus shaping their own behavior and cognitions, in conflict situations and beyond. That is, through reinforcement (vicarious and direct), children form expectancies about the utility and consequences of certain behavioral tactics and develop cognitive scripts for how conflict situations are likely to play out. These expectancies and scripts, in turn, guide future behavior.

Emery and colleagues (R. E. Emery, 1989; R. E. Emery & Kitzmann, 1995) describe a model of children's immediate reactions to interparental conflict, which illustrates how

negative reinforcement might shape children's behavior in conflict situations and has implications for the development of more general child adjustment problems. In this model, interparental conflict is viewed as an aversive event for children that can prompt a variety of negative cognitive, affective, and behavioral reactions, some of which might be construed as antisocial (yelling at or arguing with a parent). An antisocial child reaction that is sufficient to prompt the parents to stop their immediate conflict negatively reinforces that child reaction. That is, the aversive event, interparental conflict, is removed; thus, according to the principle of negative reinforcement, the child reaction that prompted the removal of the aversive event (displays of fear or anger, yelling at or arguing with a parent) is likely to be repeated. The model further proposes that, over time, through repetition of this family dynamic, this pattern of cognitive, affective, and behavioral reactions to conflict becomes internalized and ingrained in the child.

Consistent with Emery's theory, research on children's immediate responses to conflict suggests that exposure to destructive conflict is aversive for children, prompting reactions of fear and anger (see Cummings & Cummings, 1988; Cummings & Davies, 2010; Davies & Cummings, 1994, for reviews). In fact, most children have an adverse emotional response to their parents' arguments (Peterson & Zill, 1986). In addition, there is quite a bit of evidence that destructive forms of interparental conflict sometimes prompt behavioral reactions from children that might be interpreted as aggressive or oppositional, such as yelling and arguing with a parent (Jenkins, Smith, & Graham, 1989; Shelton & Harold, 2008). These immediate affective and behavioral reactions to interparental conflict have been linked to more general measures of child behavior problems (e.g., Cummings et al., 1989). However, it is not entirely clear from the available data whether negative reinforcement is the key mechanism operating to link children's immediate reactions to interparental conflict with more general measures of their adjustment.

Cognitive-Contextual Framework

According to Grych and Fincham's (1990) cognitive-contextual framework, when children witness an incident of interparental conflict, they attempt to derive meaning from it. They do so by appraising the situation and attempting to understand what is happening and how it might affect them and their family (threat appraisals), as well as why it is happening (blame appraisals) and what they can do in response (coping appraisals). These appraisals are posited to lead to behavioral responses to the immediate situation (coping behaviors). In figures illustrating the framework (e.g., Grych & Cardoza-Fernandes, 2001; Grych & Fincham, 1990), appraisal processes and behavior are depicted in a sequence of three steps or stages, with threat appraisals (primary processing of the conflict) preceding blame and coping appraisals (secondary processing of the conflict), which, in turn, lead to a behavioral response (coping behavior). However, Grych and colleagues acknowledge that these steps can occur simultaneously and that their influence on each other can be reciprocal. Children's threat and blame appraisals are held to be especially important. Although the model is called "cognitive"-contextual, these appraisals are actually conceptualized to include both cognitive and affective processes. For example, threat appraisals include thoughts about danger (e.g., a parent might be harmed or the family might split up) and the emotion of fear, whereas blame appraisals include thoughts about responsibility and, with self-blame, the emotion of guilt.

The cognitive-contextual framework offers hypotheses about how specific aspects of interparental conflict and the family context might influence children's threat and blame appraisals (Grych, 1998; Grych & Fincham, 1990). For example, when interparental conflict is about a child-related issue, as compared to something else (e.g., parents' work), it is hypothesized that children are more likely to blame themselves for the conflict. It is also hypothesized that conflict about child-related issues is likely to be more threatening to children, because of the potential spillover into parent-child interactions and negative consequences for the children. As interparental conflict becomes more hostile and angry and includes physically aggressive and emotionally abusive behaviors, it is hypothesized that children are more likely to view the conflict as threatening. Children's prior exposure to interparental conflict is hypothesized to influence appraisals as well, because these previous experiences have presumably shaped children's expectations about the course of future conflicts. Prior exposure to IPV, for example, is expected to sensitize children to the possibility that future conflicts might also culminate in violence.

The original formulation of the cognitive-contextual framework (Grych & Fincham, 1990) focused on children's immediate responses to interparental conflict—that is, their appraisals and coping behaviors in response to an incident of conflict. Yet they also offered some hints about how particular appraisals and coping behaviors in response to a conflict incident might lead to maladaptive behavior more broadly. For example, they made reference to R. E. Emery's (1989) model described earlier in the section "Social Learning and Social Cognitive Theory" as a process that might maintain children's maladaptive cognitive, affective, and behavioral responses to interparental

conflict. In later writings, Grych and colleagues expanded on how these immediate appraisals and coping behaviors might lead to child adjustment problems more broadly. For example, Grych, Seid, and Fincham (1992) proposed that children who frequently appraise interparental conflict as threatening may develop symptoms of anxiety disorders, particularly if the conflict occurs very frequently; similarly, children who frequently appraise interparental conflict as their fault may develop symptoms of depressive disorders. Along this same line, children who appraise interparental conflict as both threatening and their fault, and who are unable to stop it from occurring, may develop a sense of hopelessness that leads to a variety of internalizing problems (Grych, Fincham, Jouriles, & McDonald, 2000).

Many studies find that as children feel increasingly threatened by or at fault for interparental conflict, their risk for adjustment problems increases. In fact, a robust empirical literature has linked children's threat and self-blame appraisals to their internalizing problems (Rhoades, 2008). Although there is some evidence that these appraisals are also linked to externalizing problems, the findings are much more consistent with internalizing problems (Fosco et al., 2007; Rhoades, 2008). It should also be acknowledged here that there is quite a bit of evidence suggesting certain child coping behaviors in response to interparental conflict (particularly children attempting to interrupt parental conflict in an aggressive or oppositional manner) are consistently linked with broad measures of children's internalizing and externalizing problems (Rhoades, 2008). Moreover, the results of a handful of studies have now accumulated to suggest children's threat appraisals, self-blame appraisals, or both mediate effects of interparental conflict on child adjustment problems (e.g., Fosco & Grych, 2008; Gerard, Buehler, Franck, & Anderson, 2005; Grych et al., 2000; Grych, Harold, & Miles, 2003; Kim, Jackson, Conrad, & Hunter, 2008; Mann & Gilliom, 2004). Most of this research has focused on school-age children and young adolescents, but the theorized processes linking interparental conflict with child adjustment are likely to apply to younger children as well, with the caveat that their appraisals are likely to be less complex and more concrete than those of older children (McDonald & Grych, 2006).

Consistent with the cognitive-contextual framework, the family context in which the interparental conflict occurs influences how interparental conflict relates to children's threat and blame appraisals. Deboard-Lucas, Fosco, Raynor, and Grych (2010) demonstrated how several different family variables moderate relations between interparental conflict and blame appraisals. For example, the association between interparental conflict and children's self-blame appraisals was stronger when mothers reported low levels of support for their children's negative emotions; when mothers responded to their children's negative emotions in a dismissive, punitive, or upset way; and when mothers were more coercive.

Another pathway by which exposure to interparental conflict might adversely affect adjustment is by undermining adolescents' sense of self-efficacy (Fosco & Feinberg, 2015). Adolescence is an age marked by a striving for a sense of autonomy (Bandura, 1994); it is also an age when individuals are confronted with many challenges (Laursen & Collins, 2009). Self-efficacy is the belief that one is capable of achieving one's goals, despite challenges (Bandura, 1994). It has been described by some as the foundation for well-being (Pajares, 2006). Fosco and Feinberg (2015) found evidence for a developmental cascade model, in which interparental conflict was positively linked to adolescents' threat appraisals, which were negatively related to adolescents' self-efficacy beliefs. In turn, self-efficacy beliefs were associated with adolescent adjustment (subjective well-being, internalizing problems, externalizing problems).

Fosco, DeBoard, and Grych (2007) proposed several modifications to the cognitive-contextual framework to better represent children's experiences in families characterized by IPV, especially in families where the violence is frequent and severe. For example, the scope of appraisals was expanded. Specifically, in addition to the threat, blame, and coping appraisals described in the original model, children are hypothesized to appraise interparental conflict (and the specific behavioral tactics, such as violence) along the degree to which it is justified or acceptable. Blame appraisals also include self-blame for failure to protect family members from getting hurt by the violence (e.g., protecting the mother from the father). In addition, some of the modifications put a greater emphasis on how externalizing problems might emerge within the context of IPV. For example, the meaning children ascribe to interparental conflict is theorized to affect not only their behavior but how they regulate their emotions and how they perceive various family members and close relationships within the family. Drawing from the work of Jenkins (2000), children exposed to interparental conflict that is characterized by anger are hypothesized to develop patterns of emotional responding that are organized around the emotion of anger. That is, anger becomes the default or automatic response to upsetting stimuli, and this begins to occur even in situations when anger is not typically elicited. These children, over time, are hypothesized to develop automatic anger responses to conflicts with others.

The modifications to the cognitive contextual framework have not yet received much research attention within families characterized by frequent and severe IPV. However, some of the modifications are consistent with the results of empirical evaluations of tenets of social cognitive theories, indicating that attitudes about the acceptability of violence mediate associations between IPV and both child aggressive behavior and adolescent violence in romantic relationships. Similarly, several studies now indicate that the experience and expression of anger mediates the association between exposure to IPV and adolescent violence in romantic relationships (Kinsfogel & Grych, 2004; Wolfe, Wekerle, Scott, Straatman, & Grasley, 2004).

Emotional Security Hypothesis Theory

According to Davies and Cummings's (1994) emotional security hypothesis and subsequent writings about emotional security theory (EST) by Cummings and Davies and colleagues, the concept of children's emotional security in the *interparental* relationship is central to understanding how interparental conflict affects child adjustment. Children are hypothesized to have a higher-order goal of wanting their parents' marital relationship to be stable. That is, in order to preserve a feeling of being safe, secure, and protected within their family, children need to feel confident that their parents can effectively work out their differences and resolve disagreements. Children who are emotionally secure in the interparental relationship have confidence in the stability of their parents' relationship with one another. They have confidence that interparental conflict will not threaten this stability; nor will it adversely affect children's own physical or psychological well-being. Children's emotional security in the interparental relationship is conceptually distinct from their emotional security in the parent-child relationship. Children can be insecure about the interparental relationship but secure in their parent-child relationships, and vice versa.

Children's emotional insecurity (or difficulties in preserving a sense of security) in the interparental relationship is inferred from three interrelated component processes, each of which is a type of response to interparental conflict. First, there might be generalized negative emotional reactivity (e.g., fear, anger, and sadness in response to the conflict). As suggested earlier, children often respond to displays of destructive conflict with negative emotions. However, when children are emotionally insecure in the interparental relationship, the negative emotions are likely to be heightened and more persistent. Second, interparental conflict might prompt children to behave in a manner that reduces either their parents' conflict or at least the children's exposure to it. Examples of such behaviors might include antisocial behaviors (yelling at or arguing with a parent), avoidance behaviors to minimize exposure (running away from conflict incidents), and even behaviors that might be construed as prosocial or helpful (trying to help solve the disagreement, trying to comfort one or both parents). Third, interparental conflict may result in internalized representations or working models of relationship functioning. This might include pessimistic expectations about the implications of the interparental conflict that children may hold for themselves and their families (e.g., the conflict will lead to the breakup of the family). These three component processes have been referred to as the "ABCs" of children's responses to interparental conflict (Cummings & Davies, 2010), referring to affect, behavior, and cognition. It is not necessary for each of the three component processes to be operating to infer emotional insecurity. Rather, these three responses are hypothesized to be distinct but interrelated.

These three different responses to interparental conflict may help children address the immediate threats posed by the conflict. However, these same responses may also lead to externalizing or internalizing adjustment problems through a variety of pathways and processes. For example, by definition, negative emotional reactivity is distressing to children, and a prolonged state of such emotions, triggered by prolonged exposure to destructive interparental conflict, or even a cognitive preoccupation with the conflict, can drain children emotionally. As a result, the capacity to draw on emotional resources when dealing with other important developmental challenges is diminished. In addition, certain behavioral responses to interparental conflict might turn into patterns of behavior that generalize to other contexts in which they are not appropriate. For example, Davies and Cummings (1994) made reference to R. E. Emery's (1989) model—on how children who attempt to regulate their parents' conflict may become aggressive or disruptive during marital disputes, and how this behavior might be negatively reinforced. If this family process is repeated, it might result in a more persistent and generalized pattern of child antisocial behavior. Thus, in the long run, children's emotional insecurity in the interparental relationship is expected to confer risk for adjustment difficulties.

Consistent with the assertion that children's emotional insecurity in the interparental relationship leads to child adjustment problems, results from many studies link the individual components from which emotional insecurity in the interparental relationship is inferred—emotional reactivity to conflict, regulation of conflict exposure, and

internal representations of the marital relationship—with children's externalizing and internalizing problems (e.g., Davies & Cummings, 1998; Davies, Forman, Rasi, & Stevens, 2002; Davis, Hops, Alpert, & Sheeber, 1998; Harold & Conger, 1997). Furthermore, individual components of children's emotional security, as well as latent variables constructed from these individual components, have been found to mediate the relation between interparental conflict and child adjustment (Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006; Davies et al., 2002; El-Sheikh, Cummings, Kouros, Elmore-Staton, & Buckhalt, 2008; Kouros, Merrilees, & Cummings, 2008; Mann & Gilliom, 2004).

Consistent with EST, different family contextual variables can influence how interparental conflict relates to children's emotional insecurity in the interparental relationship. For example, Kouros, Merrilees, and Cummings (2008) found the link between interparental conflict and children's emotional insecurity to be stronger when fathers reported higher levels of depressive symptoms. Davies and colleagues (2002) showed how several different family variables moderate associations between interparental conflict and emotional insecurity. For example, parenting difficulties and parent-child attachment insecurity led to stronger relations between interparental conflict and children's emotional insecurity in the interparental relationship. Family cohesiveness, in contrast, led to weaker relations.

Another pathway by which children's emotional insecurity in the interparental relationship may lead to child externalizing and internalizing problems is by adversely affecting children's sleep (El-Sheikh, Buckhalt, Cummings, & Keller, 2007). Specifically, children's emotional insecurity in the interparental relationship has been posited to interfere with the quality and duration of children's sleep. When children do not obtain enough high-quality sleep, it negatively influences their day-to-day functioning (Kouros & El-Sheikh, 2015). They are more irritable, have difficulties concentrating, and are not motivated to follow through on tasks and responsibilities, which are all symptoms of different forms of psychopathology (e.g., depressive disorders, oppositional defiant disorder). In families in which there are frequent or prolonged periods of destructive interparental conflict, there may also be prolonged sleep disruptions, contributing to a more general pattern of disrupted behavioral and emotional functioning. Emotional insecurity in the interparental relationship mediates links between destructive interparental conflict and indices of the quality of children's sleep (Kelly & El-Sheikh, 2013). In addition, sleep disruptions mediate links between children's emotional insecurity in the interparental relationship and a variety of child adjustment difficulties (El-Sheikh et al., 2007).

Advances in the Formulation of EST

Davies and Sturge-Apple (2007) make use of concepts from ethology and evolution to refine and extend certain aspects of EST, and they articulate more specific hypotheses regarding components of EST. Specifically, in the original formulation of EST, the three indicators of emotional insecurity (generalized negative emotional reactivity, regulation of conflict exposure, and pessimistic expectations about the implications of the interparental conflict for themselves and their families) were conceptualized as linearly related to one another, with each reflecting the common goal of preserving security in the interparental relationship. In the new formulation, the pattern of response across the three indicators is given much more emphasis than it was in the original account of EST. That is, different profiles of children's emotional security/insecurity to interparental conflict are hypothesized (e.g., secure, mobilizing, dominant, caregiving). These profiles are distinguished from one another by the specific emotions, cognitions, and behaviors included in reactions to conflict. They are also distinguished by their origins (a complex function of current ecological conditions, individual developmental histories, and prior experiences with interparental conflict) and by the types of adjustment problems most likely to emerge as a result of these pattern-based responses. For example, the secure profile is characterized by well-regulated, low-level distress reactions to interparental conflict. Children with this pattern are hypothesized to have confidence in their parents' relationship in a way that maintains family harmony. This pattern is theorized to evolve, in part, from witnessing well-managed parental disputes in the context of cohesive interparental and family relationships. These children are not expected to develop significant adjustment problems as a consequence of witnessing destructive bouts of interparental conflict. Children with the dominant profile, in contrast, would react to interparental conflict with high levels of behavioral distress, loss of control, dysregulation, aggression, low levels of subjective distress, and appraisals of threat. They are theorized to have been exposed to elevated levels of intense, poorly resolved interparental conflict, family disengagement, interparental dissatisfaction, parental dysphoria, avoidant parent-child attachment, and parental physical abuse and neglect. Over time, they would be expected to develop generalized patterns of aggressive, antisocial behavior.

There are a number of additional elaborations as well. To offer several examples, the new formulation provides an evolutionary basis for expecting certain types of interparental conflict to be frightening and harmful to children. Specifically, many evolutionary models suggest that humans are predisposed to respond with fear to stimuli that were significant threats to our ancestors. These stimuli may include angry faces, which are much more likely to be observed during conflict characterized by hostile, angry, and aggressive interchanges than by dysphoric, withdrawn, or indifferent interactions. The ability to recognize fear in others is also likely to have been evolutionarily adaptive, because others' fear responses likely signaled impending danger. Accordingly, observing one parent being fearful of another may be particularly likely to pose a threat to children's emotional security and, over time, their adjustment. The new formulation also emphasizes the primacy of initial, nonconscious, automatic processing of threat cues and affective responses to those cues, followed over time by the development of responses that operate under some cognitive control. Thus, this aspect of the reformulation implies that fearful affect plays a primary role as a cause of cognition, which distinguishes this theory from those positing that children's cognitive appraisals of a particular conflict incident mediate the link between that incident and their emotions. In addition, the new formulation downplays the role of constructive interparental conflict in contributing to children's emotional security.

There is already some empirical support for aspects of this new formulation of EST. Indeed, findings by Davies and Forman (2002) on different profiles in children's immediate responses to interparental conflict helped prompt the reformulation. More recently, Davies and colleagues (2012) found that when destructive and constructive conflict behaviors are considered simultaneously, destructive conflict is associated with children's emotional insecurity but constructive conflict is not, even though it does contribute to future child adjustment.

Specific Emotions Theory

Similar to the cognitive-contextual framework and EST, specific emotions theory (Crockenberg & Langrock, 2001) also holds that the effect of interparental conflict on children depends on children's interpretation of what the conflict means for themselves and their family. However, the focus is on the children's interpretation of how the conflict affects their ability to attain certain goals. Children's goals vis-à-vis interparental conflict can be broad, such as attaining security in the interparental relationship (as in EST), or specific, such as being able to invite a friend over after school. The meaning the conflict has for goal attainment leads children to experience specific emotional reactions to the conflict. For example, when the conflict is perceived to block a goal or make it unattainable, children are theorized to respond with anger. Repeated blocking of goals because of interparental conflict is expected to lead to sadness as well. When the interparental conflict poses a looming but uncertain threat to the children's goals, fear is the consequence. Children can, of course, have multiple goals simultaneously, and they may experience multiple emotions in reaction to any given conflict (e.g., fear over insecurity in the interparental relationship and anger because plans for a family activity are canceled because of the conflict). Over time, the patterns of children's reactions to conflict are thought to be reflected in more generalized patterns of adjustment. Thus, angry reactions translate to a broader pattern of aggressive or externalizing behavior problems, whereas fearful and sad reactions translate to internalizing problems. Recognizing that multiple reactions can occur simultaneously, specific emotions theory posits that the co-occurrence of different emotions influences how each is expressed. For example, when angry reactions to interparental conflict are accompanied by fear, the fear may reduce the likelihood of aggression or increase the likelihood of withdrawal or avoidance, thus setting the stage for the development of internalizing symptoms.

Specific emotions theory hypothesizes a second direct-effects pathway, which involves the same-sex modeling process derived from social cognitive theory. A same-sex modeling hypothesis specifies that children disproportionately attend to and display the behavior of their same-sex parent, and by the age of 5 or 6 years, children have developed gendered scripts that have been incorporated into their personal identities (Levy & Fivush, 1993). Thus, during incidents of interparental conflict, boys are expected to be more likely to attend to their fathers than to their mothers. The opposite is expected of girls. Similarly, to the extent that fathers' and mothers' behavior differs during incidents of conflict, boys' behavior should be more parallel to that of their fathers, whereas girls' behavior should be more parallel to that of their mothers.

Data testing this theory are sparse. However, there is empirical evidence consistent with some of its predictions. For example, specific emotions experienced by boys in response to interparental conflict have been found to interact with the fathers' behavior to predict specific types of adjustment problems (Crockenberg & Langrock, 2001). Specifically, boys' anger in response to interparental conflict interacted with fathers' maritally aggressive behaviors to predict boys' externalizing problems. Similarly, boys'

fear in response to interparental conflict interacted with fathers' maritally aggressive behaviors to predict boys' internalizing problems. In contrast, girls' specific emotions in response to interparental conflict did not interact with fathers' martially aggressive behaviors to predict girls' adjustment problems. In addition, boys' emotions in response to interparental conflict did not interact with mothers' maritally aggressive behaviors to predict boys' adjustment problems. Interestingly, for girls, the associations predicted by this theory failed to emerge, raising questions about its applicability for both boys and girls.

Trauma Theory

Individuals can experience traumatic stress symptoms after experiencing events that pose a significant threat of physical injury, severe harm, or death to an individual or others, and which evoke intense fear. In some circumstances, interparental conflict can be considered a traumatic stressor. Considerable evidence indicates that children exposed to IPV—which by many definitions poses a threat of physical harm to a child's caregiver and thus is frightening to a child—are at elevated risk for developing symptoms of posttraumatic stress (Evans, Davies, & DiLillo, 2008; Graham-Bermann & Levendosky, 1998; Kitzmann, Gaylord, Holt, & Kenny, 2003). Moreover, in many families marked by IPV, the family violence occurs repeatedly. Sustained or repeated exposure to multiple traumatic events, known as complex trauma, is associated with particularly detrimental child outcomes (Cloitre et al., 2009; Margolin & Vickerman, 2007).

A large body of research has outlined ways in which the development and functioning of biological stress-response systems may be disrupted by exposure to significant and/or prolonged stress (De Bellis, 1999; Gunnar & Quevedo, 2007). The hypothalamic-pituitary-adrenal (HPA) axis is a neuroendocrine system that helps govern the organism's response to stress. Exposure to IPV can lead to dysregulated HPA axis functioning, including alterations in cortisol reactivity and diurnal patterns of cortisol release (Davies, Sturge-Apple, Cicchetti, Manning, & Zale, 2009; Saltzman, Holden, & Holahan, 2005; Davies, Sturge-Apple, Cicchetti, & Cummings, 2007). Increased cortisol can result in neuronal damage and in other changes in HPA functioning and secretion of neurohormones that can prompt pruning of receptors for those hormones, thus physically altering the functioning of the entire system. Such alterations compromise the child's physiological responses to stress going forward. The sympathetic nervous system (SNS) is also activated by traumatic events, resulting in increases in the level of circulating catecholamines (e.g., norepinephrine). Such increases not only increase arousal (i.e., the fight-or-flight syndrome) but over time can also result in pruning of receptors that would dampen their effect. Over time, such lasting physical changes in the structure and functioning of the stress-response systems, especially while those systems are still developing, hold serious implications for a child's future abilities to respond adaptively to stress.

There is substantial theory on the roles of particular psychological and social factors in the relation between exposure to a significant stressor and the likelihood of traumatic stress symptoms. Independent of the IPV itself, each child's unique configuration of characteristics shapes how he or she responds to it; these characteristics include the child's genetics, temperament, attachment functioning, existing psychopathology, functioning of the stress-response system, and developmental competencies in multiple domains (i.e., affective, cognitive, behavioral, and social). These both influence and, over time, are influenced by the child's efforts to respond and adapt to the stress and distress that exposure to severe forms of interparental conflict, such as IPV, entails. Meta-analytic findings confirm theoretical propositions that factors subsequent to an episode of IPV exposure also figure heavily in a child's risk of developing posttraumatic stress symptoms (Trickey, Siddaway, Meiser-Stedman, Serpell, & Field, 2012). These include factors specific to the IPV, such as everyday reminders or harbingers of it, its reoccurrence and patterning of occurrence, and the extent to which it may lead to or be associated with other potentially traumatic stressors, such as child maltreatment. They also include the child's processing of the event and its consequences and the child's attributions about his or her own emotions, behavior, and coping during and after the event. In addition, because IPV tends to recur, living under an ever-present threat that violence may erupt may itself be a traumatic stressor (Margolin & Vickerman, 2007).

Indirect-Effects Models

Parenting

Consistent with decades of research on child development and developmental psychopathology, most of the direct-effect theories just reviewed acknowledge that the quality of the parent-child relationship is an important determinant of child adjustment. In these theories, aspects of parenting or the parent-child relationship are presumed to partially mediate the link between interparental conflict and child adjustment problems. Similarly, most family systems theories consider the association between

interparental conflict and child adjustment to be a function of disrupted family processes, including parenting and the parent-child relationship. In this section of the chapter, we briefly review some of the empirical evidence on the relation of interparental conflict to parenting and to parent-child relationship variables. We then describe theory explaining the relation. For simplicity, we use the term *parenting* to refer to the multitude of characteristics, behaviors, and processes considered in this research.

Results of numerous studies show interparental conflict to be associated with both broad dimensions of parenting (e.g., acceptance/rejection) as well as with specific parenting behaviors, ranging from the amount of general conversation that parents engage in with their children to harsh and physically abusive parenting behaviors. In addition, changes in parenting that are associated with interparental conflict can occur quickly, even during or shortly after a conflict incident (seconds, minutes, days). Or they can unfold slowly over time, becoming fully manifest only months later. Experimental and well-controlled longitudinal studies provide evidence of causation: that interparental conflict causes alterations in parenting. For example, Jouriles and Farris (1992) randomly assigned parents to discuss either a highly conflictual or nonconflictual topic for them as a couple. During the discussion, their child was in another room, playing a game that involved making a substantial mess. Immediately after the couples' discussion, one (randomly chosen) parent, who had been instructed to have the child clean up the mess, joined the child in the playroom. Results indicated that the nature of the parents' discussion with one another influenced parent-child interaction during the cleanup task. Specifically, the level of general conversation (parent-child chitchat about matters unrelated to cleaning up the room) was consistently high after the nonconflictual couple interaction. In contrast, it was noticeably lower immediately following the conflictual couple interaction, gradually increasing over the course of the parent-child interaction. In addition, fathers gave more vague and confusing instructions to the child immediately following the conflictual couple interaction.

There is now also a substantial body of research suggesting that parenting mediates the relation between interparental conflict and child adjustment problems. In fact, the results of several studies suggest that when multiple dimensions of parenting are considered, parenting sometimes fully mediates the relation. For example, Fauber, Forehand, Thomas, and Wierson (1990) used data from parents and adolescents to form latent variables of parental psychological control, rejection/withdrawal, and lax control. When these were considered simultaneously, psychological control and rejection/withdrawal fully mediated the link between interparental conflict and child internalizing problems and partially mediated the link between interparental conflict and child externalizing problems. Harold, Fincham, Osborne, and Conger (1997) used children's reports across several measures of parent-child interaction to construct constructs reflecting mother-child and father-child hostility. These constructs fully mediated the link between interparental conflict and child externalizing problems and partially mediated the link between interparental conflict and child internalizing symptoms. Similarly, Gonzales, Pitts, Hill, and Roosa (2000) collected children's reports of parental acceptance and support (similar to the rejection/withdrawal variable of Fauber et al., 1990), inconsistent discipline, and hostile control (similar to the psychological control variable of Fauber et al., 1990, and the hostility measures of Harold et al., 1997). When these parenting variables were considered simultaneously in a mediation model, parental acceptance and support and parental inconsistent discipline fully mediated the link between child reports of interparental conflict and child reports of child adjustment problems. However, the mediation effects were not replicated when using parent reports of child adjustment problems.

A number of explanations have been offered for the link between interparental conflict and parenting. The spillover hypothesis, or some variant thereof, is perhaps the most widely acknowledged process for explaining how interparental conflict affects parenting (see Erel & Burman, 1995; Krishnakumar & Buehler, 2000, for reviews). According to this hypothesis, negative emotions and behavior in the interparental relationship permeate or spill over into the parent-child relationship. For example, overt anger or hostility between parents during a conflictual interaction may spill over into the parent-child relationship, leading to anger and hostility toward the child, including overly harsh and physically aggressive discipline (Appel & Holden, 1998; Jouriles, McDonald, Slep, Heyman, & Garrido, 2008). Patterson (1982) described how interparental conflict alters parents' moods and, consequently, disrupts many parenting behaviors that could contribute to the development of child adjustment problems. These include monitoring children's activities and whereabouts, consistent enforcement of rules, delivery of contingent consequences for child misbehavior, and effective problem solving. Similarly, frustration induced during interparental conflict may contribute to frustration in the parent-child relationship, which manifests itself

as a low tolerance for child misbehavior and the use of power-assertive child management techniques (Gerard, Krishnakumar, & Buehler, 2006). It has also been hypothesized that the preoccupation and emotional fatigue generated by interparental conflict influences the degree to which parents can be warm, supportive, and emotionally available for their children (e.g., Fosco et al., 2007).

The spillover hypothesis is often conceptualized in the context of a micromodel of family interaction (e.g., Jouriles & Farris, 1992; Patterson, 1982). That is, an episode of interparental conflict generates negative affect in the parents, and these emotions influence how the parents interact with their children either shortly after the conflict episode (minutes, hours, or days), or sometimes even during the conflict itself (e.g., when a child intervenes to attempt to stop the conflict). The spillover hypothesis, however, has also been conceptualized to play out over longer periods of time. For example, a variant of the spillover hypothesis is that interparental conflict contributes over time to heightened levels of parenting stress or diminished parental mental health, which then interferes with the parents' capacity to parent optimally (Levendosky & Graham-Bermann, 2001; Levendosky, Huth-Bocks, Shapiro, & Semel, 2003). Consistent with this hypothesis, mothers' mental health symptoms have been found to mediate associations between mothers' experience of IPV during pregnancy and preschoolers' adjustments problems (Flach et al., 2011; Levendosky et al., 2006).

Investigators have also used the spillover hypothesis, or some variation of it, to link interparental conflict to the erosion of the quality of the parent-child relationship (Davies & Sturge-Apple, 2007; Owens & Cox, 1997). For example, as suggested by the spillover hypothesis, the residual distraction and distress from interparental conflict detracts from parents' emotional availability to their children. Over time, the parents' emotional unavailability may diminish the child's sense of the parents as reliable sources of support and comfort. In addition, witnessing a parent's distress, fear, anger, or loss of emotional control may also alter the child's perception of the parent as a source of safety, strength, or protection.

In contrast to the spillover hypothesis, the compensatory hypothesis posits that parents attempt to compensate for negativity in the interparental relationship by investing more heavily in the parent-child relationship. Nevertheless, heavy investment in the parent-child relationship is not always beneficial for children. For example, detrimental effects may emerge if parents view the parent-child relationship as a substitute for the interparental relationship. In such cases, children may be burdened by feelings that they must emotionally support their parents as adult partners typically support one another (Peris, Goeke-Morey, Cummings, & Emery, 2008). Some studies using observational measures of parenting, however, have found associations between interparental conflict and more empathic parenting (Belsky, Youngblade, Rovine, & Volling, 1991; Mahoney, Boggio, & Jouriles, 1996). Similarly, in one qualitative study, 20% of battered women reported that their experiences with violence had some positive effects on their parenting, such as giving them greater empathy for their children (Levendosky, Lynch, & Graham-Bermann, 2000).

Although the spillover and compensatory hypotheses are both employed as explanations of the link between interparental conflict and parenting, testing these hypotheses can be very challenging, partly because the optimal time frame for capturing these processes is not clear from theory or research. In fact, it might be argued that both processes can operate simultaneously within the same family, or even the same parent, at different points in time. In a recent test of the spillover and compensatory hypotheses, Kouros, Papp, Goeke-Morey, and Cummings (2014) had parents independently rate the emotional quality of their relationship with their spouse and with their child each day for 15 days. The authors found that fathers' daily ratings of poor marital quality predicted lower father-child relationship quality on the same day, which is consistent with the spillover hypothesis. In contrast, mothers showed improvement in the quality of the mother-child relationship when marital quality was rated poorly on the previous day, which is consistent with the compensatory hypothesis.

Weakening of Boundaries between Family Subsystems

According to family systems theory, clear boundaries between the parents' relationship with one another (the marital subsystem) and the parents' relationships with their children (the parent-child subsystems) are crucial to healthy family functioning (Kerig, 1995; Minuchin, 1974). Clear boundaries establish roles for family members that are developmentally and socially appropriate and are sensitive and appropriately responsive to the emotional needs of family members. In the absence of clear boundaries, children may be cast in roles that are inappropriate for the developmental level (e.g., the parentified child) and that do not meet their emotional needs. Family systems theorists suggest that interparental conflict weakens boundaries between the marital and parent-child subsystems and, as a consequence, influences the development of child adjustment problems.

Weak boundaries between the marital and parent-child subsystems might be conceptualized as a type of parenting deficit or problem. That is, it might be argued that it is the parents' responsibility to establish and maintain clear boundaries between these two subsystems. Parents blur the boundaries when they draw the children into their interparental conflicts. Examples of this include when one parent engages in behaviors to attempt to recruit children into an alliance or coalition against the other parent. These processes have been given a number of labels in the family systems literature, including triangulation and the formation of cross-generational alliances. Blurring the boundaries between marital and parent-child subsystems might involve circumstances in which one parent talks badly about the other parent to the children or offers special privileges and gifts in an effort to get the child to take the side of a parent. Boundaries are also blurred when parents let their children intervene or involve themselves into their conflicts. Children might try to do this for a variety of reasons. For example, they might blame themselves for their parents' conflicts (especially when the conflict is about them or something they did) and thus feel responsible for stopping such conflicts. Another example is that in violent families, children may feel a need to protect one or both parents from physical harm. Thus, they intervene to prevent the conflict from escalating to a point where a parent becomes injured. Parents might also blur the boundaries between these two family subsystems as part of the aftermath of interparental conflict. Examples include when they turn to their children to provide them with support and comfort; such a process has been labeled as parentification, adultification, and role reversal. Support and comfort might be sought to deal with the troubled marriage or for addressing other life stressors, because the parent does not receive support and comfort from his or her spouse.

There is evidence from prospective research that the blurring of boundaries between the marital and parent-child subsystems contribute to child problems, as well as processes that are likely to lead to child problems. For example, Fosco and Grych (2010) found triangulation related positively to parent-adolescent conflict over time. Buehler, Franck, and Cook (2009) found positive associations between triangulation and adolescent externalizing and internalizing problems, as well as peer rejection.

Coparenting

Another indirect-effects model, which overlaps with parenting and family systems models, emphasizes the construct of coparenting and the extent to which mothers and fathers cooperate and support each other in raising their children. McHale and colleagues (McHale, Kuersten, & Lauretti, 1996) propose two types of coparenting dynamics, overt and covert, both of which can be affected by interparental conflict. Overt coparenting dynamics involve interactions between the parents about the child. Interparental conflict may result in one parent actively interfering with or undermining the other parent's interactions with the child, which may leave the child confused or compelled to defend or choose one parent over the other. Alternatively, when coparenting is disrupted by interparental conflict, one caregiver may withdraw from, reduce the frequency of, or otherwise alter the nature of interactions with the child (McHale et al., 1996; Katz & Gottman, 1996). In contrast, covert coparenting occurs when a parent delivers messages about the other parent while alone with the child (McHale & Ramussen, 1998). Ideally, such messages are positive and reflect a strong parental alliance. Coparenting that has been corrupted by interparental conflict can be seen in interactions in which one parent casts the other in a negative light, attempts to persuade the child to take sides against the other parent, or attempts to win the child's affection at the other parent's expense. Although research is sparse, there is some evidence that overt coparenting processes mediate the link between interparental conflict and child adjustment problems. For example, Katz and Low (2004) found that hostile-withdrawn coparenting behaviors mediate associations between IPV and children's anxiety and depression. Stroud, Meyers, Wilson, and Durbin (2015) found marital functioning to be related to children's internalizing and externalizing problems through reductions in coparenting warmth.

Other Explanations and Considerations

Cox, Paley, and Harter (2001) theorize that through various family and parenting processes, interparental conflict may strain sibling relationships, which contributes to the development of child adjustment problems. For example, elaborating on the family systems theory concepts of triangulation and the formation of cross-generational alliances, it seems plausible that if a child is aligned with one parent against the other, that child is likely to receive preferential treatment from the parent with whom the alliance is formed. Preferential treatment of children can strain sibling relationships and influence how one sibling treats the other. Because sibling interactions provide children opportunities to develop social interaction (e.g., conflict management) and coping skills (E. R. Anderson, Hetherington, Reiss, & Howe, 1994), strained relationships

can influence the development of these skills and thus the development of adjustment problems. Alternatively, interparental conflict may lead to behavior problems in one child, which then contribute to the development of behavior problems of one or more siblings. For example, older siblings typically exert more influence on younger siblings than vice versa (Stoneman & Brody, 1993). If interparental conflict leads to adjustment problems in an older child, that child's problems might then adversely affect younger siblings (Erel, Margolin, & John, 1998). Research on interparental conflict and sibling relationships is sparse, but there is some evidence consistent with the idea that sibling relationships may be an important variable in the link between interparental conflict and child adjustment (Piotrowski, Tailor, & Cormier, 2014; Tailor, Stewart-Tufescu, & Piotrowski, 2015).

Noting the high degree of co-occurrence for violence between intimate adult partners and violence directed at children, Slep and O'Leary (2001) proposed an integrated theoretical framework for family violence, drawing from the largely separate research literatures on risk factors for IPV and risk factors for physical child abuse. Slep and O'Leary highlighted the fact that there is considerable overlap in the risk factors for the perpetration of each of these forms of family violence, including individual-level variables (e.g., growing up with violence in their own family of origin, problems with impulsivity, problems with substance use and abuse, depressive symptoms) as well as an assortment of family- and community-level variables (e.g., economic strain, stressful events, social isolation). The collective presence of these variables is hypothesized to lay the groundwork for an individual to direct violence toward multiple family members—anyone who happens to provoke the high-risk individual. Tests of this integrated theoretical framework indicate that individuals who engage in both IPV and violence directed at children, compared to individuals who engage in only one of these forms of family violence or no violence at all, report higher collective levels of these risk factors (Slep & O'Leary, 2009).

Interparental conflict and IPV have also been associated with dimensions of peer interaction and peer relations. To offer a couple of examples, investigators have found interparental conflict to be positively associated with friendship instability and indirectly related to friendship quality (Schwarz, Stutz, & Ledermann, 2012). IPV has been found to be positively associated with peer victimization and peer bullying (Knous-Westfall, Ehrensaft, MacDonell, & Cohen, 2012). Additional research is necessary to evaluate whether peer relations mediate links between interparental conflict and child adjustment problems.

CHILD ATTRIBUTES AND FAMILY/COMMUNITY FACTORS CONTRIBUTING TO INDIVIDUAL DIFFERENCES

There is considerable variability in children's adjustment within families marked by interparental conflict. For example, even in samples of families characterized by extreme levels of conflict, such as IPV that is frequent and severe enough to prompt a parent (usually the mother) to seek refuge at a domestic violence shelter, there are marked differences in child adjustment. Some of the children develop externalizing problems, others develop internalizing problems or both externalizing and internalizing problems, and still others develop few or no problems (Grych, Jouriles, Swank, McDonald, & Norwood, 2000). This is true not only across children in different families but even among siblings within the same family (Skopp, McDonald, Manke, & Jouriles, 2005).

A developmental psychopathology perspective conceptualizes individual development as the interplay between a changing organism growing up in a changing context (Cicchetti, 1993; Davies & Cicchetti, 2004). This conceptualization implies that the development of child adjustment problems within the context of interparental conflict varies as a function of changes occurring within the child (e.g., maturation), within the interparental relationship, and in the child's family and social environment. In this section of the chapter, we describe how individual attributes of the child might influence the way that interparental conflict adversely affects child adjustment. These attributes include child sex, developmental considerations, immediate behavioral responses to interparental conflict, characteristic coping behaviors and cognitive styles, neurobiological responses to interparental conflict, and genetic influences. We then consider aspects of the broader family and community context that might influence the effect of interparental conflict on child adjustment.

Child Sex

Child sex has received quite a bit of attention in this research literature, in part because early research on the association between marital and child problems suggested that the association was stronger for boys than for girls (Grych & Fincham, 1990; Reid & Crisafulli, 1990). However, continued research, particularly with relatively large and representative community samples (e.g., Jouriles, Bourg, & Farris, 1991), called this conclusion into question, and later meta-analytic reviews failed to support the notion that child sex moderates the association

between interparental conflict and child adjustment problem (Buehler, Anthony, Krishnakumar, & Stone, 1997). In addition, child sex also does not appear to moderate the association between many hypothesized mediators of the link between interparental conflict (e.g., threat and self-blame appraisals, negative affect) and child adjustment problems (Rhoades, 2008). This is not to say that child sex is unimportant for understanding the association between interparental conflict and child adjustment. Rather, it is likely that the role played by child sex is complex, and a clear and consistent pattern of findings has not yet emerged. It is our view that other child and family attributes, some of which may be associated with child sex, are likely to be more promising in understanding the heterogeneity in the association between interparental conflict and child adjustment problems.

Developmental Considerations

A child's developmental level is often acknowledged as important for understanding the link between interparental conflict and child adjustment. Studies thus far, however, have not evaluated how developmental processes influence this link, beyond examining age as a moderator of specific associations. Changes occur in children's competencies across multiple domains (cognitive, emotional, social, physical) in the course of normal development, and these changes are relevant to how children are affected by interparental conflict. To illustrate, next we briefly discuss how normal developmental changes in cognition might be salient to concepts from theories on the link between interparental conflict and child adjustment. We also discuss developmental transition periods that might be important and conclude with a discussion on why greater attention to developmental processes is needed to guide the next generation of theory and research on interparental conflict and child adjustment.

According to Piaget's theory of cognitive development, children rely on their sensory and perceptual abilities to explore their environment and make sense of their world. Infants quickly begin to form schemas—internal representations of people, objects, and events—to organize their experiences. These schemas may be very simple at first but become increasingly sophisticated as the child assimilates new experiences into existing schemas and alters existing schemas to accommodate new experiences. A schema of one's caregiver is one of the earliest to develop; based on their experiences, infants develop an internal working model of their caregiver that allows them to predict how responsive, reliable, and trustworthy she or he is and will be, especially during times of stress.

Several of the direct-effect models reviewed earlier point to the importance of children's schemas about their parents' relationship with one another. For example, both the cognitive-contextual framework and EST posit that children create internal representations of the interparental relationship, which are based on their experiences within the family, including their exposure to interparental conflict. Both theories also hold that children become distressed when they perceive the security or stability of the interparental relationship to be threatened. When sustained or repeated over time, this distress can lead to more pervasive adjustment problems. Based on Piaget's theory on children's cognitive development, it is reasonable to assume that internal representations of the interparental relationship begin to form early in a child's life, but the definition of early—and, by implication, late—is unclear. It is also not clear when key aspects of these internal representations are likely to develop, such as when children begin to view their parents' relationship as something that is supposed to be stable, and when this view itself crystallizes, becoming unwavering over time. It might be argued that this information is key to understanding the ages or developmental stages at which EST and the cognitive-contextual framework become applicable for understanding the association between interparental conflict and child adjustment.

According to the cognitive-contextual framework, children's appraisals about interparental conflict (threat and self-blame appraisals) are key to understanding how the conflict affects children. However, young children lack the cognitive abilities necessary for making sophisticated appraisals and attributions. Before age 7 or so, children typically do not understand that others do not see the world from their vantage point. They may be able to reason deductively but can apply those reasoning skills only to real, concrete scenarios. Thus, they use only concrete characteristics of events to make attributions. At around age 11, when children enter the formal operational stage of cognitive development, they begin to learn to think abstractly and reason about hypothetical problems. It is only then that they become able to form sophisticated attributions and appraisals.

Some have argued that appraisals of interparental conflict are more salient predictors of children's adjustment when children are 10 years of age or older, as compared to younger age groups. For example, in a sample of children who were living with extreme IPV, Jouriles, Spiller, Stephens, McDonald, and Swank (2000) found

that younger children (ages 8–9) made more self-blame attributions than older children (ages 10–12), but the relation of self-blame with externalizing and internalizing problems was stronger for the older age group. In a meta-analytic review, Rhoades (2008) found that children's threat and self-blame appraisals were more strongly associated with their externalizing and internalizing problems after the age of 10. This is not to say, though, that younger children's appraisals of interparental conflict are unimportant or not useful. McDonald and Grych (2006), for example, found that children's self-blame appraisals accounted for the relation between interparental conflict and child internalizing problems in a sample of 7- to 9-year-olds. Ablow, Measelle, Cowan, and Cowan (2009) found that 5-year-olds' self-blame appraisals mediated relations between interparental conflict and child internalizing problems. Taken together, this body of research suggests that children's appraisals of interparental conflict are salient predictors of their adjustment problems, but that more robust and stronger associations are likely to be found in samples of children over the age of about 10.

It is also important to consider normal developmental transition periods, such as the transition to school or the onset of puberty. Jaffee and Poulton (2006) proposed that the relation between mothers' depression and child adjustment should be strongest during transition periods because children are more reliant on their mothers during those periods to help guide them in adapting to a changing situation, and depressed mothers are less able to offer that guidance. This reasoning can be applied to interparental conflict; interparental conflict that drains parents' emotional resources, increases their negative affect, or otherwise diminishes their ability to offer support (as suggested in our review of indirect-effect models) should be most problematic for child development during periods when children most need parental support to help navigate important transitions.

Greater consideration of developmental processes will be important for advancing both theory and research on the topic of interparental conflict and child adjustment. With regard to theory, many of the hypothesized mechanisms linking interparental conflict with child adjustment (e.g., cognitive and emotional abilities) change as a function of development and can differ dramatically across children of different ages. In fact, some of the mechanisms invoked by certain theories likely apply only to children during specific developmental periods. In addition, the way we conceptualize and measure these hypothesized mechanisms needs to be developmentally appropriate. That is, although the underlying mechanisms posited to be important may be the same across development, the *manifestation* of these mechanisms may change over time. Therefore, the measures we use need to be developmentally sensitive to account for this heterotypic continuity in children's development.

Behavioral Responses to Interparental Conflict (Stress)

Several theories of the relation between interparental conflict and child adjustment suggest that children's immediate behavioral responses to conflict are key to understanding how interparental conflict eventually influences child adjustment. More precisely, many of the theories hypothesize that children respond to destructive interparental conflict with distressing emotions or cognitions, which prompt certain behavioral responses. Although there is a wide range of potential behavioral responses, they are often categorized as either involvement or avoidant behaviors (Laumakis, Margolin, & John, 1998; O'Brien, Bahadur, Gee, Balto, & Erber, 1997; Rhoades, 2008; Shelton & Harold, 2008). Involvement behaviors include certain types of antisocial behaviors, such as yelling at the parents or creating a distraction (e.g., fighting with a sibling) to try to get their parents to stop arguing. However, they may also include behaviors that are prosocial in nature, such as attempting to problem-solve with parents or comfort their parents. Common avoidant behaviors include moving to another room or going outside when a conflict erupts. Avoidance has sometimes also been conceptualized to include cognitive avoidance strategies, such as trying not to think about the conflict.

Involving themselves in their parents' conflicts puts children in the midst of what may sometimes be emotionally intense, hostile parental interactions. Contagion theories and related data suggest that children exposed to such situations may take on their parents' angry, aggressive feelings and behaviors themselves (e.g., Cummings & Cummings, 1988; Cummings, Goeke-Morey, & Papp, 2004; Cummings, Iannotti, & Zahn-Waxler, 1985). In addition, some children yell at or argue with a parent to attempt to stop the conflict (Shelton & Harold, 2008), and this aggressive behavior may sometimes succeed in stopping the conflict (Jenkins, Smith, & Graham, 1989). As reviewed earlier under social cognitive theories, this family process in which a child responds to parents' conflict with aggressive behavior and the parents' conflict ceases may reinforce the child's use of aggression, increasing the probability that it will recur and perhaps develop into more generalized aggressive response patterns (Davis, Hops,

Alpert, & Sheeber, 1998; R. E. Emery & Kitzmann, 1995; Patterson, 1982).

Children's involvement in interparental conflict might also lead to or reflect problematic family processes that can have negative consequences for child development. As reviewed earlier, family systems theories suggest that clear boundaries between the marital and child subsystems define appropriate family roles (e.g., who is the parent and who is the child) and predict healthy child functioning (Kerig, 2005; Minuchin, 1974). Children's attempts to get their parents to stop fighting might be conceptualized as a boundary disturbance or breakdown in the family role structure—a form of role reversal. From this perspective, when children attempt to manage their parents' conflicts, they are assuming an adult or parent role within the family. Doing this burdens children with responsibilities well beyond their years, which can be very stressful and lead to negative outcomes (Johnston, Gonzalez, & Campbell, 1987; Kerig, 2005; Peris et al., 2008).

In contrast to involvement in interparental conflict, avoidance behaviors have been theorized to have both positive and negative effects on child adjustment (O'Brien et al., 1995; Shelton & Harold, 2008). For example, successful avoidance shields children from the hostility and coercive and violent tactics sometimes expressed during conflicts or from becoming a target of parental hostility or violence themselves. Because it might be easier for children to modulate their own emotions and thoughts when they physically distance themselves from the conflict, avoidance behaviors may also help children cope with it. Avoidance might also reflect healthy or positive family characteristics. As noted, family systems theorists hypothesize that clear boundaries between the marital and child subsystems predict healthy child functioning (Kerig, 2005; Minuchin, 1974). Avoidance of interparental conflict might thus reflect such clear boundaries.

Children's avoidance of interparental conflict, however, might also lead to negative child outcomes through several different processes. Avoidance of interparental conflict might generalize to other potentially distressing events or interactions. Learning theories suggest that avoidance of interparental conflict might be reinforced if it reduces distressing cognitions and emotions prompted by the conflict. Over time, the relief that comes from avoiding exposure to interparental conflict may lead the child to begin to avoid other life events with the potential to cause distress (Rhoades, 2008). The broader research literature on children's stress and coping is consistent with this idea, suggesting that a disengaged coping pattern, one that includes avoidance, increases risk for internalizing and externalizing child problems (Compas, Connor-Smith, Saltzman, Thomsen, & Wadsworth, 2001).

Avoidance of interparental conflict might also interfere with the development of adaptive skills for managing emotions and cognitions under stress. This hypothesis is consistent with challenge models in the developmental psychopathology literature (Davies & Sturge-Apple, 2007), in which children's exposure to stress, in small doses, is hypothesized to have "steeling" effects, especially if these exposures occur in otherwise supportive contexts. Specifically, exposure to a stressor might inoculate children to subsequent exposures by prompting them to develop effective ways of coping with stress and adversity (Garmezy, Masten, & Tellegen, 1984; Rutter, 1987). As applied to interparental conflict, challenge models suggest that exposure to destructive interparental conflict can help children develop effective skills for dealing with it, as well as for dealing with other difficult, stressful situations. Therefore, avoiding interparental conflict might interfere with the development of those skills.

Basic developmental processes might play a role in predicting children's behavioral responses to interparental conflict. For example, research on the developmental neurobiology of traumatic stress (Pynoos, Steinberg, Ornitz, & Goenjian, 1997) suggests that it is not until approximately age 8 that children begin to actively entertain thoughts of personally addressing or disarming the source of the stress, in contrast to avoiding or escaping it. Similarly, as their cognitive processes develop, children also begin to weigh the benefits and risks of behaviorally responding to their parents' conflict. In mild conflict, the risk to the child of misbehaving or otherwise intervening to derail or stop the conflict may be low, and this strategy therefore may be effective. The risk of intervening in conflict that involves physical aggression is higher; however, children may nonetheless intervene if they perceive the risk of *not* intervening to be even greater. Although young children sometimes intervene in order to stop their parents' fighting, the use of this strategy is expected to be more common among older children (preadolescent or adolescent) (Davies, Myers, & Cummings, 1996; Shelton & Harold, 2007). It is also noteworthy that intervening in interparental conflict is more closely associated with child adjustment problems among older (over 10 years), as compared to younger, children (Rhoades, 2008).

The empirical literature linking involvement in and avoidance of interparental conflict to child adjustment problems is mixed. Most studies have found involvement and avoidance both to be positively associated with child adjustment problems (e.g., Davies, Forman, et al., 2002;

Nicolotti, El-Sheikh, & Whitson, 2003; Shelton & Harold, 2008). However, the opposite has been found, as well, particularly with child avoidance. For example, O'Brien, Margolin, and John (1995) found children's avoidance of interparental conflict to be negatively associated with child anxiety symptoms, and Kerig and colleagues (1998) found girls' avoidance of interparental conflict to be negatively associated with externalizing problems.

Characteristic Coping Behaviors and Cognitive Styles

Related to the section on children's immediate behavioral responses to interparental conflict, some children may have characteristic ways of coping with stressful events, which might moderate associations between interparental conflict and child adjustment problems. In fact, some theorists have conceptualized children's immediate behavioral responses to interparental conflict as coping behaviors (e.g., Kerig, 2001). The few studies that have examined children's coping behaviors as potential moderators of the association between interparental conflict and child adjustment problems have yielded intriguing results. Nicolotti, El-Sheikh, and Whitson (2003), for example, found that a combination of support and active coping (e.g., having other people listen to their feelings about problems; planning or thinking about ways to solve problems) moderated associations between IPV and child adjustment problems. Interestingly, this form of coping served a protective function for girls; higher levels of support and active coping mitigated the association of IPV with depression and self-esteem difficulties. However, this coping style increased the magnitude of these associations for boys. Rogers and Holmbeck (1997) also found the association between IPV and child adjustment problems to be weaker among children who made greater use of social supports. (Sex differences were not examined.)

Other characteristic coping behaviors have also been found to moderate associations between interparental conflict and child adjustment problems. Nicolotti and colleagues (2003) found that greater avoidance coping (e.g., avoiding the problem by physically leaving, staying away from it, or imagining it to be better) is associated with a stronger relation between parental IPV and children's externalizing and internalizing problems and self-esteem difficulties. In contrast, distraction coping (e.g., engaging in physical activity or entertainment activities to avoid thinking about the problem) functioned as a protective variable, weakening the association between IPV and child depressive symptoms. Drawing from the broader literature on child coping may help refine our understanding of how children's responses to interparental conflict can contribute to the development of adjustment problems. For example, children's perceptions of how much control they have over their parents' relationship, and their ability to predict interparental conflict (Compas, 2009)—key factors in understanding why psychological stress is harmful to one's mental health—may be important factors to consider as well.

The broader literature on psychopathology, particularly on depression, suggests that certain cognitive styles or predispositions interact with the occurrence of stressful environmental events to produce depressive symptomatology. For example, models of depression suggest that a negative attributional style (a predisposition to explain stressful or negative events in a particular way) increases risk for depressive symptoms when negative or stressful life events occur (e.g., Metalsky, Joiner, Hardin, & Abramson, 1993). Although research has yielded data consistent with this hypothesis, in one study in which interparental conflict was conceptualized as the stressor (O'Donnell, Moreau, Cardemil, & Pollastri, 2010), a pessimistic attributional style reduced children's risk for depressive symptoms in response to interparental conflict. Although this result was not expected and is somewhat difficult to interpret, it helps illustrate that the integration and application of broad theories on the development of psychopathology might enrich our understanding of the association between interparental conflict and child adjustment problems.

It should also be acknowledged that children's threat and self-blame appraisals of their parents' conflict typically are thought of as mediators of the link between interparental conflict and child adjustment problems, but several investigators have also conceptualized them as moderators. This conceptualization is similar to that described earlier for theories of depression, in which children are proposed to have cognitive predispositions toward interpreting and explaining negative events in a particular manner. With threat and self-blame appraisals, children may have characteristic ways of viewing interparental conflict or conflictual interactions in general (e.g., as potentially escalating and spilling over into other interactions), and this cognitive style might moderate the link between interparental conflict and child adjustment problems. A study by Kerig (1998) found some evidence of this: Children's self-blame and threat appraisals potentiated some of the associations examined between interparental conflict and child adjustment problems. However, others have failed to find such moderation effects (e.g., Grych, Fincham, McDonald, & Jouriles, 2000).

Neurobiological Responses to Interparental Conflict (Stress)

Considering child attributes in general, and biological factors such as children's physiological responses to stress specifically, will likely help explain the multifinality of child outcomes in the context of interparental conflict and offer more precision in delineating pathways to specific child outcomes. Researchers have noted that physiological reactivity, regulation, and recovery in response to stress may modify the type and severity of child adjustment problems that develop in the context of interparental conflict (El-Sheikh & Erath, 2011; Steinberg & Avenevoli, 2000). Biological responses to stress may serve as a vulnerability (i.e., risk) factor to exacerbate relations between interparental conflict and child adjustment, or may serve as a protective factor to buffer children from the negative consequences of exposure to interparental conflict.

Exposure to stress elicits responses from the autonomic nervous system (ANS) and the HPA axis. Children's ANS functioning has more commonly been examined as a moderator of relations between interparental conflict and child adjustment problems, whereas HPA axis functioning (e.g., cortisol reactivity, recovery, or diurnal patterns) has more commonly been tested as a mediator. This is consistent with direct-effect models based on trauma theory (described earlier), which posit that exposure to interparental conflict predicts changes in HPA axis functioning, which in turn is responsible for later adjustment problems (e.g., Davies, Sturge-Apple, & Cicchetti, 2011; Davies, Sturge-Apple, Cicchetti, Manning, & Zale, 2009; Koss et al., 2013; Lucas-Thompson, 2012; see also Repetti, Robles & Reynolds, 2011, for theoretical discussion of risky families and HPA axis functioning). This section focuses on research that documents children's ANS activity as a moderator of relations between interparental conflict and child adjustment.

The ANS is responsible for involuntary functions, such as cardiovascular functioning and respiration, and is involved in the human stress response. El-Sheikh and Erath (2011) outlined five ways that ANS activity may increase risk for, or protect against, children's adjustment problems in the context of family conflict: (1) Baseline levels of ANS activity may affect how ready children are to respond to interparental conflict. In addition, ANS activity may (2) indicate how sensitive children are to the effects of interparental conflict, (3) influence children's emotions, cognitions, and behavior in response to interparental conflict in the short term, (4) influence activity of other stress response systems, like the HPA axis, and (5) change the response of other systems over time so that they become dysregulated.

The ANS is divided into two branches, the parasympathetic nervous system (PNS) and the SNS. Both are considered to be stable, individual difference variables, supporting their role as moderators of relations as opposed to mediators. For example, indicators of PNS (El-Sheikh, 2005; Hinnant, Elmore-Staton, & El-Sheikh, 2011) and SNS (El-Sheikh, 2007; Hinnant et al., 2011) activity have been found to be stable among school-age and early adolescent children over a 2- to 3-year time period. However, ANS functioning in infancy and early childhood may be more malleable and, therefore, less likely to serve as a moderator during those developmental periods (El-Sheikh & Erath, 2011).

The PNS supports resting functions and serves to decrease heart rate, dilate blood vessels, and increase digestive and reproductive efforts. Reduced PNS activity, or vagal withdrawal (also referred to as vagal suppression), is an automatic response to stress. It allows diversion of resources to deal with the stressor, including engaging attention, gathering and processing information, and using appropriate response strategies. Physiologically, reduced PNS activity results in rapid, moderate increases in heart rate. Once the stressor has diminished, PNS activity increases again to return the organism to a resting state. In general, vagal withdrawal is an adaptive response to stress and is related to positive outcomes (Beauchaine, 2001, 2012; Calkins & Keane, 2004; Porges, 2007). Extreme vagal withdrawal, however, or vagal augmentation (increased PNS activity during stress) is considered a maladaptive response to stress and is related to negative physical and mental health outcomes (Beauchaine, 2012; Bornstein & Suess, 2000; Calkins, Graziano, & Keane, 2007).

Respiratory sinus arrhythmia (RSA), which is the rhythmic fluctuation in heart rate during phases of the breathing cycle, is used as a measure of PNS activity. Baseline levels of RSA are used to index vagal tone and RSA change from baseline during stress reflects PNS reactivity. In the context of interparental conflict, research has found that low baseline RSA is a vulnerability factor; children with low levels of baseline RSA have greater internalizing, externalizing, and physical health problems (e.g., Dietrich et al., 2007; El-Sheikh, Harger, & Whitson, 2001; Katz & Gottman, 1995). Decreased RSA activity, indicative of PNS withdrawal, is protective, whereas increased RSA activity (or less withdrawal) has been found to exacerbate the negative relation between interparental conflict and child adjustment problems (El-Sheikh & Whitson, 2006; Katz, 2007; Leary & Katz, 2004). For example, El-Sheikh

and Whitson (2006) found an interaction between vagal withdrawal and marital conflict, such that for girls, vagal withdrawal to a lab stressor was associated with fewer internalizing problems 2 years later in the context of high interparental conflict. Notably, although most research has focused on school-age and older children, G. A. Moore (2010) found that interparental conflict was related to lower baseline RSA and less RSA withdrawal among 6-month-olds during a still-face paradigm. This study, however, did not test RSA and RSA reactivity as a moderator of relations between interparental conflict and infant adjustment.

Activation of the SNS during stress prepares the body for the flight-or-fight response, resulting in increased heart rate, blood pressure, and oxygen flow throughout the body and mobilizing the body to respond to stress. In the short term, SNS activation is adaptive; however, chronic activation may lead to "wear and tear" on the body, resulting in physical and mental health problems. Noninvasive measures of the SNS include skin conductance level (SCL), and pre-ejection period (PEP), which measures the time between heart beat onset and the ejection of blood into the aorta. Changes from baseline in SCL and PEP during stress or a challenge task assess SCL reactivity and PEP reactivity, respectively. Increases in SCL and decreases in PEP (i.e., shorter intervals) as compared to baseline levels reflect greater SNS activity, and are associated with increases in heart rate. In the context of interparental conflict, children who exhibit high SCL reactivity have higher levels of adjustment problems, particularly among girls (El-Sheikh, 2005; El-Sheikh, Keller, & Erath, 2007). Fewer studies have examined PEP as a moderator in the context of interparental conflict. Obradović, Bush, and Boyce (2011) found that children who showed decreased PEP from baseline during a task (indicating increased SNS activity, and referred to as high PEP reactivity in this study) had elevated internalizing problems in the context of high marital conflict as compared to children who showed increases in PEP during a challenge task.

Most of the previous research has examined PNS and SNS functioning as separate moderators, but recent theoretical perspectives advocate examining *interactions* between PNS and SNS functioning (Berntson & Cacioppo, 2004; Del Guidice, Hinnant, Ellis, & El-Sheikh, 2012; El-Sheikh & Erath, 2011). The PNS and SNS do not operate in isolation, and interaction models may better capture children's stress responses. Children's risk for adjustment problems in the context of interparental conflict, therefore, may not rest solely on how one of these systems operates but rather on whether these two systems work in tandem to promote the same directional response.

For example, the adaptive calibration model (Del Guidice, Ellis, & Shirtcliff, 2011) posits four prototypical response patterns to stress, some more adaptive than others. The response patterns are sensitive, buffered, vigilant, and unemotional. Berntson and Cacioppo's (2004) doctrine of autonomic space also proposed four response patterns, which clearly map onto measurements of PNS and SNS cardiac-related activity. These include reciprocal parasympathetic activation (PNS activation, SNS inhibition), reciprocal sympathetic activation (SNS activation, PNS inhibition), coactivation (PNS activation, SNS activation), and coinhibition (PNS inhibition, SNS inhibition). Salomon, Matthews, and Allen (2000) found that reciprocal sympathetic activation is a normative response to stress in children.

In three independent cross-sectional samples, El-Sheikh and colleagues (2009) examined interactions between PNS activity, SNS activity, and interparental conflict in the prediction of children's externalizing behavior problems. The results were consistent across samples and reporters (parents, teachers): Coactivation and coinhibition of the PNS and SNS placed children at increased risk for externalizing problem in the context of marital conflict. In contrast, reciprocal parasympathetic and reciprocal sympathetic activation operated as a protective factor. The results suggested that coordinated actions of the PNS and SNS buffer children from the adverse effects of interparental conflict. In a longitudinal study, El-Sheikh, Keiley, Erath, and Dyer (2013) also found evidence that coinhibition may be a risk factor for poor adjustment. Children who showed coinhibition to a laboratory challenge task had increasing trajectories of depressive symptoms over a 3-year period in the context of interparental conflict. However, they also found that reciprocal parasympathetic activation was related to elevations in depressive symptoms, which is inconsistent with El-Sheikh et al. (2009).

Interactions may occur not only between PNS and SNS functioning but also between baseline and reactivity levels within the same system. For example, Hinnant and El-Sheikh (2009) found that interactions among interparental conflict, baseline level of RSA, and RSA reactivity, such that low baseline levels of RSA in the context of higher RSA suppression strengthened the positive association between marital conflict and internalizing problems 2 years later, whereas low baseline levels of RSA in the context of RSA augmentation (increases in RSA activity) predicted greater externalizing problems 2 years later for children experiencing higher levels of interparental

conflict. In other words, although low basal levels of RSA are related to greater child adjustment problems, RSA regulation (withdrawal/suppression versus augmentation) may buffer children from experiencing problems or further exacerbate child adjustment problems in the context of interparental conflict.

Finally, although HPA axis activity can be conceptualized as a mediator of relations between interparental conflict and child adjustment, there is some evidence that it may interact with PNS reactivity to predict child adjustment problems. Specifically, across two samples, El-Sheikh, Arsiwalla, Hinnant, and Erath (2011) found that children with the lowest levels of anxiety and depression symptoms showed a pattern of higher basal cortisol levels and higher basal RSA. Future research may consider examining interactions between HPA and ANS functioning in the context of interparental conflict in predicting children's adjustment. Alternatively, ANS functioning may alter the mediating role of the HPA axis in the interparental conflict–child adjustment link (i.e., moderated mediation).

The role of children's biological responses to stress as moderators may be more complex than previous research has documented. Whereas the research discussed earlier shows that low basal PNS activity, less PNS withdrawal or PNS augmentation, and higher SNS reactivity are risk factors, exacerbating the risk of child adjustment problems in the context of interparental conflict, recent perspectives in the literature call for research to move beyond diathesis–stress or "dual-risk" models (Belsky & Pluess, 2009; Ellis, Boyce, Belsky, Bakermans-Kranenburg, & Van Ijzendoorn, 2011). Based on developmental-evolutionary models, biological sensitivity to context theory (Boyce & Ellis, 2005; Ellis, Essex, & Boyce, 2005) and differential susceptibility to environmental influences theory (Belsky, 1997; Belsky & Pluess, 2009) propose that the biological factors, including neurobiological factors (e.g., pattern of physiological responding to stress), that place children at risk for adjustment problems in the context of adverse environments are the same factors that allow children to thrive in positive environments. For example, biological sensitivity to context theory would predict that there is a curvilinear relation between heightened ANS functioning (as well as adrenocortical and other stress responses) and interparental conflict in predicting children's adjustment problems. That is, whereas children with increased RSA or SNS reactivity may be at increased risk for adjustment problems in the context of destructive interparental conflict, they may also be more sensitive to the positive effects of secure, stable, and positive interparental relationships. Differential susceptibility to environmental influences theory suggests further that there will be no association between destructive interparental conflict and child adjustment among children who do not have heightened RSA or SNS reactivity.

Genetic Influences

A goal of behavioral genetics research is to tease apart the relative contributions of genetic and environmental influences on behaviors. Recent behavioral genetics studies have focused on these sources of influence in the cascade of effects from interparental conflict through parenting to child adjustment. In an elegantly designed study, Harold and colleagues (2013) found compelling evidence of environmental, rather than genetic, influences for the relation between interparental conflict and hostile parenting and for the mediating role of hostile parenting in the relation between interparental conflict and children's externalizing problems. Moreover, across varying levels of parents' genetic relatedness to their children (i.e., neither parent, mother only, father only, or both parents genetically related to the child), they found the magnitude of the effect of interparental conflict on hostile parenting to be stronger for fathers than for mothers. Finding greater effects of interparental conflict on fathering than mothering converges with findings from other studies on interparental conflict and parenting (e.g., Davies, Sturge-Apple, Woitach, & Cummings, 2009).

In a related study, Harold, Elam, Lewis, Rice, and Thapar (2012) examined links among interparental conflict, hostile parenting, and parent and child antisocial behavior. They found fathers' parenting and fathers' antisocial behavior predicted child antisocial behavior indirectly via fathers' parenting in genetically related and genetically unrelated father-child pairs. For mothers, however, only mothers' antisocial behavior mediated the link between interparental conflict and child antisocial behavior in genetically unrelated mother-child pairs. In genetically related pairs, both mothers' parenting and mothers' antisocial behavior mediated the link. Studies such as this, which consider multiple pathways of influence, will be important for articulating how, and how much, the effect of interparental conflict on child adjustment differs across mothers and fathers.

The design of the Harold et al. (2013) study controlled for the effects of passive genotype-environment correlation (i.e., shared genetic factors underlie and thus influence parent and child behavior) on the links between interparental conflict, parenting, and child adjustment. It did not examine evocative genotype-environment correlations—that is,

whether genetically influenced child behaviors may have evoked particular parenting responses (i.e., commonly referred to as child effects). A study examining whether interparental conflict moderates evocative child effects on parenting found evidence for genetic as well as environmental child evocative effects and also found that those effects are moderated by interparental conflict (Ulbricht et al., 2013). The study employed a large sample that included monozygotic twin pairs; dizygotic twin pairs; sibling pairs from nondivorced families; and sibling, half-sibling, and unrelated sibling pairs from stepfamilies, allowing careful parsing of genetic and environmental effects. Child-based genetic effects, along with shared and nonshared environmental (child) factors were associated with mothers' and fathers' negative parenting, and these effects varied across levels of interparental conflict. Specifically, as marital adjustment declined, evocative child effects on parenting increased, while the role of shared family experiences declined. However, there were some differences in the pattern of specific relations of marital adjustment variables (e.g., global maladjustment, conflict over children) on child-based genetic and child-specific nonshared environmental effects on parenting across mothers and fathers. As interparental conflict increased, fathers' negative parenting was more influenced by nonshared environmental effects whereas mothers' negative parenting was more influenced by their children's genetically mediated characteristics. Assuming the commonly accepted idea of parenting serving to mediate the relation between interparental conflict on child adjustment, findings from this study are consistent with a dynamic process in which both interparental conflict and individual characteristics of the child affect parenting, which in turn affects child adjustment. What this study adds is that child effects on parenting are stronger in families with greater interparental conflict.

In contrast to behavioral genetics research, molecular genetics focuses on understanding effects of particular genes and genetic configurations on behavior. Molecular genetics studies have shed light on several aspects of the link between interparental conflict and child adjustment. For example, Sturge-Apple, Cicchetti, Davies, and Suor (2012) examined whether differential susceptibility to environmental influences (see Belsky, 1997 for details of this theory) might explain variation in the link between interparental conflict and parenting sensitivity. In this study, investigators examined oxytocin receptor (OXTR) and serotonin transporter (5-HTT) genes—both of which have been previously linked (albeit not in consistent ways) to parenting (Bakermans-Kranenburg & van IJzendoorn, 2008; Mileva-Seitz et al., 2011)—as moderators of the relation between interparental conflict and mothers' parenting sensitivity. Results were consistent with differential susceptibility theory. For OXTR rs53576, mothers with the GG genotype showed greater differential maternal sensitivity at different levels of interparental conflict; for the 5-HTT promoter polymorphism, mothers with one or two copies of the short allele demonstrated differential susceptibility for both sensitive and harsh parenting.

In a study examining etiological pathways to two child disorders that often covary (attention-deficit/hyperactivity disorder [ADHD] and oppositional defiant disorder [ODD]), Martel and colleagues (2012) found moderating effects of the 5-HTT promoter polymorphism on the relation between children's self-blame for interparental conflict and symptoms of ODD. Children with the short allele of the 5-HTT promoter polymorphism experienced greater ODD symptomatology regardless of their level of self-blame for interparental conflict, whereas those without the short allele had greater ODD symptomatology when self-blame for interparental conflict was higher.

The studies reviewed in this section serve as examples to help illustrate the complexity and interplay of the biological, psychological, and social processes that govern the ways that family conflict and parenting shape child adjustment, and vice-versa. Research using genetically sensitive designs, such as those described, and careful consideration of the issues raised by these studies, such as genetic and environmental sources of influence, shared versus nonshared environmental influence, the influence of mothers' versus fathers' parenting, the directionality of effects (e.g., child evocative effects), and the precise nature of the effects (e.g., direct, mediated, moderated, and moderated effects consistent with differential susceptibility), can greatly sharpen theory and knowledge on the variability in outcomes among children exposed to interparental conflict.

Interparental Conflict and the Broader Family and Community Context

Children are embedded in their families, which are in turn embedded in a complex network that includes peer groups, neighborhoods, and broader cultural contexts. Cumulative risk models of child psychopathology highlight the potential importance of considering these different contexts when attempting to understand the association between interparental conflict and child adjustment. Specifically, destructive interparental conflict commonly occurs in family contexts in which there are also other types of family problems (e.g., parental psychopathology, parental criminal behavior, economic stressors, etc.). Cumulative risk models suggest that it is the accumulation of family problems, rather than the presence of any single type of

family problem, that is responsible for child adjustment problems. In other words, this perspective suggests that destructive interparental conflict may not be sufficient to produce child adjustment problems, especially if it occurs alone or in isolation from other family problems. However, destructive interparental conflict, in combination with other family problems, is hypothesized to be much more likely to lead to child adjustment problems.

Quite a bit of empirical evidence has amassed that is consistent with certain facets of these cumulative risk models of child adjustment problems, and many of these studies have included interparental conflict as one of the risk factors. For example, Rutter (1979) examined the influence of multiple risk factors for child adjustment problems (e.g., severe marital discord, paternal criminality, maternal mental disorder) and found that the accumulation of risk factors had an exponential association with child adjustment problems. Specifically, the presence of an isolated family stressor did not increase risk for child adjustment problems; in contrast, the presence of two family stressors resulted in a fourfold increase in child adjustment problems, and the presence of four or more family stressors resulted in a tenfold increase in child adjustment problems. Appleyard, Egeland, van Dulmen, and Sroufe (2005) similarly examined the influence of multiple risk factors (e.g., IPV, child maltreatment, low SES) for child adjustment problems, and these investigators found evidence for a linear relation between the number of risk factors present and child adjustment problems, but no evidence for the exponential association.

In this section of the chapter, we focus on documented interactions between interparental conflict and other variables in the prediction of child adjustment problems. That is, we focus on family and community variables that have been found to moderate associations between interparental conflict and child adjustment problems. These variables include direct associations between interparental conflict and child adjustment problems as well as indirect associations involving mediating pathways (moderated mediation). Although we cover variables that have been found to amplify risk for child adjustment problems, we emphasize those that have been found to mitigate risk. We organize this section around three topics: attributes of the family, peer relationships, and community attributes.

Attributes of the Family

A commonly advanced hypothesis is that positive aspects of the parent-child relationship protect children from the adverse effects of interparental conflict. Consistent with this, several investigators have found positive parenting behaviors or a positive parent-child relationship to buffer children from the adverse effects of destructive interparental conflict. Frosch and Mangelsdorf (2001), for example, found that observers reported more child behavior problems when the children's parents exhibited higher levels of interparental conflict and mothers were less warm and supportive in their parenting. However, if mothers were more warm and supportive in their parenting, fewer child behavior problems were reported, even in the presence of higher levels of interparental conflict. Similarly, others have found a positive parent-child relationship to weaken the association between destructive interparental conflict and child adjustment problems (e.g., Davies, Harold, Goeke-Morey, & Cummings, 2002; Kennedy, Bybee, Sullivan, & Greeson, 2010; Skopp, McDonald, Jouriles, & Rosenfield, 2007). In addition to finding that parental warmth and positive parental behaviors (e.g., affection, engagement, positive structuring, and responsiveness) mitigate the association between interparental conflict and a variety of negative child outcomes, Katz and Gottman (1997) found that parental "emotion coaching" (acting as a coach for the child during their child's stressful times and emotional moments—teaching the child to identify and regulate emotions) reduced the magnitude of the association between interparental conflict and child adjustment. Katz, Hunter, and Klowden (2008) replicated this, finding that mothers' emotion coaching reduced the magnitude of the association between IPV and children's odd behavior during a peer provocation.

Several investigators have attempted to examine how parents' conversations with their children about interparental conflict might influence child adjustment problems. McDonald, Jouriles, Rosenfield, and Leahy (2011) examined mothers' responses to children's questions about interparental conflict in a sample of families in which there was a recent incident of IPV. They found that the extent to which mothers' responses addressed the explicit content of their children's questions about interparental conflict was negatively associated with child adjustment problems. This finding is consistent with those reviewed in the preceding paragraph, suggesting that positive aspects of the parent-child relationship may buffer children from the adverse effects of destructive interparental conflict. Gomulak-Cavicchio, Davies, and Cummings (2006) also examined mothers' communications with children about their disputes, but these investigators found that maternal communications highlighting family stability and warmth appeared to magnify the risk posed by interparental conflict. These authors were prudent in their interpretation of this counterintuitive finding, but the finding is not inconsistent with the finding of McDonald et al. That is, it may be that answering the child's specific questions,

rather than offering general comfort or a sense of safety, may help a child better cope with interparental conflict. Collectively, findings on the effects of positive parent-child communications and/or positive parent-child relationships suggest that they are likely to be more complex than a simple buffering or protective hypothesis might suggest.

To offer an example of this complexity, we highlight a finding in a study conducted by Skopp, McDonald, Jouriles, and Rosenfield (2007). In this study, parental warmth toward the child (operationalized by items such as "I comfort my child when he/she seems scared, upset or unsure" and "My child and I hug and/or kiss each other") was examined as a moderator of the association between men's IPV and child externalizing problems. The findings were complex and differed for mothers' and fathers' warmth expressed toward male and female children. However, one of the more interesting findings was that men's IPV related positively to child externalizing problems in families where the men were warmer toward the child. This finding is generally consistent with the finding reported by Gomulak-Cavicchio, Davies, and Cummings (2006), in that a presumably positive parent-child interaction appeared to amplify the risk associated with interparental conflict. It is also consistent with findings in other literatures suggesting that the risk for child conduct problems is amplified when antisocial fathers are highly involved in their children's care (Jaffee, Moffitt, Caspi, & Taylor, 2003) as well as with the social cognitive theory explanation that children are more likely to emulate an adult's behavior when they share a warm bond with that adult (Bandura, 1986). Again, the effects of positive parent-child communications and/or positive parent-child relationships appear to be complex.

Parents' relationships with others in the family may also have an impact on how interparental conflict affects child adjustment, and in equally complex ways. Fosco and Grych (2007) assessed how often parents expressed positive affect toward family members (the specific target of the positive affect was not specified) and found that the association between interparental conflict and child adjustment problems was slightly stronger for families in which the parents expressed greater positive affect. In other words, more frequent expression of parental positive affect in the family appeared to exacerbate rather than buffer against the effect of interparental conflict on child adjustment. Fosco and Grych were appropriately cautious in interpreting this result. Nonetheless, this counterintuitive finding points to the inherent complexity in how family interactions transact with interparental conflict in the prediction of child adjustment problems.

Maternal symptoms of psychopathology have also been found to moderate associations between children's exposure to interparental conflict and child adjustment problems. Specifically, maternal depressive symptoms and psychological distress amplify associations between children's exposure to IPV and child adjustment problems of preschoolers (Martinez-Torteya, Bogat, von Eye, & Levendosky, 2009), school-age children (Levendosky & Graham-Bermann, 2000), and adolescents (Levendosky, Huth-Bocks, & Semel, 2002). Levendosky and colleagues (2002) have offered several hypotheses for children's increased vulnerability to the effects of IPV in the context of maternal depression. These explanations involve other family processes, such as mothers' diminished emotional availability to their children when experiencing both IPV and depression, and children having to take on more of a caregiver role within the family.

High rates of co-occurrence for IPV and physical child abuse (Appel & Holden, 1998; Jouriles et al., 2008) have sparked investigations of the joint effects of these two forms of family violence on child functioning. Although the results of these studies are not entirely consistent, most investigators report evidence for additive effects. That is, both forms of family violence appear to contribute independently to subsequent child adjustment problems (Jouriles, Mueller, Rosenfield, McDonald, & Dodson, 2012; Litrownik, Newton, Hunter, English, & Everson, 2003). Attempts to document multiplicative effects (e.g., show that the presence of child abuse amplifies associations between IPV and child adjustment problems) have generally not been successful (Litrownik et al., 2003).

Peer Relationships

An important task during childhood is the development of beneficial and satisfying peer relationships. Acquiring the ability to develop and maintain meaningful peer relationships is among the most important developmental tasks during middle childhood and adolescence, and peer problems, although not technically a psychological disorder, might rightfully be conceptualized as a type of child adjustment problem. In fact, peer problems are characteristic of a wide range of child psychological disorders. As one might expect from the research reviewed thus far, interparental conflict has consistently been found to be associated with children's problematic peer relationships (e.g., Erel et al., 1998; Gottman & Katz, 1989; McHale et al., 1999; Stocker, Ahmed, & Stall, 1997; Stocker & Youngblade, 1999).

When considering children's peer relationships in the link between interparental conflict and child adjustment

problems, the question becomes whether peer relationships can influence what is arguably a within-family process. Wasserstein and LaGreca (1996) found that support from a close friend moderated the link between interparental conflict and grade-school children's adjustment problems; interparental conflict was associated with child problems only among children who had received low levels of support from a close friend. Rogers and Holmbeck (1997) found that a measure of peer avoidance (interpreted as perceived peer availability) moderated the association between IPV and child adjustment problems, so that children in high-conflict families who reported greater peer availability had fewer adjustment problems than their counterparts in high-conflict families who reported less peer availability. Criss, Pettit, Bates, Dodge, and Lapp (2002) reported a similar moderator effect in a longitudinal study with a sample of younger children (kindergarten to second grade). Specifically, marital conflict was associated with externalizing problems only among children with low levels of peer acceptance.

Community

Families, of course, are nested within the broader context of communities. There has been speculation, but little research, on whether children's exposure to interparental conflict and violence in the family interacts with aspects of the family's community in influencing child development (Cicchetti & Lynch, 1993). On the other hand, the concept of polyvictimization—experiencing multiple types of violence across multiple settings— has begun to attract considerable attention among child victimization researchers (Finkelhor, Ormrod, & Turner, 2007). This is because it is becoming increasingly clear that exposure to multiple types of violence (e.g., violence between the parents, violence within the community, violence at school) is much more likely than exposure to a single, isolated type (Margolin et al., 2009).

In general, research on polyvictimization suggests that children who are exposed to multiple types of violence fare worse than those exposed to a single type of violence. For example, Mrug, Loosier, and Windle (2008) found that cumulative violence exposure across settings (home, school, and community) was a stronger correlate of adolescents' externalizing and internalizing problems than exposure in any single setting. Similarly, Margolin, Vickerman, Oliver, and Gordis (2010) found that an index of children's cumulative violence exposure (including IPV, community violence, and parent-to-youth aggression) was a stronger predictor of youth problems than violence exposure in any single domain. What is less clear is how these different types of violence exposure might interact with one another in predicting child adjustment problems. Investigations of how children's exposure to different types of violence interact with one another often provide no evidence of interaction effects (e.g., Kennedy, Bybee, Sullivan, & Greeson, 2010), or interactive effects that are contrary to expectations. For example, in a prospective study, high levels of community violence exposure mitigated relations between witnessing IPV and adolescents' anxiety, depression, and delinquency (Mrug & Windle, 2010). Possible explanations for this result include the idea that IPV might simply be less salient to (and perceived as a more normal phenomenon for) adolescents whose environments also include community violence.

There are a number of studies on how poverty or low family SES might moderate the association between interparental conflict and child problems. As noted, cumulative stress models of child psychopathology (e.g., Rutter, 1979) suggest that living in poverty might potentiate associations between interparental conflict and child adjustment problems, and findings from early studies were consistent with this hypothesis. For example, Jouriles, Bourg, and Farris (1991) found that marital arguments were more strongly associated with child conduct problems in families of lower, rather than higher, SES. However, more recent research suggests that the joint effects of these two family stressors may not be that clear cut. El-Sheikh and colleagues (2008) examined SES as a moderator of the emotional security theory explanation for the link between interparental conflict and child adjustment problems, and they found no differences based on high or low SES. Yoo and Huang (2012) found that poverty moderated associations between IPV and child adjustment problems, but the magnitude of the association was smaller among impoverished families.

Culture

Many of the associations between specific forms of interparental conflict and child adjustment problems have been documented in different countries and cultural contexts. Similarly, associations between hypothesized mediators of the relation between interparental conflict and child problems have been linked to child problems in different cultural contexts. To offer some concrete examples, the longitudinal association between witnessing parental IPV during childhood or adolescence and being involved in a violent relationship as an adolescent or young adult has been documented in many different samples within the United States (e.g., Amato & McNeal, 1998; Cui, Durtschi, Donnellan, Lorenz, & Conger, 2010; Ehrensaft, Cohen, & Brown, 2003; Ireland & Smith, 2009; Linder & Collins,

2005) as well as in samples in Canada (Wolfe, Wekerle, Scott, Straatman, & Grasley, 2004), New Zealand (Fergusson, Boden, & Horwood, 2006), and the Philippines (Fehringer & Hindin, 2009). Associations between children's appraisals of interparental conflict as threatening and child internalizing problems have been observed in the United States (e.g., Grych et al., 2000), Canada (Kerig, 1998), Wales (Davies, Harold, Goeke-Morey, & Cummings, 2002), and Australia (Dadds, Atkinson, Turner, Blums, & Lendich, 1999). Bradford and colleagues (2003) found evidence for the hypothesis that interparental conflict affects child adjustment indirectly through disruptions to parenting in samples of adolescents from Bangladesh, Bosnia, China, Colombia, India, Germany, Palestine, South Africa, and the United States. Experimental studies of children's immediate responses to conflict between adults have been observed to be similar among United States and Israeli children (Shamir, Cummings, Davies, & Goeke-Morey, 2005) and among children from Welsh families (Davies et al., 2002; Goeke-Morey, Cummings, Harold, & Shelton, 2003). Children's emotional security as a mediator of relations between interparental conflict and child adjustment problems has been documented with families from the United States (e.g., Cummings, Schermerhorn, Davies, Goeke-Morey, & Cummings, 2006) and Wales (Davies et al., 2002). In short, it appears that many of the documented relations between interparental conflict and child adjustment problems are not specific to any particular culture.

What is much less clear is how specific aspects or dimensions of one's culture might influence associations between interparental conflict and child adjustment problems. In general, there is a dearth of theory specific to this topic, with several notable exceptions. For example, McLloyd and colleagues (2002) have discussed the potential importance of extended family networks and have suggested that relations between interparental conflict and child adjustment problems may be weaker among ethnic minorities in the United States because of their extended family networks. Such extended family networks are hypothesized to provide support to family members and presumably buffer children from the negative impact of conflict exposure. Empirical support for this particular hypothesis is mixed, with some researchers finding results that could be interpreted as consistent with this argument (e.g., Tschann, Flores, Pasch, & VanOss Marin, 1999) and others not (e.g., El-Sheikh et al., 2008). Developing sound theoretical explanations for possible differences across cultures and then examining cultural differences in the association between interparental conflict and child adjustment remains an important direction for future research.

TRANSLATIONAL IMPLICATIONS

For many, *translational research* refers to the formation of clinical interventions through the use of scientific knowledge. Applied to the topic of this chapter, translational implications might be conceptualized to refer to the ways in which knowledge about the association between interparental conflict and child adjustment might be used to help promote healthy child development. Of course, one simple answer to this question is preventing children's exposure to destructive interparental conflict. Doing this might involve the deployment of intervention programs targeted at couples with children, such as programs that attempt to develop healthy and effective conflict resolution skills. However, preventing or halting destructive interparental conflict is not always simple or easy. Even the severing of a couple's intimate relationship (divorce, separation) does not always result in children no longer being exposed to destructive interparental conflict. Furthermore, what should be done once children have already been exposed to destructive interparental conflict?

This section starts with a review of empirically supported interventions for children who have been exposed to interparental conflict. We begin with those interventions designed specifically for children exposed to interparental conflict; most of these interventions focus on children who have been exposed to IPV. Next, we review interventions that focus on reducing destructive interparental conflict and interventions that are salient to children's exposure to interparental conflict but that do not focus specifically on children exposed to violence. Our review of interventions is comprehensive, but it is not intended to be exhaustive. We hope that it is illustrative, however, providing readers with an idea of the breadth of interventions pertinent to this topic as well as ideas for further intervention work in this area.

Figure 12.1 summarizes the various mechanisms and pathways by which interparental conflict is believed to influence child adjustment. This diagram summarizes the theory and data reviewed in earlier sections and provides an organizing framework for discussing the translational implications of research on children's exposure to interparental conflict.

Interventions Designed for Children Exposed to IPV

Project Support

Project Support (Jouriles et al., 2001, 2009; McDonald, Jouriles, & Minze, 2011) was originally designed to reduce conduct problems among children, ages 3 to 8 years, who had been exposed to frequent and severe IPV. Conduct

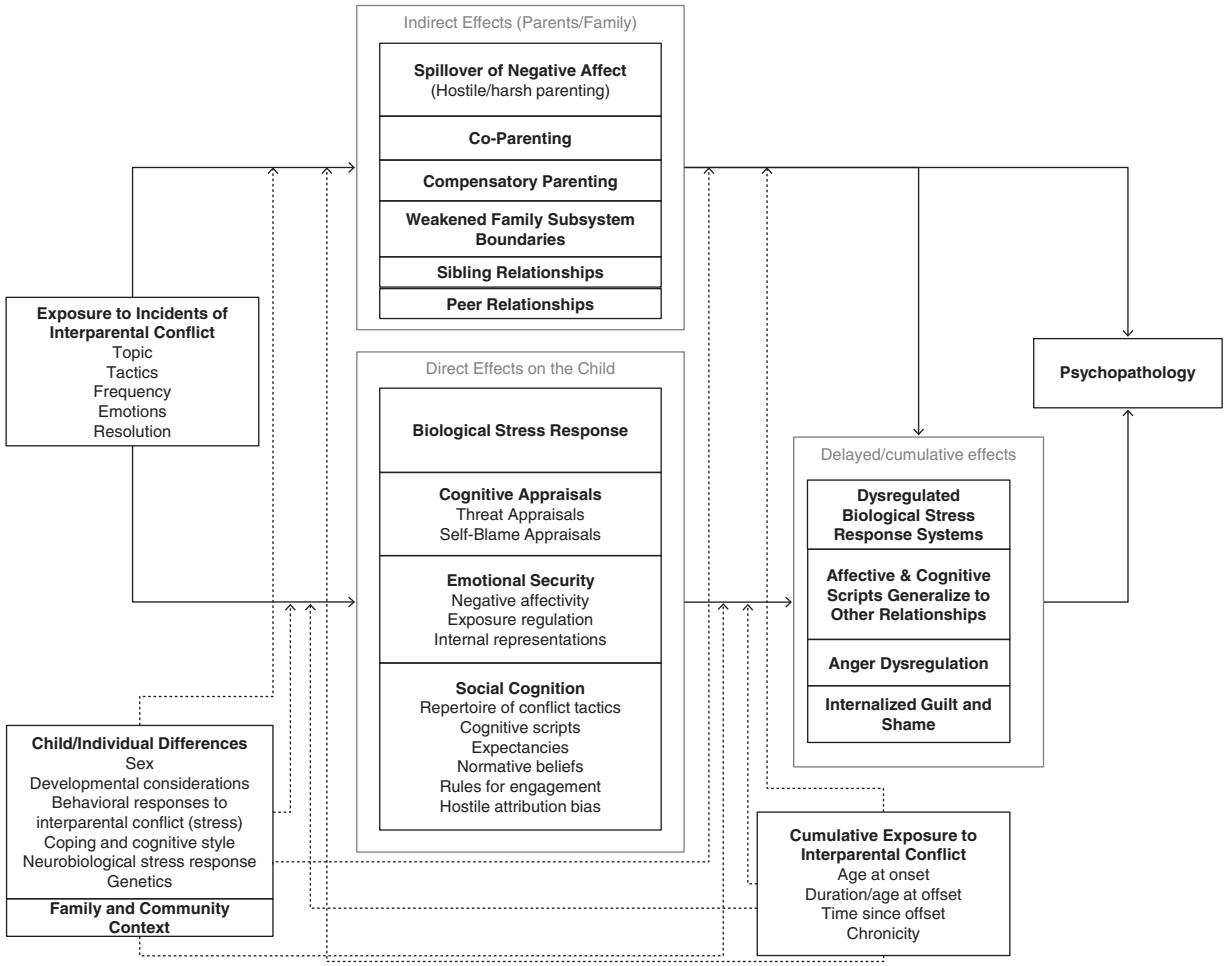

Figure 12.1 Organizational Framework for Mechanisms and Pathways by which Interparental Conflict and Violence are Theorized to Influence Child Adjustment.

problems are frequently observed among children who have been exposed to such violence, and they tend to be fairly stable without intervention. The Project Support intervention is based on social cognitive theory on the development of antisocial behavior, basic research linking interparental conflict to parenting, research on dimensions of parenting that moderate associations between interparental conflict and child adjustment problems, and clinical research evaluating interventions for child conduct problems. It is consistent with principles of developmental psychopathology, which point to the parent-child relationship as a primary source of influence on child development.

Project Support includes two components, the provision of social and instrumental support to the mothers and parent training, which is conceptualized as the principal avenue through which children's conduct problems are ameliorated. The parent training component attempts to improve the quality of the parent-child relationship by teaching and encouraging warm, attentive, and supportive parenting behaviors. It also attempts to reduce children's exposure to hostile and aggressive behavior and to create a more predictable environment for children. Intervention services are delivered in weekly home visits for about 6 months. Two randomized controlled trials of Project Support (Jouriles et al., 2001, 2009; McDonald, Jouriles, & Skopp, 2006) have been conducted with families in which the mothers had recently departed from a domestic violence shelter and had a child who met diagnostic criteria for oppositional defiant disorder or conduct disorder. Families in these studies were randomly assigned to receive Project Support or to a services-as-usual comparison condition.

Results of both trials indicated that Project Support was effective in improving mothers' parenting and reducing children's conduct problems, and results observed at posttreatment were maintained over both studies' follow-up periods (20 months posttreatment in study 1, 12 months in study 2). In both studies, rates of clinical levels of child

conduct problems at the last follow-up assessment were markedly lower in the Project Support condition than those in the services-as-usual condition (Jouriles et al., 2009; McDonald et al., 2006). In addition, mothers in the Project Support condition reported their children to be happier, to have better social relationships, and to have lower levels of internalizing problems relative to children in the comparison condition (McDonald et al., 2006). Mothers were less harsh and more consistent in their parenting, and mothers' parenting was found to mediate the effect of the intervention on children's conduct problems (Jouriles et al., 2009).

Kids' Club

The Kids' Club is a 10-week group program designed to address adjustment problems among 5- to 13-year-old children who have been exposed to IPV (Graham-Bermann, 1992). Grounded in social cognitive theory, the intervention focuses on teaching children about IPV, promoting healthy beliefs and attitudes, reducing anxiety and worry, and improving social skills (Graham-Bermann & Hughes, 2003). Two forms of the intervention were evaluated in a randomized controlled trial (n = 181) with a sample of mothers and their children ages 6 to 12: a group intervention offered only to the children, and one with the child group intervention plus a separate parenting group intervention for mothers. The comparison group received no services. For externalizing problems and attitudes about violence, only the child-plus-mother intervention resulted in positive change. Internalizing problems improved for children in all three groups. However, when clinical levels of internalizing problems were considered, only the intervention conditions reduced internalizing problems to nonclinical levels, with the child-plus-mother condition showing a greater reduction (Graham-Bermann, 2000; Graham-Bermann, Lynch, Banyard, Devoe, & Halabu, 2007). A Preschool Kids' Club, which targets anxiety reduction and conduct problems and which also includes a parenting group for mothers, has also been evaluated, although with somewhat less efficacious outcomes (Basu, Malone, Levendosky, & Dubay, 2009; Graham-Bermann & Halabu, 2004).

Child-Parent Psychotherapy

Child-Parent Psychotherapy (CPP) is an intensive intervention that focuses on improving the mother-child relationship to help children cope with trauma symptoms (Lieberman, Van Horn, & Ippen, 2005). CPP is based in attachment theory, social cognitive theory, and ecological models of therapy. It was designed for preschool-age children and focuses primarily on the mother-child dyad as the vehicle through which to help children exposed to IPV. Goals include promoting affect regulation in both the mother and child, changing maladaptive mother and child behavior as well as mother-child interaction, facilitating developmentally appropriate mother-child interaction, developing a trauma narrative, and developing hope and trust in the parent-child relationship (Lieberman, Ghosh Ippen, & Van Horn, 2006). Lieberman and colleagues (2006) conducted a randomized controlled trial evaluating CPP in comparison to monthly case management plus individual psychotherapy. Participants were 75 children ages 3 to 5 years who had witnessed IPV and their mothers. Families participated in an average of 32 sessions over the course of a 1-year treatment period. Results at posttreatment indicated that trauma symptoms and behavior problems decreased among children in the CPP condition but not among those in the comparison condition (Lieberman, Van Horn, & Ghosh Ippen, 2005). Improvements in behavior problems were maintained at the 6-month follow-up (results for trauma symptoms were not reported in the follow-up evaluation) (Lieberman et al., 2006).

Community Advocacy Program

Sullivan and colleagues developed and evaluated a community advocacy intervention for women who were victims of IPV. The program involved a trained advocate working individually with the women several times a week for 16 weeks to help the family access community resources and support. The intervention had been shown to reduce women's depression and the recurrence of violent victimization and to increase social support (Sullivan & Bybee, 1999). To help the children in violent families, the investigators expanded the intervention to include a support and educational group for children that focused on safety, feelings, and self-respect. They evaluated this expanded intervention in a sample of 80 mothers and their children ages 7 to 11. Of the 9 hours per week that advocates spent with each family, approximately 5 were spent interacting with the children (Sullivan, Bybee, & Allen, 2002). The enhanced program yielded only modest effects on child well-being (Sullivan et al., 2002). Children in both groups experienced a decline in the amount of IPV witnessed, with this decline occurring earlier for children in the intervention condition. Children in both groups also had increased self-competence (self-concept and feelings of self-adequacy) at posttreatment, but by the 4-month follow-up, the self-competence of control-group children had returned to pre-intervention levels. There were no group differences in behavior problems.

Trauma-Focused Cognitive Behavioral Therapy

Trauma-Focused Cognitive Behavioral Therapy (TF-CBT; Cohen, Mannarino, & Deblinger, 2006) has been shown to reduce trauma symptoms in children who have developed posttraumatic stress disorder (PTSD) or symptoms of PTSD in response to potentially traumatizing events (e.g., child abuse). A randomized controlled trial evaluated its efficacy for 140 children ages 7 to 14 who had been exposed to IPV and who had IPV-related symptoms of PTSD (Cohen, Mannarino, & Iyengar, 2011). Children were randomly assigned to either a TF-CBT condition or a child-centered therapy (CCT) condition. Children and their mothers were seen by the same therapist, but in separate sessions, once a week for 8 weeks, with the exception that in two of the TF-CBT sessions, the mother and child were seen together.

TF-CBT provides education about trauma and teaches relaxation skills, affect expression and regulation, and coping skills. It also includes helping children develop a narrative about their IPV experience. In the course of developing the narrative, the therapist can assist children in correcting maladaptive cognitions and in coping with trauma reminders and events as they emerge. Children also share their experiences of IPV with their mother in the joint sessions. In CCT, children and parent direct the content of their sessions; the therapist provides reflection, empathy, emotional support, and encouragement.

Results indicated that TF-CBT was superior to CCT in reducing trauma symptoms, particularly hyperarousal and avoidance symptoms, and anxiety symptoms. TF-CBT did not differ from CCT in reducing the reexperiencing of symptoms, which was not unexpected, given that the children lived in homes in which IPV recurred. Treatment effects were not observed for depression or behavior problems. A review of the collective evidence amassed for the effects of TF-CBT (i.e., not just for IPV-related trauma, but for other types as well, such as trauma related to child abuse) suggests that it appears to be efficacious in reducing trauma symptoms, but its efficacy for behavior problems and depression is less clear (de Arellano et al., 2014).

Mapping to the Organizational Framework and Future Directions

With the exception of Sullivan and colleagues' community advocacy intervention, each of the interventions just reviewed includes a component that targets changes in the parent-child relationship. Although there is some overlap, the theoretical foundation for the intervention varies across the interventions, as do the processes believed to mediate intervention effects. However, the parenting component to each appears more similar than different. Each focuses on improving parenting skills and the affective quality of the parent-child relationship (in particular, improving maternal warmth and parent-child communication). Given the centrality of parents to the development of preschool and young school-age children, a focus on parenting is appropriate, and it may well be that the effects of these interventions are primarily attributable to their influence on parenting. However, the contribution of the other components of the interventions to improving child adjustment remains unclear.

To illustrate, each of the interventions also targets reductions in maternal distress by providing emotional and social support and providing mothers with a safe arena in which to talk about their experience of IPV and how it has affected their lives and their children. However, changes in parenting were found to mediate the effects of Project Support on child behavior problems, whereas reductions in mothers' psychological distress did not. Furthermore, community advocacy, which successfully addressed mothers' emotional distress but which did not include a parenting component, did not have demonstrable effects on child behavior problems. This finding does not imply that additional intervention targets, such as responding to the suffering of mothers who have been victims of IPV, are not necessary or helpful (or simply morally right), but just that doing *only* that is not sufficient to help the children.

Kids' Club, TF-CBT, and the community advocacy program include components targeting the child's immediate and delayed responses to IPV, including social cognitions and appraisals, negative affect, and affect regulation. Kids' Club and TF-CBT also work to help children develop coping skills to reduce the extent to which they are negatively affected by the conflict and IPV. Little is known about the relative efficacy of the parent-focused and child-focused components in those interventions that offer both. Graham-Bermann and colleagues' (2007) comparison of the child-only versus the child-plus-mother Kids' Club and Jouriles, McDonald, and colleagues' (2009) explicit analysis of mediating processes for Project Support reflect the kind of careful approach that is needed to optimize services for families of children exposed to IPV. A reasonable step for researchers would be to evaluate multiple plausible mediating pathways (such as those identified in the figure) simultaneously, from multiple plausible theoretical perspectives, to begin to drill down on the mechanisms that account most strongly for effects of IPV on child adjustment. Similarly, in conducting intervention research, it would be useful also to evaluate multiple

mediating pathways, to help isolate those that account most strongly for intervention effects.

It follows from several theories (e.g., attachment, cognitive-contextual, emotional security, trauma) that enhancing the child's sense of safety and security in the family should positively influence child mental health; however, the mechanisms responsible for this expected outcome differ across the different theories. Similarly, social cognitive theory and trauma theory posit different mechanisms to explain how IPV can lead to externalizing problems in children. Testing these mechanisms together in evaluation research will help clarify both theories and can shed light on how interventions based on these theories achieve their effects. Evaluating multiple mediating processes simultaneously would significantly advance knowledge in this area, and would aid intervention developers. Similarly, evaluating competing hypotheses about mediating processes and outcomes would help illuminate the key pathways by which IPV influences child adjustment. Finally, intervention researchers should attend to the multifinality in outcomes of children exposed to IPV. As much as we need to know what outcomes can be prevented or improved, knowing that an intervention is *not* effective for a problem that occurs commonly among children in violent families can be just as important. As an example, the version of TF-CBT used for the IPV-exposed sample was not found to improve child behavior problems. However, in a different population (sexually abused children), TF-CBT developers found that a 16-week TF-CBT program that did not included a trauma narrative component helped improve parenting as well as child behavior problems (Deblinger, Mannarino, Cohen, Runyon, & Steer, 2011). The authors speculated that omitting the trauma narrative left more time to devote to teaching and practicing the parenting skills, thereby reducing behavior problems. This finding is consistent with what theory and data would suggest. Such efforts bring the field closer to being able to offer flexible and demonstrably effective interventions that can be tailored to meet a child's specific needs and circumstances.

The interventions just reviewed were provided to children recruited from community agencies. The samples varied in the nature and levels of child adjustment problems, and the interventions differed in treatment modality (e.g., group versus dyadic) and duration (e.g., 10 weeks, 6 months, 1 year), yet the interventions were effective in helping the children. Indeed, after intervention, the problems of a sizable number of children were found to have diminished from clinical to normative levels on standard measures of child psychopathology. Thus, although the interventions were seemingly tightly focused in concept (i.e., targeting children "exposed to IPV"), they differ on a number of dimensions. The results from these interventions studies hold important implications for community agencies hoping to offer empirically supported interventions for children and their families. It suggests the need to assess child adjustment broadly and offer interventions that target those problems identified by the assessment. For now, this might mean that if trauma were the predominant problem, CPP or TF-CBT might be appropriate, depending on the child's age. If behavior problems predominate, Project Support or Kids' Club would be appropriate. Because comorbidity is the rule rather than the exception, however, many children in violent families may present with multiple, long-standing adjustment problems, including disrupted biological stress-response systems. Research thus far offers little guidance in this circumstance for prioritizing or organizing intervention approaches. In addition, many social services agencies are not equipped to offer a wide array of interventions, or lengthy interventions, which may be needed for families with severe and complex child adjustment problems. Research that helps to sort out how best to sequence or combine intervention components so that they can efficiently and effectively address multiple targets (such as the research on adaptations of TF-CBT) is needed.

The field of implementation research has helped to underscore the importance of training practitioners to deliver interventions reliably and efficaciously. For psychosocial interventions, such training often involves education, behavioral practice, coaching/supervision until mastery, and follow-up performance monitoring (Fixsen, Naoom, Blase, Friedman, & Wallace, 2005). Such intensive training activities, however, are often beyond the means of most social services agencies (e.g., domestic violence agencies), especially those with high staff turnover rates, such as some child welfare agencies. Although there is pressure from the public policy arena for human services agencies to provide evidence-based programs, there is also pressure, especially for publicly funded agencies, to provide services to as many people as possible. Such pressure may result in dollars being directed away from training and monitoring staff performance toward increasing the numbers of service providers and their caseloads. Such issues slow the uptake of effective intervention programming into the community. Another translational area that is underdeveloped is in the education of service providers. Intervention researchers are commonly embedded in doctoral programs in psychology or related fields, medical schools, or public health programs. However, most

professionals who provide services to children in violent families have a master's degree, often in social work, counseling, or family therapy. Developing training partnerships with those educational pipelines might offer opportunities for building a stronger workforce and expanding its capacity.

Interventions to Reduce Interparental Conflict and Protect Child Well-being

Happy Couples and Happy Kids

Cummings, Faircloth, Mitchell, Cummings, and Schermerhorn (2008) conducted a randomized controlled trial evaluating the effects of Happy Couples and Happy Kids (HC/HK), a 4-week intervention that includes psychoeducation about marital conflict and its effects on children's emotional security in the interparental relationship and coaching in couple communication skills. A booster session was provided 6 and 12 months after the intervention. A community sample of families with a child between 4 and 8 years of age were randomly assigned to one of two forms of HC/HK or to a self-study comparison group. In one of the HC/HK groups, only the parents (the couple) participated; in the other HC/HK group, the child participated in a separate group while the parents were in session. Approximately half of the couples were maritally distressed at the outset of the study. Participants receiving the HC/HK intervention had superior outcomes in comparison to the self-study group, and outcomes did not differ across the two HC/HK conditions. For the HC/HK groups, destructive interparental conflict was reduced, constructive conflict increased (e.g., resolution, support behaviors), and there were improvements in parenting and child adjustment (Child Behavior Checklist total problems scale) at 1-year (Cummings et al., 2008) and 2-year (Faircloth, Schermerhorn, Mitchell, Cummings, & Cummings, 2011) follow-up assessments. Moreover, analyses of the patterns of change over time indicated that improvements in the couples' knowledge and handling of conflicts preceded improvements in marital satisfaction, parenting, and child adjustment outcomes. No changes were observed in the comparison group.

Interventions Salient to Children's Exposure to Interparental Conflict

A number of interventions that were not originally designed to address the issue of children's exposure to interparental conflict have since been found to do so. These include marriage education and parenting interventions as well as various couples' interventions. We turn to these now.

Marriage Education and Parenting Interventions

Over 30 years of research on marriage and relationship education programs attests to their utility in increasing couples' relationship satisfaction and improving the ways that couples manage conflict (Hawkins, Blanchard, Baldwin, & Fawcett, 2008). These effects can be very long-lived (e.g., 10 years; C. P. Cowan, Cowan, & Barry, 2011). There are many marriage and relationship education programs to choose from, several of which have been subjected to sustained and rigorous evaluation. Among these, however, thus far only a few have considered whether children benefit.

Family Foundations is a "transition to parenthood" prevention program for expectant couples. It is designed to enhance coparenting, or the ways that parents work together, coordinate, support one another, and manage conflict about childrearing (Feinberg, Jones, Kan, & Goslin, 2010). The intervention includes education about the kinds of stresses and coparenting conflicts parents might expect after their baby is born and teaches couples communication, problem solving, and conflict-management skills. A sample of 169 couples was randomly assigned to participate in Family Foundations or to a no-treatment control condition. At the 3.5-year follow-up (when children were 3 years old), couples in the Family Foundations condition reported themselves to be less overreactive and less lax with their child, less likely to physically punish their child, and to have lower levels of parenting stress than couples in the comparison group. Family Foundations had positive effects on children's social competence; for families of boys, there were positive effects on couples' relationship quality and children's externalizing problems. There were no intervention effects on child internalizing problems.

Based on knowledge that "the single most powerful predictor of fathers' engagement with their children is the quality of the men's relationship with the child's mother, regardless of whether the couple is married, divorced, separated, or never married," P. A. Cowan, C. P. Cowan, and colleagues (2008, p. 54) developed a novel intervention designed to increase low-income fathers' engagement with their children (P. A. Cowan, C. P. Cowan, Pruett, Pruett, & Wong, 2009). In a randomized controlled trial of 289 families, expectant couples or those whose youngest child was under 7 years old were randomly assigned to one of three conditions: a 16-week, father-only intervention; a 16-week couple intervention; or a 3-hour, single-visit comparison condition. The content of the father-only and

couples group sessions was identical, and included sessions that focused on parenting and on couple issues. However, in-session exercises differed somewhat across the two formats (e.g., in the father-only group, some exercises that required the partner's participation were assigned as homework rather than completed during the session). At the 11-month follow-up, among families in the father-only and couple intervention conditions, fathers' engagement with their children increased, their parenting stress decreased, and fathers reported fewer parental conflicts about discipline. In addition, those in the couples' groups had stable couple relationship satisfaction over the follow-up period. This is in contrast to the comparison condition, where couple adjustment declined over the 11-month follow-up period. Post hoc tests indicated that children's adjustment remained stable in the two intervention conditions but declined in the comparison condition. This study is noteworthy for its focus on low-income, minority families (67% of the sample was Hispanic) and on fathers, in particular.

The Cowans and their colleagues also evaluated an intervention for parents with a child entering preschool (C. P. Cowan et al., 2011). The evaluation was a randomized controlled trial in which 100 families were assigned to a low-dose control condition (i.e., once-per-year consultation with the interviewer team) or to one of two 16-week intervention groups, one which focused on the couple relationship and one on parenting. Each group session included time allotted for presentation and discussion of the curricular material, and a 20- to 30-minute "check-in" period for couples to discuss issues that had arisen since the last session. The difference between the two group formats was how these check-in discussions were managed. In the couples group, the discussion focused on addressing the issues as a couple whereas in the parenting group, the focus was on addressing the issue from a parenting perspective. For example, if there were concerns about child discipline, the discussion in the couples group would center on how the couple could work together to resolve the issue. In the parenting-focused group, the discussion would focus instead on healthy discipline practices. In addition to contrasting these two intervention formats, the investigators examined their effects over a long period of time, conducting follow-up assessments when the children entered fourth grade and when they entered high school, using multimethod assessments of outcomes. Couple relationship satisfaction was stable over the 10-year follow-up period for those in the couples group, whereas it declined for those in the parenting and control groups (although there was a slight advantage for those in the parenting group compared to the control group). Couple communication quality improved through fourth grade for those in the couples group, whereas it was stable for those in the parenting group and declined for those in the control group. However, when the children entered high school, those effects had dissipated. There were also modest positive intervention effects on child adjustment, with child hyperactivity declining in the couples group condition but not in the control condition, and marginally significant findings of a declining trajectory for child aggression in the couples group but an increasing one in the control group. No group differences emerged for anxiety/depression. The results suggest that for primary prevention, a couple-focused program confers long-term protection for couples' and children's adjustment and that the protective effect is superior to those of an intervention focused solely on parenting. This line of research is exemplary in considering both couples and parenting interventions with sensitivity to the clinical setting and in evaluating treatment effects over a lengthy time period.

Couples' Therapy

In addition to increasing relationship satisfaction and reducing conflict generally, behavioral couples therapy has also been found to reduce interparental conflict over children (Gattis, Simpson, & Christensen, 2008). Moreover, in one evaluation of couples therapy that included assessment of child outcomes, improvements in child adjustment were observed during the treatment period; however, they were not maintained over the follow-up period (Gattis et al., 2008).

Couples therapy effects on child adjustment were also examined in a randomized controlled trial of behavioral couples therapy (BCT) plus individual treatment for substance use in a sample of alcohol- and substance-using men involved in an intimate relationship (Kelley & Fals-Stewart, 2002). The study included three groups. All participants received 20 weeks of individual treatment for substance use plus 12 additional weeks of intervention. For the additional 12 weeks, one group received couples therapy; one group received continued individual substance use treatment; and in one group, the couple attended substance abuse education sessions. Although the sample for the study was selected based on alcohol and substance use rather than on couple functioning, the mean level of relationship satisfaction for the couples that participated fell well into the distressed range. All three of the interventions deployed in the study were effective in reducing men's alcohol and substance use (although the couple intervention achieved somewhat greater reductions). However, in addition to its positive effects on alcohol and substance use, BCT also

increased relationship satisfaction, reduced couple conflict and violence, and improved the psychosocial functioning of the children (children ranged from 6 to 16 years of age). Increases in relationship satisfaction and reductions in alcohol and drug use both contributed to the improvements in child adjustment. Specifically, at pretreatment, 50% of children of drug-using men and 32% of children of alcohol-using men exhibited clinical levels of adjustment problems. At the 12-month posttreatment follow-up, these figures were 15% and 5%, respectively. No statistically significant changes in couple relationship satisfaction or child adjustment were observed in either of the two comparison conditions at the 12-month assessment. A later pilot study evaluating treatment for alcohol-abusing men (Lam, Fals-Stewart, & Kelley, 2008) compared BCT to an intervention that included parent skills training plus BCT and to individual treatment for alcohol abuse. Although couples' adjustment was not assessed in this study, parent skills training plus BCT was superior to BCT and the control condition in reducing children's adjustment problems. Careful studies such as this are at the heart of translational science. They help move the field away from interventions that address a single problem in a narrowly defined population and toward the complexities that confront clinicians in the community.

Initial evaluation research (albeit nonexperimental) has found Couples Coping Enhancement Training (CCET), a marital distress prevention program that includes content addressing stress and coping as well as communication and conflict skills, to be effective in improving couples' satisfaction and individual and dyadic coping with stress (e.g., Bodenmann, Pihet, Shantinath, Cina, & Widmer, 2006). To examine its effects in families with children, a sample of 100 couples with a child between the ages of 2 and 12 years, and who were "experiencing their children's upbringing to be demanding" were recruited. Families were assigned to either CCET or a no-treatment control condition, and it was hypothesized that CCET would reduce couples' conflicts about their children. Results indicated that CCET had positive effects on couples' communication and coping; however, effects on conflicts about children did not emerge (Ledermann, Bodenmann, & Cina, 2007).

Parenting Interventions that Reduce Interparental Conflict

Interventions that focus on parenting have also been shown to exert indirect positive effects on parents' marital satisfaction, with those effects mediated by the improvements in the child's adjustment (McEachern et al., 2013). The Family Check-Up program is a parenting intervention designed to address emerging emotional and behavioral problems among toddlers at high risk for those problems. The Family Check-Up program was founded on principles of motivational interviewing and takes a family-oriented approach to defining treatment targets and doses. Results of a randomized controlled trial with a high-risk sample of 731 families with a 2-year-old child indicated that children whose families participated in the Family Check-Up were less likely to have emotional, behavioral, or comorbid problems at age 4 than children in the control group, and the program's effects on child adjustment were mediated by changes in parenting (Connell et al., 2008; Dishion et al., 2008). A subsequent study of a subset of 435 of the original families indicated that reductions in child problems from age 2 to 4 predicted positive change in the parents' relationship satisfaction over the 3-year period from age 2 to 5 (McEachern et al., 2013).

Similar findings emerged in a randomized controlled trial evaluating the effectiveness of the Oregon Parent Management Training intervention in improving marital functioning (Bullard et al., 2010). Over 30 years of rigorous empirical research supports the efficacy of Oregon Parent Management Training in addressing child conduct problems. This evaluation study included newly married couples in which the husband was the stepfather to the wife's biological children, and the target child for the study had five or more conduct problem symptoms. This parenting intervention had positive effects on marital functioning as well as on child adjustment problems, and these were maintained at the 2-year follow-up. Moreover, the effects on marital functioning were mediated by the improvements in children's behavior problems. For families in the no-treatment control condition, marital functioning, parenting practices, and child behavior problems all deteriorated over the follow-up period.

Mapping to the Organizational Framework and Future Directions

Most of the interventions with a couple-oriented component are designed to alter the dynamics of interparental conflict, which may affect downstream changes in family functioning and can have effects on child functioning as well. The idea to offer particular kinds of prevention programs during key transition periods of family development seems wise (It has been advocated for close to two decades; e.g., Cowan & Cowan, 1995). Marriage education programs are already in wide use for couples planning to marry or newly married. Transition-to-parenthood

programs that include a focus on interparental conflict are less common, and transition-to-school (elementary, middle, or high school) programs with interparental conflict and relevant parenting components are scarce outside the realm of empirical research. Such programs could capture families at points when family relational dynamics and the problems they confront are expected to change in important ways, and could provide couples with skills for managing conflict through the transition.

In contrast to prevention programs designed to prevent problems before they emerge or become serious are interventions for families in which problems—whether couple problems, child problems, or both—are already identified. It appears from the brief review earlier that adding a BCT-type couple intervention to treatments that address other problems in the family (e.g., fathers' substance use; fathers' engagement with their children) or address parenting can reduce interparental conflict and improve the interparental relationship as well as child adjustment. At this juncture, although there are decades of research on couples therapy and parent training, it is still unclear when and under what circumstances one of them might suffice to address both parent and child problems. Developmental considerations may also pertain to the selection and timing of intervention. For example, perhaps the timing of couples therapy has implications for its effects on child adjustment. If interparental conflict is addressed before it becomes entrenched or severe, or before it results in child adjustment problems, couples therapy may possibly be sufficient to prevent the onset or progression of child problems. Once the developmental unfolding of child adjustment problems reaches a certain point, however, a parenting intervention may be necessary to ameliorate them. Using the organizational framework as a guide, research that considers such factors can help advance theory and treatment research in this area.

DIRECTIONS FOR FUTURE RESEARCH

Throughout this chapter, we have hinted at gaps in the empirical literature on interparental conflict and child adjustment as well as some of the important questions we believe researchers still need to address. The remainder of this chapter describes broad directions for scholars to consider in advancing knowledge in this area.

Improving Theoretical Integration and Precision

Since the early 1990s, tremendous progress has been made in understanding how and why interparental conflict influences child adjustment. As noted earlier, much of this progress can be attributed to the development of theories specifically accounting for associations between interparental conflict and child adjustment. Investigators have begun to empirically test these theories and have identified a variety of psychological and biological processes that potentially explain associations between interparental conflict and child adjustment.

One direction for future research is to examine more thoroughly how some of these hypothesized processes operate jointly in accounting for child adjustment or, even more precisely, in accounting for the effects of interparental conflict on child adjustment. Although there are some notable exceptions in the literature (e.g., Buehler et al., 2007; Davies et al., 2002), most investigators examine hypothesized mediators central to a single, specific theory. That is, investigators testing the cognitive contextual framework will focus on children appraisals of interparental conflict, whereas investigators testing EST focus on emotional insecurity of the interparental relationship. Of course, it makes sense to limit the focus when initially attempting to establish the efficacy of a theory. However, we believe we are now at a point at which it makes sense to begin to explore the integration of the various theoretical explanations. Investigating hypothesized mediators from different theories in tandem is one way to begin to do this; it seems plausible that several of the hypothesized mediating processes proposed by different theories simultaneously operate to influence child adjustment.

Related to this point, it is important to develop and test theory that considers the complexity of how disparate processes (cognitive, emotional, behavioral, biological) might operate together to influence child adjustment within the context of destructive interparental conflict. A number of plausible hypotheses can be generated and tested about how these different processes operate in tandem. For example, one plausible hypothesis is that multiple processes are important, and they exert additive or interactive effects on child adjustment. It is also plausible that a particular process explains the effects of most, or all, of the others. Furthermore, some processes may have stronger implications for longer-term problems than others. In addition, some processes may have stronger implications during certain developmental periods than others. Other, more complex hypotheses about how these processes operate in tandem can be proposed as well.

It might also be fruitful to consider more thoroughly how destructive interparental conflict operates within the broader family context to influence children's adjustment. Investigators have already begun work in this

area by examining how positive aspects of interparental functioning might contribute to positive child outcomes. Similarly, research is being conducted to examine how child functioning influences interparental conflict and how different family variables interact with destructive interparental conflict in the prediction of child problems. From a broader developmental psychopathology perspective, it will also be important for researchers to consider the transactions with and influences of the larger socio-ecological context in which children live and to gain a better understanding of environmental processes and events that contribute to children's risk and resilience in the face of interparental conflict.

We believe it might also be advantageous to consider how destructive interparental conflict fits within other theories about the development of psychopathology. For example, many theories exist on the development of specific types of psychological disorders or the development of specific dimensions of psychopathology. It would be worthwhile for researchers to glean what is known from empirical tests of some of these theories and attempt to integrate concepts from these areas into research on interparental conflict and child adjustment.

Translating Research into Practice

Interventions for children (and their families) exposed to destructive interparental conflict already exist. Similarly, interventions designed to reduce destructive interparental conflict are fairly widespread, especially within the marital/family therapy literatures. Although rigorous evaluations of interventions in this area are still rare, results from several well-designed studies show that these interventions can be effective in reducing child adjustment problems. It is important to note, however, that while some of these interventions are grounded in theory and research on interparental conflict and child adjustment, others are based only loosely on theory and research in this area. In addition, as with most clinical interventions and prevention programs, there is also considerable room for improvement.

We believe an important direction for future research is to improve what we know about how to help children in families characterized by destructive interparental conflict. One way to do this is to understand more thoroughly how existing interventions work, especially those interventions that have been found to be effective in reducing child problems. For example, are these interventions altering specific processes (within the family and/or child) that might be leading to treatment gains? Are there key processes that need to be altered for children/families to benefit from treatment? There is some evidence that changes in mother-child interaction contribute to treatment gains for children who have been exposed to frequent and severe IPV conflict (e.g., Jouriles et al., 2009), but much more work in this area is necessary. For example, processes (cognitive, emotional, behavioral, biological) that are hypothesized to be key in theories linking interparental conflict with child adjustment problems need to be examined more comprehensively in this intervention research.

In addition, given that it is well established that destructive interparental conflict can lead to child adjustment problems and that effective interventions already exist, it should be a priority to ensure that the empirically supported interventions actually reach the children/families who can benefit from them. To date, most of the interventions reviewed in this chapter have remained largely in the confines of the academic settings in which they were developed. The dissemination and implementation of evidence-based interventions is a scientific field in its own right, but little has been done to formally disseminate interventions in this particular area of research.

CONCLUSION

Substantial progress has been made in establishing a reliable link between interparental conflict and children's development as well as in developing and testing theory on how and why interparental conflict confers risk for child adjustment problems. In addition, progress is being made in translating this basic science into programs to promote higher-quality interparental relationships and optimal child development (in the context of interparental conflict). Yet many questions remain unanswered, especially for the development of a more nuanced understanding of the link between these two aspects of family life. Ultimately, a richer understanding of the processes underlying the relation between interparental conflict and child adjustment, and knowing which children are especially vulnerable (and resilient) to the effects of destructive interparental conflict, will allow for more effective intervention programs aimed at improving children's lives.

INTRODUCTION

The development of aggressive behavior patterns has long captured the theoretical and empirical attention of developmental psychopathologists. Although much of this work has focused on physically (e.g., hitting, kicking) or overtly (i.e., physical aggression combined with verbal aggression, such as verbal insults) aggressive behavior,

This chapter is dedicated to the memory and legacy of Dr. Nicki R. Crick, a pioneer in the study of relational aggression. The rich body of theoretical and empirical work covered in this chapter is a testament to the far-reaching influence of Crick's contributions to the field of developmental psychopathology. We thank Alexandra Sullivan, Chelsea Krisanda, Casey Gates, and Lacey Evans for their assistance in compiling references for this chapter. Preparation of this manuscript was facilitated by a grant from the National Science Foundation (0819148) to the first and last authors. Please direct all correspondence to the first author at 2 Colchester Ave., Department of Psychological Science, University of Vermont, Burlington, VT, 05405; dmurrayc@uvm.edu.

in recent years there has been significant interest in the development of relational aggression. Relational aggression, defined as behaviors intended to hurt or harm others using relationships as the vehicle of harm, includes behaviors such as spreading malicious gossip, socially excluding peers, and using the silent treatment (Crick & Grotpeter, 1995). The goal of this chapter is to evaluate the state of knowledge regarding relational aggression two decades after Crick and Grotpeter's (1995) seminal publication on the topic. First, we focus on conceptual challenges in defining relational aggression, normative and atypical developmental trajectories, and theoretical and empirical work regarding gender differences in such conduct. Second, we address potential mechanisms involved in the development of relational aggression, including biobehavioral, cognitive-emotional, and social processes. Third, we consider both positive and negative developmental outcomes associated with involvement in relational aggression. Fourth, we discuss implications of research on relational aggression for both cross-cultural research and interventions. Finally, we consider the significance of a developmental psychopathology perspective for the study of relational aggression as well as the most critical directions for future research in this area.

DEFINING RELATIONAL AGGRESSION

Historical Perspectives

Numerous theoretical models and traditions have guided the study of the development of aggressive behavior (for reviews, see Crick & Zahn-Waxler, 2003; Ostrov & Godleski, 2010). A review of the historical record suggests that eminent scholars such as Gordon W. Allport were examining indirect aggression as early as 1941 (Allport, Bruner, & Jandorf, 1941). In 1961, Arnold H. Buss, in his classic "Psychology of Aggression," noted that:

> From the aggressor's vantage point, the best model of aggression is one that avoids counterattack. Indirect aggression solves the problem by rendering it difficult to identify the aggressor. Indirect aggression may be verbal (spreading nasty gossip) or physical (a man sets fire to his neighbor's home). These examples illustrate the two ways in which aggression can be indirect. Gossip is indirect in that the victim is not present. . . . Damaging a person's possessions is indirect in that the victim is not hurt or injured, but objects associated with and valued by him are destroyed. (p. 8).

Moreover, Buss (1961) cites Eron, Laulicht, and Walder (1956) and their "Rip Van Winkle research team" for the development of a peer rating instrument that includes an assessment of indirect aggression: "Who makes up stories and lies to get other children in trouble?" (p. 269). Much of the early work regarding nonphysical forms of aggression, including indirect aggression, focused on gender differences in such conduct. Norma D. Feshbach (1969) conducted an empirical study of direct and indirect aggression and found that girls displayed significantly higher levels of indirect aggression than did boys. Nearly two decades later, Lagerspetz, Björkqvist, and Peltonen (1988) examined gender differences in aggressive behaviors among 11- and 12-year-old boys and girls in Finland. Using peer reports and individual interviews, these authors identified a 3-factor solution to children's responses to the question "what do they/I do when angry with another boy/girl in the class?" The first factor indicated "what we have called 'indirect means,' and includes circumventory behaviour that exploits social relations among peers to harm the person at whom the anger is directed" (Lagerspetz et al., 1988, p. 409). This factor included 10 items, such as "tells untruth behind back," "says to others: 'Let's not be with him/her,'" "starts being somebody else's friend in revenge," "argues," and "sulks" (p. 409). The second factor focused on "direct means of aggression," and the third factor (two items) included "peaceful means of solving conflicts" (p. 409). It is clear that this conceptualization of indirect aggression was influenced by the writing of Arnold Buss (1961), which was appropriately cited by the authors (p. 404). In 1992, Björkqvist, Lagerspetz, and Kaukiainen further clarified: "Indirect aggression is a type of behaviour in which the perpetrator attempts to inflict pain in such a manner that he or she makes it seem as though there has been no intention to hurt at all. Accordingly, he or she is more likely to avoid counter aggression and, if possible, to remain unidentified" (p. 118). This definition mirrors recent descriptions of passive aggression, which is conceptually distinct from relational forms of aggression (e.g., Nelson, Springer, Nelson, & Bean, 2008). Moreover, unlike relational aggression, indirect aggression is unlikely to occur in young children (Björkqvist et al., 1992).

In 1989, Robert Cairns and colleagues introduced the related term *social aggression*, which they defined as the "manipulation of group acceptance through alienation, ostracism, or character defamation" (Cairns, Cairns, Neckerman, Ferguson, & Gariépy, 1989, p. 323). As originally conceptualized by Cairns and colleagues, social aggression involves the peer *group* and thus may be different from indirect aggression, which may involve either dyadic or group-level transgressions. Moreover, unlike relational aggression, social aggression likely would not

be displayed at younger ages when the importance of the larger peer group and social status is not yet established. In their 6-year longitudinal study examining the growth in aggressive behavior from fourth grade to early adolescence, Cairns and colleagues found that social aggression was highly representative of girls' aggressive behavior during early adolescence.

Building on the concepts of indirect and social aggression, Crick and Grotpeter (1995) identified a relational form of aggression that they argued was relatively common among girls. They cited prior work on indirect and social aggression but suggested that the central element of girls' aggressive behavior patterns was the use of interpersonal relationships to harm others. More specifically, these authors argued that "girls' attempts to harm others would focus on relational issues and would include behaviors intended to significantly damage another child's friendships or feelings of inclusion by the peer group . . . harming others through purposeful manipulation and damage of their peer relationships" (p. 711). Rather than focusing on efforts to avoid detection or retribution, as was often highlighted in theoretical formulations of indirect aggression, Crick and Grotpeter proposed a central role of children's social goals in their selection of aggressive behaviors. From this perspective, girls were expected to engage in relatively high levels of relational aggression because these behaviors reflect the relational issues that are characteristic of female peer groups. This initial study demonstrated that girls were not only more relationally aggressive than school-age boys but that, relative to their nonrelationally aggressive peers, children that engaged in high levels of relational aggression were at increased risk for serious adjustment problems (i.e., greater probability of peer rejection, loneliness, and symptoms of depression).

In 1997, Galen and Underwood expanded on the definition of social aggression. They argued that "the construct of *relational aggression* may not capture all of the forms of aggression evident in girls' peer interactions. Negative facial expressions and gestures and subtle jabs at another's self-esteem may also be important features of girls' aggressive behavior. . . . Social ostracism or relationship manipulation may begin with rolling of eyes, tossing of hair, and turning away from a peer" (p. 590). Accordingly, nonverbal acts beyond the silent treatment (which was included in Crick and Grotpeter's original measure in 1995) were considered to be important behaviors for empirical investigation.

In recent years, research on indirect, relational, and social aggression has flourished, and studies have documented that these constructs provide significant information regarding key developmental processes. However, considerable disagreement persists regarding the degree of overlap among these constructs (see Archer & Coyne, 2005). There are clearly some components of indirect aggression that are not shared by relational aggression. For instance, indirect physical aggression, wherein the identity of the perpetrator is unknown (e.g., placing gum on a peer's chair), has been considered to be an exemplar of indirect aggression (see Goldstein, Tisak, & Boxer, 2002). As these behaviors do not use relationships as the vehicle of harm, however, they would not be considered cases of relational aggression. Additionally, there are some components of social aggression that are not shared by relational aggression (e.g., nonverbal acts such as eye rolling). Methodologically, then, research instruments developed to assess each form of aggression are likely to capture somewhat different behavioral patterns.

Perhaps more important, there are several reasons to expect distinct risk factors, developmental trajectories, and developmental outcomes associated with each of these defined subtypes of aggression. For instance, investment in relational goals, such as the establishment of close interpersonal relationships, may be most strongly associated with the enactment of relational forms of aggression. Developmentally, relational aggression may be observed at earlier ages than either indirect or social aggression (see the section titled "Developmental Manifestations of Relational Aggression"). Moreover, given the central role of damage to interpersonal relationships in relational forms of aggression, interdependent cultural contexts may be particularly relevant to the developmental outcomes associated with relational forms of aggression (see Kawabata, Crick, & Hamaguchi, 2010). Thus, despite the conceptual overlap among these subtypes of aggression, we believe that it is critically important for researchers to be precise in their use of terminology, to adopt terms and associated methods that are theoretically based, and to maintain the fidelity of the methodology of the original instrument developers.

Forms and Functions of Aggression

Although all aggressive behaviors involve actions intended to hurt, harm, or injure another person, developmental scholars have made distinctions between forms (i.e., the whats) and functions (i.e., the whys) of aggressive behaviors (e.g., Little, Jones, Henrich, & Hawley, 2003; Prinstein & Cillessen, 2003). Researchers have identified a number of distinct forms of aggression, including physical, relational, verbal, nonverbal, and electronic aggression.

However, in the last two decades, the most common delineation in developmental psychopathology research has been between physical and nonphysical forms of aggression, with relational aggression being a key construct in most of these studies (e.g., Burnette & Reppucci, 2009; Crick, 1995; Kliewer, Dibble, Goodman, & Sullivan, 2012; Preddy & Fite, 2012).

Physical aggression is defined as acts intended to hurt others via physical force or the threat of physical force (Crick & Grotpeter, 1995). Classic examples of physical aggression include behaviors such as hitting, pinching, kicking, biting, and taking objects (Crick & Grotpeter, 1995). In contrast, relational aggression is defined as behaviors that damage or threaten to damage close relationships to hurt, harm, or injure another person (Crick & Grotpeter, 1995). Relational aggression may be manifested in different ways during different developmental periods (see "Developmental Manifestations of Relational Aggression" section), but it includes both direct and indirect behaviors and may be displayed verbally or nonverbally (Nelson, Springer, et al., 2008). Prototypical examples of direct relational aggression include telling someone that they are not invited to a party (exclusion) or placing one's hand on a chair so another child cannot sit down. Indirect relational aggression includes gossip and rumor spreading. Physical and relational aggression have emerged as unique factors in several studies (e.g., Crick & Grotpeter, 1995), are theorized to be associated with different social goals (Crick & Grotpeter, 1995), and have been found to be associated with different risk factors and developmental outcomes (see Crick, Ostrov, & Kawabata, 2007; Ostrov & Godleski, 2010).

Scholars have also distinguished between the functions of aggression. Although various terms are used within the psychological sciences, the two functions of aggression are typically referred to as proactive aggression (i.e., also known as instrumental, premeditated, or cold-blooded) and reactive aggression (i.e., also known as hostile, impulsive, or hot-blooded; Vitaro, Gendreau, Tremblay, & Oligny, 1998). Proactive aggression is defined as goal-directed aggressive behavior; in contrast, reactive aggression is concurrently displayed in response to a real or perceived threat and is often motivated by hostility or anger (Vitaro et al., 1998). Despite some overlap in the display of these functions, evidence indicates that these subtypes of aggression are distinct factors (e.g., Poulin & Boivin, 2000). Moreover, proactive and reactive aggression have different theoretical underpinnings (i.e., social learning theory for proactive aggression and the frustration-aggression hypothesis for reactive aggression; Bandura, 1973; Berkowitz, 1962). Accordingly, unique developmental precursors and social-psychological adjustment outcomes are related to proactive and reactive functions of aggression (for a meta-analysis, see Card & Little, 2006).

Despite the tradition in psychological research of examining forms and functions of aggression separately, more recent research has taken into account both forms and functions of aggression. There are two main methodological approaches to examining forms *and* functions of aggression. The first uses a two-dimensional combination approach in which the two forms (i.e., physical and relational) and the two functions (i.e., proactive and reactive) are crossed, yielding four subtypes of aggression: proactive physical, reactive physical, proactive relational, and reactive relational (e.g., Ostrov & Crick, 2007; Prinstein & Cillessen, 2003). This approach is purported to be ecologically valid (Underwood, 2003), and research adopting this method has demonstrated unique correlates of subtypes of aggression in early childhood (e.g., Ostrov, Murray-Close, Godleski, & Hart, 2013), middle childhood (e.g., Mathieson & Crick, 2010), adolescence (e.g., Prinstein & Cillessen, 2003), and emerging adulthood (e.g., Bailey & Ostrov, 2008).

However, the two-dimensional combination approach is plagued by high levels of statistical overlap between proactive and reactive physical aggression as well as proactive and reactive relational aggression. For this reason, Little and colleagues introduced a structural equation modeling method to disentangle form and function by creating statistically pure form and function latent variables (Little et al., 2003). Several studies have now successfully used this approach with child and adolescent samples (e.g., Fite, Stauffacher, Ostrov, & Colder, 2008; Fite, Stoppelbein, Greening, & Gaertner, 2009; Murray-Close & Ostrov, 2009; see a related approach in Sijtsema, Ojanen, et al., 2010), and these models have revealed unique predictors and outcomes associated with the pure constructs. For example, in keeping with theory, hostility was associated with pure reactive, physical, and relational aggression but not with proactive aggression (Little et al., 2003).

Other researchers, however, have suggested that functions reflect differences in severity, rather than type, of aggression (Marsee et al., 2014; Stickle, Marini, & Thomas, 2012). For instance, using person-centered analyses, Marsee and colleagues (2014) identified three groups of relationally aggressive adolescent girls in two samples (voluntary residential and involuntarily detained): nonaggressive, reactive relationally aggressive, and combined proactive/reactive relationally aggressive. Consistent with a severity (rather than typology) model, some evidence indicated that the combined group exhibited the most

severe adjustment difficulties. Interestingly, these three groups emerged for girls but not for boys. The findings suggest that proactive relational aggression is unlikely to occur in the absence of reactive relational aggression and that girls who exhibit proactive relational aggression may be exhibiting aggressive behaviors that are more severe in nature. Future research is needed to examine the unique and shared developmental pathways that these forms and functions denote for individuals in various contexts.

DEVELOPMENTAL CHANGE IN RELATIONAL AGGRESSION

Mean Changes in Relational Aggression

Evidence indicates that relational aggression emerges quite early in development; in fact, observational studies have documented these behaviors in children as young as 30 months old (Crick, Ostrov, Burr, et al., 2006). Moreover, relational aggression has been reported among the elderly in assisted living facilities (Trompetter, Scholte, & Westerhof, 2011), suggesting that these behaviors may occur with some frequency across the life span. However, a significant question for developmental psychopathologists is whether the frequency of relational aggression changes across development. As Underwood, Galen, and Paquette (2001) discussed, there has been considerable debate in the field regarding whether social and relational aggression are common, normative social behaviors or whether such conduct reflects a relatively atypical and maladaptive behavior pattern. As these researchers pointed out, the answer to this question may depend on the developmental period under consideration, highlighting the need for work identifying typical developmental trajectories of relational aggression.

A number of theorists have argued that there will be important developmental differences in the use of relational aggression as a result of cognitive, social, and biological changes. In early theoretical discussions of this issue, Björkqvist et al. (1992) suggested that aggression is a relatively normative behavior, but as young children are limited by their social and cognitive skills, they must rely on unsophisticated forms of aggression, such as physical aggression (see also Lagerspetz & Björkqvist, 1994). As children get older and their social and cognitive abilities improve, however, they are hypothesized to replace these physically aggressive behaviors with more covert forms of aggression, such as indirect aggression (Lagerspetz & Björkqvist, 1994). The successful use of relationally aggressive behaviors, such as spreading a rumor about a peer, may require relatively advanced social-cognitive skills (e.g., theory of mind abilities) and verbal abilities (e.g., Bonica, Arnold, Fisher, Zeljo, & Yershova, 2003).

In fact, findings from several past studies indicate that indirect and relational forms of aggression are related to heightened social-cognitive abilities broadly defined (Andreou, 2006; Kaukiainen et al., 1999; for review, see Sutton, Smith, & Swettenham, 1999). Relational aggression in preschoolers has been found to be related to expressive and receptive language abilities (Bonica et al., 2003; Hawley, 2003b; although see Côté, Vaillancourt, Barker, Nagin, & Tremblay, 2007; Estrem, 2005; Kikas, Peets, Tropp, & Hinn, 2009), deception skills (Ostrov, 2006; Ostrov, Ries, Stauffacher, Godleski, & Mullins, 2008), theory of mind (Renouf et al., 2010), and, in females, moral maturity (Hawley, 2003b). In addition, although somewhat sophisticated relationally aggressive acts (e.g., secret spreading) have been documented in children as young as 3 years of age, the identity of the perpetrator is known and the behaviors are based on the here and now rather than events in the past (Ostrov, Woods, Jansen, Casas, & Crick, 2004). Taken together, these findings suggest that advances in social-cognitive skills across development may at times promote relationally aggressive behavior; however, it is important to note that improved skills in these areas may be most likely to predict aggressive conduct in subsets of youth who exhibit impairments in other cognitive abilities (see Crick & Dodge, 1999).

Significant social changes during childhood and adolescence may also lead to increased use of relational forms of aggression. Because relational aggression targets relationships as the vehicle of harm, these behaviors may be most effective in the context of established social networks (Archer & Coyne, 2005) and close, intimate friendships (e.g., Murray-Close, Ostrov, & Crick, 2007), both of which become more common during adolescence (e.g., Berndt, 1996). In recent years, theorists have argued that relational aggression may be an effective strategy to establish and maintain high status in the peer group, particularly during adolescence (Cillessen & Mayeux, 2004; see the "Developmental Outcomes: Potential Positive Correlates" section). As youth approach adolescence, they increasingly prioritize high peer status over other domains (LaFontana & Cillessen, 2010); thus, relational aggression may be perceived as a particularly important tool during this developmental period. Additionally, as children's concerns about the social repercussions of behaviors increase, they may be inclined to select aggressive strategies that are less likely to lead to negative social sanctions, such as social or

relational aggression (e.g., Karriker-Jaffe, Foshee, Ennett, & Suchindran, 2008).

Finally, some researchers have argued that biological changes related to puberty may predict increases in relationally aggressive conduct (e.g., Kistner et al., 2010). Puberty is accompanied by a host of physical changes, including increases in reproductive hormones, such as testosterone. Reproductive hormones, in turn, may facilitate aggressive behaviors in the context of competition for mates (Archer, 2006). Although little work has examined the role of reproductive hormones in relationally aggressive behaviors, Sánchez-Martín et al. (2011) provided initial evidence that testosterone was positively associated with relational aggression in 9-year-old males and females. Pubertal changes may also facilitate relational aggression because they lead to competition for access to sexual partners; in fact, several researchers have argued that relational aggression may be used as a strategy to derogate sexual rivals (Kistner et al., 2010; Pellegrini & Long, 2003; White, Gallup, & Gallup, 2010). Consistent with this perspective, dating popularity is associated with relational aggression, particularly among girls (Pellegrini & Long, 2003), and in one study, earlier age of first intercourse was related to heightened self-reported indirect aggression (White et al., 2010). Finally, early puberty may function as a transitional stressor that promotes aggressive conduct; for instance, Susman et al. (2007) found that early puberty was associated with higher relational aggression in girls. Similarly, Hemphill et al. (2010) found that pubertal stage was positively associated with social aggression among younger, but not older, adolescents.

Consistent with the perspective that cognitive, social, and biological changes across early and middle childhood promote relational forms of aggression, an emerging body of work indicates that relational aggression becomes increasingly common as youth approach adolescence (e.g., Karriker-Jaffe et al., 2013), particularly among girls (Kawabata, Tseng, Murray-Close, & Crick, 2012; Kistner et al., 2010; Murray-Close et al., 2007). For instance, Murray-Close et al. (2007) reported that, among girls only, relational aggression increased in frequency over the course of one calendar year during late elementary school. In their person-centered analyses of trajectories of indirect aggression from ages 2 to 8, Côté et al. (2007) found that most youth exhibited low, stable levels of indirect aggression. However, a subset of youth evidenced increases in their indirect aggression across the course of the study, and girls outnumbered boys in this trajectory group. Interestingly, some of these children also exhibited a pattern of decreasing physical aggression, providing partial support for the hypothesis that youth will replace their physically aggressive behaviors with relational or indirect aggression as their cognitive and social skills mature (see also J. L. Miller, Vaillancourt, & Boyle, 2009; although see Vaillancourt, Brendgen, Boivin, & Tremblay, 2003).

However, not all researchers have documented increases in relational aggression during childhood and early adolescence. For instance, Spieker et al. (2012) reported that girls exhibited fairly stable levels of relational aggression from third to sixth grade, whereas boys exhibited declines in their involvement in such conduct. Additionally, Underwood et al. (2009) found that social aggression decreased in frequency from third to seventh grade, and person-centered analyses indicated that the sample was characterized by one group of children who displayed stable and low levels of social aggression and another group that initially engaged in relatively high levels of social aggression but exhibited decreases in such conduct across the study.

One potential explanation regarding these mixed findings is that relational aggression becomes increasingly common as youth approach preadolescence but then declines in frequency following the transition to adolescence (Karriker-Jaffe et al., 2008). In fact, at least some of the cognitive, social, and biological processes hypothesized to underlie increases in the use of relational aggression are likely to have stabilized or waned by late adolescence. For instance, the social changes thought to promote increased involvement in relational aggression (e.g., heightened focus on peers and social status) may become less common as friendships become more autonomous in nature (Karriker-Jaffe et al., 2008). Similarly, as youth get older, biological transitions, such as puberty, may be less stressful and thus may be less likely to predict increased risk for engagement in relational aggression (Hemphill et al., 2010).

Although most work on developmental trajectories of relational aggression has focused on early and middle childhood, some preliminary evidence indicates that relational aggression becomes somewhat less common in later adolescence. For instance, Cleverley, Szatmari, Vaillancourt, Boyle, and Lipman (2012) reported that most youth exhibited decreases in their engagement in indirect aggression across adolescence; however, a small subset of participants maintained fairly high levels of such conduct across the course of the study. Moreover, this group of youth contained approximately equal numbers of males and females. Karriker-Jaffe et al. (2008) reported that social aggression exhibited curvilinear change across adolescence, with a peak around 14 years of age (see also Karriker-Jaffe et al., 2013). Hemphill et al. (2012) found that levels of relational aggression decreased from

grades 9 to 11 in a sample of Australian adolescents. Taken together, then, preliminary evidence suggests that relational aggression may increase in frequency from early childhood to early adolescence, peak in early to midadolescence, and then subsequently decline in frequency. Future prospective longitudinal studies are needed to confirm these developmental changes.

Developmental Manifestations of Relational Aggression

The focus on mean change in overall levels of relational aggression, however, may obscure more fine-grained developmental differences in the manifestation of relationally aggressive behaviors. For instance, Crick et al. (2007) argued that relational aggression in young children may most often be direct and easily observable (e.g., threatening to end a friendship; turning away from a peer to indicate exclusion; secret spreading in front of the victim). As children mature, however, they may become more sophisticated in their use of relational aggression; for instance, youth may be more likely to engage in indirect relationally aggressive behaviors or behaviors that involve third parties (e.g., rumor spreading; Crick et al., 2007). In fact, although sophisticated relationally aggressive behaviors have been observed in preschool children, these displays tend to be direct and easily observable by the targets (Ostrov et al., 2004; Fanger, Frankel, & Hazen, 2012). Longitudinal studies that explore developmental changes in the use of distinct relationally aggressive behaviors (e.g., threats of friendship withdrawal; spreading malicious gossip; social exclusion) may significantly advance our understanding of the developmental consequences of relational aggression. It is possible, for instance, that unsophisticated relationally aggressive behaviors (e.g., direct verbal threats to end a friendship) may be more strongly associated with maladjustment as compared to more covert behaviors (e.g., spreading gossip or engaging in exclusionary behaviors with a cover story; Fanger et al., 2012), particularly when enacted in developmental periods when such unsophisticated conduct is relatively atypical. Similarly, verbal and nonverbal relationally aggressive behaviors may have distinct implications for adjustment (see Blake, Kim, & Lease, 2011, for a recent application of this idea to social aggression).

In addition, the contexts that elicit relational aggression may change across development. In young children, relational aggression is more likely to occur in sibling relationships than in friendships; however, over time, youth increasingly use these behaviors against friends (Stauffacher & DeHart, 2006), and, by middle childhood, friendships are an important context for the use of relational aggression (Crick & Grotpeter, 1996). With the emergence of romantic relationships in adolescence, youth may begin to use relational aggression against romantic partners (Linder, Crick, & Collins, 2002). In fact, some evidence indicates that in young adulthood, relational aggression more frequently occurs in the context of romantic relationships than in friendships, perhaps because these relationships become particularly salient during this developmental period (Goldstein, 2011; although see Goldstein & Tisak, 2004). Moreover, youth may target others' romantic relationships as a means of social manipulation or control (e.g., stealing a friend's boyfriend; Crick et al., 2007). However, much of the research regarding relational aggression has focused on the use of these behaviors in same-sex peer groups, and most measures fail to assess the relational context of aggression (Goldstein & Tisak, 2004). An important question for future research is whether there is continuity across relationships (e.g., friends, romantic relationships) in the use of relational aggression. Longitudinal studies may provide important insights regarding the potential transfer of relationally aggressive behaviors across developmental contexts (e.g., from sibling relationships to friendships; Stauffacher & DeHart, 2006).

Developmental Challenges in Assessment

A number of assessment techniques are available for the measurement of relational aggression across developmental periods, including systematic observational procedures in the classroom and on the playground (e.g., McNeilly-Choque, Hart, Robinson, Nelson, & Olson, 1996; Ostrov & Keating, 2004), semistructured observations (Ostrov et al., 2004), observational ratings (Murray-Close & Ostrov, 2009), peer nomination techniques (Crick & Grotpeter, 1995; McNeilly-Choque et al., 1996), teacher reports (Crick, 1996; McNeilly-Choque et al., 1996), structured interviews (Tackett & Ostrov, 2010), parent reports (Casas et al., 2006; Ostrov & Bishop, 2008), and self-reports (Little et al., 2003; Murray-Close, Ostrov, Nelson, Crick, & Coccaro, 2010). Details regarding methods for measuring relational aggression have been discussed elsewhere (Crick et al., 2007); however, two methodological challenges to the assessment of relational aggression merit comment because they have significant implications for the study of developmental change in relational aggression.

First, there is currently a lack of clarity in the literature regarding items that assess relational, rather than social or indirect, aggression. As discussed, there is considerable conceptual overlap between these forms of aggression (Archer & Coyne, 2005), and it is not uncommon for

researchers to use measures developed to assess relational aggression (or slight adaptations of these measures) in studies of indirect or social aggression. Given the similarities among social, indirect, and relational aggression (Archer & Coyne, 2005), this approach is understandable and in many circumstances may not have important implications for study findings. However, distinctions between these behaviors may be important for some critical developmental questions. For instance, the transition to indirect aggressive behaviors hypothesized to occur as youth get older (Björkqvist et al., 1992; Crick et al., 2007) underscores the possibility that developmental differences in aggressive behavior may partially depend on the subtype of aggression being assessed. More specifically, relational aggression may be more prevalent than indirect aggression among young children because relationally aggressive behaviors are often very direct (e.g., covering one's ears to ignore a peer). Additionally, the processes that underlie developmental increases in relational aggression may differ from those that give rise to increases in social or indirect aggression. For instance, as damage to relationships is the defining feature of relational forms of aggression, these behaviors may be most strongly tied to increases in close and intimate relationships (see Murray-Close et al., 2007) and most predictive of adjustment problems related to impairment in close relationships.

We believe that it will be important for researchers to develop instruments that can better distinguish between these related, but conceptually distinct, subtypes of nonphysical aggression. In an example of efforts in this area, Nelson, Springer, et al. (2008) developed a coding scheme to identify subtypes of aggression in emerging adults' descriptions of peer-based mean behaviors. This scheme, including direct and indirect relational aggression, ignoring, gestural nonverbal aggression, and passive aggression, could be adapted to assess subtypes of aggressive behavior in youth. Results from this study documented important differences in emerging adults' engagement in these behaviors and highlighted how measures that are nuanced and theoretically based may help elucidate the processes underlying the development of relational aggression.

Second, efforts to characterize developmental change in relational aggression, as well as research on developmental differences in the correlates of relational aggression, are limited by methodological differences in the assessment of relational aggression across developmental periods. Naturalistic systematic observations have primarily been used with preschool-age children (e.g., Ostrov & Keating, 2004), likely because the heightened reactivity to traditional observation techniques often displayed among older children serves as a threat to the validity of the measures. Additionally, teacher reports may be more valid for use during early and middle childhood, as compared to adolescence, because relational aggression may be relatively direct, unsophisticated, and easily observed by onlookers (Crick et al., 2007). During adolescence, in contrast, parents and teachers may not be privy to many instances of relational aggression. Given the covert nature of relationally aggressive behaviors, Crick et al. (2007) suggest that peer nomination procedures are likely the most valid assessments of such conduct during late childhood and adolescence, although self-report measures of relational aggression are common and are meaningfully associated with outcomes (e.g., Little et al., 2003).

The differences in the techniques that are most developmentally appropriate (and most commonly employed) across age groups create challenges for developmental psychopathology researchers. Specifically, true developmental change in relational aggression (and the correlates of such conduct) may be obscured by different assessment techniques and/or changes in the validity of a particular approach across development. For instance, declines in parent-reported relational aggression may reflect true developmental change in such conduct or may instead reflect improvements in adolescents' abilities at concealing these behaviors from their parents. A critical direction for future research, then, is the continued development and refinement of methods for assessing relational forms of aggression across developmental periods.

AGGRESSION AND GENDER

Theoretical Perspectives Regarding Aggressive Girls

Research on relational aggression challenged the longstanding assumption in the field of developmental psychopathology that aggression was highly atypical in females during childhood. In one highly influential theoretical account of aggression in females, Keenan and Shaw (1997) suggested that norms against aggression in girls, and accompanying socialization experiences, led females to shift from predominantly externalizing to internalizing problems across development. Additionally, girls' earlier maturation was argued to serve as a buffer against the emergence of problem behaviors such as aggression (Keenan & Shaw, 1997). Although several researchers suggested that girls may engage in aggressive behaviors during adolescence (e.g., Moffitt & Caspi, 2001; Silverthorn & Frick, 1999), there was a consensus among most developmental theorists that such conduct was quite rare among females during

childhood. Empirical support from decades of aggression research bolstered these arguments; for instance, Maccoby and Jacklin (1974) argued that gender differences in aggression were one of the rare true gender differences.

In their seminal publication on the topic of relational aggression, however, Crick and Grotpeter (1995) argued that the common assumption among developmental psychopathology researchers that girls did not exhibit significant difficulties such as aggression during childhood, termed the *benign childhood* hypothesis (Crick & Zahn-Waxler, 2003), was incorrect. Instead, Crick and colleagues suggested that these apparent gender differences resulted from a failure to assess aggressive behaviors that were salient for females, such as relational aggression. Theoretically, relational aggression was expected to be more common than physical aggression among females for several reasons. First, girls were hypothesized to employ relationally aggressive behaviors because such behaviors are consistent with the focus on interpersonal relationships and social functioning typical in female peer groups (e.g., Crick & Grotpeter, 1995; Crick & Zahn-Waxler, 2003). Socialization against physical aggression from significant others, such as parents and peers, was also posited to reduce girls' reliance on physical aggression and promote the use of more socially acceptable and covert forms of aggression, such as relational aggression (Crick et al., 2007). Björkqvist et al. (1992) suggested that the relatively advanced cognitive maturation among girls, hypothesized by others to buffer girls from engagement in aggressive conduct (Silverthorn & Frick, 1999), may actually facilitate the use of more sophisticated aggressive behaviors, such as indirect aggression. Furthermore, girls' lower physical strength was argued to limit their capacity to effectively use physical forms of aggression, increasing the appeal of more indirect approaches (Björkqvist, 1994).

Gender Differences in Relational Aggression

Despite these theoretical claims, however, research findings regarding gender differences in relational aggression have been mixed. Findings from several early studies on relational aggression provided evidence that girls were more likely than boys to engage in such conduct from preschool through childhood (see Crick et al., 2007, for review). However, Card, Stucky, Sawalani, and Little (2008) provided meta-analytic findings indicating that although gender differences in indirect aggression favoring girls were statistically significant, they were too small to be meaningful. Nonetheless, the study of relational aggression remains critical in research efforts to understand aggressive behavior problems in girls. Females are relatively unlikely to engage in physical forms of aggression, and there appears to be greater overlap between physical and indirect aggression in males compared to females (Card et al., 2008). These findings suggest that aggressive boys may frequently employ both physical and indirect aggression, whereas aggressive girls may preferentially select indirect or relational forms of aggression; that is, the modal type of aggression (i.e., within-group gender difference) is relational rather than physical among girls (e.g., Ostrov, Kamper, Hart, Godleski, & Blakely-McClure, 2014; Putallaz et al., 2007; see also Ostrov & Godleski, 2010). In fact, findings from recent person-centered analyses indicate that across several populations (i.e., community, voluntary residential treatment, and involuntary detained), adolescent girls are more likely than boys to be classified as highly relationally, but not physically, aggressive (Marsee et al., 2014). As a result, studies that do not assess relational, indirect, or social forms of aggression may fail to identify the vast majority of aggressive females.

Additionally, several researchers have emphasized the importance of moving beyond a focus on mean-level differences in relational aggression to instead explore gender differences in developmental trajectories, mechanisms, and outcomes associated with such conduct (e.g., Ostrov & Godleski, 2010; Spieker et al., 2012; Underwood, 2003). In fact, several of the developmental processes thought to promote engagement in relational aggression (e.g., increases in intimacy in close friendships; pubertal changes) may differ between males and females, potentially leading to meaningful gender differences in trajectories of relational aggression over time (e.g., Kistner et al., 2010; Murray-Close et al., 2007). For instance, gender differences in pubertal timing may result in a relatively early increase in relational aggression among girls during the transition to adolescence (Kistner et al., 2010). Card et al. (2008) failed to find meta-analytic evidence that gender differences in indirect aggression differed across developmental periods; however, measurement differences across these periods may have obscured gender differences in true developmental change (Card et al., 2008), highlighting the need for longitudinal research in this area.

In fact, some longitudinal research has provided preliminary evidence for distinct patterns of developmental change in relational aggression in males versus females. For instance, several studies have reported that girls were more likely than boys to exhibit increases in relational aggression (or to maintain relatively high levels of such conduct) as they approached adolescence (Kawabata et al., 2012; Kistner et al., 2010; Murray-Close et al., 2007; Spieker

et al., 2012). However, other studies have failed to find gender differences (Cleverley et al., 2012; Karrifer-Jaffe et al., 2008; Underwood et al., 2009). Clearly, additional research exploring gender differences in longitudinal change in relational aggression, with attention on the methods used to assess such conduct, is needed.

It will also be important for researchers to consider the question of gender differences across relational contexts and across subtypes of relationally aggressive conduct. In fact, some evidence indicates that relational aggression is more common than physical aggression in girls', but not boys', friendships (Crick & Nelson, 2002). Goldstein (2011) reported that although young adults did not differ in their use of relational aggression against friends, females were more likely than males to engage in such conduct in the context of romantic relationships (for additional research regarding gender differences in romantic relational aggression, see Goldstein, Chesir-Teran, & McFaul, 2008; Linder et al., 2002). These preliminary findings suggest that across developmental periods, gender differences may exist in some (e.g., romantic relationships) but not other (e.g., friendships) relational contexts.

In addition, research in this area may benefit from a more fine-grained analysis of the types of relationally aggressive behaviors used against relationship partners. For instance, Nelson, Springer, et al. (2008) found that college students reported that males most often engaged in direct physical aggression (e.g., hitting), particularly against other males. In contrast, participants reported that females frequently engaged in indirect relational aggression (e.g., gossip) against both males and females and in direct relational aggression (e.g., guilt trips) against males. These findings suggest that gender differences in relational aggression may depend on the gender of the target as well as whether the relational aggression is direct or indirect in nature. Future work is necessary to elucidate whether gender differences exist across relational contexts (e.g., friendships, romantic relationships) and relationally aggressive behaviors (e.g., indirect, direct). It will also be important to assess whether the magnitude of these gender differences changes across development.

RISK FACTORS: BIOBEHAVIORAL PROCESSES

Genetic Risk

Developmental psychopathologists have highlighted the need for interdisciplinary research, including neurobiological, neuropsychological, and psychophysiological approaches, in the study of the development of maladaptive behavior patterns for decades (e.g., Cicchetti, 1993). Several biobehavioral perspectives regarding the development of relational aggression have emerged in recent years, including studies of genetic risk for involvement in relationally aggressive behaviors. Using a quantitative genetic design, Brendgen et al. (2005) examined the relative genetic and environmental contributions to physical and social aggression in a sample of 6-year-old twin pairs. Findings indicated that social aggression was only weakly related to genetic factors (20% of the variance for teacher-reported social aggression; 23% of the variance for peer-reported social aggression) and was associated with both shared and nonshared environmental influences. These findings contrasted with the results for physical aggression, which indicated substantial heritability (63% of the variance for teacher-reported physical aggression; 54% of the variance for peer-reported physical aggression) and virtually no influence of shared environmental factors. Interestingly, although the genetic influence on social aggression was relatively low, it overlapped with genetic risk for physical aggression, suggesting similar genetic etiological factors for both forms of aggression (Brendgen et al., 2005). In contrast, the nonshared environmental risk factors for physical versus social aggression appeared to be relatively distinct.

In their study of 6- to 18-year-old twins, Tackett, Waldman, and Lahey (2009) reported relatively high estimates of genetic influence on a latent variable including mother- and self-reported relational aggression (63% of the variance). However, as in the work of Brendgen et al. (2005), shared environmental risk emerged; the authors suggested that relational aggression may be more susceptible than physical aggression to parent and shared peer group influences (Tackett et al., 2009), highlighting the important role of environmental factors in the emergence of such conduct. The role of the shared environment in the development of relational aggression has not always been replicated in genetic studies, however. In a follow-up study using a subsample of participants from Brendgen et al. (2005) when youth were 7 years old, Brendgen et al. (2008) failed to find evidence for shared environmental influences on a composite of teacher- and peer-reported social aggression. Tackett et al. suggested that distinct informants may account for some of the mixed findings in this area and highlighted the need for greater empirical attention to measurement of relational aggression in behavior genetic designs.

Behavioral genetics studies provide significant insight regarding potential etiological factors involved in the development of relationally aggressive conduct. However,

a number of significant questions remain. For instance, emerging molecular genetic studies have documented specific candidate genes in the development of antisocial behavior, particularly in the context of environmental risk (e.g., Kim-Cohen et al., 2006). Given evidence of similar genetic risk for both forms of aggression in quantitative genetic designs (Brendgen et al., 2005), researchers should extend this work to molecular genetic studies to explore whether similar genetic polymorphisms are related to physical and relational forms of aggression. It will also be essential to evaluate whether similar environmental stressors are involved in gene-environment (G×E) interactions in the development of physical versus relational aggression. Brendgen et al. (2008) reported a G×E interaction in the association between friends' physical aggression and participants' own involvement in such conduct; a parallel interaction was not found in participants' social aggression. These findings highlight the possibility that distinct environmental stressors may interact with genetic risk in predicting relationally aggressive behaviors, as compared to more traditionally studied forms of aggression (e.g., physical aggression). Finally, genetically informed, longitudinal designs are necessary to evaluate the extent to which genetic factors contribute to stability and change in relational aggression over time and whether the patterns of these contributions are similar for physical and relational forms of aggression (see Neiderhiser, Reiss, & Hetherington, 1996, for an application to antisocial behavior).

Psychophysiological Stress Systems

In addition to genetic risk, researchers have recently begun to examine the role of individual differences in functioning of psychophysiological stress systems, including the autonomic nervous system (ANS; see Murray-Close, 2013a), in the development of relational aggression. The ANS is comprised of two distinct branches, the sympathetic nervous system (SNS), which coordinates the body's fight-or-flight responses to stress, and the parasympathetic nervous system (PNS), which reflects rest-and-digest functions. In several theoretical formulations, low SNS arousal is hypothesized to serve as a risk factor for the development of aggressive conduct. According to fearlessness theory, low SNS activity reflects temperamental fearlessness (Ortiz & Raine, 2004), which in turn may interfere with the efficacy of socialization against aggressive behavior. Fearless youth may be relatively unresponsive to punishment and unconcerned about potential negative repercussions of engaging in aggressive conduct (e.g., retaliation from victims). From a stimulation-seeking perspective, low SNS is experienced as an aversive physiological state; thus, youth may engage in aggressive behaviors in an effort to increase their arousal to more comfortable levels (Sijtsema, Veenstra, et al., 2010). However, some researchers have argued that heightened, rather than blunted, SNS arousal is a risk factor for aggressive conduct, particularly when SNS overarousal occurs following aversive or threatening events (e.g., Hubbard et al., 2002). From this perspective, exaggerated SNS reactivity to negative events is hypothesized to reflect dysregulated emotional reactions to stress (e.g., anger), thus increasing risk for aggressive responses (see Murray-Close, 2013a). Indices of PNS functioning, in contrast, are argued to reflect biological differences in regulatory abilities, such that high resting PNS arousal, and greater PNS withdrawal following challenge, portend greater emotional and attention regulation capacities (Calkins & Keane, 2004; Porges, 2007). This greater self-regulation, in turn, is expected to facilitate the inhibition of aggressive impulses.

To date, the vast majority of research regarding the association between ANS arousal and aggression has focused on physical forms of aggressive behavior (see Murray-Close, 2013a, for review). However, an emerging body of research explores the association between ANS arousal and relational forms of aggression, with some work documenting distinct correlates of relational, as compared to physical, aggression (Murray-Close & Crick, 2007). Some of this research has provided evidence that exaggerated stress reactivity is related to increased risk for relational aggression. In early work in this area, for instance, Murray-Close and Crick (2007) found that heightened systolic blood pressure reactivity was associated with relational aggression in girls but not boys. More recently, in a sample of female emerging adults, Murray-Close (2011) found that heightened SNS reactivity to stress was associated with relational aggression against romantic partners, particularly among women who also exhibited additional risk factors for aggression (e.g., hostile attribution bias for romantic relational provocations). However, consistent with fearlessness and/or stimulation-seeking theories, other research has documented blunted SNS arousal among relationally aggressive youth. For instance, Sijtsema, Shoulberg, and Murray-Close (2011) reported that blunted SNS reactivity was associated with relational aggression in a sample of female children and adolescents. In a study with preschoolers, Gower and Crick (2011) found that low resting heart rate and blood pressure were associated with elevated

levels of relational aggression; in some analyses, findings emerged primarily in youth who also exhibited poor effortful control. Although more limited, some studies have also documented associations between PNS withdrawal and relational aggression, although the direction of effects has varied across studies (e.g., Murray-Close, 2011; Sijtsema et al., 2011).

Preliminary research regarding the association between relational aggression and neuroendocrine indices of stress, such as cortisol, has also provided support for the notion that underarousal of stress systems serves as a risk factor for relationally aggressive conduct. Cortisol, a hormone released by the adrenal cortex in response to stressful experiences, exhibits a diurnal rhythm with a peak in cortisol levels 30 minutes after waking followed by gradual decrease throughout the day. Murray-Close, Han, Cicchetti, Crick, and Rogosch (2008) found that relational aggression was associated with low morning cortisol and blunted change in cortisol across the day. However, findings are preliminary, and some researchers have failed to find associations between cortisol and indirect aggression (e.g., Vaillancourt & Suderani, 2011).

The mixed findings regarding the associations between both ANS and neuroendocrine stress systems and relational aggression highlight the possibility that both heightened and blunted stress arousal may predict elevated levels of relational aggression, depending on additional moderating factors. For instance, the physiological stress profiles associated with relational aggression may vary for males versus females (Murray-Close et al., 2014; see Murray-Close, 2013a, for review). Effects may also depend on the presence of additional risk factors (e.g., relational victimization; Murray-Close, 2011; Murray-Close et al., 2014; see also Murray-Close, Holland, & Roisman, 2012) or whether the aggression is proactive (i.e., planful, unemotional, and goal-directed) or reactive (i.e., emotional, retaliatory) in function. In fact, Murray-Close and Rellini (2012) recently reported that blunted ANS reactivity to stress was associated with proactive relational aggression whereas exaggerated ANS reactivity was associated with reactive relational aggression; however, findings emerged only among women with a history of sexual abuse. Interestingly, the moderating role of contextual risk has varied across studies, with some research indicating that physiological arousal is more strongly related to relational aggression among youth without high levels of contextual risk (e.g., without a history of abuse; Murray-Close et al., 2008; see the "Multilevel Perspectives" section for a discussion of potential explanations regarding these differing findings). A relatively understudied moderator in research regarding the association between relational aggression and physiological reactivity is the type of task used to elicit stress reactivity; in fact, Murray-Close and colleagues (2014) recently documented that girls' perpetration of relational aggression was at times associated with distinct profiles of reactivity to relational (e.g., experiences of exclusion) versus instrumental (e.g., property damage) peer stressors. It will be essential for future research to consider moderators of the association between stress physiology and relational aggression, with particular attention to the processes thought to underlie these associations.

Additional Biological Factors

Several potential biological risk factors for relational aggression should be incorporated in future research in this area. For instance, despite the large body of research documenting associations between androgens such as testosterone and physically aggressive behavior (Archer, Graham-Kevan, & Davies, 2005), limited research has examined whether androgens are implicated in relational aggression. In preliminary research in this area, testosterone was positively associated with relational aggression in a sample of 9-year-old children, once effects of gender were controlled (Sánchez-Martín et al., 2011). Coyne, Manning, Ringer, and Bailey (2007) found that low right-left ratios of the length of the index finger to ring finger, thought to reflect greater exposure to prenatal androgens, were related to indirect aggression in a sample of women. Taken together, these results highlight the possibility of both organizational and activational effects of androgens in the development of relational aggression.

Emerging research has also documented associations between event-related potentials and relational aggression, perhaps reflecting attentional deficits among aggressors (Godleski, Ostrov, Houston, & Schlienz, 2010). Additional psychophysiological indices thought to reflect motivational and emotional processes, such as startle and electroencephalography, have been found to be related to physical aggression (e.g., Peterson, Shackman, & Harmon-Jones, 2008; Verona & Kilmer, 2007). It will be important for researchers to extend this work to include relational forms of aggression, particularly in research areas that have documented gender differences in the prediction of physically aggressive conduct (e.g., Verona & Kilmer, 2007).

Finally, researchers should incorporate social affective neuroscience perspectives to explore the neural

mechanisms underlying relationally aggressive behaviors, including investigating whether neuroscience models of physical aggression (e.g., Davidson, Putnam, & Larson, 2000) can be applied to relational forms of such conduct. In one recent functional magnetic resonance imaging study with adolescent girls, experiences of relational victimization were related to decreased activity in brain regions associated with executive functioning when viewing peer faces with varying affective expressions (Baird, Silver, & Veague, 2010). However, to our knowledge, researchers have not yet examined the neural activation patterns associated with the perpetration of relational aggression using functional magnetic resonance imaging methods, despite the central role ascribed to emotional processes in such conduct (see the "Emotion and Emotion Regulation" section). Given the hypothesized importance of reactivity to relational stressors among relationally aggressive youth (Crick, Grotpeter, & Bigbee, 2002), these studies may benefit from incorporating procedures that can assess neural activation patterns associated with social exclusion (e.g., Eisenberger, Lieberman, & Williams, 2003).

RISK FACTORS: COGNITIVE AND EMOTIONAL PROCESSES

The Crick and Dodge (1994) Reformulated Social Information Processing Model of Children's Adjustment

It has been over two decades since Crick and Dodge (1994) published their seminal review and reformulation of the social information processing (SIP) model of children's adjustment (originally proposed by Dodge, 1986). This review provided clear evidence that unique tendencies in processing cues from the social world could help explain behavioral differences between children. In particular, the accumulated evidence strongly indicated that heightened levels of physical (or overt) aggression were consistently associated with processing biases and deficits at every step of the model. Experimental and intervention designs have been particularly effective in demonstrating a causal role of these SIP mechanisms in children's engagement in aggressive acts. The proposition of the model (see Figure 13.1 for a representation) is that children come to process social cues in a consistent, automated fashion

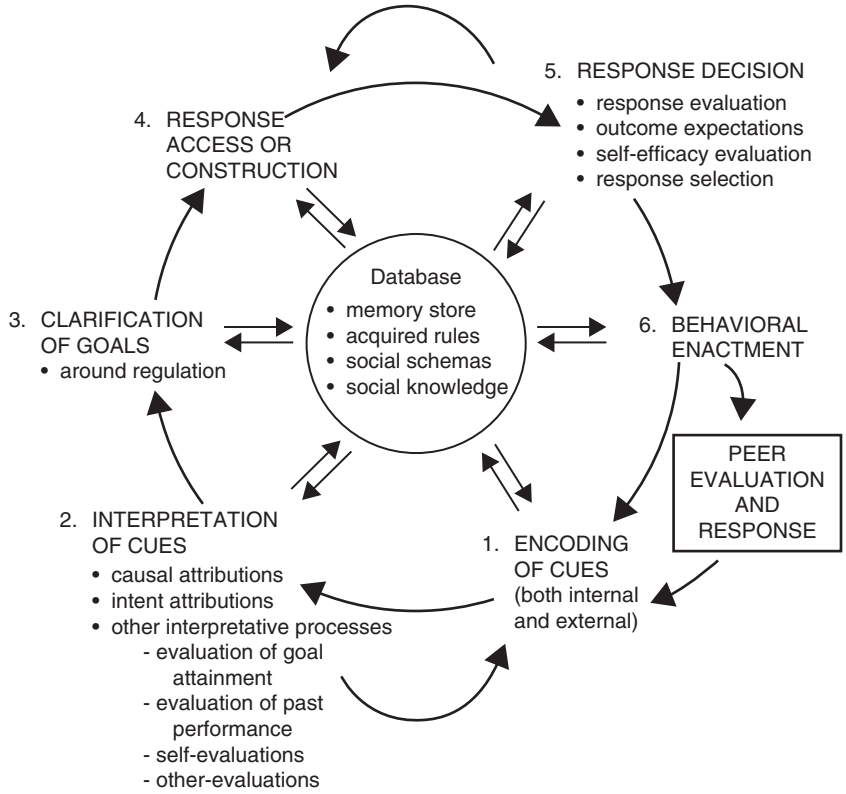

Figure 13.1 The Reformulated Social Information Processing Model. *Source:* Crick, N. R., & Dodge, K. A. (1994). A review and reformulation of social information-processing mechanisms in children's social adjustment. *Psychological Bulletin, 115*, 74–101. which can predispose them to aggressive action against others (whether warranted or not). The steps of the reformulated model, leading up to behavioral enactment (step 6), include (1) encoding of external and internal cues, (2) mental representation and interpretation of those cues, (3) clarification or selection of a social goal, in the context of current interpretation, (4) access or construction of potential responses, and (5) response decision (which response seems most appropriate, given current interpretation and social goals). Prior experience (in the database) provides context for current processing.

During the first two steps of this model, individual differences in children's processing are evident as they selectively attend to cues, which are then subject to interpretation. Aggressive children are more likely to attend to cues consistent with negative expectations of the intent of others (based on prior experiences and associated social schemata; Dodge & Tomlin, 1987). The aggressive child's enhanced attention to cues which may be perceived as hostile (Gouze, 1987) facilitates interpretation of those cues in a biased manner. In particular, aggressive children tend to have a hostile attributional bias (HAB), in which they are more likely to perceive hostile intent, even when cues are ambiguous and therefore do not lend themselves to such an interpretation (Crick & Dodge, 1994). This relationship between HAB and social adjustment tends to be quite robust across studies, at least in regard to physical aggression (Orobio de Castro, Veerman, Koops, Bosch, & Monshouwer, 2002); in effect, aggression serves as a defense against perceived provocation.

At step 3, children select a goal or desired outcome for the current situation. These goals may either enhance or detract from optimal relationship functioning (Slaby & Guerra, 1988). In this regard, aggressive children are more likely to embrace goals that damage relationships (e.g., revenge or instrumentality of aggression) as they navigate social interactions, consistent with their tendency to perceive hostile cues from others. At step 4, children are hypothesized to access possible responses from memory or to construct novel responses in unfamiliar social situations. The number of responses, their order, and the tenor of each individual response may be informative in the evaluation of the child's processing at this step. The response repertoires of aggressive children are characterized by more aggressive and less prosocial approaches (Quiggle, Garber, Panak, & Dodge, 1992).

Finally, at steps 5 and 6, the potential responses are evaluated and the most appropriate response selected for behavioral enactment. Aggressive children tend to evaluate aggressive responses more positively and are less likely to believe that competent responses will be effective in dealing with peers (Quiggle et al., 1992). These evaluations appear to be particularly relevant to engagement in proactive aggression (Crick & Dodge, 1996). Finally, at step 6, the behavior is displayed. Importantly, consistent with the model, the manner in which peers respond to this behavior will impact subsequent encoding and processing of cues. That is, children that enact an aggressive behavior will often experience retaliation from peers, which may confirm their prior intent attributions and allow for faster automated processing in similar social situations in the future (Crick & Dodge, 1994).

Gender, Subtypes of Aggression, and Hostile Attribution Bias

At the time of the Crick and Dodge (1994) review of SIP research, physical and verbal aggression had been the focus of prior work, largely because constructs such as indirect and relational aggression were just beginning to capture the attention of developmental scientists. There was promise evident, however, in the application of the SIP model to relational aggression. For instance, Crick (1995) hypothesized that relationally aggressive children, like their physically aggressive counterparts, would also exhibit HAB. However, Crick argued that relational disputes (e.g., provocations with a relational tone, such as being left out) would be particularly provocative for relationally aggressive children, especially girls, because these youth view such behavior as highly distressing and disruptive to their interpersonal goals. In contrast, Crick argued that boys would find instrumental disputes (provocations involving physical dominance, territory, and material objects) to be most distressing and thus would react with physical aggression. This hypothesis raised the possibility that HAB may be context-specific; that is, relational scenarios were not expected to be provocative to physically aggressive children, and instrumental scenarios were not expected to be provocative to relationally aggressive children.

In the first two studies that assessed the validity of these hypotheses (Crick, 1995; Crick et al., 2002), results generally aligned with expectations. Peer-nominated relational aggression corresponded with higher levels of children's self-reported relational HAB and emotional distress. Girls were also more likely than boys to feel such distress. Several recent studies have provided additional support for Crick's (1995) initial hypotheses. For instance, Gentile, Coyne, and Walsh (2011) found instrumental HAB mediated the association between fall media violence exposure and spring physical aggression, particularly for boys. In addition, relational HAB mediated the relation between fall

media violence exposure and spring relational aggression, and this effect was stronger for girls. With a sample of preadolescents, Yeung and Leadbeater (2007) found that relational HAB was associated with relational aggression concurrently as well as over time. Moreover, HAB for relational provocations partially mediated the association between relational victimization and concurrent relational aggression, though only at Time 1 (see also Ostrov, Hart, Kamper, & Godleski, 2011; Ostrov & Godleski, 2013). In a sample of adults, Murray-Close et al. (2010) found that HAB for relational provocations and feelings of distress were associated with relational aggression against romantic partners, controlling for relational aggression against peers.

However, others have reported findings that do not confirm the expected conceptual specificity linking subtypes of aggression to forms of HAB. Godleski and Ostrov (2010) explored temporal associations between HAB and aggression, using data from the National Institute of Child Health and Human Development Study of Early Child Care and Youth Development (NICHD SECCYD). In longitudinal analyses, third-grade aggression, gender, and relational and instrumental HABs (composites based on yearly assessments from third to fifth grade) were entered as predictors of sixth-grade subtypes of aggression. When controlling for earlier aggression and gender, instrumental HAB rather than relational HAB predicted later relational aggression and physical aggression. When temporal order was reversed (third-grade aggression predicting the HAB composites), both relational and physical aggression were associated with relational and instrumental HABs. Taken together, then, the findings suggested a more generalized association between aggression and HAB. Additional studies have failed to find any association between HAB for relational provocations and relational aggression. For example, Crain, Finch, and Foster (2005) reported that relational HAB showed no connection with relational aggression in one sample of girls, and, in the second female sample, HAB for relational provocations was associated with *lower* levels of relational aggression.

In an effort to further validate the Crick hypothetical scenarios for measuring HAB, Nelson, Mitchell, and Yang (2008) utilized confirmatory factor analysis to test whether responses to the different provocation contexts (instrumental and relational) could be statistically distinguished and whether all of Crick's original scenarios would appropriately load with the expected latent factor (two additional items were included in data collection as backup). Results showed that 9 of 10 Crick scenarios loaded on the appropriate factor; one relational provocation was replaced. The resulting instrumental HAB factor was related to physical aggression for boys, but children's relational HAB was not associated with relational aggression. In addition, the authors reported that for three of the five relational provocations, the majority of children in the study (58%–70%) responded with HAB. Accordingly, most relational scenarios were highly provocative and did not appear to elicit HAB from a relationally aggressive minority alone.

Moderators and Methodological Issues in the Hostile Attribution Bias-Aggression Connection

These mixed findings highlight the possibility that there may be important moderators of the association between HAB and relational aggression. For example, Mathieson and colleagues (2011) recently examined moderators suggested by Crick's relational vulnerability model. They found relational HAB to predict relational aggression only for girls who experienced high levels of relational victimization by peers and also reported high emotional distress in reaction to Crick's relational provocation scenarios. This study has clear empirical and clinical implications, suggesting that relational factors may cluster together to increase risk for engagement in relational aggression, particularly among girls.

In addition, proactive and reactive functions of relational aggression might be differentially associated with HAB. Prior research regarding physical aggression suggests that HAB is more strongly associated with reactive rather than proactive functions (Crick & Dodge, 1996). Although limited research has been conducted in the area of relational aggression, preliminary findings support the suggestion that HAB for relational provocations may be more strongly associated with reactive than proactive functions of relational aggression. For instance, Bailey and Ostrov (2008) found that reactive physical aggression corresponded uniquely with instrumental HAB, whereas reactive relational aggression was uniquely associated with relational HAB. In a study with adults, Murray-Close et al. (2010) reported that HAB for relational provocations was uniquely associated with reactive but not proactive relational aggression.

In addition to moderators, the mixed findings may be partly due to methodological, analytical, and sample differences that limit the direct comparison of findings. For instance, Crain et al. (2005) assessed HAB in response to ambiguous situations in friendships rather than the mix of peer and friend situations captured in Crick's original measure. Additionally, their hypothetical situations focused on female characters only. Given Crick's (1995) suggestion that the link between HAB and aggression

may be context-specific, these findings underscore the possibility that HAB may be more strongly associated with relational aggression in some contexts (e.g., in the larger peer group) than others (e.g., in close friendships). In physical aggression research, intent attributions have been assessed in many different ways (e.g., hypothetical scenarios, videotaped scenarios with actors), and effect sizes vary across these methodologies (Orobio de Castro et al., 2002). Relational provocation assessments have predominantly focused on hypothetical scenarios, so there is much work yet to be done to incorporate and compare results of different methodologies. The studies have also varied in that some incorporated a categorical approach to defining aggression (i.e., using cutoffs to establish extreme groups for aggression; e.g., Crick, 1995; Crick et al., 2002) whereas others have utilized a dimensional approach (i.e., using continuous aggression scores; e.g., Crain et al., 2005; Nelson, Mitchell, et al., 2008). Only Godleski and Ostrov (2010) have compared the utility of a categorical and a dimensional approach with the same sample.

Research is also needed to assess whether these processes might differ across samples. Preliminary research examining the association between HAB and relational aggression in clinical populations has provided mixed results. MacBrayer, Milich, and Hundley (2003), for example, found that children with a disruptive behavior disorder (attention-deficit/hyperactivity disorder [ADHD], oppositional defiant disorder, bipolar) were more likely to exhibit HABs of both types. In contrast, Mikami, Lee, Hinshaw, and Mullin (2008) did not find girls with ADHD to have higher HAB scores. Moreover, connections between SIP and aggression were actually stronger for comparison girls than for girls with ADHD. Relational provocation scenarios may also be more or less provocative across different gender, cultural, and age groups, which may in turn enhance or weaken the strength of the association between HAB and aggression.

Social Information Processing and Relational Aggression: Beyond Hostile Attribution Bias

Although the majority of research regarding SIP processes and relational aggression has focused on HAB, several studies have also considered other steps in the SIP model as well as the presence of latent knowledge structures in the database (which informs each step of the model). For example, Arsenault and Foster (2012) recently examined how attention and memory processes might be biased in aggressive children, leading to difficulties at step 1 of the SIP model—encoding of cues. Children saw videos of unambiguous overtly and relationally aggressive provocations. During the videos, a red light would flash near the video screen, and the child had to press the space bar at that time. Reaction times were measured to assess children's latencies as an index of attention. Children's accuracy of recall to video content was also assessed. Results showed that relational aggression was associated with attention shifting and free recall for the relationally aggressive provocations, even after controlling for overt aggression. Relationally aggressive children, therefore, were particularly fixated on relationally aggressive events shown on the videotape.

Crick and Werner (1998) examined response decision, the fifth step of the model, in the prediction of relational and physical (overt) aggression in third- to sixth-grade children. Children responded to hypothetical provocation scenarios (both relational and instrumental) in which the harmful intent of the provocateur was clear. They rated the appropriateness of physically aggressive, relationally aggressive, and prosocial responses to the provocation. Results showed that physically aggressive boys and girls positively evaluated physically aggressive responses to instrumental conflicts. In contrast, relationally aggressive children were not more likely to positively evaluate relationally aggressive responses to relational provocations. Contrary to expectations, physically aggressive girls saw physically aggressive responses more positively in the context of a relational provocation. Moreover, relationally aggressive boys favored relationally aggressive responses to instrumental provocation. Gender differences showed that boys were more positive about physically aggressive responses, and girls favored relationally aggressive responses. Some of these results are consistent with the original conceptualization of Crick (1995), whereas others differ.

Finally, several studies have shown that normative beliefs about the appropriateness of aggression are related to engagement in relational aggression, potentially because these beliefs enhance selection of aggressive responses at step 5 of Crick and Dodge's (1994) model. For instance, Poteat, Kimmel, and Wilchins (2011) found that beliefs regarding the appropriateness and effectiveness of violence were associated with bullying, physical fighting, and relational aggression for both male and female adolescents (see also Leff et al., 2014). Goldstein and Tisak (2010) found that adolescents viewed gossip and physical aggression as very wrong, but social exclusion was considered somewhat acceptable. Moreover, the more acceptable study participants presumed physical aggression or gossip to be, the more likely they were to admit engaging in physical aggression and relational aggression, respectively (no findings

emerged for social exclusion). Werner and Hill (2010) assessed whether children's individual normative beliefs and classroom-level norms favoring relational aggression would predict increased engagement in such conduct over the course of one year. Results showed that approval of relational aggression increased with the transition to middle school. Moreover, increases in relational aggression were predicted by individual norms favoring relational aggression and a peer group context highly supportive of relational aggression.

Toward an Integrated Gender-Linked Model of Aggression

Recently an integrated model for understanding gender differences in the development of physical and relational aggression in early and middle childhood was proposed by Ostrov and Godleski (2010). This model, depicted in Figure 13.2, posited a new framework that expanded on the existing social-cognitive and gender schema models and specifically integrated the SIP model of children's adjustment (Crick & Dodge, 1994) with the Schematic-Processing Model of Sex Role Stereotyping (Martin & Halverson, 1981). The model begins with the traditional six steps of the SIP model. However, Ostrov and Godleski proposed that the gender schematic processing model can be fully incorporated in the SIP model via the database and that these gendered processing patterns influence each of the traditional six SIP steps.

At step 1 of the SIP model, Ostrov and Godleski (2010) argued that past gender-relevant peer experiences, stored as memories, would be accessed during ambiguous provocation situations when encoding cues. Gender schemas were argued to influence the interpretation of cues at step 2 and the clarification of goals at step 3. At step 4, when generating possible responses to the provocation, behavioral responses that are most consistent with children's gender identity, self-construal, and past experiences (i.e., influenced by various socialization agents and the individual's history of adaptation) are more likely to be activated and accessible. Next, the authors proposed that

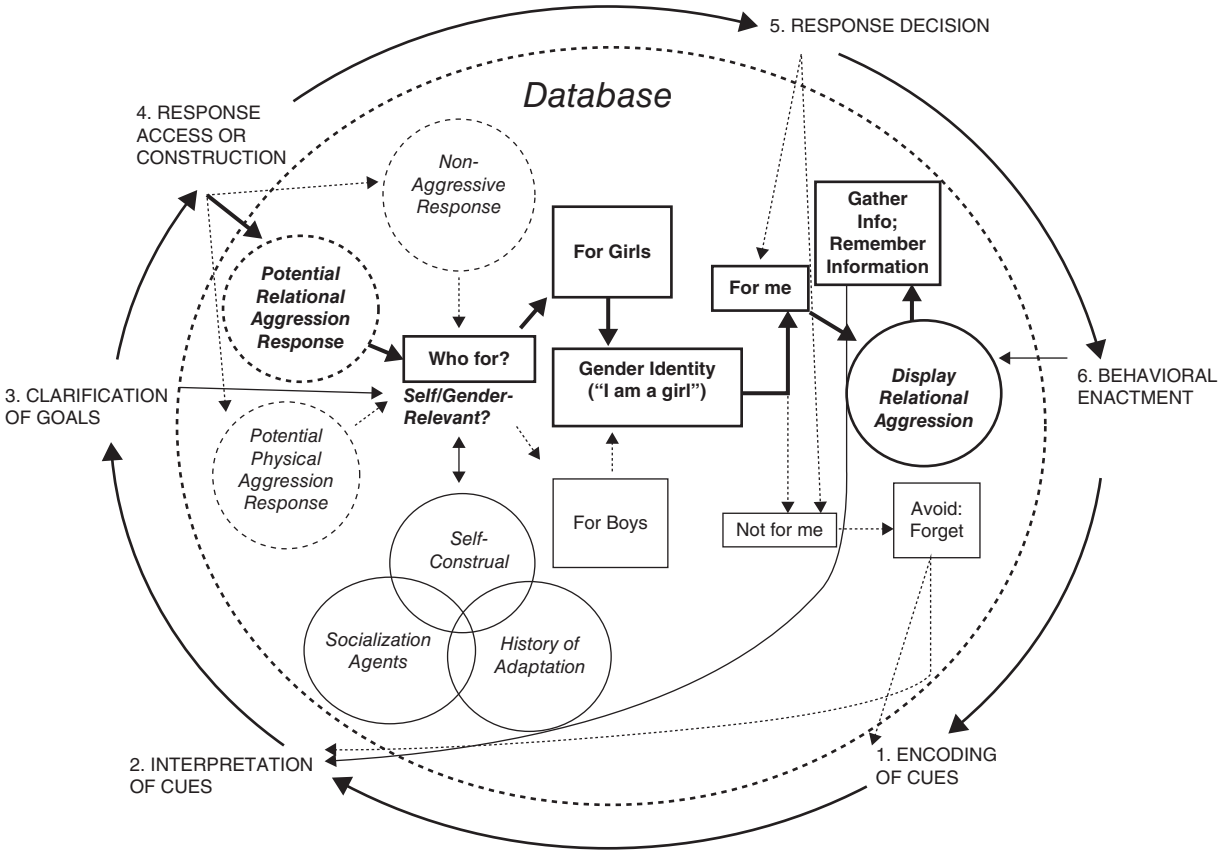

Figure 13.2 Gender-Linked Model of Aggression Subtypes. *Source:* Ostrov, J. M., & Godleski, S. A. (2010). Toward an integrated gender-linked model of aggression subtypes in early and middle childhood. *Psychological Review, 117*, 233–242. Copyright © 2010 by the American Psychological Association. Reprinted with permission.

youth will be probabilistically more likely to engage in aggressive behaviors that they consider self-relevant and typical of their gender. Finally, after enacting an aggressive behavior, youth will be more prone to remember such conduct when it is deemed gender- and self-relevant than when the behavior is inconsistent with their gender- and self-schemas.

This gender-linked model of aggression posits several predictions. For example, this model suggests within-group gender differences and preferences. That is, children are theorized to prefer to use gender-consistent aggressive behaviors and avoid the display of gender-inconsistent aggressive acts. From this perspective, the critical question regarding gender differences in relational aggression is not whether girls are more relationally aggressive than boys. Instead, this model posits that girls will more frequently select relationally aggressive behaviors than physically aggressive behaviors whereas boys will more frequently select physically aggressive behaviors than relationally aggressive behaviors. In fact, this prediction has been supported in prior research with a sample of preschoolers (Ostrov et al., 2014) and a large sample of ethnically diverse girls and boys in middle childhood (Putallaz et al., 2007).

This model also predicts that gender will serve as an important moderator of associations between aggression and future social-psychological adjustment problems. This gender-linked model of aggression subtypes argues that because girls are more sensitive to close interpersonal relationships and base their aggressive reactions on interpersonally related social cognitions (e.g., HAB for relational provocations), they will exhibit more negative adjustment outcomes when they display and receive relational aggression from their peers (Ostrov & Godleski, 2010). Using the NICHD SECCYD, Spieker et al. (2012) found some support for this hypothesis. Specifically, initial levels of relational aggression predicted adolescent self-reports of depression for girls but not boys. In another study, relational aggression was significantly and uniquely associated with future relational victimization among preschool girls but not among preschool boys (Ostrov, 2008). Overall, this model suggests that the field should move toward more sophisticated questions that address causal mechanisms and developmental trajectories to more appropriately understand the role of gender in the development of aggression among children.

Emotion and Emotion Regulation

A significant body of research has highlighted the important role of emotions in the development of aggressive behaviors. Frick and Morris (2004) identified two temperamental pathways to aggressive conduct, each characterized by a distinct set of underlying emotion processes. In the first pathway, dysregulated negative emotional experiences, particularly with respect to anger and frustration, promote antisocial and aggressive behavior. From this perspective, angry reactions to peer stress may increase the likelihood that a child will respond to real or perceived provocation with aggressive conduct. Exaggerated negative emotional responses to stress may also interfere with the development of the social-cognitive and social skills necessary to inhibit aggressive behaviors. In fact, emotion regulation deficits and emotion-related processes have been implicated as potential contributors and mediators in numerous models of the development of aggression (e.g., Shields & Cicchetti, 1998).

Emerging research has documented an important role of negative emotionality and/or poor regulation of negative affect in relationally aggressive conduct. For instance, Ostrov et al. (2013) recently reported that anger was associated with increases in relational aggression in a sample of preschool children followed across 4 months. In work with child and adolescent samples, relational aggression has been found to be related to negative affect and neuroticism (Tackett, Kushner, Herzhoff, Smack, & Reardon, 2014), angry responses to provocation (Marsee & Frick, 2007), the inability to tolerate frustration and anger (Little et al., 2003; Musher-Eizenman et al., 2004), affective lability (Tackett et al., 2014), elevated levels of hostility (Little et al., 2003), ineffective coping (including the tendency to be overwhelmed by emotions; Tackett et al., 2014), and poor ability to manage emotions during stress (Gower et al., 2014). Indices of anger and hostility are also associated with relational aggression against romantic partners in adulthood (Murray-Close et al., 2010), suggesting that these emotional processes may be important in the emergence of relational aggression across relational contexts. More general emotion regulation capacities, such as the ability to express emotion appropriately, have not always been found to predict relational aggression (e.g., Ostrov et al., 2013), potentially highlighting the significance of emotional regulation capacities specifically related to anger or frustration.

In the second pathway to aggression identified by Frick and Morris (2004), relatively low levels of emotional arousal may serve as a risk factor for aggressive conduct. For this pathway, a failure to experience normative levels of fear is hypothesized to interfere with experiences of guilt and anxiety regarding transgressions; as a result, socialization efforts against aggression may be relatively

ineffective among these youth. In fact, a large body of research suggests that low levels of fear, guilt, and empathy are risk factors for aggressive or antisocial conduct. For instance, psychopathy, a personality profile including impaired affective (e.g., unemotional style) and interpersonal (e.g., manipulativeness) processes, is related to severe antisocial conduct (Frick & Morris, 2004). In recent years, researchers have documented that emotional processes consistent with psychopathy (e.g., cold affect) are associated with indirect aggression (Coyne & Thomas, 2008; Czar, Dahlen, Bullock, & Nicholson, 2011) and romantic relational aggression (Coyne, Nelson, Graham-Kevan, Keister, & Grant, 2010; Czar et al., 2011) in college student samples. Although psychopathy is multifaceted and includes factors beyond emotional functioning, some evidence indicates that primary psychopathy (i.e., cold affect and social manipulativeness) is more strongly related to indirect aggression than secondary psychopathy (i.e., criminal tendencies, erratic lifestyle, impulsivity; Coyne & Thomas, 2008; Vaillancourt & Sunderani, 2011). Moreover, indirect and relational forms of aggression are specifically associated with the coldheartedness factor of psychopathy (Warren & Clarbour, 2009) and are related to low levels of empathy (Smits, Doumen, Luyckx, Duriez, & Goossens, 2011). Taken together, these findings suggest that low emotional arousal may play an important role in relational forms of aggression during early adulthood.

Researchers have also reported relatively low levels of emotional arousal in relationally aggressive children and adolescents. In early research in this area, Kaukiainen et al. (1999) found that low empathy was related to heightened levels of indirect aggression in a sample of adolescents. More recently, Tackett and colleagues (2014) documented that a lack of empathy was associated with relational aggression in a large sample of adolescents. Similarly, MacEvoy and Leff (2012) reported that lower levels of sympathy for victimized peers were associated with more relational aggression in a predominantly African American sample of third to fifth graders. Longitudinal work highlights the potential role of emotional underarousal in the emergence of relational aggression; for instance, Batanova and Loukas (2011) found that empathic concern was related to decreases in relational aggression in middle school students followed across 1 calendar year.

In related work, several researchers have documented that callous-unemotional (CU) traits, characterized by low levels of guilt and empathy, are associated with relational aggression (e.g., Lau & Marsee, 2013). For instance, Marsee and Frick (2007) reported that CU traits were positively associated with proactive relational aggression in a sample of incarcerated female adolescents. Similarly, Kerig and Stellwagen (2010) found that CU traits were positively correlated with relational aggression during early adolescence, although this effect did not persist once impulsivity was controlled. In a study with Japanese children and adolescents, Onishi, Kawabata, Kurokawa, and Yoshida (2012) reported that individuals who experienced feelings of guilt for engaging in relational aggression were less likely to choose to participate in such conduct in response to a series of hypothetical scenarios. Overall, then, findings across developmental periods have provided support for a relatively unemotional pathway to relational aggression.

Several factors may moderate the association between emotional processes and relational aggression. For instance, as reactive functions of aggression reflect dysregulated emotional reactions to stress or provocation, a propensity to experience anger and frustration may be more strongly related to reactive, as compared to proactive, functions of relational aggression (see Frick & Morris, 2004). In fact, in one study with adults, hostility and anger were more strongly associated with reactive as compared to proactive relational aggression (Murray-Close et al., 2010). Additionally, Marsee and Frick (2007) reported that anger to provocation was uniquely associated with reactive, but not proactive, functions of relational aggression in a sample of adjudicated female adolescents (although see Ostrov et al., 2013). In contrast, a failure to experience fear, empathy, and guilt may lower inhibitions against the use of aggression for instrumental purposes (i.e., proactive aggression). Consistent with this suggestion, Marsee and Frick (2007) found that CU traits were more strongly related to proactive relational aggression than reactive relational aggression. Some researchers have also provided evidence that emotional processes are more strongly associated with relational forms of aggression in females than in males; for instance, Marsee, Silverthorn, and Frick (2005) found that CU traits were positively correlated with relational aggression in female, but not male, fifth to ninth graders. However, findings regarding gender differences have been mixed; in fact, some studies have failed to find evidence of gender differences (Czar et al., 2011), and others have reported that emotional processes are more strongly associated with relational aggression in males than in females (e.g. Loudin, Loukas, & Robinson, 2003). Additional research is necessary to explore the conditions under which distinct emotional processes translate into relationally aggressive conduct.

RISK FACTORS: SOCIAL PROCESSES

Parenting and Attachment

Developmental psychopathologists have considered multiple social risk factors in the development of relationally aggressive conduct, including familial processes such as parenting and attachment. In a recent meta-analytic review of research in this area, Kawabata, Alink, Tseng, van IJzendoorn, and Crick (2011) identified four clusters of parenting that may play an important role in the development of relational forms of aggression: psychological control, negative/harsh (coercive), uninvolved (permissive), and positive parenting. A comprehensive discussion of the parenting factors associated with relational aggression is beyond the scope of this chapter and available elsewhere (e.g., Kawabata et al., 2011); however, we review some of the main theoretical and empirical findings in this area. Importantly, many of the studies described next have considered both mother and father influences as well as the potential role of child gender. Although the vast majority of studies concern the relational aggression construct, a handful of studies feature indirect or social aggression.

Psychological Control

Many of the early studies of the role of parenting behaviors in the development of relational aggression are based on the supposition of social learning theory that parents influence their children's social behaviors via modeling (Kawabata et al., 2011). From this theoretical perspective, studies explored whether relational aggression in children might mirror parental strategies like psychological control (e.g., threats of love withdrawal; see Nelson & Crick, 2002, for details). In one of the first studies in this area, Hart, Nelson, Robinson, Olsen, and McNeilly-Choque (1998) reported that relational aggression was not associated with a small set of psychological control items in a sample of Russian preschoolers. However, when the full complement of psychological control items in this data set were considered dimensionally, a number of important associations emerged (Nelson, Yang, Coyne, Olsen, & Hart, 2013). Casas et al. (2006) also documented the utility of a dimensional approach to psychological control in predicting early childhood relational aggression with a U.S. sample. In an interesting extension of this work, Nelson, Hart, Yang, Olsen, and Jin (2006) explored how combined and differential parenting by mothers and fathers predicted relational aggression in a sample of Chinese preschoolers. A latent sum and difference structural equation model showed that combined psychological control (i.e., cumulative engagement in psychological control by mothers and fathers) was associated with heightened levels of relational aggression in girls. Interestingly, the extent to which fathers engaged in higher levels of psychological control was also positively associated with relational aggression in girls. In contrast, psychological control was not related to relational aggression in boys. These gender differences mirror findings reported by Nelson and Crick (2002) indicating that paternal psychological control predicted relational aggression in daughters in a sample of third graders.

Associations between psychological control and relational aggression have emerged in studies across developmental periods. For instance, Gaertner and colleagues (2010) reported that psychological control predicted relational aggression among a group of children ages 9 to 12 years. In a Belgian sample of 8- to 10-year-old children, Kuppens, Grietens, Onghena, and Michiels (2009a) found support for the specialized associations between parental control and child relational aggression proposed by Nelson and Crick (2002). Specifically, parental psychological control was associated with child relational, but not physical, aggression. Soenens, Vansteenkiste, Goossens, Duriez, and Niemiec (2008) also demonstrated with a Belgian adolescent sample that parental psychological control (by fathers or mothers) predicted increased adolescent relational aggression. Some evidence indicates that parental psychological control predicts relationally aggressive behavior across relational contexts (e.g., in dating relationships, Leadbeater, Banister, Ellis, & Yeung, 2008; in sibling relationships, Campione-Barr, Lindell, Greer, & Rose, 2014). Kawabata and colleagues (2011) provided meta-analytic evidence that paternal, but not maternal, psychological control was positively associated with relational aggression. In their more recent meta-analysis, Kuppens, Laurent, Heyvaert, and Onghena (2013) reported a positive yet weak association between parental psychological control and child relational aggression. Taken together, findings are consistent with the hypothesis that parental psychological control contributes to child relational aggression, although some evidence suggests that effects more often emerge in the context of paternal, rather than maternal, behaviors.

Negative/Harsh (Coercive) Parenting

According to social learning theory, negative or harsh parenting practices may teach children that aversive and aggressive behaviors, including relational aggression, are an effective strategy to get one's own way (Nelson & Crick, 2002). From this perspective, modeling of negative parent behaviors may lead children to engage in novel aggressive behavioral patterns (e.g., parent hostility may incite child

relational aggression; Kawabata et al., 2011). Negative parenting behavior may also interfere with the establishment of secure attachment relationships, ultimately increasing risk for involvement in relational aggression. Researchers have explored a variety of types of negative parenting behaviors, including parent-child conflict, coercion, inconsistent discipline, parental negativity, and child maltreatment (see Kawabata et al., 2011).

Findings from several studies suggest that negative parenting is associated with children's engagement in relational aggression during early childhood. In early research testing these hypotheses, Hart et al. (1998) reported that maternal physical/verbal coercion was positively associated with relational aggression in a sample of Russian preschool children. More recently, Ostrov and Bishop (2008) assessed whether general indicators of parent-child conflict were associated with teacher ratings or observations of preschool aggression. Results showed that, for both teacher ratings and observations, conflict uniquely predicted relational aggression above and beyond physical aggression and gender. Although findings are mixed (A. Russell, Hart, Robinson, & Olsen, 2003; Sandstrom, 2007), some researchers have also provided evidence indicating that authoritarian parenting is associated with relational aggression (e.g., Casas et al., 2006). Similarly, McNamara, Selig, and Hawley (2010) documented that mothers who provided little warmth and autonomy support, in combination with highly restrictive control, had young children who were more (relationally) aggressive.

Similar findings have emerged in older children. For instance, Nelson and Crick (2002) found that maternal coercive control predicted relational aggression in third-grade children. Brown, Arnold, Dobbs, and Doctoroff (2007) videotaped mother-child interactions and coded for parental overreactivity (harsh/coercive) and negative maternal affect in a sample 5- to 8-year-old children who were predominantly European American or Puerto Rican. Among the European American participants, negative affect and overreactivity predicted heightened levels of relational aggression. In the multivariate context, negative affect proved more important than other parenting variables. However, no significant associations emerged among the Puerto Rican dyads (n = 18). Replication with larger samples is necessary to determine whether Puerto Rican children react differently to parenting than European American children.

Although limited research has examined the role of child maltreatment in the development of relational aggression, preliminary findings suggest that more severe instances of negative parenting, such as abuse, may portend risk for relational aggression. Specifically, Cullerton-Sen et al. (2008) found that a documented history of child maltreatment was associated with elevated levels of relational aggression among youth ages 6 to 12 years. Interestingly, child maltreatment was associated with relational aggression for girls only, and findings primarily emerged in the context of sexual abuse. In a study with adults, a history of abuse was associated with heightened levels of reactive and romantic relational aggression (Murray-Close et al., 2010). These results highlight the potential role of severe forms of negative parenting, such as abuse, in the development of relational aggression.

Several studies have also examined the association between early negative parenting and trajectories of indirect or social aggression. For example, Browne, Odueyungbo, Thabane, Byrne, and Smart (2010) found that hostile-ineffective parenting, wherein parents demonstrate annoyance, antagonism, and mood-dependent behavior, increased the risk of a child's development of indirect aggression over the course of 6 years. Vaillancourt, Miller, Fagbemi, Côté, and Tremblay (2007) examined predictors of different developmental trajectories of indirect aggression in children from age 2 to age 10. They identified two groups: increasing users (35%) and stable low users (65%). For boys only, parental inconsistency (lack of follow-through) at age 2 predicted an increased likelihood of belonging to the increasing group. Using the same data set, Côté et al. (2007) assessed the joint development of physical and indirect aggression from age 2 to age 8. Results showed that hostile parenting at age 2 predicted high levels of both physical and indirect aggression over time. Underwood et al. (2009) examined six different developmental trajectories for social and physical aggression, following children from age 9 to age 13. Maternal authoritarian parenting predicted children's membership in the high increaser group. Meta-analytic findings further underscore the important role of negative parenting in the development of relational aggression: Kawabata and colleagues (2011) reported that both maternal and paternal negative parenting were positively associated with relational aggression.

Uninvolved (Permissive) Parenting

Theorists have also hypothesized that permissive parenting may be associated with elevated levels of child relational aggression; from this perspective, parents may fail to intervene when their children are aggressive, thereby reinforcing these undesirable behaviors (Casas et al., 2006). Consistent with this hypothesis, Casas et al. (2006) found that permissive parenting styles were associated with child relational

aggression. Similarly, Leadbeater et al. (2008) reported that low levels of parental monitoring were associated with greater use of relational aggression in the context of dating relationships among 12- to 18-year-old adolescents. In Underwood and colleagues' (2009) examination of joint developmental trajectories of social and physical aggression across age 9 to age 13, maternal permissive parenting predicted children's membership in the high increaser and medium increaser groups. Some evidence suggests that permissive parenting behaviors may be more strongly associated with relational aggression in girls as compared to boys. For instance, Sandstrom (2007) reported that maternal permissiveness was positively associated with relational aggression in 9- to 11-year-old girls but was unrelated to such conduct in boys. In observational work in this area, Brown et al. (2007) documented that videotaped mother-child interactions characterized by laxness were positively associated with relational aggression for girls but negatively associated for boys. However, meta-analytic findings do not suggest gender moderation; instead, findings indicate that both maternal and paternal permissiveness are positively associated with relational aggression in both boys and girls (Kawabata et al., 2011).

Positive Parenting

Researchers have hypothesized that positive parenting, including secure attachment relationships, authoritative parenting styles, and positive affect, may reduce children's risk for involvement in relational aggression (Kawabata et al., 2011). In early international research in this area, Hart et al. (1998) reported that paternal responsiveness (an authoritative dimension) was most predictive of Russian preschoolers' relational aggression, even when controlling for other parenting dimensions (although see Casas et al., 2006). Casas et al. (2006) were the first to assess whether attachment security was related to relational aggression in a preschool sample (see Michiels, Grietens, Onghena, & Kuppens, 2008, for a theoretical synopsis regarding attachment). They found the association to be specific to gendered dyads. Whereas relationally aggressive girls were less likely to have a secure attachment with their mother, relationally aggressive boys were less likely to have a secure attachment with their father.

Other positive parenting behaviors have also been shown to predict reduced risk for involvement in relationally aggressive conduct. For instance, Brown et al. (2007) reported that more positive affect observed in mother-child dyadic interactions was associated with less relational aggression. In addition, parent-child bonding has been found to predict lower levels of social aggression (Karriker-Jaffe et al., 2013). Browne et al. (2010) reported that parental consistency (parental follow-through with discipline and requests) and positive interaction (parental praise/amount of quality time with child) acted as buffers against the development of indirect aggression over the course of 6 years. Similarly, Vaillancourt et al. (2007) found that more positive parent-child interactions at age 2 reduced the likelihood that boys would exhibit increasing trajectories of indirect aggression from age 2 to age 10. Finally, parental control, including consistent rules and monitoring, have been associated with lower levels of social aggression (Karriker-Jaffe, Foshee, Ennett, & Suchindran, 2013). Meta-analytic findings have confirmed the important role of positive maternal and paternal parenting behaviors in child involvement in relational aggression (Kawabata et al., 2011).

Directions for Future Research

Despite the burgeoning literature regarding parenting correlates of relational aggression, several critical questions remain. First, it will be important for researchers to examine the mechanisms that link parenting practices to child relational aggression; for instance, aversive parenting may enhance a child's HAB (Nelson & Coyne, 2009), which may in turn be linked to relational aggression. In addition, positive parenting may promote adaptive child behaviors, such as disclosure (e.g., not keeping secrets from one's parents), that prevent relationally aggressive conduct. In fact, higher levels of relational aggression have been reported among youth who engage in lower levels of disclosure (Gaertner et al., 2010) and higher levels of concealment (Leavitt, Nelson, Coyne, & Hart, 2013) in their interactions with their parents. Moreover, child disclosure may serve as a stronger predictor of adolescent antisocial conduct than parental monitoring (Criss et al., 2015). It may also be useful for researchers to examine interactions among parenting behaviors; in fact, in one study, the combination of high parental solicitation and psychological control predicted increased engagement in child relational aggression (Gaertner et al., 2010). Moreover, the majority of studies of parenting and relational aggression either make use of concurrent data or, if they are longitudinal, do not attempt to ascertain reciprocal effects between parenting and child aggression. This limitation is significant, given evidence of evocative gene-environment correlations in behaviors such as aggression (Brendgen, 2012). In one of the only studies to assess bidirectional associations over time, Kuppens, Grietens, Onghena, and Michiels (2009c) used a cross-lagged panel design (three measurement points at 1-year intervals) with a middle-childhood sample. Parents

and children reported on parental psychological control, and child aggression was reported by parents, peers, and teachers. Reciprocal effects emerged for mother-child dyads, whereas father-child dyads were best characterized by unidirectional parent effects, at least when parents reported on both psychological control as well as aggression.

Future research may also benefit from greater attention to cultural differences in associations between parenting behaviors and relational aggression. Some evidence suggests that cultural factors may influence the degree to which parents adopt psychologically controlling behavior. Using longitudinal data collected in seventh grade and ninth grade, Shuster, Li, and Shi (2012) found that, controlling for Time 1 physical and relational aggression, maternal endorsement of the cultural value of social harmony predicted less engagement in parental psychological control, which in turn was associated with Time 2 relational aggression. These findings highlight the potential role of cultural values in parenting practices and, ultimately, children's engagement in relational forms of aggression.

Parental Beliefs and Expectations

Although most research regarding the association between parenting and child relational aggression has focused on parenting behaviors, a few studies have also highlighted the important role of parent expectations in children's aggressive behavior. Murray, Haynie, Howard, Cheng, and Simons-Morton (2010) conducted a unique study with African American sixth graders living in an urban community plagued with violence. Over the course of 3 months, they assessed how initial parental expectations and practices predicted overt and relational aggression at school. Multivariate analyses demonstrated that parental expectations that their child would engage in peaceful solutions to conflict (a) buffered against overt aggression when parental support and responsiveness was relatively low and (b) buffered against both overt and relational aggression in the context of high psychological control by parents.

Several studies have examined maternal beliefs about relational aggression and how these beliefs translate into discipline responses, child beliefs, and child behavior. For instance, in a study of parents of preschoolers, Werner, Senich, and Przepyszny (2006) found that, relative to physical aggression, mothers reported they would be less upset, angry, and sad in response to their child's engagement in relational aggression. Accordingly, relational aggression was also perceived as less deserving of parental intervention. However, mothers who said that they would intervene by helping their child understand that he or she had violated a social or moral convention had children who were less relationally aggressive. Similarly, Werner and Grant (2009) found that mothers perceived relational aggression as more normative and acceptable than physical aggression and their children to be less responsible for their engagement in such behavior. Children's perceptions of relational aggression tended to correspond with those of their mothers. The more mothers considered relational aggression to be problematic, however, the more they reported they would use sternness and disapproval in response to their daughters' relational aggression. Daughters of more stern mothers were in turn more likely to be prosocial and better accepted by peers (these associations did not emerge for boys). Although preliminary, findings from these studies highlight the critical need for research regarding the role of parental views of aggression in the development of child relational aggression.

Interparental Conflict

Prior research has indicated that marital conflict is related to childhood adjustment difficulties, including physical aggression, particularly when child exposure to conflict is high (Cummings, 1994). A number of potential mechanisms could explain this association. From a social learning perspective, children may model interparental aggression, believing it is acceptable behavior. Parents may inappropriately interpret the intentions of one another (e.g., demonstrate HAB), and the child may adopt similar thinking in interpreting his or her own social experiences and thereby act more aggressively. Depending on each child's individual coping style, interparental conflict may also generate background anger, a stressor that heightens arousal in children and potentially elicits aggression in some children (Cummings, 1987). Finally, marital conflict may undermine parenting and the parent-child relationship, thereby leading to more child aggression.

Few studies have assessed whether marital conflict is related to the development of relational aggression. In one notable exception, Hart and colleagues (1998) assessed overt marital conflict (e.g., verbal hostility, quarreling, and physical abuse) and marital exclusion (e.g., avoiding, ignoring, and withdrawing affection) in their Russian preschooler study. Results showed that overt marital conflict, but not marital exclusion, was positively associated with relational aggression among boys but not among girls. Other work, however, has documented effects for girls. Specifically, Underwood, Beron, Gentsch, Galperin, and Risser (2008)

examined interparental conflict strategies (stonewalling, triangulation, verbal aggression, and physical aggression) in the prediction of children's social aggression. Notably, the interparental conflict strategies were collectively modeled in structural equation modeling as one latent construct (negative conflict strategies). Results showed that only the maternal negative conflict strategies predicted social aggression, and findings emerged for daughters but not for sons. More recently, Karriker-Jaffe et al. (2013) reported that family conflict was positively associated with social aggression for both boys and girls, although analysis of trajectories of social aggression indicated that compared to boys from high-conflict families, girls from high-conflict families exhibited higher initial levels of social aggression (at age 11) and a more gradual decline in these behaviors across adolescence.

Although preliminary, these findings highlight the potential role of marital relationships and interactions in child relational aggression. Future research in this area may be enhanced by more careful definitions of interparental relational aggression, such as the distinction between direct and indirect forms of relational aggression. Consistent with this idea, Carroll and colleagues (2010) developed a measure reflecting two subtypes of marital relational aggression: social sabotage (indirect) and love withdrawal (direct). Study results showed that wives were more likely to be relationally aggressive than husbands, and such tactics were concurrently associated with lower marital quality and higher marital instability. The next step is to determine whether these forms of marital relational aggression are uniquely predictive of relational aggression in children. Given that children are not likely to witness social sabotage or some forms of love withdrawal, the negative impact may occur via mechanisms other than direct observation of these subtle behaviors, such as impaired parenting or witnessing co-occurring overt marital conflict. Future studies must attend to the specific processes that link interparental conflict and child relational aggression, such as parenting behaviors. For instance, Li, Putallaz, and Su (2011) have assessed how interparental conflict styles may indirectly predict child overt and relational aggression via coercive or psychological control. Using a sample in Beijing, China, they found that fathers' overt interparental conflict was associated with boys' aggression, and this relation was mediated by paternal coercive control. Maternal covert conflict was positively related to boys' aggression, and this association was mediated by maternal psychological control. Given evidence of differences in effects based on both parent and child gender (e.g., Li et al., 2011), future work in this area should also carefully evaluate the role of gender in the processes linking interparental conflict and child relational aggression.

Sibling Relationships

By middle childhood, time spent with siblings tends to outweigh other relationships (McHale & Crouter, 1996); thus, there is good reason to suppose that siblings may substantially affect each other's involvement in relationally aggressive conduct. Sibling relationships differ significantly from peer acquaintances or friendships in ways that may promote the development of relational aggression. For instance, the greater intimacy of family relationships allows siblings access to a great deal of private and potentially damaging information about each other (precisely the type of information that would lend itself to relational aggression). Additionally, as sibling relationships are involuntary, siblings must learn to deal with each other's eccentricities, potentially leading to relatively high levels of conflict. Sibling interactions may also be influenced by the nature of marital or parent-child relationships, reflecting the systemic workings of a family. As briefly noted earlier, evidence indicates that preschoolers engage in more relational aggression with siblings than with friends. Following these children and their siblings from age 4 to age 8, Stauffacher and DeHart (2006) observed that by the time the target child was 8 years old, sibling and friend dyads no longer differed in their levels of relational aggression. Specifically, over the 4-year period, friend dyads increased in their relational aggression, whereas the same behavior between siblings declined.

Several factors, including child gender and age, may influence the frequency and type of relational aggression used against siblings. With respect to frequency, Campione-Barr et al. (2014) found that, within the context of sibling dyads, younger siblings were more often the target of sibling relational aggression than older siblings. With respect to type of relational aggression, Stauffacher and DeHart (2005) found that girls with younger siblings tended to use nonverbal (ignoring) strategies with siblings, whereas girls with older siblings tended to focus on more verbal strategies. Boys, in contrast, preferred verbal forms of relational aggression, regardless of the age of the sibling. Understandably, sibling relational aggression is tied to other aspects of the sibling relationship. In particular, relational aggression is more likely if there is less emotional support and more negativity between siblings, regardless of the gendered nature of the dyad (same versus opposite sex) or the age of siblings (Updegraff, Thayer, Whiteman, Denning, & McHale, 2005).

Ostrov, Crick, and Stauffacher (2006) suggested that use of relational aggression in the context of sibling relationships may provide a training ground for younger siblings to learn aggressive behavioral strategies; from this perspective, youth may model their older siblings' relational aggression and thus may be at increased risk for engaging in these behaviors in the peer context. These authors observed both siblings of a given dyad in the same preschool environment (the younger sibling enrolled 1 to 2 years later). Observations showed that older sisters were more relationally aggressive than older brothers. Older siblings were also more aggressive than younger siblings with same-sex peers. Consistent with expectations, older siblings' relational aggression toward peers was predictive of the same behavior in younger siblings (this was also found for peer-directed physical aggression).

Only two studies have considered how parent-child dynamics may be connected to sibling relational aggression (Campione-Barr et al., 2014; Updegraff et al., 2005). In the first, Updegraff and colleagues (2005) reported that when parents provided less emotional support to their children, sibling relational aggression increased. Less time with fathers also predicted higher levels of sibling relational aggression. Interestingly, parents who intervened in sibling conflict with authoritarian practices (e.g., punishments) tended to have children, particularly daughters, who engaged in relational aggression. In the second study, Campione-Barr et al. (2014) found that maternal psychological control predicted heightened use of sibling relational aggression in a sample of adolescents. Although the findings from these studies may suggest that inadequate parenting contributes to sibling relational aggression, another possibility is that parents are reacting to aggressive siblings with less warmth and involvement and greater psychological control. Finally, differential treatment of siblings by parents is relevant: Children report less sibling relational aggression when parents are perceived to be evenhanded (Updegraff et al., 2005). However, work in this area is still in its infancy, and additional research is needed to identify the developmental precursors and outcomes associated with use of relational aggression in the sibling context.

Peer Relationships

Much of the extant relational aggression research has focused on these behaviors in the context of the peer group, and several peer processes have been identified that may serve as risk factors in the development of relational aggression. More specifically, researchers have suggested that peer status, peer victimization, and quality of close dyadic relationships may all contribute to the emergence of relational forms of aggression.

Peer Status

One of the most robust correlates of relational aggression across developmental periods is low peer status, including low preference (e.g., Crick & Grotpeter, 1995), and its associated components of high rejection (i.e., frequently being identified by peers as disliked) and low acceptance (i.e., rarely being identified by peers as liked). Most researchers in this area have proposed that engagement in relational aggression leads to poor peer status (see the "Developmental Outcomes: Maladaptive Correlates" section); however, the vast majority of this work has been cross-sectional in nature, and there is reason to expect that low status in the peer group may also precede the use of relationally aggressive behaviors. One influential causal model of the relation between low preference and aggression suggests that low preference leads to a constrained pool of potential partners comprised primarily of peers who also have impaired social skills (Bierman, 2004). This smaller peer group likely contributes to the behavioral homophily (associating with other similar peers) often observed among aggressive children (Parker, Rubin, Price, & DeRosier, 1995). Perhaps more important, this process contributes to a negative spiral whereby rejected children become more and more socially incompetent relative to their well-accepted peers, promoting higher levels of both physical and relational aggression over time (Bierman, 2004).

Recent research has documented both homophily and socialization of relational aggression in peer groups (Sijtsema, Ojanen, et al., 2010), suggesting that this may be a plausible mechanism involved in the development of relational aggression. In fact, although evidence is mixed (e.g., Orue & Calvete, 2011; Ostrov et al., 2013; Tseng, Banny, Kawabata, Crick, & Gau, 2013), several researchers have found that indices of low preference are longitudinally associated with future relational aggression. For instance, Zimmer-Gembeck, Crick, and Geiger (2005) reported that low social preference predicted increases in relational aggression across 3 years, although in this study, effects were significant only for boys. In addition, Werner and Crick (2004) reported that rejection by peers predicted elevated levels of relational aggression one year later in a sample of elementary school children. Murray-Close and Crick (2006) also found that increases in peer rejection over time were dynamically associated with increases in relationally aggressive behaviors.

However, other researchers have suggested that *high* peer status may serve as a social risk factor for the development of relationally aggressive conduct. Foundational to much of this research is the distinction between perceived popularity (based on most and least popular nominations by peers) and preference. Perceived popularity is an indicator of children's social status and impact whereas preference is an indicator of children's likability (Parkhurst & Hopmeyer, 1998). Perceived popular youth benefit from possessing what is described as "the expressive equipment of popularity": physical attractiveness, athleticism, and evidence of significant material wealth (Lease, Kennedy, & Axelrod, 2002, p. 87; see also Rosen & Underwood, 2010). In short, these youth have superficial traits that make them well positioned for popularity.

Some researchers have argued that perceived popular children employ relationally aggressive behavior in efforts to maintain their high social status and power (Sandstrom & Cillessen, 2006). Consistent with this hypothesis, findings from several studies indicate that high levels of perceived popularity are related to increases in relational aggression over time (Rose, Swenson, & Waller, 2004; Tseng et al., 2013), particularly among girls (Cillessen & Mayeux, 2004). Interestingly, some evidence suggests that a curvilinear effect best represents the association between popularity and relational aggression, such that elevated engagement in relational aggression is evident in youth with both high and low levels of popularity (Prinstein & Cillessen, 2003). Moreover, although the majority of research suggests that indices of low preference serve as a risk factor for relational aggression, findings are mixed. For instance, some work indicates that *high* social acceptance is related to increases in relational aggression over time among youth (Tseng et al., 2013), especially girls (Orue & Calvete, 2011; see also Kuppens, Grietens, et al., 2009b). However, it is possible that positive associations between preference and the development of relational aggression are an artifact of the overlap between preference and popularity. Consistent with this notion, Prinstein and Cillessen (2003) found that when both popularity and preference were included in one model, social preference was related to decreases in relational aggression over time among girls (see Adams, Bartlett, & Bukowski, 2010, for evidence that social dominance may serve as a suppressor variable in the association between low preference and heightened relational aggression). These findings suggest that relationally aggressive behaviors may be more strongly linked to high peer status when measures focus on perceived popularity as compared to preference.

These results also raise the possibility that low and high peer status may promote relational aggression for different reasons; specifically, low preference or unpopular youth may use relational aggression to deal with negative experiences in the peer group, whereas popular children may engage in relational aggression because their high social status provides them with social power for the effective use of these behaviors (see Kuppens, Grietens, et al., 2009b) and because peers fail to censure them when they engage in such conduct (Rose, Swenson, & Waller, 2004). These findings also suggest that researchers interested in investigating the role of peer status in the development of relational aggression should include multiple facets of status, including preference and popularity, so that the unique role of each can be assessed (e.g., Bowker, Ostrov, & Raja, 2012).

There are several important directions for future research regarding the processes underlying the association between peer status and the development of relational aggression. First, it will be important for researchers to assess the extent to which relations between peer status and relational aggression are incidental such that they reflect the action of third variables (see Rubin, Bukowski, & Parker, 2006). For example, depressive symptoms may function as a third variable that promotes both rejection by peers as well as aggressive behavior (e.g., Agoston & Rudolph, 2013). As another example, relational aggression may be associated with poor functioning in the peer group as a result of its overlap with other problematic behaviors, such as physical aggression. In fact, in one study, the relation between relational aggression and lower acceptance became nonsignificant when overt aggression was controlled (Smith, Rose, & Schwartz-Mette, 2009). However, some research indicates that peer rejection longitudinally predicts relational aggression, even when controlling for physical aggression (Murray-Close & Crick, 2006), suggesting that negative peer relationships may be uniquely associated with relational aggression. It will also be important to examine potential third variables in the relation between high peer status and relational aggression; for instance, positive child characteristics, such as social skills, may promote both positive peer outcomes (e.g., acceptance, popularity) as well as relational aggression (Orue & Calvete, 2011).

Second, future research should test transactional models (Sameroff & MacKenzie, 2003) of the relations between social status and relational aggression. Transactional views of development suggest bidirectional and mutually influencing correlations between key variables that in combination may best explain a developmental pathway. From this perspective, peer status may interact

with child characteristics to promote involvement in relational aggression. For example, it is possible that peer rejection in conjunction with maladaptive social information-processing patterns (e.g., HAB; see the "Risk Factors: Cognitive and Emotional Processes" section) better predicts relational aggression than either of these factors individually (see the "Moderation Models" section). Given evidence of gender differences in the association between peer status and later relational aggression (e.g., Cillessen & Mayeux, 2004), it will also be important for future research to evaluate the extent to which peer status differentially predicts relational aggression in boys versus girls. Recent cognitive models of relational aggression (see the "Toward an Integrated Gender-Linked Model of Aggression" section) highlight the important role of gender schemas in children's aggression; from this perspective, peer status may most strongly predict relational aggression in girls because youth select aggressive behavior patterns that are consistent with their gender schemas.

Several additional moderators of the association between relational aggression and popularity merit empirical attention. For instance, a relatively egalitarian classroom status hierarchy may promote relationally aggressive strategies among higher-status youth because it increases their need to defend their desirable social positions (Zwaan, Dijkstra, & Veenstra, 2013). Additionally, Mayeux and Cillessen (2008) found that perceived popular adolescents who also knew they were popular exhibited the highest concurrent levels of peer-reported aggression (relational aggression for girls and overt aggression for boys). Awareness of high status may provide license for aggressive behavior or alternatively attune the adolescent to the need to fight to maintain status. Finally, given the theoretical processes proposed to underlie relations between peer status and later relationally aggressive conduct, researchers should examine whether associations depend on whether the aggression is proactive versus reactive in function. Insofar as rejected youth use relational aggression to cope with negative peer experiences, they may be more likely to engage in reactive relational aggression. In contrast, if popular youth use relational aggression to maintain their high social status, they may be particularly likely to engage in proactive relational aggression. Consistent with this suggestion, in one study, proactive relational aggression was positively associated with popularity but not preference (Prinstein & Cillessen, 2003). However, reactive relational aggression was positively related to both popularity and preference (Prinstein & Cillessen, 2003), perhaps because high-status youth used relational aggression to defend challenges to their coveted social positions. Longitudinal research is necessary to further explore how peer status relates to the development of proactive and reactive functions of relational aggression.

Victimization

Relational aggression and victimization have been found to be moderately correlated at all points in development (e.g., Crick et al., 2001), and evidence indicates that a subset of relational perpetrators are also victims (Gros, Gros, & Simms, 2010). Engaging in relational aggression may lead to tit-for-tat responses whereby the relational aggressor may also become a victim (see the "Developmental Outcomes: Maladaptive Correlates" section). However, it is also plausible that victimization serves to elicit relationally aggressive responses over time (e.g., Ostrov, 2010; Ostrov & Godleski, 2013). In fact, when asked how they respond to experiences of victimization, middle school and high school students commonly identified aggressive strategies (Waasdorp & Bradshaw, 2011). Researchers have proposed several mechanisms whereby experiences of peer victimization may promote aggressive behavior. Victimized youth may engage in aggression in an effort to retaliate against their tormentor or to prevent future victimization experiences (Yeung & Leadbeater, 2007). The experience of being a frequent target of relational victimization may result in feelings of isolation, loneliness, and low self-esteem (Gomes, Davis, Baker, & Servonsky, 2009). These adjustment difficulties may lead relational victims to lash out at their tormentors in a fashion similar to what they have experienced. Some evidence also suggests that experiences of relational victimization are associated with heightened HAB for relational provocations (Hoglund & Leadbeater, 2007; Yeung & Leadbeater, 2007), which in turn has been found to predict involvement in relational aggression in some studies (see the "Risk Factors: Cognitive and Emotional Processes" section). Additionally, similar to their rejected peers, victimized youth may have a limited pool of social interaction partners, thus reducing opportunities for learning positive social behaviors (Hanish & Guerra, 2002).

Several researchers have provided evidence consistent with the suggestion that peer relational victimization predicts increased relationally aggressive conduct. Sullivan, Farrell, and Kliewer (2006) reported that relational victimization was associated with heightened levels of concurrent relational aggression in a sample of predominantly African-American eighth graders; interestingly, although effects emerged for both boys and girls, associations were stronger for boys. Longitudinal work has provided evidence that experiences of relational victimization may promote

relationally aggressive conduct over time. For instance, Yeung and Leadbeater (2007) reported that relational victimization was related to preadolescents' engagement in relational aggression 5 months later. Sugimura and Rudolph (2012) found that relational victimization in second grade was associated with engagement in relational aggression in third grade. Finally, using data from the NICHD SECCYD, Ostrov and Godleski (2013) reported that relational victimization in third grade was associated with relational aggression in sixth grade.

An important question is whether the experience of any type of peer maltreatment predicts increased levels of relationally aggressive conduct or whether there is specificity between the type of victimization and children's behavioral responses. Theoretically, there is reason to expect that experiences of relational victimization will be particularly likely to elicit relationally aggressive responses. For instance, Yeung and Leadbeter (2007) suggested that relational victimization may be more likely than other forms of victimization to promote HAB for relational provocations and thus relationally aggressive behaviors. It is also possible that youth learn to engage in aggressive behaviors by modeling their tormentors' conduct (Ostrov, 2010). Consistent with these suggestions, Ostrov (2010) reported that teacher-reported relational victimization predicted increases in observed relational, but not physical, aggression across the school year in a sample of preschoolers. In contrast, physical victimization predicted increases in physical aggression in this study. However, several of the theoretical processes proposed to underlie the association between victimization and aggression (e.g., using aggression to prevent future victimization; Yeung & Leadbeater, 2007) suggest that youth may use relational aggression in response to a variety of peer victimization experiences; thus, it will be important for future research to evaluate the relative influence of distinct subtypes of peer maltreatment in the development of relationally aggressive conduct.

Preliminary research has tested some of the theoretical mechanisms proposed to account for the association between relational victimization and relationally aggressive conduct. For instance, Ostrov et al. (2011) provided evidence supporting a social processes model in which the desire for exclusivity with close friends and HAB for relational provocations mediated the association between relational victimization and relational aggression in a sample of female emerging adults. Similarly, Yeung and Leadbeater (2007) found that HAB for relational provocations partially mediated the association between relational victimization and concurrent relational aggression in a sample of preadolescents. However, significant mediation did not emerge in longitudinal analyses. Some researchers have further suggested that victimization may serve as a mechanism linking peer rejection and relational aggression. For instance, Adams et al. (2010) found that victimization by peers (a composite including both physical and relational forms of victimization) mediated the relation between low peer liking and relational aggression in fifth- and sixth-grade males and females. Moderation effects were also documented, such that peer dislike predicted relational aggression only among youth who were highly victimized.

There are several directions for future work on the relation between peer victimization and the development of relationally aggressive conduct. First, researchers may benefit from evaluating the role of chronicity and severity of victimization in the development of relational aggression. In fact, preliminary evidence indicates that chronic victimization may be particularly likely to elicit relationally aggressive behaviors. Specifically, Rudolph, Troop-Gordon, Hessel, and Schmidt (2011) found that levels of victimization (a composite of both physical and relational victimization) in second grade and increases in these experiences into fifth grade predicted heightened relational aggression in fifth grade (controlling for second-grade relational aggression). Interestingly, this association was stronger among girls than boys. These gender differences support the suggestion that girls who are targeted by negative treatment by peers may be particularly likely to select relationally aggressive responses because such conduct is consistent with their gender schemas (see the "Toward an Integrated Gender-Linked Model of Aggression" section). In regard to severity, it is possible that even infrequent episodes of relational victimization may elicit relationally aggressive responses if the victimization is very severe in nature. Moreover, given evidence that aggression and victimization by parents and siblings may also influence children's behaviors within the peer group (Casas et al., 2006; Stauffacher & DeHart, 2005), future research should consider the role of victimization across multiple contexts.

Relational Aggression in Friendship Groups and Dyadic Contexts

To date, the majority of research examining peer risk factors for the development of relational aggression has focused on processes occurring in the larger peer context (e.g., peer status; peer victimization). However, as relational aggression involves the manipulation of and damage to interpersonal relationships, it is likely that such conduct

often emerges in the context of close, dyadic relationships (Grotpeter & Crick, 1996) and friendship groups (e.g., Espelage, Holt, & Henkel, 2003; Low, Polanin, & Espelage, 2013). In fact, relational aggression occurs in romantic relationships (Casas & Albers, 2014; Linder et al., 2002) and close friendships (Grotpeter & Crick, 1996) with some frequency. Youth with mutual antipathy relationships (i.e., enemy relationships in which both members of the dyad report disliking the other peer) also engage in heightened levels of relational aggression, perhaps in part because they use these behaviors to harm their disliked peers (Murray-Close & Crick, 2006). Thus, it is essential for researchers to understand the friendship group and dyadic processes that may contribute to the emergence of relationally aggressive conduct.

Several researchers have suggested that the qualities and characteristics of close friends, such as their aggressive behavior and social status, may play an important role in the development of children's and adolescents' relationally aggressive conduct. In fact, one important mechanism argued to underlie the development of aggressive behavior problems is socialization by close friends in the context of friendship networks (Espelage et al., 2003; Sijtsema, Ojanen, et al., 2010). More specifically, researchers have documented that aggressive youth choose friends who are also highly aggressive (i.e., selection), and, over time, these youth exert mutual social influence on each other's aggression (i.e., socialization; see Espelage et al., 2003). From this perspective, a salient social risk factor for the development of relational aggression may be time spent with relationally aggressive friends. Moreover, relationally aggressive youth may be particularly likely to experience this risk factor because they select friends who are similar to themselves.

In fact, researchers have provided evidence of both selection and socialization processes in relationally aggressive youths' friendship groups. For instance, Sijtsema, Ojanen, and colleagues (2010) found that relationally aggressive adolescents were more likely to become friends with relationally aggressive peers across one calendar year. Several potential mechanisms may underlie these selection effects. For instance, relationally aggressive individuals may be viewed by their peers as undesirable social partners, and, as a result, their opportunities for friendships may be constrained to other aggressive peers (Parker et al., 1995). However, at least some relationally aggressive individuals appear to be socially attractive (Hawley, Little, & Card, 2007), and children may actively choose friends who are similar to themselves, given the salient role of similarity in interpersonal attraction (Simon, Aikins, & Prinstein, 2008). Interestingly, popularity may be the primary driver of friendship formation and aggression similarity a by-product of the association with popular friends (Dijkstra, Berger, & Lindenberg, 2011).

An emerging body of research also provides support for the notion that youth are influenced by their friends' engagement in relational aggression. In one study, nonaggressive third-grade girls who were best friends with relationally aggressive girls became significantly more relationally aggressive themselves a year later (Werner & Crick, 2004). More recently, Sijtsema, Ojanen, et al. (2010) used social network analysis to document that young adolescents adopted relationally aggressive behavior patterns from friends, and findings persisted even when controlling for friendship selection effects. Similarly, Low and colleagues (2013) reported that sixth and seventh graders who were members of social networks that engaged in high levels of relational aggression exhibited increases in their own perpetration of such behavior across the course of one calendar year. Moreover, some evidence indicates that socialization processes may be more powerful in the development of relational forms of aggression than in physical aggression or physical fighting (Espelage et al., 2003; Low et al., 2013; Sijtsema, Ojanen, et al., 2010), underscoring the important role of friend and social network socialization in these behaviors.

Researchers have identified several moderators of socialization processes in the development of relational aggression. For instance, some evidence indicates that socialization of relational aggression in friendship groups is especially likely when the child is not powerful or socially central; specifically, Lansford and colleagues (2009) found that in girls' cliques, peripheral group members were more likely than more central group members to engage in levels of indirect aggression consonant with the indirect aggression of the group leader. Socialization processes may also be most pronounced for youth who are already aggressive; consistent with this suggestion, Simon et al. (2008) reported that only sixth to eighth graders who were highly relationally aggressive and in romantic relationships with relationally aggressive partners exhibited increased involvement in such conduct over time.

Several studies have also provided evidence indicating that friends' social status or social centrality may be associated with youth's relationally aggressive conduct. For instance, Peters, Cillessen, Riksen-Walraven, and Haselager (2010) found that girls with popular best friends were more likely to engage in relationally aggressive behavior. The authors suggest that popular friends may form a coalition and engage in relational aggression against others

in an effort to gain or maintain high status. However, other research has highlighted the role of friendships with low-status peers in the development of relational aggression. More specifically, Neal and Cappella (2012) have shown that relationally aggressive children tend to have high social network centrality (in terms of the number of relationships), but only if these relationships are with poorly connected peers. Therefore, children's relational aggression is enhanced when they are connected to many peers who are dependent on them for social resources. These authors suggest that relational aggression may be particularly effective when used against friends who do not have alternative options for obtaining relational benefits such as social support and companionship. Taken together, findings raise the possibility that having low-status friends promotes relational aggression against these same friends, whereas having high-status friends promotes the use of relational aggression against other members of the peer group.

Some evidence also suggests that relationship qualities may play a role in the development of relational aggression. Specifically, relative to nonaggressive youth, relationally aggressive children's friendships are characterized by high levels of intimacy (closeness and self-disclosure), conflict, betrayal, relational aggression within the relationship, and exclusivity (Cillessen, Jiang, West, & Laszkowski, 2005; Crick, Murray-Close, Marks, & Mohajeri-Nelson, 2009; Grotpeter & Crick, 1996). This particular cluster of relationship qualities is problematic because it suggests that children with relationally aggressive friends are divulging highly personal information and secrets, either elicited by the relationally aggressive friend or by choice, and that this information can be used against them when relationship problems arise. Although most work in this area has been cross-sectional, results from one longitudinal study indicate that increases in intimate disclosure by a friend are associated with increases in relational aggression for girls only (Murray-Close et al., 2007). These findings are provocative because they suggest that some friendship characteristics that are frequently viewed as positive (e.g., intimacy) may at times facilitate the use of relational aggression.

Media Exposure

The association between violent media exposure consumption and physically aggressive behavior has been thoroughly reviewed in the literature (see Anderson & Bushman, 2001; Anderson et al., 2010). Numerous theoretical models help to explain how exposure to aggressive media models can increase the likelihood of aggressive behavior over time (e.g., general aggression model [GAM], Carnagey & Anderson, 2003; script theory, Huesmann, 1986). The theoretically predicted links between exposure to violent media or aggressive content and aggressive behavior in children/adolescents are robust across types of methodology (i.e., longitudinal and cross-sectional studies; experimental and correlational studies) and cultures (see Anderson & Bushman, 2002). These effects have also been successfully extended to the investigation of nonphysical forms of aggression (i.e., relational and indirect aggression) in several studies (e.g., Archer & Coyne, 2005; Coyne et al., 2008; Gentile, Mathieson, & Crick, 2011). For example, Gentile, Coyne, et al. (2011) recently documented that school-aged children's exposure to media violence early in the academic year was associated with higher relational aggression (as well as physical and verbal aggression and low levels of prosocial behavior) later in the school year. Media exposure is also related to use of relational aggression in the context of romantic relationships; in one study, Coyne et al. (2011) found that exposure to relational aggression in the media was associated with romantic relational aggression for both young adult men and women.

There is also interesting evidence for what is referred to as the crossover effect (see Coyne, Archer, & Eslea, 2004; Coyne et al., 2008) in which viewing one type of media violence (e.g., physical) can lead to other types of aggression (e.g., relational) among viewers. For example, in a well-known longitudinal study, Huesmann, Moise-Titus, Podolski, and Eron (2003) found that girls who viewed physical violence on television as children engaged in more indirect aggression as adults. Ostrov, Gentile, and Crick (2006) documented a similar process among young preschool-age children. The GAM (see Carnagey & Anderson, 2003) predicts that media violence does not just influence aggression via social learning and modeling; rather, the exposure increases aggressive affect, arousal, and cognitive scripts (Ostrov, Gentile, & Mullins, 2013). Scripts or cognitive knowledge structures provide heuristics for how to act in given situations (Huesmann, 1986). Long-term exposure to aggressive media models can lead to aggressive behavior scripts and schemas as well as desensitization to aggressive or violent episodes (Carnagey & Anderson, 2003; Smith & Donnerstein, 1998). Viewing large amounts of relationally aggressive media may be associated with beliefs about the acceptability of relational aggression. A recent study showed that school-age children who viewed relationally aggressive television and movie models exhibited greater subsequent approval of relational

aggression (i.e., normative beliefs about the acceptability of relational aggression) if they also had parents who did not actively mediate or discuss and scaffold the programming during the exposure (Linder & Werner, 2012). Finally, one recent experimental study documented that exposure to television clips depicting relational aggression was associated with HAB for ambiguous relational (but not instrumental) provocation scenarios (Martins, 2013); thus, HAB may serve as a cognitive mechanism linking aggressive media exposure and relational aggression.

Recent work has also demonstrated how exposure to other forms of media content, including educational programming, may serve as a risk factor for relational aggression. For example, Ostrov et al. (2013) showed that exposure to educational media was associated with increases in parent-reported, teacher-reported, and observed relational aggression in a 3- to 5-year-old sample. These effects persisted over more than a 2-year period (Ostrov et al., 2013). The authors believed that children are modeling the aggressive behavior that is often shown as part of a friendship problem in these social-emotional-based programs. That is, although these programs are designed to ultimately teach social skills to children, young children may fail to connect the lesson or moral that is contained at the end of the 15- or 30-minute program with the aggressive behavior shown near the beginning (Ostrov, Gentile, et al., 2006; Ostrov et al., 2013). Thus, even shows that are deemed developmentally appropriate may place children at risk for learning and, ultimately, displaying relational aggression. Future research is needed to examine the role of active parental mediation versus other more passive coviewing parental approaches in these prospective links (see Linder & Werner, 2012).

DEVELOPMENTAL OUTCOMES: MALADAPTIVE CORRELATES

A significant question regarding the development of relational aggression is whether these behaviors are typical and normative, or whether they portend risk for the development of psychopathology (e.g., Underwood et al., 2001). Consistent with the suggestion that relational aggression is problematic and reflects developmental risk, an extensive literature has demonstrated that such conduct is associated with maladaptive correlates both concurrently and over time. Although relational aggression occasionally is conceptualized as the outcome of other adjustment problems (e.g., Ostrov, 2010; Zimmer-Gembeck et al., 2005) or psychiatric disorders (e.g., Belden, Gaffrey, & Luby, 2012), it is more frequently hypothesized to serve as a precursor or risk factor for psychopathology across development. Prior reviews (see Crick & Zahn-Waxler, 2003; Zahn-Waxler, Crick, Shirtcliff, & Woods, 2006) have demonstrated the theoretical and empirical support for prospective links between relational aggression and maladaptive outcomes. The review in this chapter provides a discussion of some of the most well-documented correlates of relational aggression, with particular attention to recent literature.

Internalizing Problems

A number of theorists have suggested that engagement in relational aggression will promote the developmental of internalizing symptoms, including depressive symptoms, anxiety, withdrawn behavior, and somatic complaints. Relational aggression may serve as a risk factor for internalizing problems because these behaviors interfere with successful negotiation of key developmental tasks, such as the establishment of positive peer relationships (e.g., Kamper & Ostrov, 2013; Murray-Close et al., 2007). In addition, relational aggression may be experienced as interpersonally stressful for both perpetrators and victims and may reflect maladaptive beliefs about the self and relationships; these factors, in turn, are often conceptualized as developmental vulnerabilities for depression (e.g., Rudolph et al., 2000). In fact, studies spanning developmental periods have documented positive associations between relational aggression and internalizing problems (e.g., Fite, Stoppelbein, Greening, & Preddy, 2011). Importantly, several of these studies controlled for levels of physical aggression (e.g., Crick, Casas, & Mosher, 1997), indicating that relational aggression may provide unique information regarding these adjustment difficulties. In fact, Underwood, Beron, and Rosen (2011) recently found that high trajectories of social, but not physical, aggression across third through seventh grades were uniquely related to internalizing problems at age 14. Additional longitudinal work suggests that relational aggression serves as a risk factor for the development of internalizing problems. For example, relational aggression has been found to predict increases in internalizing symptoms over time for school-age children (Crick, Ostrov, & Werner, 2006). Moreover, relational aggression and internalizing problems have been found to track together in a dynamic fashion over time during early adolescence (Murray-Close et al., 2007), and some evidence indicates that these associations emerge across cultural contexts (e.g., in Chinese culture; Kawabata

et al., 2012). Finally, in a longitudinal study of youth in early adolescence, peer-reported relational aggression was associated with increases in depressive-anxious symptoms (Ellis, Crooks, & Wolfe, 2009). In an effort to isolate the specific internalizing outcomes associated with relational aggression, researchers have also examined relations with narrow-band symptoms of depression and anxiety. In an early investigation in this area, Crick and Grotpeter (1995) demonstrated that relationally aggressive school-age children (i.e., 1 standard deviation above the sample mean) exhibited higher levels of depressive symptoms (as indexed by the Child Depression Inventory) than their nonaggressive peers. Consistent with the hypothesized role of stress in the emergence of internalizing pathology among relational aggressors, in one recent study, relational aggression predicted heightened levels of depressive symptoms only among youth who frequently ruminated about peer stressors (e.g., being targeted by peer aggression; Mathieson, Klimes-Dougan, & Crick, 2014). Interestingly, some evidence suggests that the association between relational aggression and depressive symptoms is stronger for girls than for boys. For instance, Crick et al. (1997) reported that relational aggression was uniquely (i.e., controlling for physical aggression) associated with depressed affect for girls, but not boys, during early childhood. In one of the largest longitudinal studies on the topic to date, Spieker et al. (2012) documented that relational aggression during middle childhood was associated with more depressive symptoms at age 15, but only for girls (although see Underwood et al., 2011). These gender differences may reflect the important role of interpersonal stress in the development of depressive symptoms for girls (see Ostrov & Godleski, 2010).

Past research has also examined associations between relational aggression and symptoms of anxiety. Anxious youth may use relational aggression to divert negative peer attention to others (Marsee, Weems, & Taylor, 2008) or in response to perceived negative evaluations (Gros et al., 2010). In fact, in a psychiatric inpatient sample of 4- to 12-year-olds, relational aggression was associated with heightened levels of anxiety (Becker, Luebbe, Stoppelbein, Greening, & Fite, 2012). In another study, reactive relational aggression predicted increased levels of anxiety in a sample of 6- to 17-year-olds (Marsee et al., 2008). Studies in emerging adulthood have also documented positive associations between relational aggression and multiple types of anxiety (Gros et al., 2010), including social anxiety (Storch, Bagner, Geffken, & Baumeister, 2004). Given the suggestion that relational aggression may be used as a strategy to deal with anxiety (e.g., Marsee et al., 2008), future longitudinal work is necessary to explore the direction of effects between relational aggression and symptoms of anxiety. Moreover, since similar underlying processes (e.g., dysregulated emotional responses) may portend risk for both anxiety and relationally aggressive conduct (Marsee et al., 2008), it will be important for future research to examine whether symptoms of anxiety and relational aggression share common developmental pathways.

Externalizing Problems

Relational aggression may be related to indices of externalizing pathology for several reasons (Crick & Zahn-Waxler, 2003). On one hand, several researchers have hypothesized that relational aggression will serve as a risk factor for the development of externalizing symptoms, including attention problems, conduct disorder symptoms, and oppositional defiant disorder symptoms (e.g., Crick, Ostrov, & Werner, 2006; Prinstein, Boergers, & Vernberg, 2001). From this perspective, engagement in relational aggression may place youth on a developmental trajectory toward adjustment problems, perhaps in part because such conduct interferes with successful functioning across a variety of domains (e.g., peer relationships; internalizing problems; see Crick, Ostrov, & Werner, 2006). For instance, relationally aggressive youth may select into friendships with similarly aggressive peers; in turn, these peers may socialize youth to increasingly engage in negative behaviors (Sijtsema, Ojanen, et al., 2010). Alternatively, it has been posited that relational aggression is part of a broader antisocial behavior or externalizing construct (see Burt, Donnellan, & Tackett, 2012; Tackett & Ostrov, 2010; Tackett et al., 2009) and serves as a marker of conduct and other externalizing problems (e.g., Tiet, Wasserman, Loeber, McReynolds, & Miller, 2001). From this perspective, relational aggression may be associated with other indices of externalizing symptomatology because they are related manifestations of a similar underlying pathology.

In fact, an emerging body of research indicates that relational aggression is positively associated with various indices of externalizing symptoms. For instance, relational aggression has been found to be related to heightened hyperactivity-impulsivity in early childhood (Ostrov & Godleski, 2009) and symptoms of ADHD in middle childhood (Tseng et al., 2012). The links between relational aggression and ADHD symptoms appear robust and have been documented in several cultures (e.g., a Taiwanese sample; Tseng et al., 2012) and in normative as well as clinical samples (e.g., an inpatient psychiatric

sample; Becker et al., 2012; although see Belden et al., 2012). For instance, Zalecki and Hinshaw (2004) reported that relational aggression was most prevalent among girls (ages 6 to 12) attending a summer camp who were diagnosed as having ADHD-combined subtype, rather than ADHD-inattentive subtype, or nondiagnosed comparison girls. Relational aggression is also associated with other forms of externalizing pathology; for instance, in a study with adults, relational aggression was elevated among individuals with intermittent explosive disorder (Murray-Close et al., 2010).

Developmental psychopathologists have also documented unique associations between relational aggression and conduct problems. Findings from the NICHD SECCYD indicated that relational aggression during middle childhood predicted heightened delinquency and risky behavior (Spieker et al., 2012). Relational aggression was also moderately associated with symptoms of oppositional defiant disorder and conduct disorder in a study of 9- to 17-year-old girls and boys (Keenan, Coyne, & Lahey, 2008). Some evidence indicates that relational aggression serves as a risk factor for later conduct problems; in one study, relational aggression among school-age children was uniquely related to future delinquency over time, controlling for physical aggression (Crick, Ostrov, & Werner, 2006). Several researchers have documented gender differences in these relations; for instance, Prinstein and colleagues (2001) found that relational aggression was associated with externalizing symptoms, but only for girls. However, others have reported stronger associations for boys; for instance, although Spieker et al. (2012) reported that relational aggression was related to risky behavior for both boys and girls, the strength of the association was stronger for boys.

Despite these interesting findings, future work is needed to better understand whether relational aggression places youth on a developmental trajectory toward externalizing symptoms and/or whether relational aggression is best conceptualized as a marker or indicator of externalizing difficulties. In their confirmatory factor analyses of disruptive behavior in a large, representative community sample of girls, Loeber and colleagues (2009) found that relational aggression consistently emerged as a unique factor (i.e., along with oppositional behavior/conduct problems, inattention, hyperactivity impulsivity) with both parent and teacher ratings. These findings suggest that despite overlap in constructs, relational aggression is distinct from existing measures of conduct problems.

However, the question remains regarding whether relational aggression is best conceptualized as a subset of antisocial or externalizing behavior problems. Burt et al. (2012) reported that social aggression was uniquely associated with known predictors and correlates of antisocial behavior, suggesting that such conduct may reflect a distinct subtype of antisocial conduct. Moreover, although externalizing problems are often conceptualized as developmental outcomes of relational aggression, effects are likely bidirectional in nature; in fact, Belden et al. (2012) reported that youth with preschool-onset disruptive disorders were more than five times as likely to be identified as relational aggressors 2 years later. Similarly, a 4.5-year follow-up of Zalecki and Hinshaw's (2004) summer camp study revealed that multiple informants rated girls with ADHD to have higher relational aggression scores relative to comparison girls, with moderate to large effect sizes (Mikami et al., 2008). One potential interpretation of these bidirectional associations is that relational aggression is a behavioral manifestation of underlying externalizing pathology or antisocial conduct (see Burt et al., 2012); in effect, engagement in externalizing behaviors may encourage conceptually related behaviors, such as relational aggression. We echo other calls to continue to examine how relational aggression findings are similar or different from those of "pathological externalizing behaviors" (Tackett et al., 2009, p. 731).

Peer Problems

Several researchers have argued that relational aggression will increase risk for peer problems and other social concerns (e.g., Preddy & Fite, 2012), which may in turn interfere with the successful negotiation of stage-salient developmental tasks in middle childhood and adolescence (Sroufe, Egeland, & Carlson, 1999). Scholars have posited that because children view relationally aggressive behavior as harmful and distressing (Crick, Bigbee, & Howes, 1996), victims and other peers may dislike aggressors. Crick and Grotpeter (1995) were the first to show that relationally aggressive children (1 standard deviation above the sample mean) were more rejected by their peers than nonaggressive children. Crick et al. (1997) also revealed positive associations between peer-reported relational aggression and peer-reported peer rejection when controlling for physical aggression. Crick, Ostrov, Burr, et al. (2006) documented that observations of relational aggression predicted future teacher-reported peer rejection, addressing potential concerns of shared method variance in earlier work in the area. Additionally, Tseng and colleagues (2013) reported that relational aggression was associated with increases in peer rejection across the fifth grade in a sample of

Taiwanese youth. Studies examining subtypes of relational aggression have found that proactive relational aggression is uniquely associated with decreases in peer rejection and relational victimization over time, whereas reactive relational aggression is uniquely associated with increases in peer rejection and relational victimization over time (Ostrov et al., 2013, 2014). Collectively, these findings highlight the possibility that some functions of relational aggression may be used to achieve positive status in the peer group (see the "Developmental Outcomes: Potential Positive Correlates" section).

Peer rejection resulting from relational aggression may further compromise perpetrators' ability to form high-quality peer relationships, ultimately leading to feelings of loneliness and psychological distress (Ostrov & Godleski, 2013) or resulting in victimization by peers (Ostrov, 2008). In fact, past work has shown that relational aggression is associated with feelings of loneliness (Soensens, Vansteenkiste, Goossens, Duriez, & Niemiec, 2008). Additionally, consistent with a sequential social process model, Ostrov (2008) found that relational aggression was associated with peer rejection, which, in turn, placed young children at risk for future relational victimization. Testing a similar model using data from the NICHD SECCYD, Ostrov and Godleski (2013) provided evidence for an indirect social process model such that the direct link between relational aggression in third grade and relational victimization in sixth grade was mediated by loneliness in fifth grade. These findings highlight the relatively complex mechanisms linking relational aggression and negative peer outcomes.

To date, the majority of research regarding how relational aggression relates to problems with peers has focused on difficulties within the larger peer group (e.g., rejection or victimization). Fewer studies have been conducted that examine the implications of relationally aggressive behaviors for adjustment in the context of close friendships and romantic relationships. However, the consequences of relational aggression may differ across relational contexts; in fact, Goldstein and Tisak (2004) reported that adolescents' and young adults' expectations regarding the outcomes of relational aggression (e.g., whether the relationship partner would want to continue the relationship if he or she used relational aggression; likelihood of retaliation) differed by relational context. Additionally, Murray-Close et al. (2010) reported that risk factors for relational aggression (e.g., HAB for relational provocations, anger) were positively associated with romantic relational aggression, even when controlling for peer-based relational aggression, raising the possibility that individuals who engage in relational aggression across relational contexts may be at particularly high risk for the development of psychopathology. Moreover, there is good reason to believe that relationally aggressive behaviors in close relationships will be particularly harmful as such conduct violates the common expectation of trust and intimacy (see Goldstein & Tisak, 2004).
